A sentence $\mathbf{w}$ is reordered by choosing the permutation that minimizes the cost $C(\pi|\mathbf{w})$. The minimization problem is an asymmetric TSP problem, which is converted to a symmetric TSP problem with double the number of states (Visweswariah et al., 2011) and then is solved using the Lin-Kernighan heuristic. The costs $c(m,n)$ are parametrized as a linear model

$$c(m,n) = \theta^T \Phi(\mathbf{w}, m, n)$$

where Φ is a vector of binary feature vectors as described in (Visweswariah et al., 2011). θ is a weight vector learned from reorderings derived from hand alignments using the MIRA update algorithm.

Although the base reordering model does not require a parser, for English→German reordering we experimented with using the TSP model that works on top of an input parse tree. Since English-German word order differences mainly relate to verb movements, we transform the parse tree so that any internal node which has a verb as a descendant is expanded down to its children. If a node does not have a verb descendant we represent the entire subtree by the constituent label of the node. Thus the parse tree in Figure 2 gets transformed to the following being passed as input to the reordering model: *NP-SBJ can read NP PP-TMP*.

2.2.1 Features

We adopted the same base features as described in (Visweswariah et al., 2011) and also experimented with additional features specific to word order differences in English-German. The basic features $\Phi(\mathbf{w}, m, n)$ are binary features that fire based on the identity of the words w_m and w_n and the POS tags of these words. Additionally there are features that examine the identities of words and POS tags one word to the left and right of the positions m and n (see (Visweswariah et al., 2011) for details of feature templates used).

Specific to the English→German direction reordering we use transformed parses (see above) as input and use the constituent labels instead of the words. Additionally, to handle the fact that verbs move to the end of the clause in subordinate clauses, we mark if a verb is a descendant of an SBAR node in the parse tree on the POS tag of the word.

Specific to the German→English direction we added an extra feature template that fires if word w_m and w_n are verbs and there is no verb between positions m and n.

2.3 Manual Rules

We do not have a suitable German parser. Therefore, as an alternative method to the TSP-based method (in the German→English direction only) we consider reordering using hand-crafted rules. The rules use German-side POS sequence as features and focus on verbs:

- Move full verb behind its closest auxiliary to the left
- Move negation behind closest auxiliary to the left
- In a subordinate clause, move auxiliary and full verbs behind an estimated subject
- Void any of the above rules that would cross a barrier token (e.g., a comma)

The rules are applied to a sentence repeatedly until there is no word movement. As will be shown, this small set of heuristic rules improves the output quality. We will compare this method with an unreordered baseline as well with a system pre-ordered via the TSP method.

2.4 Sentence Pre-Selection

The quality of reordering rules, i.e. their precision, depends on several factors: (1) the alignment, tagging, and parsing accuracy, and (2) the bilingual training data quality. The latter is considered here from a point of view of suitability for extraction of meaningful reordering patterns. Bilingual corpora typically contain sentence pairs with a varying degree of mutual parallelism. While a sentence pair may be considered an acceptable translation, the individual sides may differ significantly in terms of their syntactic and clausal structure. Non-literal translations may introduce considerable noise into the rule extraction. Consider this example taken from the Europarl (Koehn, 2005) corpus:

- English: *A ban would have less serious repercussions in this respect if it applied throughout the EU.*
- German: *Im Falle eines europäischen Verbots von Nachtflügen sind diese Folgen weniger stark ausgeprägt.*
- Gloss: *In case of a European ban of night flights are these consequences less strongly contrastful.*

Obviously, issues will arise for rule extraction given that these two sentences are composed quite differently. In particular the verb "applied" remains unaligned in this case thus introducing an error to the estimated target position for the corresponding set of node descendants, as described in Section 2.1.

To mitigate the impact of noise in bilingual data we propose an automatic sentence preselection algorithm. The goal here is to assign a quality score to each sentence pair given its automatic alignment and to select a subset of higher quality (i.e. literally translated) sentences for the rule extraction. We borrow the confidence measure proposed originally for block extraction in (Huang, 2009) and adopt it as an indicator for sentence parallelism. A description of the algorithm follows.

Let (V,W) denote a bilingual sentence pair where $V = \{v_1,...,v_I\}$ and $W = \{w_1,...,w_J\}$ is the source and the target sentence, respectively. The sentences are word-aligned via a set of alignment links $A = \{a_{ij}\}$. The alignment A represents the best way to relate the content of V to W and is obtained by automatic means (e.g. Giza or Maxent methods). The quality measure involves calculating two quantities:

$$P(W|V,A) = \epsilon \prod_{j=1}^{J} \sum_{\forall i:a_{ji} \in A} p(w_j|v_i) \tag{5}$$

which is the lexical probability of the target sentence given the source words and their alignment, and

$$P(W|V) = \frac{\epsilon}{(I+1)^J} \prod_{j=1}^{J} \sum_{i=1}^{I} p(w_j|v_i) \tag{6}$$

the lexical probability of W given V, independent of A. The terms $p(w_j|v_i)$ are Model 1 word translation probabilities as estimated during training. The constants ϵ and $\frac{1}{(I+1)^J}$ are due to the simplifying assumptions of Model 1 as described in (Brown et al., 1993), namely sentence lengths, and alignments being all equally probable. These constants will later cancel out. Similar to the above, transposed quantities $P(V|W)$ and $P(V|W,A')$ are also obtained using Model 1 probabilities in in the reverse direction along with their corresponding alignment A'. Noting that

$$P(W,A|V) = P(A)P(W|V,A) = \frac{1}{(I+1)^J} P(W|V,A) \tag{7}$$

we now define the bilingual sentence confidence score as follows:

$$F(V,W) = \frac{1}{J} \log \frac{P(A,W|V)}{P(W|V)} + \frac{1}{I} \log \frac{P(A',V|W)}{P(V|W)} \tag{8}$$

Since $F(V,W)$ is an average of alignment posteriors $P(A|V,W)$ and $P(A'|V,W)$, we expect it to produce large values for translations with sharp posterior distributions which, in turn, can be viewed as relatively literal and complete. For sentence pairs with a lower degree of parallelism, for incomplete, or perhaps incorrect translations $F(V,W)$ should tend to be small.

The overall sentence pre-selection step consists of calculating $F(V,W)$ values for all sentence pairs in the reordering training corpus followed by thresholding and selecting a certain proportion of best scoring sentences for the rule training. In our case the proportion was set to be around 50%.

In our preliminary experiments we observed translation quality gains of up to 1 point BLEU due to this selection method.

3 Related Work

A significant quantity of work in syntax based reordering has accumulated in the machine translation literature. Relevant to our topic, there have been studies investigating sources of improvements (Zwarts and Dras, 2007) due to syntax-based reordering. Initial efforts (Niessen and Ney, 2001) were made at improving German-English translation using handwritten rules by handling two phenomena: question inversion and detachable verb prefixes in German. In (Collins et al., 2005; Carl, 2007) rules are developed for translation from German to English based on source POS and manual rules covering a variety of patterns including verb movement.

There have been studies that try to learn rules from the data, among others (Ringger et al., 2004; Rottmann and Vogel, 2007; Zhang et al., 2007; Crego and Habash, 2008; Niehues and Kolss, 2009; Khalilov and Sima'an, 2011). Work by Rottmann and Vogel utilizes sequences of source POS and the corresponding alignments to automatically extract reordering rules along with their left and right context. They then reorder a source sentence using applicable rules thus obtaining a word lattice for decoding. Building on this work, Niehues

and Kolss explore an extension of such rules introducing a variable length gaps to better generalize long range reordering patterns. Both studies report significant gains in BLEU scores for both English→German and German→English translation.

The work in (Rottmann and Vogel, 2007; Niehues and Kolss, 2009) relates to both our parse-based as well as feature-bases reordering methods in that they take the context of the reordered tokens into account - a key to English-German word order. Our method, like (Niehues and Kolss, 2009), allows for gaps in the matching patterns. In contrast to the above mentioned work, the parse-based method operates on the entire source parse, including coarse levels where reordering can induce long range word movements. We use contextual information from the parse tree thus modeling left and right context which, in contrast to (Niehues and Kolss, 2009), is hierarchical. Our second, feature-based method operates on word level and takes into account arbitrary syntactic and lexical source features. The method utilizes machine learning to find appropriate model to capture most beneficial source word order, given a set of automatic alignments.

Recently, reordering models that can learn to reorder source sentences to make them match the target language order without requiring a parser have been proposed. (Tromble and Eisner, 2009) propose a model based on the Linear Ordering Problem, where for each pair of words in the sentence the cost that one of them occurs somewhere before the other is modeled. (DeNero and Uszkoreit, 2011) take a two pronged approach where they first learn to parse the sentence and then learn a reordering model on the resultant parses. (Visweswariah et al., 2011) proposed a model based on the Travelling Salesman Problem to learn to reorder sentences where costs of a word immediately preceding another word in the sentence are learned. This model was shown to be better than (Tromble and Eisner, 2009) in terms of reordering performance. In this work we extend and apply the (Visweswariah et al., 2011) to German-English reordering.

While the focus of our paper is on pre-ordering techniques, there has been considerable work on handling the reordering problem as part of the decoding process (Chiang, 2007; Yamada and Knight, 2002; Galley et al., 2006; Liu et al., 2006; Zollmann and Venugopal, 2006). These approaches are computationally expensive compared with phrase based systems due to the inclusion of bilingual parsing in the decoding process.

4 Experimental Evaluation

4.1 Parse-Based Rules

The rule extraction was performed using approximately 2.6 million sentence pairs obtained through the sentence pre-selection process as described in Section 2.4, operating at a 50% sentence rejection rate. The sentence pairs were aligned by a maximum entropy aligner (Ittycheriah and Roukos, 2005) trained using a subset of the Europarl corpus, and selected computer manual corpora). A maximum entropy parser (Ratnaparkhi, 1999) was used to generate the parse trees for the English side in the English→German direction, and a maximum entropy tagger to generate POS (using the Stuttgart-Tübingen tag set (Schiller et al., 1995)) for the German side in the German→English direction. With a significance threshold of 1.2 and minimum count threshold of 20, we obtain about 3200 rules in the final reordering model.

4.2 TSP-Based Model

For both English→German and German→English reordering we train the TSP-based models on a set of hand alignments (roughly 30K sentences) and a subset of machine alignments selected using the sentence pre-selection method described in Section 2.4 (roughly 300k sentences). For English→German we use the transformed English parse as described in Section 2.2 instead of the original word sequence.

During development stage we used the monolingual BLEU score (mBLEU) to compare the reordered output to a reference reordering derived from hand alignments on a test set of 400 sentences from the news domain. For German→English we obtain larger improvements, going from a mBLEU score of 61.5 for unreordered German to 72.5 for German reordered using the TSP-based model. For English→German we get a relatively modest improvement; going from 64.2 for unreordered English to 67.6 for reordered English.

4.3 SMT Model

The phrase-based systems were trained in both directions using same amounts of training data. In a first stage, smaller models were created adhering to the WMT2010 constrained training condition (WMT Website, 2010). In a second stage, about 16M sentence pairs spanning a variety of publicly available (e.g. Europarl) as well as internal corpora (IT and news domains) served the training of unconstrained systems. The phrase pairs were extracted based on a union of HMM and maxent alignments with corpus-selective count pruning. The lexicalized distortion model (Al-Onaizan and Papineni, 2006) was used with a window width of up to 5 and a maximum number of 2 skipped (not covered) words during decoding. The distortion model assigns a probability to a particular word to be observed with a specific jump. The decoder uses a 5-gram interpolated language model spanning the various domains mentioned above, except in the constrained mode where a single 5-gram language model was trained on the WMT2010 training data (WMT Website, 2010).

4.4 Evaluation Sets

The methods were evaluated in contrastive experiments utilizing the following (single-reference) test sets:

- *News*: 166 sentences (8700 words) from the news domain.
- *TechA:* 600 sentences from a computer-related technical domain, this has been used as a dev set.
- *TechB:* 1038 sentences from a similar domain as *TechA* used as a blind test.
- *Dev09:* 1026 sentences defined as the *news-dev2009b* development set of the Workshop on Statistical Machine Translation (WMT) 2009 (WMT Website, 2009). Results of others on this set can be found, for example, in (Popovic et al., 2009).
- *WMT10:* 2034 sentences from news domain used as the eval set in the WMT 2010. Results of others on this test set can be found in (WMT Website, 2010).

4.5 Evaluation Metrics

The translation quality in our experiments is evaluated using BLEU (Papineni et al., 2002), as well as using human assessment. The latter is carried out by a judge rating the quality of three translations for each source sentence. The defined assessment levels correspond to

following judgements: 0=Exceptionally poor, 1=Poor (difficult to understand the meaning), 2=Not good enough (errors in grammar, vocabulary, and style make understanding difficult), 3=Good enough (there are errors, however one can understand the meaning with a reasonable confidence), 4=Very good (there may be minor errors, but one can understand the meaning with high confidence), 5=Excellent (the information is presented clearly and with appropriate grammar, vocabulary, and style.) When performing the assessment, the reviewer is presented the source and the competing (blind) translations with their order randomized. The ratings are averaged within the test resulting in a single human score per system. We employed a single judge, who was not involved in the related technical work, and who is proficient in both English and German.

4.6 Results

The cased BLEU scores for English→German are shown in Table 1, and for German→English in Table 2. Overall, we make the following observations: (1) the scores behave consistently between the constrained and unconstrained training, (2) all reordering methods in both directions improve the BLEU scores over their unreordered baselines, (3) the parse- and TSP-based methods seem to fare comparably across the testsets with BLEU differences less than 0.3 points, (4) while the manual rules for German→English do improve the translation quality, the automatic TSP reordering outperforms the manual rules by more than 1 BLEU point leading to overall improvements of about 2 points in the unconstrained condition. Tables 3 and 4 show

English→German Test	Baseline (no RO)	Parse-Based RO Cased BLEU	TSP RO	Diff (TSP vs. Bsl.)
TechA	0.170	**0.184**	0.181	+0.019

4.6.1 Discussion

In the German→English direction the results let us conclude that the TSP method leads to improvements in the translation quality. A post-review analysis of the human assessment indicates that most gains can be linked to either word order or better phrase match. The latter is a consequence of more monotone alignments and thus an improved phrase extraction. We have investigated the latter point by recording the count of phrase pairs extracted from the same training corpus (WMT2010) with and without reordering. While in the unreordered system, the extraction resulted in 30.0M phrase pairs, in the reordered system this number increased to 36.3M phrase pairs - corresponding to about 20% increase in extraction efficiency. The reordered phrases also tend to be slightly longer, on average. An example from the human assessment illustrates the nature of the improvement:

- Source: *Die Vergabekriterien sind für alle Kategorien klar definiert, wie auch ihre Beurteilung.*
- Baseline: *The award for all categories clearly defined, and their assessment.* (Rating: 2)
- TSP-RO: *The lending criteria are clearly defined for all categories, as well as their assessment.* (Rating: 5)

The baseline output seems to suffer not only from incorrect word order but also from dropping essential words (“criteria” and “are”), both of which are rectified in the reordered output.

We observe a somewhat different picture for the English→German SMT with results mixed between the automatic and the human metrics. The improvements in BLEU fail to produce noticable difference for the human judge. This could be caused by several factors. First, the overall translation quality is low (2.4), therefore word order improvements may not help in presence of dominant errors. An example from the assessment sheet illustrates this issue:

- Source: *The fix is to relax these attributes as optional.*
- Baseline: *Der Fix ist sich zu entspannen diese Attribute optional sein soll.* (Rating: 1)
- TSP-RO: *Der Fix ist diese Attribute als optionale zu lockern.* (Rating: 1)

Clearly, the word choice of the baseline ("sich zu entspannen" - "to rest" or "to unwind") is poor as is its placement. The reordered system has undoubtedly better word order and arguably better word choice, however, the judge still considered the overall translation as "poor."

Second, correctly placing the verbs in the English→German direction may be a harder problem. Elaborating on this conjecture, we may first consider the relevant word patterns in the two language directions: while going into English the reordering moves (mostly) verbs together (e.g., with the auxiliary verb being an anchor), it moves them far apart when going into German. Given that these verbs (e.g., auxiliary and their main verb) tend to form a single semantic unit of the sentence, they will thus be captured by the phrase extraction as a unit. Conversely, when splitting the verb groups and moving them apart, the positive effect of a more monotone word alignment may be out-weighed by the fact that these verbs will not be captured in one unit. Moreover, we hypothesize an accurate verb placement to be a harder problem going into German than into English. In the latter case an unambiguous placement pattern is typical, e.g., a main verb being placed immediately behind its auxiliary. On the other hand, the placement of a main verb to resemble German depends heavily on the parser accuracy (clause boundaries), and it can sometimes be ambiguous (e.g., verbs may or may not move past embedded clauses). One way to mitigate this problem might be combining reordered and unreordered phrase pairs in the training and then rely on word reordering lattices being used inside the decoder to choose the best matching alternative (as proposed in (Rottmann and Vogel, 2007)), which, however, increases the search complexity of the SMT system.

4.7 Future Directions

We described two methods for syntactic source reordering developed for English-German SMT. Our results indicate that both methods, applied as a pre-processing step, lead to improvements, as measure by BLEU. Significant gains in human assessment of the translation quality are observed for German→English, however, no observable changes were achieved for English→German according to the judge. The latter finding poses several questions: (1) why does same reordering method help significantly more in one direction than vice versa? and (2) how can the discrepancy between our automated metric BLEU and the human assessment results be mitigated? Regarding (1) we hypothesized the reordering problem to be harder when going into German due to a higher word "scatter" as well as sensitivity to parser and tagger accuracy. We plan to further investigate this problem and to refine both methods to to increase their robustness. Independently, the challenge of the overall low quality of the English→German remains to be addressed. Improving the baseline could help the reordering gains in BLEU to show up also in the human assessment, as a better word order will arguably tend to make more impact going from a rating of 3 to a rating of 4, or 5, than, say, from 1 to 2. English→German translation is a challenging language pair and we believe significant improvements will be achieved only by addressing several problems beyond just word ordering. These include generating correct inflections, grammatical agreement, and preventing content word loss. Our results also confirm human assessment to be a necessary component of the overall system evaluation helping to avoid over-optimistic conclusions.

ABSTRACT
We take up the challenge of learning a grounded model of language when our agent has a body of machine learning algorithms and no prior knowledge of either the physical domain or language, in the sense of "least commitment". Based on a 2D video and co-occurring raw text, we demonstrate how this cognitively inspired model segments the world to obtain a meaning space, and combines words into hierarchical patterns for a linguistic pattern space. By associating these two spaces under temporal co-occurrence constraints, we demonstrate the acquisition of term-meaning pairs for names, actions and relations. We next map physical arguments for actions and relations to syntactical constructions resembling a cognitive grammar framework. Thus the system is able to bootstrap a rudimentary lexicon and syntax. While experiments are primarily in English, we present partial results for Hindi obtained without any change in the methods, to indicate its potential application to other languages.

1 Language learning: The minimal-commitment approach

We investigate a minimal-commitment approach to learn both a grounded lexicon and some rudimentary grounded syntax of an unknown language. By *minimal commitment*, we wish to restrict the prior knowledge available to our learning agent to a minimal set of abilities, and almost no resources or models of the language or domain. By *grounded lexicon* we would like to learn a bipolar relation between a unit of language and a perceptual pattern, and *grounded syntax* refers to a similar mapping from syntactic patterns to relations or events in the perceptual space (Langacker, 1987). Further, given the minimal prior knowledge formalism, the set of perceptual schemas that constitute models for meaning are obtained from the visual input in an unsupervised manner. The input to the work consists of visual sequences with simple shapes, and a set of narratives of this situation generated by adult subjects. We focus on the relation of *containment* (A in B), and the event of *chase*, and show how constructions corresponding to these are learned.

There are many works dealing with the grounded learning of words (Roy and Reiter, 2005; Siskind, 1994; Steels, 2003; Regier, 1996). Our input for word learning however, is significantly more challenging, since the narrative is a set of sentences from an unconstrained narrative, and the lexical and syntactic choices as well as the referential intentions of the speakers vary considerably. This problem is partly resolved by enabling the agent with a bottom-up model of dynamic attention, which has been shown to help computational simulations of word learning (Yu and Ballard, 2007; Mukerjee and Sarkar, 2007).

A more significant difference with earlier work is that target of the reference (a set of "concepts") is not given, but has to be discovered. A few approaches (Regier, 1996; Roy and Reiter, 2005) do discover some aspects of the semantics, but the structure is given. Thus, all approaches to grounding permit the agent to have some knowledge of the task domain in order to constrain the structures for the conceptual space; some provide a set of predicates outright (Siskind, 1994; Bergen et al., 2004; Dominey and Boucher, 2005; Caza and Knott, 2012). Let us illustrate the difficulty of making no semantic commitment with the example for containment. Without the convenience of a pre-defined predicate, the relation of being contained (the target for "in") cannot be known *a priori* but has to be first discovered as a distinct cluster in some sensory space. However, we demonstrate that such clusters emerge at least for some of the concepts of interest. In this work we simply use mean-shift clustering, but in other situations we have found that the presence of intrinsic goals can substantially improve the discrimination (e.g. for the containment task, the agent may have an intrinsic goal of inserting an object into an orifice such as a mouth).

Since the perceptual discovery operates independent of language, we assume that a set of such characterizations are already available at the start of the linguistic association process. The availability of such proto-concepts also has strong cognitive plausibility; infants are able to discriminate situations from 3 months onwards, and by 9 months, it is this ability to cluster data into groupings that lead human infants to discover the phonemic structure of their language (Mandler, 1992). One of the observations of this work is that this pre-linguistic proto-semantic discovery enables a set of categories that are specific to the domain and the goals of the agent, and eventually lead to a set of predicates that are more relevant to the situation and hence more likely to appear in linguistic discourse. Thus, this unsupervised discovery process forms the scaffolding on which the bootstrapping process works.

Attempts to learn grammatical structure range from attempts that ignore semantics altogether

to richly grounded models. The purely syntactic forms have been quite successful in inducing probabilistic grammars for tasks such as machine translation (Marino et al., 2006), and analysis of such as n-grams and path alignment have been used to determine grammars from single language corpora as well (Solan et al., 2002). In our work, we use the approach based on simple n-grams, as well as the more sophisticated (Solan et al., 2002) model, to identify the candidate syntactic structures that will be associated with the proto-semantic structures to discover constructions.

Grammar inductions that model the semantics are given a semantic structure which is matched to user narratives, obtained for instance while performing a task. The visual inputs are analyzed using a vision system into the actions identified, and these are then used to induce some aspects of grammar. This is used to learn some grammatically distinct structures (such as active or passive voice, or prepositional terms) in (Dominey and Boucher, 2005). Another body of work considers formal logical description of scenes, and induces probabilistic grammars by unambiguous sentence pairing. An impressive gain in this area has been to reduce the commitment to language knowledge, so that grammatical structures of questions in languages as different as Turkish and Japanese can be learned (Kwiatkowski et al., 2010). However, the scalability of a process that requires a large numbers of predicate specific training sets limits the scalability of the method. The objective of minimizing commitment to prior language models is essentially aimed at modeling the ability to acquire any ambient grammar.

The present work differs from all these in minimizing the dependence on prior knowledge of either the perceptual space or the language being learned. Both the perceptual structures as well as syntactic structures are obtained using unsupervised techniques, and the association performed thereafter. One important observation is that the semantics helps narrow the corpus to those sentences uttered while a specific concept is in focus, thus helping acquire structures related to it.

1.1 Capabilities of the learning agent

Start Frame	End Frame	Subject 1	Subject 2
617	635	the little square hit the big square	they're hitting each other
805	848	the big square hit the little square	and they keep hitting each other
1145	1202	the big square goes inside the box; (and) the door closes	another square went inside the big square

Table 1: Sample descriptions of events. Note the differing referential and lexical choices.

We may now define the capabilities of our minimal commitment language learning agent. We assume the agent has a) a wide range of machine learning algorithms, b) some awareness of the mental state of other agent (*Theory of Mind (Mukerjee and Sarkar, 2007)*), c) task-independent (bottom-up) dynamic perceptual attention, d) a mechanism for fixing goals (intrinsic motivation). In addition we also assume the agent has the ability to segment words from the linguistic inputs. We note that possibly such an ability may have been based on earlier exposure to the target language.

The input for our agent is a video sequence (based on Heider/Simmel (Heider and Simmel,

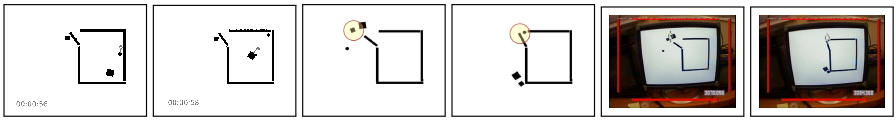

Figure 1: *Perceptual input: 2D video based on Heider/Simmel. Also showing dynamic attention model*. Three rigidly translating shapes, a big-square (**[BS]**), a small-square (**[SS]**) and a circle (**[C]**) interact playfully (velocities shown with arrows). Part of the container, a door (**[D]**) opens or closes at times. Figures 3 and 4 show the synthetic gaze computation, and Figs 5 & 6, actual gaze data for a viewer, showing reasonable correlation to predicted gaze.

1944), Fig. 1)[1]. The English linguistic database consists of 40 commentaries, collected from subjects who were simply asked to "describe the video", while they differ in certain respects, the speakers were not constrained in any form in terms of lexical choice, focus, or other aspects of their narratives. A group of 13 was collected as part of (Hard and Tversky, 2003) were asked to comment on a fine-grained vs coarse-grained temporal segmentation of the video. The other 27 narratives were collected by us. All narrators were students in the 20-25 age-group. The English narratives constitute a corpus of 4200 words (700+ sentences), and exhibit a wide range of linguistic variation both in focus (perspective) and on lexical and construction choice (see Table 1). Both the visual and the linguistic input are unlabelled.

It is possible that better results may be possible with a stronger social emphasis than was maintained in this work (e.g. joint attention vs individual attention). However, the requirement that an actual human be present makes it more difficult to scale up. As it exists, the system can possibly be tuned for a number of domains and languages.

2 Language acquisition as association

The problem of language acquisition with minimal commitment has two phases. In the pre-associative phase, the problem is to identify the semantic and syntactic primitives independently.

- *Perceptual structure discovery*. Given a perceptual space W, discover the set of structures Γ in this space, possibly focusing on high-frequency situations, or those that are relevant to its goals. Some patterns $\gamma \in \Gamma$ are simple (e.g. a shape that moves rigidly), versus others that are encode relations over space or time. Some of the simpler patterns participate in the more complex interactions.
- *Linguistic structure discovery*. Given a linguistic space L, the system is exposed to a set of sentences, each a sequence of words (w). It attempts to identify sequential patterns Λ (possibly hierarchical) that, would enable a more compact description of the input.

Strictly speaking the strong independence of the perceptual and linguistic spaces is required only for a small set of initial phrase-meaning mappings; subsequently, mappings that are known to be present in the situation can substantially constrain other possibilities, leading to great efficiencies in acquisition (Yu, 2008; Bloom, 2000) (the vocabulary spurt). In this work, we are focused on the very first, bootstrapping steps, so we maintain a strict independence. We note however, a small aspect of this independence. We observe that both linguistic and conceptual

[1]This video was developed and some of the narratives collected by (Hard and Tversky, 2003). We are grateful to Barbara Tversky for permission to use this data in this different enterprise.

structures are hierarchically organized. Thus, the a relation *A contains B* is defined over objects A and B, which are themselves structures on their own right. Thus, it is reasonable that A and B would be brought to awareness (reified) before the relation of containment. Hence, if the names of two participating objects are known, then we do use this knowledge to constrain phrases that may describe a relation between them.

We note that each sentence in the input is uttered over a particular temporal window, and includes a set of linguistic patterns, $\lambda_1, ...\lambda_m$. If the perceptual patterns observed during this utterance interval are $\gamma_1, ...\gamma_n$, then one may expect some of these λ to be mapped to some of the γ. Over many narratives describing similar situations, we are able to access a large set of such association candidates; and the association process merely posits some of the strongest co-occurrences in this large set. This association task may now be defined: Map fragments of language to the patterns of the perceptual data. Discover mappings from the meaning space to the syntax space, i.e $\gamma \in \Gamma \mapsto \lambda \in \Lambda$, where γ, λ are the perceptual and linguistic patterns that co-occur during a sentence-utterance duration.

For each pattern γ or λ, the system should be able to determine if a given perceptual or linguistic situation is an instance of the particular pattern or not. Since the initial discovery of these patterns are based on unsupervised methods like clustering, binary discriminations can be performed by bayesian techniques on the two distributions; and new instances assigned to a suitable class, or a new cluster may be initiated. In general, this means that each distribution may change significantly as more experience accumulates, but in this work, we shall not be expanding our repertoire of concepts so we shall not encounter this situation.

We note that what we are learning on the linguistic side is far from what is normally understood by syntax. We are learning merely a map from the sentential space S to a pattern space Γ, which is chosen so as to induce the largest structures that do not cause contradictions. As we shall see, these structures will use hierarchies which look rather like syntactic categories, but are quite different from traditional parts of speech or other treatments. However, we note that there can be many grammars that explain a given set of sentences, and the grammar that describes this particularly input may differ substantially from human-crafted grammars.

We observe that the grounding - i.e. the availability of a mapping to a space outside the set of logical tokens - is a very crucial part of the process by which the initially learned mappings are expanded on in further usage. Without it we would not be able to constrain the linguistic parts that are relevant when a known mapping arises(Langacker, 1987; Bergen et al., 2004).

In the first pre-associative stage, we need to define the perceptual structures. In the video (Fig. 1), the referent objects – a big square, a small square and a circle (from now on referred to as **[BS]**, **[SS]** and **[C]** respectively) – are a set of rigid translating pixels, and are easily segmented. We note here that while we claim a low degree of domain dependence, had the video been 3D or the agents been humans, it would have imposed considerable difficulties. Thus, to an extent, the perceptual analysis is limited to this kind of domain, but nonetheless, there is nothing specific to the scene. The segmented objects constitute the first level of the perceptual abstraction, and despite the variation in the names for these objects in the narrative, associating these is much simpler compared to the multi-object relations or actions.

3 Association measures

The learning objective is to create mappings between the meaning space Γ and the sentential space Λ. Suppose $\Gamma = \cup_i \gamma_i$ and $\Lambda = \cup_i \lambda_i$ be the random variables denoting the said spaces.

Each γ_i denotes a particular hypothesis for a realization of the meaning space. For example, in a verb meaning space created through clustering of motion features, γ_i would denote a cluster. Similarly, for a reference resolution task containing objects o_i, $\gamma_i = o_i$. The λ_i's similarly define partitions of the sentential space, which, based on context, might denote monograms, bigrams or other syntactical structures derived from the purely linguistic input.

We follow a statistical approach to map the two domains to each other (Fazly et al., 2010)[2] instead of an inductive approach(Siskind, 1996), since, not only ours in an unconstrained commentary, but knowing even the position of the referring expressions would be unhelpful because of noise introduced in any single isolated evidence. Though they do not use unconstrained linguistic input, there is much research on cross-situational associations between words and their meanings(Frank, 2010; Roy and Pentland, 2000; Smith and Yu, 2008; Yu et al., 2005; Yu and Ballard, 2007). We employ two association measures to correlate the meaning and sentential spaces. The *relative association*, a Bayesian metric, is defined as

$$P(\gamma_j|\lambda_i) = \frac{P(\lambda_i|\gamma_j)P(\gamma_j)}{P(\lambda_i)} \propto \frac{P(\lambda_i|\gamma_j)}{P(\lambda_i)} = A^{rel}_{ij}.$$

While working well for frequent linguistic elements, the metric is prone to give erroneous results for rare occurrences. For instance, it gives a maximum value of 1 to the correlation between a word w, which has been uttered only once in the whole discourse, and the meaning it has co-occurred with. We, consequently, also employ an information theoretic measure, the *mutual association*, defined as

$$A^{mut}_{ij} = P(\lambda_i, \gamma_j) \log \frac{P(\lambda_i, \gamma_j)}{P(\lambda_i)P(\gamma_j)}$$

because it's the contribution of each (λ_i, γ_j) pair in the mutual information of Γ and Λ

$$I(\Gamma, \Lambda) = \sum_i \sum_j P(\lambda_i, \gamma_j) \log \frac{P(\lambda_i, \gamma_j)}{P(\lambda_i)P(\gamma_j)}$$

It might also be noted that while A^{rel}_{ij} was inadequate for low frequency words, A^{mut}_{ij} gives unusually high scores for highly frequent words like *the* which have only syntactic relevance, due to a high $P(\lambda_i, \gamma_j)$, thus supporting the use of both measures for the investigation.

The goal of this work, however, is not to discover which association measure works best for word learning. The idea we are trying to support is that all categories – nouns, verbs, relational prepositions etc. – can be mapped to their corresponding meaning space through simple associations. Many association measures have been proposed in literature, which work differently in different situations. It seems cognitively implausible that an infant uses only one kind of association to discover the linguistic element with the highest correlation with the meaning and learns that as the label. Neither are many association measures too different in their output, except for a few artefacts. We instead propose that instead of looking for a *perfect* association metric to discover a single label, a more plausible approach would be to discover a *label set*, which would be refined through further syntactical, perceptual or social evidence. Since Bayesian and information-theoretic associations are well-known in NLP, we take the above

[2]However, while (Fazly et al., 2010) use an artificial meaning space for word-meaning correlation, with the meaning space created from sentential input only and essentially treated as a given, we form the meaning space from perceptual input.

[BS]			[SS]			[C]		
word(s)	A_{ij}^{rel}	A_{ij}^{mut}	word(s)	A_{ij}^{rel}	A_{ij}^{mut}	word(s)	A_{ij}^{rel}	A_{ij}^{mut}
square	0.70	1.41	little	0.66	0.79	circle	0.79	2.11
big	0.89	1.11	small	0.72	0.63	square	0.41	1.54
box	0.69	0.78	square	0.46	1.12	little	0.68	1.22
the big	0.87	0.71	small square	0.93	0.53	the little	0.71	0.81
big square	0.94	0.75	little square	0.89	0.46	little circle	0.91	0.60
large square	0.86	0.15	the little	0.70	0.54	the big	0.48	0.61

Table 2: *Noun label learning*: Word associations for the referent objects in attentional focus.

two as representative. As we shall see, both work in most situations. Note that we make no assumptions on the category of words or distinguish them as nouns/verbs. However, different machine learning algorithms are required for learning perceptual objects, events, and spatial relations; thus these are distinguished in the semantic space.

3.1 Noun reference resolution

Noun learning is well known to be easier than verbs(Fleischman and Roy, 2005). In our case, the rigid shapes are easily segmented and tracked, and the mapping of object labels to their visual representation is achieved with the help of a bottom-up dynamic saliency model. Many computational approaches have been proposed for grounded word learning(Iida et al., 2011; Prasov and Chai, 2008), though instead of working on unconstrained utterances, the referring phrases are a given. (Fang et al., 2009) uses static referents in game-like contexts, as opposed to our dynamic referents. We observe that unlike many of these approaches, our learning agent is exposed to complex discourse in which phrases are embedded, and not by isolated one-word labels.

We use visual attention to constrain the region of visual interest and identify the constituents participating in an utterance. In fact, past works like (Prasov and Chai, 2008; Iida et al., 2011) have used gaze cues from speakers to conduct reference resolution. In our case, however, since the learner is presented with only the visual stream and is not in the presence of the speaker, attention is mediated by visual saliency alone, and not by cues received from the speaker's gaze. Therefore, to simulate gaze-based visual attention, we follow the assumption of Perceptual Theory of Mind(Mukerjee and Sarkar, 2007), that the salient features that our cognitive agent discovers through image processing, would also be salient for the speaker involved in the associated commentaries, letting us correlate the visual and linguistic elements coherently. (Mukerjee and Sarkar, 2007) uses a bottom-up visual attention model to predict the gaze, the results of which are shown in Figure 1. This works as our eye-gaze model for the perceptual input. The salient agents being attended to constitute the meaning space Γ, with γ_i = object feature set. For example, the hypothesis denoting **[SS]** might represent γ_{SS} = [color:`black`, size: `25 × 25 px.`, shape: `square`, orientation: `NIL`].[3] Notice that this schema varies according to the number of features the agent is capable of deriving. The object in visual salience is then correlated with utterances that have temporal overlap with the object in focus. Since we do not assume any syntactic information at this point, every linguistic element

[3]Notice that shape: `square` is a high level concept. At present, the model can only determine through image processing techniques that length = breadth and **[BS]** and **[SS]** are of similar shape.

C1 (Come-Close)		C2 (Move-Away)		C3 (Chase)		C4 (Chase)	
move	0.033	chase	0.066	chase	0.479	chase	0.371
toward	0.028	away	0.025	try	0.115	try	0.106
corner	0.023	move	0.022	start	0.093	run	0.050

Table 3: Associating language labels to action clusters from the unsupervised algorithm

is a possible label for the objects. The association between mono- and bi-grams with the objects, for both the association measures, are shown in Table 2[4].

3.2 Verb acquisition

Once the objects are discovered, the next step is to derive perceptual relations for their interaction with each other and the surrounding. We next turn to modeling the mutual interaction between moving agents (for our input, [BS], [SS], [C]). We assume that our artificial agent is capable of employing basic unsupervised machine learning on image data, particularly the ability to segment a picture/frame, generate spatial features and cluster them into separate classes, to achieve the above mentioned goals.

Attempts to learn verbs have involved neurally inspired models of contact actions (x-schemas, (Bailey, 1997)); or a set of actions and their visual parses (Siskind, 1994; Dominey, 2005). As mentioned earlier, our perceptual schemata are discovered based on unsupervised clustering in the perception space. In this case, our perceptual extraction process depends on a specific feature that is not discovered, but these are fairly general and involve the product and difference of relative position and velocity. In earlier work (Satish and Mukerjee, 2008), we show that temporal data mining on the sequence of these feature vectors, based on Merge Neural Gas (Strickert and Hammer, 2005), yields four action clusters, two of which correspond to [come-closer] and [move-away], and two correspond to [chase].

These clusters constitute the hypothesis space for verb acquisition. These are next related to the linguistic input. For this, those sentences, which overlap temporally with the period when the action clusters are active, are taken into account, using an approach similar to (Roy and Reiter, 2005). At this point, it is assumed that the learner knows the nouns (discovered in Section 3.1), which are not considered as labels for verbs. Extremely frequent words (e.g. *the*, *an* etc.) are also dropped from consideration for mapping to actions. The strongest associations for the action clusters are shown in Table 3, with Clusters 3 and 4 (**[chase]**) having a strong association with the word *chase*.

3.3 Perceptual schema for containment

In spatial reasoning, there have been several attempts at defining spatial relations involving continuum measures defined over different geometric features on object pairs. Regier(Regier, 1996), a seminal work in preposition grounding, uses angle measures and a connectionist

[4]Notice that one word association alone might not provide sufficient information since some objects might be referred to through phrases, the validity of which is considered in Section 4.1. Also, to compare both the measures side by side, the mutual association has been scaled appropriately. The most frequent monogram *the* has been ignored in these results, which has the highest A_{ij}^{m} in all the four cases. It would later be eliminated from the probable label set anyway as it provides no information due to its occurrence in all the four label sets.

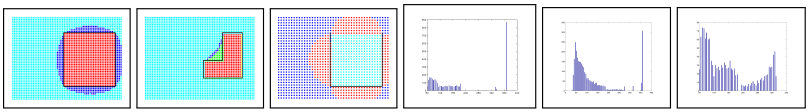

Figure 2: *Clustering through spatial features*: Figs 1-3 represent Visual Angle feature clusters. The inside of all the containers has been clearly identified as a separate cluster only in the latter case. Figs 4-6 are the visual angle histograms.

network to correlate videos and prepositions. The work, however, is limited in the sense that Regier uses videos annotated with single words like IN, OUT, THROUGH etc. while we hope to learn these schemas by clustering the untagged video. Also, because his videos are tagged with prepositions, he never has to work to *discover* the preposition; we have to discover these units from the unconstrained unparsed narrative. (Mukerjee and Sarkar, 2007) use the same dataset as ours, but use a measure based on visual proximity - the *Stolen Voronoi Area* - to cluster space using Kohonen SOMs. We initially tried these two approaches and found that in unsupervised clustering tasks (k-means and mean-shift), these earlier models do not work well for distinguishing the inside and outside of irregular (L- or U-shaped) containers. In a supervised scenario they show good results training with sophisticated neural-nets over multiple epochs, but our goal is to try not to use supervision data.

Another feature implicated in place learning in animals is *visual angle*- the angle subtended by a landmark on the retinal image. We attempted to improve on the previous features by using a single feature – the total angle subtended by a landmark at the object position. With this measure, we find that when the resulting feature space is clustered, one of the clusters works quite well for identifying the IN-schema. Computing this feature involves computing the angle that the landmark, **[box]**, would subtend at each point in the space; the result is measured and clustered using *Mean-Shift*(Fukunaga and Hostetler, 1975), so as to get non-parametric natural clusters. We can see in Fig 2 that one cluster completely covers what may be thought as the inside of **[box]**, whereas the the outside is graded between a number of clusters. If we accept this as a characterization for an image schema for containment, then the distribution of visual angle in this cluster(say the *IN-cluster* or $\mathscr{C}_{in}$) will serve to represent this relation. To test whether this model really represents the *category* of containment relations, we generalize and evaluate it over a number of other shapes. The results of clustering on two novel shapes is shown in Fig 2. We find that regions with varied levels of 'IN-ness' have been separately grouped, validating our choice of features. While for closed convex shapes the measure has a clear demarcation of 'inside'(360° angle), as is evident from the angle histograms in the figure, it gives a more graded assessment for open figures as well, such as the open-top square.

The clusters are the hypothesis space for spatial schemas. The correlation of the prominent IN-cluster($\mathscr{C}_{in}$) with words is shown in Table 4. The sentence space contained all the utterances that occurred when any of the objects in attention was inside the IN-cluster. Of interest to us is also the *change in state*, so that sentences overlapping with the object in attention moving in/out of the IN-cluster are also considered separately(Table 4, results to the right). Words *in/inside/into* are prominent, as are *into,enter* and *out,leave* for transitions in/out of IN-cluster.

4 Linguistic construct acquisition: Rudiments of syntax

At this stage, the agent is aware of some word-meaning mappings; a cognitively plausible incremental approach would suggest that the first glimmers of sentential constructions would

IN	A_{ij}^{rel}	A_{ij}^{mut}	INTO	A_{ij}^{rel}	A_{ij}^{mut}	OUT OF	A_{ij}^{rel}	A_{ij}^{mut}
inside	0.79	11.78	into	0.82	6.98	out	0.65	5.71
into	0.90	9.43	inside	0.53	1.03	leaves	1.00	4.16
in	0.61	4.16	enters	1.00	4.85	exits	1.00	3.46

Table 4: Associating language labels to the prominent IN/containment cluster

form around these recognised words. In fact, children's initial syntactic representations may be centered around individual verbs/relational items, instead of fully abstract grammars(Tomasello, 2003). There has been much work in describing such structures(Mintz, 2003; Saffran et al., 1996). The consensus seems to be that concrete n-grams or patterns ('constructional islands') like 'in the box' emerge first, with these being generalised to abstract syntactic construction like 'in the X' through distributional information in the linguistic input. We, consequently, started our discovery of syntactic structure by analyzing bi- and tri-gram correlations for containment. While the prominent bi-grams were *inside the*, *into the* and *in the*, the tri-grams that emerged were *inside the box*, *in the box* and *into the box*.

Despite some glimmers though, the n-gram approach is not very illuminating regarding the construction encoding for containment. We specifically avoid standard parsers since we are unsupervisedly discovering syntactical structures, not trained word-class labels. We, consequently, follow a richer model of syntactic structure in the spirit of cognitive grammar(Langacker, 1987), ADIOS(Solan et al., 2002), which integrates statistical and classical (generative, rule-based) approaches to syntax. It constructs syntactic representations of a sample of language from unlabeled corpus data unsupervisedly. It first creates a Representational Data Structure(RDS) by morphologically segmenting the input sentences and creating directed edges between vertices corresponding to transitions in the corpus. It then repeatedly scans and modifies the RDS to detect significant patterns through a Pattern Acquisition(PA) algorithm. A pattern tagged as significant is added as a new vertex to the RDS graph, replacing the constituents and edges it subsumes, the process being repeated and bootstrapped. Two representative patterns found through a run of ADIOS through the whole English commentary set are presented below, which provide the first indications of grouping of words in to syntactical classes:

$$1.\ \left[\begin{array}{c} the \rightarrow \left[\begin{array}{c} big \\ large \end{array}\right] \rightarrow square \\ the \rightarrow square \end{array}\right] \rightarrow \left[\begin{array}{c} scares \\ approaches \\ chases \end{array}\right] \rightarrow \left[the \rightarrow \left[\begin{array}{c} small \\ little \end{array}\right]\right]$$

$$2.\ \left[\begin{array}{c} the \rightarrow \left[\begin{array}{c} ball \\ box \\ door \\ square \end{array}\right] \\ circle \\ it \end{array}\right] \rightarrow \left[\begin{array}{c} moved \\ moves \\ runs \end{array}\right]$$

4.1 Syntactic classes refine object labels

From Pattern 2 notice that *circle, square, box, door,it,he* (say Group 1) belong to an equivalent class. Similarly, combination of words like *the big square, the little square* etc. are syntactically similar to Group 1 (Pattern 1 & 2). *open, move* etc. , on the other hand, are syntactically completely different from the aforementioned words. Also notice that *big,little,small* by themselves are not equivalent to Group 1; but as part of a bigger phrase, like *the big square*, they are equivalent to Group 1. Similar is the story with *the*. The noun label-sets from Table 2 are now curtailed to Group 1 words only, due to their high individual and combined associativity. So, while bi- and tri-grams like *small square*, *the square* are retained due to their syntactical equivalence to monograms, utterances like *door closes, circle moves* are treated as argument structures and discarded as labels. Thus, while many of these structures may offend linguists who feel they are overfitted to this particular input, it cannot be denied that it is a working model for characterizing path level agglomerations in the input.

However, in the mean while, we would like to emphasize that the process of deriving syntactic information (this Section) and mutual association of linguistic and perceptual elements (Sec 3) are not mutually exclusive or ordered processes. Even though we have described syntactic information discovery after we have motivated perceptual to linguistic element mappings, we do not assume that they are ordered that way. In fact, being independent events and mutually informative, they might as well run parallelly.

4.2 Verb and relational argument structure

Other important *containment and chase-specific* patterns, however, are hardly discovered due to the presence of myriads of different structures leading to the diffused nature of the dataset. We, consequently, follow the cognitively plausible incremental approach. We isolate those parts of the corpus that co-occur with containment/chase situations in the perceptual input, with a view that unsupervised analysis of this sub-corpus discovers regularities that are more *specific* than can be achieved under the same computational constraints for a broader corpus. The knowledge of linguistic elements *in/into/inside* and *chase* from word-label association helps constrain the corpus to a focused sub-set of 107 sentences for IN(each containing one of those words) and 36 sentences for CHASE, which facilitates discovery of some prominent structures:

1. [Group 1 word/phrase] → [CHASE (*chases/is chasing*)] → [Group 1 word/phrase]
2. [CHASE (*chased*)] → [by] → [the] → [little]
3. [CHASE (*chases*)] → [little] → [Group 1 word/phrase]

1. [Group 1 word/phrase] → [IN] → [the]
2. [Group 1 word/phrase] → [verb] → [IN] → [the]
3. [Group 1 word/phrase] → [verb] → [IN]
4. [Group 1 word/phrase] → [verb] → [other linguistic elements] → [IN]
5. [IN]→[the]→[Group 1 word/phrase]

	CHASE			IN				
Pattern No.	**1**	**2**	**3**	**1**	**2**	**3**	**4**	**5**
Frequency	17	3	2	10	26	7	10	36
'ground-truth argument' frequency	20/34	1/3	1/2	10	18	5	9	27
'ground-truth argument' % age	59	33	50	100	69	71	90	75

Table 5: *Correlating perceptual and linguistic argument structure-CHASE & IN*

In fact, this practice of constraining hypothesis space to facilitate quick learning is supported in literature(Siskind, 1996), albeit in different contexts. Before proceeding though, we would like to emphasize that the claim is not that these are not the only patterns that are possible:[5] Our focus here is to investigate how amongst the set of plausible patterns, some are preferably acquired due to evidence and bias and strong correlation to perceptual domain. The above patterns each include at least one object term(Group 1 term) and one relation/verb term, following the hypothesis that out of patterns emerging from purely statistical data, the patterns that have a previously learned label, might be favorably acquired.

While these structures have been derived from purely linguistic input, their *grounding*(bootstrapping in perception) is possible only if they show remarkable correlation with the perceptual argument structure, which they indeed do, as can be ascertained from Table 5. In the table, 'ground-truth argument' means the perceptual and linguistic agents are in conformation. Conflict cases involve both when the linguistic agent is different from the perceptual agent (e.g. in video [CHASER] is **[BS]**, but in the utterance, [CHASER] is *circle*) and when the linguistic agent is unfamiliar (e.g. in video [CHASER] is **[BS]**, but in the utterance, [CHASER] is *big block – block* is syntactically equivalent to *square* so that the structure is valid, but the agent has not *yet* associated it with any perceptual objects from past evidence). Since Structure 1 has two referents, the total number of referents for 17 sentences is 34. While raw correlation is greater than 50%, if we discount the sentences with unfamiliar linguistic agents, there is 100% correlation between linguistic and perceptual schemas, thereby making the linguistic argument structure concrete.

All the IN patterns show more than ∼70% correlation between the two domains, leading to the grounding of respective structures. Note that the attention based model for learning nouns cannot learn the container/box, which is never dynamically salient. Thus, it's label is unknown. However it is prominent in these containment sentences, and discounting the frequent word *the* in trigrams such as "*{ inside/in/into} the box*", we may associate *box* with **[box]**, treating it as a label for the container. It logically follows since **[box]** is a physical object, and based on the past experience of the agent, should be assigned a linguistic element that syntactically confirms to concepts of other physical objects[6] like **[BS], [SS]** etc. From the above patterns, the syntactical equivalence of *box* is supported by its grouping with *door, square* etc.(see Pattern IN4). This grouping into equivalent classes is the first evidence of word category acquisition. The primary mapping of *box* to **[box]** is further strengthened from Table 5, where *box* has been taken as the 'ground-truth argument' for **[box]** and with this assumption, more than 75% of the IN2 pattern sentences agree in both perceptual and linguistic domain, thereby facilitating the

[5]In fact, from a statistical viewpoint, with change in length of input and variation in ADIOS parameters, myriads of patterns can emerge.

[6]For the present set-up, all the moving objects and the container can be derived through image segmentation, thereby being similar 'physical' objects.

[BS]			[SS]			[C]			[IN]		
word(s)	A_{ij}^{rel}	A_{ij}^{m}	word(s)	A_{ij}^{rel}	A_{ij}^{m}	word(s)	A_{ij}^{rel}	A_{ij}^{m}	word(s)	A_{ij}^{rel}	A_{ij}^{m}
बक्सा baksA/box	.77	.37	बक्सा baksA/box	.62	.44	गोला golA/ball	.83	.54	अन्दर andar/in	.80	1.30

acceptance of the assumption. In fact, of the 9 mismatched referents, only 3 are wrong (*in the door/corner/place*, while the rest are due to synonymous references (*in the room*, *in the square*).

One possible consequence of grounded syntax is a facilitation of acquisition of minor labels, synonyms and anaphoras, which are overwhelmed by other salient labels in a simple association task. While we have not entered into a serious investigation of this, some rudimentary results are apparent nonetheless. *ball* and *room* occur 5 and 6 times respectively in positions A and B in sentential domain in 'A in/inside/into B' and map exclusively to $x =$ **[C]** and $y =$ **[box]** for xINy in perception, so that they are treated as synonyms for *circle* and *box* (in this scenario). *block* has been used for both **[BS]**(75%) and **[SS]**(25%), creating an equivalence with *square*. Similarly, *it* maps to **[BS]**, **[SS]** and **[C]** in 56, 25 and 19 percent of its occurrences, thus showing the first evidence of anaphora acquisition, though we leave a detailed investigation to a future work. How these acquired structures can further be extended to assimilate metaphors and how they are developmentally salient for the concept of containment, has been investigated in much detail elsewhere (Nayak and Mukerjee, 2012).

Potential application to other languages To investigate the potential extension of this approach to other languages, we obtained results for Hindi obtained without any change in the methods. The Hindi database consisted of 10 commentaries from first-language speakers, with more than 200 sentences and 2000 words, describing the same video (e.g. तो लगता है कि यहां एक बडा बक्सा है जिसमें एक चौकोर है [to lagtA hE ki yahAN ek badA baksA hE jismeN ek chokour hE / `It seems that there is a big box here in which there is a square present.`]). Hindi is a much more richly inflected language than English, with abundance of gender and number agreements. Even verbs have several modal affixes in addition to tense and, several postpositional markers for case, which sometimes mark for source and destination as well. The constructions derived from ADIOS, therefore, are diffuse and minimal, owing to the small dataset(200 sentences, compared to 700 in English). So, while a detailed investigation of syntax grounding is far-fetched at present, the emerging patterns show consistencies with their English patterns nonetheless (*comes/runs out of box*):

$$\begin{bmatrix} \text{डब्बे(dabbA/box)} \\ \text{बक्से(bakse/box)} \end{bmatrix} \rightarrow \begin{matrix} \text{के} \\ \text{(ke/–)} \end{matrix} \rightarrow \begin{bmatrix} & \text{बाहर(bAhar/out)} & \\ \text{बाहर} & \begin{bmatrix} \text{आ(aa/come)} \\ \text{भाग(bhAg/run)} \end{bmatrix} & \text{जाता} \\ \text{(bAhar/out)} & & \text{(jAtA/goes)} \end{bmatrix}$$

Furthermore, similar results to English are found for word-to-meaning mappings (See Table 6). Also, we have पीछा(pichA/chase) as the dominant label for the verb clusters, with $(A_{ij}^{rel}, A_{ij}^{mut})$ of $(0.78, 19.79)$ and $(0.64, 13.7)$ respectively for Clusters 3 and 4 from Sec 3.2.

Conclusion and perspectives

The work described is able to learn a limited set of lexical items and grammatical constructions for a small domain. If it would be possible for the system scale up, one may suggest that such a system might be able to learn an increasing number of concepts from a larger number of domains, as it happens with children. Indeed, the holy grail of computational linguistics would be to create such semantically rich models of language, and alternatives like this approach are at the very least worth investigating further. But how difficult would it be to scale up this computational approach to new domains and new concepts?

The reason why minimal commitment is attractive is of course, precisely because it makes it easier to extend the approach to other physical domains or other languages. Situations where other concepts have saliency would make it more likely that associations with linguistic expressions mapping them would be learned. Also, with the capacity for simulation, it is no longer necessary to have direct grounding for learning everything. In a sentence where a novel term or concept is introduced, the meaning of the term, or the concept itself, may be understood by simulating what is known from the other parts of the expression. Indeed this is how humans learn the vast majority of our immense vocabularies (Bloom, 2000).

What the initial term-meaning pairing provides is an index into the space of meanings. The next time a similar expression is encountered, the new semantics are compared with the previous mental model so it can be extended. Thus if our system here, which knows "in the box", now encounters "in the basket" and "in the room", it would gradually be able to generalize the argument of "in the" to the concept of container (and would eventually reject "in the banana", say). Further, as we have demonstrated elsewhere (Nayak and Mukerjee, 2012), once the system encounters increasingly figurative expressions such as "in the team", "in the school", "in the spotlight", "in the doghouse", it would be able to extend this using the analogy mechanism inherent in the sensorimotor schemas used for grounding. We emphasize again the need for sensorimotor grounding without which such sense extensions are clearly not possible.

This work presents a view that takes seriously and implements computationally, the ideas in Cognitive Grammar (CG) (Langacker, 1987), as opposed to traditional grammars. This view is part of the models in (Regier, 1996; Bergen et al., 2004; Chang and Maia, 2001), but ours is the first to propose a model that also learns the semantics, thus freeing it up to learn new structures in new domains. What is really being learned in this process is what is called an image schema in CG and for larger structures, a more elaborate schematization. With the grounded model, as we encounter increasingly complex perceptual schema that map to longer phrases, it should also be possible to discover the processes of composition in CG.

At this point, such claims may seem too remote, but they are not completely implausible and given their potential for changing the way NLP works today, we would argue at least for the widespread development of corpora with image streams along with multiple raw text narratives in many situations and many languages. We make a humble start in this direction by making our image and text corpora in several languages available on the web. Agents that accumulate the learning from several domains may prove (or disprove, or suggest new directions) in the enterprise. The main claim we are making is that this is a novel approach to language induction, and while its potential is far from clear, at least it is worthy of further investigation.

ABSTRACT
Automatically extracting terminology and index terms from scientific literature is useful for a variety of digital library, indexing and search applications. This task is non-trivial, complicated by domain-specific terminology and a steady introduction of new terminology. Correctly identifying nested terminology further adds to the challenge. We present a Dirichlet Process (DP) model of word segmentation where multiword segments are either retrieved from a cache or newly generated. We show how this DP-Segmentation model can be used to successfully extract nested terminology, outperforming previous methods for solving this problem.

KEYWORDS: Dirichlet Process, segmentation, Bayesian learning, index term, keyphrase extraction.

Proceedings of COLING 2012: Technical Papers, pages 2077–2092,
COLING 2012, Mumbai, December 2012.

1 Introduction

Index terms and keyphrases are widely used to enhance the browsing/accessibility of documents, especially scientific literature (Gutwin et al., 1999). Index terms are the main terms and concepts in a document, as would be contained in the index of a book or edited collection of papers, for example. They typically number in the hundreds for a single volume, and are conventionally annotated for their key occurrences in the document. Keyphrases are assigned to each document in the form of a handful of terms which capture the key topics or concepts covered in the document. Keyphrases are commonly used as a means of clustering/linking documents in digital libraries. While there is no question of the utility of both index terms and keyphrases, annotating a document with index terms is an arduous and largely unrewarding task, and annotators are notoriously inconsistent at index term and keyphrase assignment (Leonard, 1977; Kim et al., 2010). As such, there is a real need for computational methods which both speed up and homogenize the assignment of index terms and keyphrases.

The focus of this paper is an unsupervised methodology for automatically identifying both index terms in a document collection and keyphrases for a single document. The methodology is called Dirichlet Process Segmentation (DP-seg) and was originally developed by Goldwater et al. (2009) for the task of word segmentation over phoneme streams, in the context of child language acquisition. DP-seg is particularly well suited to the tasks of index term identification and keyphrase extraction because: (1) it is able to identify individual type-level occurrences of a given term; (2) it is context-sensitive and able to robustly deal with "nested" multiword terminology (e.g. are *support vector* and *vector machine* also index terms, or just *support vector machine*?); (3) it is highly sensitive and can be applied to small-scale corpora (important for keyphrase extraction, where the input may be a single document); and (4) it is highly parameterizable.

Our contributions in this paper are: (1) the novel application of DP-seg to the tasks of index term identification and keyphrase extraction; (2) construction of a number of index term identification datasets spanning a number of scientific domains; and (3) extensive empirical comparison with standard methods for multiword extraction, and demonstration of the empirical superiority of DP-seg.

2 Related Work

There are several closely related language modeling tasks in this area that differ in important ways. Here we further clarify what tasks we are addressing in this paper, and review related work for each.

We define a multiword term (i.e. n-gram, where $n \geq 2$) as any contiguous sequence of terms in a sentence from some text. We use the usual convention of *types* being the list of distinct multiword terms (at a document or document collection level), and *tokens* being the specific appearances of those multiword terms in the text. Note that we can extract *types* and/or *tokens* either from a single document, or a collection of documents, and our focus for this work will be collection/corpus-based extraction.

Collocation extraction is a well known task that has been extensively researched. In collocation extraction, the goal is to extract a list of types from a single document, often of a particular type (e.g. as defined by a POS tag sequence: Evert (2004); Pecina (2008)). Evaluation is done by comparing to a gold standard produced by lexicographers. Identification of multiword expressions (MWEs) is a related task, but operates at the token level, often relative to a prede-

termined MWE type or lexicon of MWE candidates (Kim and Baldwin, 2010; Baldwin and Kim, 2009). Arguably the closest task to what we are doing is Keyphrase extraction, and indeed our content of interest is scientific literature (Witten et al., 1999; Kim et al., 2010). Keyphrase extraction operates over individual documents, often based on corpus-level lexical analysis. In this paper, in addition to experimenting over keyphrase extraction as conventionally defined, we introduce the additional task of index term extraction.

Extraction of index terms from a corpus is important and useful for a wide variety of digital library and scholarly applications. It extends keyphrase extraction (which is typically performed on a single article or document) to the broader setting of extracting all concepts from a book or collection of papers. Thus index terms tend to be more numerous than keyphrases (the index of a textbook may list hundreds of index terms). Unlike keyphrases, index terms cover all concepts appearing in text — from fairly general concepts (e.g. *training data*) to specific concepts (e.g. *textual entailment*). We are interested in both type-level extraction (for the index) and token-level identification (to be able to identify the individual occurrences in the text) of index terms. An important aspect of our task is uncovering the correct *nesting*. Extraction methods need to correctly determine when to choose a shorter and more general n-gram (e.g. *machine translation*) vs. a longer and more specific n-gram (e.g. *statistical machine translation*), while avoiding extracting nonsensical n-grams (e.g. *statistical machine*).

Keyphrase extraction is closely related to index term extraction. Recently, there was a shared task on keyphrase extraction in SemEval-2010 (Kim et al., 2010), where over twenty teams submitted systems to extract keyphrases from a set of 244 computer science articles. Evaluation was done against a matching set of gold standard keyphrases. We include this SemEval dataset in our experiments, and compare to those published results.

Perhaps the closest related work to our current work is the c/nc-value algorithm (Frantzi et al., 2000), which is designed for extracting and ranking a list of terminology types from a corpus. The c/nc-value algorithm specifically finds and ranks *nested* multiword terminology (such as *support vector* as well as *support vector machine*). The c/nc-value algorithm is a heuristic that takes as input the exhaustive list of 2- through 5-gram noun chunks. The c-value is a score that is an "effective" frequency, which includes an upweighting of $\log n$ for n-grams, to take into account the geometrically fewer n-grams as n increases. The algorithm also includes a discounting of n-grams that appear in longer n-grams. The goal of the algorithm is to discover all nested terminology. The nc-value part of the algorithm is an extra boosting of the signal by using context information. Frantzi et al. showed c/nc-value to work well for producing the lexicon of index term types from a relatively small set of documents.

3 Bayesian Segmentation

Our DP-seg model is a direct adaptation of the Bayesian model of Goldwater et al. (2009). In that work, Goldwater et al. took a stream of phonemes to discover English words, with the goal of correctly identifying word boundaries. We adapt their model and apply it to the problem of taking a stream of words, and finding suitable boundaries between multiword segments. To provide a context of what is an appropriate multiword segment, we have defined our goal as identifying and extracting index terms (i.e. terms that would plausibly appear in an index). We note that our multiword version of this problem operates on a much larger scale than the multi-phoneme problem. Instead of learning a lexicon of 1000s of words from approximately 100 phonemes, we are learning a lexicon of possibly millions of multiword segments from a list of $\sim$100,000 words.

We present and describe the DP-seg model almost verbatim from Goldwater et al. (2009). The model assumes that the sequence of n-grams or multiword segments (MWE) in the corpus is generated using the following four steps:

1. Generate the number of MWE types that will be in the MWE lexicon
2. Generate the token frequency for each MWE type
3. Generate the word-sequence representation of each MWE type
4. Generate an ordering for the set of MWE tokens.

In the unigram version of the model where multiword segments are statistically independent, the ith MWE is generated as follows:

1. Decide if mwe_i is a novel lexical item
2. **(a)** If so, generate an MWE form (words $w_1 \ldots w_M$) for mwe_i
   (b) If not, choose an existing lexical form x for mwe_i

We assign probabilities to each of the above steps as follows:

1. $\text{P}(\text{mwe}_i \text{ is novel}) = \frac{\alpha}{n+\alpha}$, $\text{P}(\text{mwe}_i \text{ is not novel}) = \frac{n}{n+\alpha}$
2. **(a)** $P(\text{mwe}_i = w_1 \ldots w_M | \text{ mwe}_i \text{ is novel}) = p_{\#}(1-p_{\#})^{M-1}\Pi_{j=1}^{M} P(w_j)$
   (b) $P(\text{mwe}_i = x | \text{ mwe}_i \text{ is not novel}) = \frac{n_x}{n}$

where α is a parameter of the model, n is the number of previously generated MWEs, n_x is the number of times lexical item x has occurred in those MWEs, and $p_{\#}$ is the probability of generating a segment boundary. We combine these probabilities to get the following expression for the distribution over mwe_i given mwe_{-i}, the previous MWE:

$$P(\text{mwe}_i = x | \text{mwe}_{-i}) = \frac{n_x}{i-1+\alpha} + \frac{\alpha P_0(\text{mwe}_i = x)}{i-1+\alpha} \quad (1)$$

where P_0 is the probability of generating the MWE anew, as per Step 2(a) above. Note that in all of the above, the MWE can consist of a single word.

As Goldwater et al. point out, this model is quite intuitive. In Step 1, when n is small, we are more likely to generate a new multiword segment. As n grows, we increasingly tend to retrieve the multiword segment from the cache. Also, the model discourages long segments through longer products of probabilities. By having the likelihood of retrieving a multiword from the cache depend on its frequency, we produce a power-law distribution of multiword types, which is appropriate for language modeling.

This model is a type of Dirichlet Process, a popular tool in Bayesian statistics for nonparametric modeling, where the dimensionality of our MWE lexicon grows with the size of the data. The Dirichlet Process has two parameters, the concentration parameter α and the base distribution P_0. Formally, $\text{mwe}_i | G \sim G$, $G|\alpha, P_0 \sim \text{DP}(\alpha, P_0)$. As is customary, we integrate out G, and estimate the conditional probability of sampling a MWE by the Chinese Restaurant Process (CRP). Simply stated, the CRP is where the ith customer entering a Chinese Restaurant sits at table i with probability proportional to the number of people sitting at table i, or sits at a new table with probability proportional to α. Note this generation of MWEs is the two stage adaptor grammar framework described by Goldwater et al. (2005), with P_0 as generator, and CRP as the adaptor. The CRP is the basis of the cache model: One either generate MWEs by either retrieving from cache (existing table), or generate anew (new table).

3.1 Inference

For inference, we use the Gibbs sampling procedure presented by Goldwater et al. The Gibbs sampler considers one possible segment boundary point at a time, so each sample is from a set of two hypotheses, H_0 and H_1. These hypotheses contain all the same segment boundaries except at the one position under consideration, where H_1 has a boundary and H_0 does not. To sample a hypothesis, we calculate the relative probabilities of H_0 and H_1. Since H_0 and H_1 are the same except for a few rules, this is straightforward. Let H^- be all of the structure and data shared by the two hypotheses, including n words. Then, given MWEs w_1 and w_2 and the combined MWE w_{12}, using Equation 1 we get:

$$P(H_0|H^-) = \frac{n(w_{12}) + \alpha P_0(w_{12})}{n + \alpha} \quad (2)$$

$$P(H_1|H^-) = \frac{n(w_1) + \alpha P_0(w_1)}{n + \alpha} \cdot \frac{n(w_2) + I(w_1 = w_2) + \alpha P_0(w_2)}{n + 1 + \alpha} \quad (3)$$

During preliminary experiments, we learned segmentations with DP-seg using between 5000 and 20000 sweeps through each corpus. We performed convergence checks to determine an appropriate number of iterations of the Gibbs sampler. Convergence can depend on thematic coherence and phrasing redundancy in the text (for example, a collection of abstracts from a PubMed search will have more repeated n-grams than a similar sized collection of full-text articles). By creating an approximate gold standard (using 20,000 iterations and averaging over 10 differently initialized runs), we determined that 5,000 iterations of the Gibbs sampler produced reasonably well-converged segmentations. For all experiments, except for those investigating the effect of parameters, we used Goldwater's settings of $\alpha = 20$ and $p_{\#} = 0.5$. We also used an annealing schedule with initial exponent of 0.1, going up to a exponent of 1 after 90% of the iterations, then no annealing for the final 10% of the iterations.

3.2 Pre-Processing

As with many NLP tasks, we have a variety of choices for preprocessing the raw input text. Some of these choices include whether to lemmatize (including stemming as a crude form of lemmatization), whether to POS tag, and whether to remove frequently occurring stopwords. Because we compare DP-seg to c/nc-value algorithm results, for the majority of experiments we selected a preprocessing strategy that was consistent with the input required by the c/nc-value algorithm. We used OpenNLP for lemmatization and POS tagging, and filtered out stopwords from a very limited list of common stopwords consisting of prepositions and determiners (fewer than 100 stopwords in total). Note that this would make terminology such as *part of speech* appear as *part speech*. Since DP-seg does not require *any* preprocessing at all, for some experiments, we omitted all preprocessing to examine its effect.[1]

4 Datasets

We used a combination of new and existing datasets for our experiments. Since there are no readily-available gold-standard datasets for index terms, we generated our own. What constitutes an index term can be subtle and debatable: some index terms are obvious, such as *semantic role labeling*; others are less so, e.g. *training data* is a concept, albeit general, that

[1]Note, however, that preprocessing has a significant impact on runtime for DP-seg: the larger the vocabulary and longer the texts, the longer the runtime.

Collection	Source	Num. Docs	Num. Words
ACL	ACL Corpus	17k fulltext	40M
NIPS	NIPS Corpus	2k fulltext	5.4M
DNA	PubMed search results	60k abstracts	7.0M
HGT	PubMed search results	7k abstracts	0.7M

Table 1: Description and sizes of the four document collections.

could reasonably be found in an index, while *data point* is probably too generic to be found in most indexes.

4.1 Document Collection Data

Our experiments start with four document collections from scientific/technical literature, described in Table 1. The ACL corpus consists of fulltext research articles from computational linguistics (Radev et al., 2009). The NIPS corpus consists of fulltext articles in machine learning and neurobiology (from `books.nips.cc`). The final two document collections are search results sets from PubMed (`www.pubmed.gov`). The DNA collection contains titles and abstracts in the search results from the query *dna microarray*. The HGT collection contains titles and abstracts in the search results from the query *horizontal gene transfer*. All four of these collections are rich in technical terminology and nested index terms, and thus ideal for experimentation.

4.1.1 Creating Gold Standard

We created a list of gold standard index terms from our four datasets to evaluate the performance of DP-seg. Because of the size of these datasets (over 80K documents and 50M words), it was not possible to annotate an exhaustive/comprehensive list of index terms. Therefore we used a pooling strategy to create a gold standard from top-ranked candidate terms, using the top-1000 index terms from DP-seg, c/nc-value and the Student's t-test (a baseline lexical association measure for collocation extraction), restricted to noun chunks. Note that the ranking for c/nc-value and t-test is based directly on the scores returned by the methods, while the ranking for DP-seg is based on the token-level frequency of each term in the output.

We used the union of all of these candidate index terms for annotation, and randomized the set so that annotators had no insights into which candidates came from which method. A preliminary observation of this list indicated that these top-ranked index terms were dominated by bigrams. Since we were interested in understanding the performance of DP-seg and c/nc-value on nested terminology, we also included for annotation the top-100 4-grams and 3-grams, and all 3-gram and 2-gram subphrases for each.

We used a pool of 25 annotators to annotate subsets of the combined list of 6500 candidate index terms, requesting a binary judgment on whether the candidate term was a plausible index term. We had a minimum of 3 annotators per candidate index term, and an average of 4.4 annotations per candidate index term. In cases of disagreement, we took the majority decision. Our instructions to annotators stated:

> For each of the following expressions, judge its appropriateness as an "index term" (as in it would be appropriate for inclusion in the index of a book or edited volume of papers). The expression has a

well-defined standalone meaning and would be appropriate for inclusion in an index of terms for that domain (e.g. *decision tree*, in the case of the machine learning domain, but not *observable markov* as it is an incorrectly-extracted sub-string of something like *partially observable markov decision process*).

The annotation tasked proved reasonably straightforward, with an inter-annotator agreement of 0.65 using Fleiss' kappa, suggesting substantial agreement.

4.2 SemEval Keyphrase Extraction Data

In addition to our four collections of index terms, we used an existing dataset for keyphrase extraction evaluation — the SemEval-2010 keyphrase extraction data. The SemEval data is a collection of 244 scientific articles released as part of a shared task for keyphrase extraction (Kim et al., 2010). In each document, there is a set of author- and reader-assigned keywords, and all keyphrases are stemmed using the English Porter stemmer. The gold standard keyphrases for each document are largely extracted from the document text, although approximately 15%-19% of the keyphrases do not appear in the paper.

To evaluate the participating systems, micro-averaged F-scores are calculated over the top-5/10/15 candidates. A candidate is considered a match if it is an exact match with one of the gold standard keyphrases; partial matching is not considered in the evaluation.

Note that there is a subtle difference between the two tasks: index term identification is annotated/evaluated at the *document collection* level (separately for each of our four document collections), while keyphrase extraction is annotated/evaluated at the *document* level. Another reason for evaluating our method over keyphrase extraction is that the task is well established, and we can benchmark DP-seg against results for pre-existing systems tuned to the task.

5 Results

Standard evaluation for this type of task is based on precision (P), recall (R) and F-score (F), at the level of either types or tokens. In our index term data, we don't have exhaustive annotations, meaning we aren't able to evaluate recall. Instead, we use precision at N (P@N), which measures what proportion of the top-N ranked n-grams match gold standard index terms. We are guaranteed coverage up to N=1000, as that is what was used to create the list of n-grams for annotation. We also use Mean Average Precision (MAP), a scalar version of the precision measurement, making it useful to evaluate choices of parameter settings or other operational decisions.

5.1 Index Term Results

The output of DP-seg is a nonoverlapping partitioning of the input corpus into a sequence of n-gram segments. For all our methods, we require an index term to be an n-gram segment of length $n \geq 2$ that is a noun chunk. Note that we start with a simplistic definition of a noun chunk: any n-gram that includes a sequence of adjectives or nouns ending in a noun. An initial indication of the segmented output from DP-seg can be seen in the segmentation of recent COLING and ACL article titles in Table 2. Based on cursory observation, many familiar bigrams (*dependency parsing*, *entity disambiguation*) appear in segments (note that we are showing the lemmatized and stopped text input). We also see some familiar longer segments (*loopy belief propagation*, *latent variable model*).

Table 3: Twelve most frequent types, corpus-wide.

Table 3 shows the 12 most frequent *n*-gram types from DP-seg, on our four corpora. The number in parentheses is the non-overlapping count of that exact type in the output of DP-seg (e.g. the 838 count of *optimization problem* for NIPS does not include any counts of *convex optimization problem*). The list of most frequent types in the table looks reasonable, given the domain of each corpus. Note that the most frequent types include some very general concepts (e.g. *training data* and *training set* are in both the ACL and NIPS top-12 list), and in the case of the PubMed search results, some unsurprising specific concepts, including our original query *dna microarray* and *horizontal gene transfer*. Note that the ACL and NIPS corpora only include bigrams in their top-12 list, reflecting the wider range of topics covered in these collections.

Table 4 and Table 5 show the 10 most frequent 3-gram and 4+ gram noun phrases from DP-seg for the ACL and NIPS corpora, with the number in parentheses again showing the count. We see that the 3-grams are approximately one order of magnitude less frequent than the bigrams shown in Table 3. We see another drop in the frequency for the 4+-grams, compared to the 3-grams. In the 4+-grams we see another phenomena: that of the definitional mention of a concept followed by the three (or more) letter acronym, such as *word sense disambiguation wsd*. In the original text, this would have appeared as *Word Sense Disambiguation (WSD)* with

capitalization and parentheses around the acronym, which is lost in our preprocessing due to lowercasing and the removal of punctuation, including parentheses.

5.1.1 Empirical Evaluation

The P@N results for DP-seg, c-value, nc-value and t-test are shown in Figure 1. The four panels correspond to each of our four corpora, with P@N on the vertical axis, and N on the horizontal axis. We see that DP-seg outperforms c-value, nc-value and t-test across the range of datasets and values of N. P@N is a useful metric operationally, since one might consider or use the top-N ranked items from a system. We see the greatest difference of DP-seg against c/nc-value and t-test for the DNA and HGT datasets. This is largely due to the greater frequency of nested terminology, and the ability to DP-seg to better handle nested terminology.

When we examine the effectiveness over the top-ranked 3- and 4-grams and their subphrases in Figure 2, we see a consistent picture of DP-seg outperforming c-value and nc-value (note: there is no t-test curve here since t-test was only used to produce bigram index term candidates). The larger difference in results, particularly in the ACL and NIPS datasets, is due to the more challenging task of correctly solving the nesting problem. DP-seg is more adept at segmenting nested terms, e.g. it correctly identifies *statistical machine translation* and *machine translation* with high frequency, but *statistical machine* on its own is ranked quite low. Conversely, c/nc-value performs poorly on this task, incorrectly listing, e.g., *horizontal gene* as one of the top-ranked index terms.

This limitation of the c/nc-value algorithm is highlighted in Table 6, which compares the top-ranked index terms from DP-seg and nc-value on the HGT dataset. We see that DP-seg has 100% precision over the top-12 returned results, while nc-value only has 75% precision. Despite its attempt to properly discount nested subphrases, c/nc-value fails to recognize that terms such

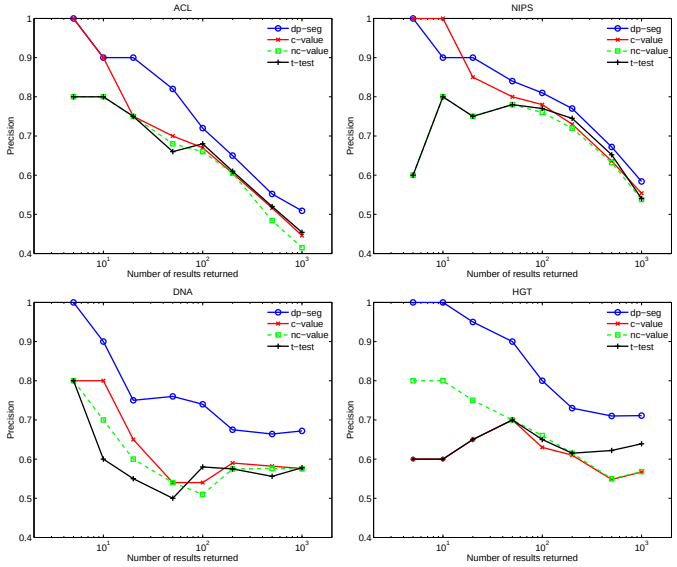

Figure 1: P@N after N results returned, for N up to top-1000 ranked results.

as *horizontal gene* do not exist.

5.1.2 Effect of Model Parameters

The DP-seg model has only two parameters: α and $p_\#$. α controls sparsity, i.e. the number of distinct n-gram types. The probability of segment boundary $p_\#$ controls the average length of n-grams. In our results to date, we have used the default values of $\alpha = 20$ and $p_\# = 0.5$.

We observe the effect of α and $p_\#$ using the NIPS and HGT datasets in Figure 3. The left panel shows the size of the n-gram lexicon versus α. As α increases eight orders-of-magnitude, we see approximately a one order-of-magnitude increase in the size of the multiword lexicon. The right panel shows the percentiles of n-gram lengths versus $p_\#$. As $p_\#$ decreases from 0.999 to 0.001 (viewing right to left), we see an increase in the length of the longest n-grams. Note that around our operating range (i.e. $p_\# = 0.5$), the curves produce a reasonable distribution of n-gram lengths. The average length of n-gram segments has a relatively weak dependence on $p_\#$. As $p_\#$ increases from 0.001 to 0.999 (arguably relatively extreme values), the average length decreases only from 1.34 to 1.30 (NIPS), and decreases from 1.28 to 1.24 (HGT).

The effect of α and $p_\#$ on Mean Average Precision (MAP) for NIPS and HGT is shown in Figure 4. We see a slight decrease in MAP as the DP concentration parameter α increases, although the reduction in MAP is slight compared to the large increase in α. As the probability of segment boundary $p_\#$ increases from 0.1 to 0.9, there is almost no effect on MAP. The rel-

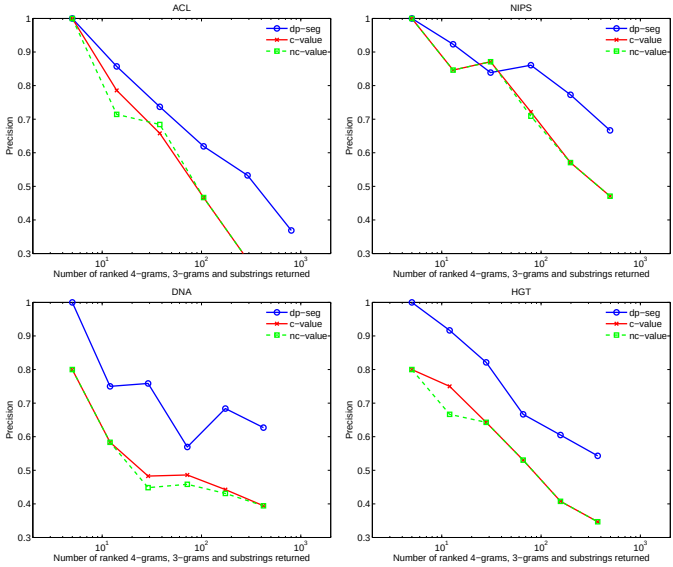

Figure 2: Precision for top-100 4-grams, 3-grams, and subphrases.

atively weak effect of the parameters on MAP is explained by MAP being a precision-focused metric, and that we only have relatively high frequency positive examples labeled. The precision/recall tradeoff is well known for this type of parameter, with precision decreasing and recall increasing as α increases.

Given our Bayesian framework, we could in principle learn α and $p_{\#}$, however we opt for the simpler choice of fixing α and $p_{\#}$, and leave this optimization for future work.

5.1.3 The Effects of Pre-Processing: POS Tagging and Stopword Removal

One advantage of DP-seg is that it can run on any stream of tokens, and does not require lemmatization, POS tagging, parsing or removal of common stopwords (stopping). To allow for a fair comparison with c/nc-value algorithm, we did POS tag and remove stopwords for datasets in Section 4, creating a single input representation used by all algorithms (including t-test). In this section we investigate the effect of relaxing this preprocessing for DP-seg, and running DP-seg without POS tags, and without removing stopwords.

The Mean Average Precision (MAP) results for HGT and NIPS are shown in Table 7a. The first row shows our baseline case of POS tagged and stopped. In the second row, DP-seg is run without POS tags. Since our gold standard only contains noun phrases, we only evaluate using noun phrases. In the third row, DP-seg is run on raw text that only has punctuation removed. Again the final output is filtered for noun phrases. We see a relatively robust result that the performance of DP-seg is relatively good, even with minimal preprocessing.

DP-seg	nc-value

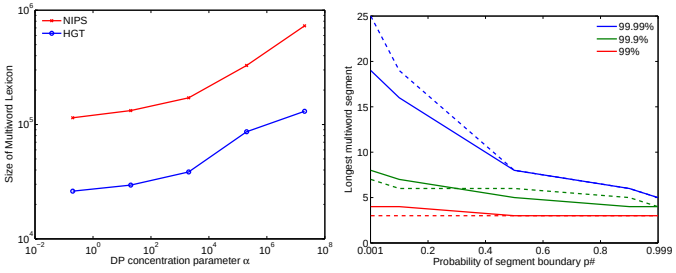

Figure 3: Effect of model parameters α and $p_{\#}$ on the lexicon size and distribution of n-gram length (in the right-hand figure, solid lines are percentiles from NIPS, and dashed lines are percentiles from HGT).

In the SemEval experiments in Section 5.2, DP-seg is run on the provided text as is, without any POS tagging or stopword removal.

5.2 SemEval Results

We ran DP-seg on the SemEval corpus of 244 fulltext articles. We used the input text as is (which was stemmed), for consistency with the published SemEval results. We performed the same evaluation as Kim et al. (2010), computing micro-averaged F-scores calculated over the top-5/10/15 candidates, with a candidate only being considered a match if there is an exact match with one of the gold standard keyphrases. We base the selection of the top-N candidates on only n-grams, ordered by the token-level frequency within the document.

The results are shown in Table 8, with the rows ordered by overall performance. DP-seg (which is completely unsupervised) easily outperforms the unsupervised TF-IDF-based baseline system. In all cases except one, DP-seg outperforms the average score across twenty special-purpose built systems for keyphrase extraction (second row). If DP-seg were competing in this shared task, it would have ranked 11th out of twenty systems based on the top-15 results (and 9th based on the top-5 and top-10 results) and beaten the average for participating systems in all of top-5, top-10 and top-15 evaluations (Kim et al., pear). Note, however, that only two of the systems that performed better than DP-seg are unsupervised (namely El-Beltagy and Rafea (2010) and Bordea and Buitelaar (2010)); all other systems are explicitly trained on the train-

ing documents provided for the task. The fact that we are competitive over the task without any tweaking of the method or reranking of the results is highly encouraging, and complements the P@N results in Section 5.1.1. Also note that this experiment was run without POS tagging and without stopwords removed, adding to the evidence that DP-seg is robust to these preprocessing choices.

6 Discussion and Conclusion

Our results indicate that DP-seg performs well at both index term identification and keyphrase extraction. As part of this, it performs well at disambiguating nested index terms from scientific literature — that is determining an optimal non-overlapping partitioning of a stream of words in a corpus — into a sequence of n-grams. Places where DP-seg tends not to perform so well are examples such as *previous work* and boilerplate text such as authors thanking *anonymous reviewers [for] helpful comments*, which are formulaic and certainly characteristic of the domains we are working with, but not appropriate index terms of keyphrases. Given that DP-seg is based simply on the text stream and doesn't capture positional information in the document, it has no way of differentiating these from conceptually-grounding index terms. One possible research direction for dealing with this issue would be to incorporate positional information (e.g. document zones or argumentative zoning (Teufel et al., 1999)).

As Goldwater et al. found, the unigram DP-seg model tends to be overconfident with very limited data. If it has never seen a particular n-gram, it is reluctant to form that n-gram, but

Method	Top-5			Top-10			Top-15		
	P	R	F	P	R	F	P	R	F
Baseline	22.0	7.5	11.2	17.7	12.1	14.4	14.9	15.3	15.1
Avg System	28.7	9.8	14.6	23.2	15.8	18.8	19.9	20.4	20.1
DP-seg	33.3	10.5	16.0	23.7	16.9	19.7	19.2	21.3	20.2
Best System	39.0	13.3	19.8	32.0	21.8	26.0	27.2	27.8	27.5

Table 8: Precision, Recall, and F-score on the SemEval dataset.

if it has seen just one occurrence, it is very likely to produce more of the same *n*-gram. In response to this, Goldwater proposed a bigram model that includes a Hierarchical Dirichlet Process (HDP) in place of the Dirichlet Process. We plan to investigate the performance of the Bigram/HDP model in future work.

One aspect of index term identification which we have ignored in this research is the location of the index term in the document collection, largely because of the much higher annotation complexity. If we are to deliver on the promise of building an automatic index generator, we need to additionally determine which instances of a given index term should be indexed. For example, for a paper which mentions *support vector machines* on every page, should each page be indexed, just the first mention, or a defining mention (e.g. in a section describing the methodology)? Related to this question is the question of index term equivalence. For example, if the paper mentions both *support vector machines* and *SVMs*, we would ideally like to be able to recognize them as interchangeable and alternative forms of the same index term. Again, the current model is unable to pick up on such equivalences, but a fully-functioned index term identification system should be able to deal with cases such as this, suggesting a direction for future work. Another possilble extension is the determination of noun chunk boundaries, which is currently based on a simple POS sequence heuristic. In terms of precision, the heuristic is robust and not problematic, but in terms of recall, we potentially miss more complex term candidates. Using a noun phrase chunker or parser could be used to boost recall.

An interesting observation is the difficulty c/nc-value has in correctly extracting highly ranked index terms for the HGT dataset, as was shown in Table 6. We believe that, while c/nc-value is designed to discount shorter *n*-grams that appear as subphrases in longer *n*-grams, the wide variety of contexts makes this a hard problem, and that there is no obvious fix to c/nc-value to solve this problem. We argue that the Bayesian segmentation and generative model from DP-seg provides a more principled solution to this problem — and one that performs significantly better. The Bayesian framework also allows for other extensions to incorporate additional lexical or syntactic data into the model. We leave these investigations for future work.

To summarize, we have applied an unsupervised Bayesian method to the tasks of index term identification and keyphrase extraction. Index term identification is the task of automatically determining terms to include in a literary index for a document collection, and we constructed a total of four datasets across a range of scientific domains. Keyphrase extraction is defined in the conventional way, and was evaluated relative to the SemEval-2010 dataset. We found the Bayesian method to outperform both a multiword terminology extraction method and a collocation extraction baseline over the index term identification task, and to rank above the average results for participating systems in the SemEval-2010 task, beaten by only two unsupervised systems (in addition to a number of supervised systems), without any tuning to the task.

ABSTRACT
We show that by making use of information common to document sets belonging to a common category, we can improve the quality of automatically extracted content in multi-document summaries. This simple property is widely applicable in multi-document summarization tasks, and can be encapsulated by the concept of *category-specific importance (CSI)*. Our experiments show that CSI is a valuable metric to aid sentence selection in extractive summarization tasks. We operationalize the computation *CSI* of sentences through the introduction of two new features that can be computed without needing any external knowledge. We also generalize this approach, showing that when manually-curated document-to-category mappings are unavailable, performing automatic categorization of document sets also improves summarization performance. We have incorporated these features into a simple, freely available, open-source extractive summarization system, called SWING. In the recent TAC-2011 guided summarization task, SWING outperformed all other participant summarization systems as measured by automated ROUGE measures.

KEYWORDS: text summarization, csi, guided summarization, tac.

Proceedings of COLING 2012: Technical Papers, pages 2093–2108,
COLING 2012, Mumbai, December 2012.

1 Introduction

Studies have been done on many facets of text summarization including multi-document summarization (Radev et al., 2004), query focused summarization (Daumé III and Marcu, 2006), personalized summarization (Díaz and Gervás, 2007), temporal summarization (Bysani et al., 2009), and more recently guided summarization (Owczarzak and Dang, 2010, 2011).

In multi-document summarization, a *topic* consists of a set of related documents. The goal is to generate a coherent summary from this set of documents with minimal information redundancy. In the guided summarization tasks defined by the recent Text Analysis Conference's (TAC) shared tasks, each topic is additionally assigned to one of several broad *categories* such as *Accidents and Natural Disasters* or *Attacks* (see Figure 1). In traditional query-focused summarization, a narrative specific to each topic serves as a hint to the content required in the target summary. However in guided summarization, the narrative is replaced with a series of category-specific templates which contain information elements, or *aspects*. For example, *WHEN* is an aspect that is shared by both the *Accidents and Natural Disasters* and *Attacks* categories. Note that aspects are not specific to a topic; rather, they are associated with the category to which the topic belongs. A summary for a topic should cater to all the aspects of its associated template. Such guided summarization can be usefully applied to product opinion summarization, personalization of summaries for users, and improving user experience in question answering scenarios.

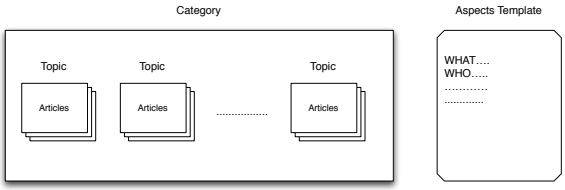

Figure 1: How articles, topics, categories and aspects come together.

Recently, Haghighi and Vanderwende (2009) proposed several content models for summarization. Their models find aspects within a topic which are subsequently combined using KL-divergence as a criterion for selecting relevant sentences. Conroy et al. (2010) augmented their CLASSY system with a query generation component that expands query terms for each aspect of the associated category by performing searches over Google, dictionaries, thesauri and authored world knowledge. Steinberger et al. (2010) generated guided summaries by framing the problem as an information extraction task. Aspect information extracted from an entity extractor is coupled with latent semantic analysis to capture relevant information. They also built lexicons for some category aspects that are not identified by the event extractor. External knowledge such as Wikipedia is also used by many groups for this task. In (Varma et al., 2010), a large set of relevant articles were manually selected from Wikipedia for each category. These articles were used to build domain models, and later to extract important sentences containing events mentioned in the template.

Most of the prior work in guided summarization focuses on producing a summary by selecting relevant aspects common within *a single topic*. However as noted earlier, aspects are shared over multiple topics in a category; thus topic-oriented models do not exploit knowledge shared among topics within the same category. We hypothesize that category-specific information does

encode a useful signal that can improve the quality of guided summaries. To this effect, we propose and develop a robust sentence-extractive summarizer adopting the standard, supervised machine learning framework: we extract features from the input documents, utilize the features to rank the importance of input sentences through a regression model, and finally apply the model on new, unseen test documents.

The fundamental innovation that our summarizer makes over the previous state-of-the-art is that it makes use of the information derived from the category of a topic to calculate the category-specific importance (CSI) of each sentence. We capture CSI through two novel features – *category relevance score* and *category Kullback-Liebler divergence score* – that are explained in later sections of the paper.

Our approach is different from (Conroy et al., 2010; Steinberger et al., 2010) which compiled lexicons manually for each category aspect. Words in these pre-compiled lexicons are treated with equal importance for a category, whereas our method automatically discerns between the different saliency of words across a category. This allows us to address the problem of low recall that hampers the performance of manually-compiled lexicons.

Aker and Gaizauskas (2009) had also made use of the concept of category-specific information for automatic captioning of images. Similar to our proposed approach, they exploited the inherent differences across different object types to influence content selection. Our work is different in two key aspects: 1) our computed statistics are based on actual content to be summarized, instead of a pre-assembled corpus, and 2) besides considering information across categories, we also make use of information across topics, within a category.

When compared with the state-of-the-art summarizers submitted to TAC-2011, our system significantly outperforms all other systems as reported in (Ng et al., 2011).

2 Corpus

The categorization of topics in the guided summarization task at TAC makes the shared task datasets suitable corpora for our work. We use the dataset provided in TAC-2010 for training our system and the TAC-2011 dataset for testing purposes. The documents in TAC-2010 are extracted from AQUAINT and AQUAINT-2; documents used in TAC-2011 came from the newswire portion of the TAC-2010 KBP source data. The test dataset consisted of 44 topics, divided into five categories. The structure of the training data is similar, containing 46 topics. We use only the articles from Set A for our experiments as the task of summarizing Set B, was an update summarization task, a separate task by itself. The distribution of topics into categories for TAC-2010 and TAC-2011 is provided in Table 1. In the rest of this paper, we abbreviate some of the category names for brevity. For example instead of *Accidents and Natural Disasters*, we will use *Accidents*.

Category	TAC-2011	TAC-2010
Accidents and Natural Disasters	9 (90)	7 (70)
Attacks	9 (90)	7 (70)
Health and Safety	10 (100)	12 (120)
Endangered Resources	8 (80)	10 (100)
Investigations and Trials	8 (80)	10 (100)

Table 1: Distribution of topics and documents into categories in TAC-2010 and 2011. The number of documents per category is shown in parentheses.

The TAC-2011 guided summarization task was to write a 100-word summary for a given topic covering all the aspects. A template of aspects for the category *Health and Safety* is shown in Table 2 as an example.

Aspect	Description
WHAT	what is the issue
WHO_AFFECTED	who are affected by the issue
HOW	how are they affected
WHY	why the health/safety issue occurs
COUNTERMEASURES	prevention efforts

Table 2: Template of aspects for the *Health and Safety* category.

Four human-written model summaries are provided per topic for each set. These summaries are used as a gold standard for evaluating machine generated summaries. Both automatic and manual measures were utilized by the TAC organizers to evaluate summaries. Automatic evaluation is commonly performed using ROUGE (Lin, 2004), and was used in TAC. ROUGE determines the quality of a summary through overlapping units such as n-grams, word sequences, and word pairs with human written summaries. Manual measures adopted by TAC organizers included pyramid scoring (Nenkova et al., 2007) and subjective assessments about the quality of the summaries. Since the original TAC manual evaluation team is not known or available, manual evaluation of new summarization systems is not possible. As such, we need a fair, objective comparison of our results with previously published results, and can only adopt automated methods. For this reason, we adopt the automatic ROUGE-2 and ROUGE-SU4 measures. While not ideal, these measures have been found to generally correlate well with manual judgments (Lin and Hovy, 2003).

3 Methodology

Our system, SWING, is a sentence-extractive summarizer that is designed to be an easy-to-use and an effective testbed for comparative evaluation of summarization methods. Input data is pre-processed using standard techniques, incorporating stop word removal and stemming for better computation of relevance. Our summarization system is fundamentally based on a supervised learning framework. A set of features is derived for each sentence in the input documents to measure their importance. We compute two classes of features, at the topic and category levels. We first discuss a set of *generic* features used in SWING. The feature scores are combined together with a set of weights derived from support vector regression (SVR) (Gunn, 1998). Finally, the Maximal Marginal Relevance (MMR) algorithm (Carbonell and Goldstein, 1998) is used to perform sentence re-ranking and selection. Later in Section 4, we introduce features to compute our key innovation: the category-specific importance (CSI) of sentences. SWING combines both generic features and CSI features to produce guided summaries.

3.1 Generic Features

Each sentence is represented by a vector of feature scores for learning. We used three features: (1) sentence position, (2) sentence length, and (3) a modified version of document frequency to calculate the generic topic relevance of a sentence.

Sentence position (Edmundson, 1969) is a popular feature used in summarization especially for news domain. The intuition is that leading sentences in a news article usually contain

important, summary-worthy information. Accordingly, the score of this feature is gradually decreased from the first sentence to the last sentence in a document based on its position.

Sentence length is a binary feature that helps in avoiding noisy short text in the summary. The value of this feature is 1 if the length of sentence is at least 10, and zero otherwise. The value 10 is empirically determined in our system tuning.

Interpolated N-gram Document Frequency (INDF) is an extended formulation of the popular document frequency (DF) measure. The efficacy of DF in summarization has been previously demonstrated by (Schilder and Kondadadi, 2008; Bysani et al., 2009). It computes the importance of a token as the ratio of the number of documents in which it occurred to the total number of documents within a topic. We extend the use of DF from unigrams to bigrams. INDF is the weighted linear combination of the DF for unigrams and bigrams of a sentence. Since bigrams encompass richer information and unigrams avoid problems with data sparseness, we choose a combination of both. The INDF of a sentence s, is computed as:

$$INDF(s) = \frac{\alpha(\sum_{w_u \in s} DF(w_u)) + (1-\alpha)(\sum_{w_b \in s} DF(w_b))}{|s|}$$

where w_u are the unigram and w_b are the bigram tokens in sentence s. α is the weighting factor that is set to 0.3, after tuning on the development set.

3.2 Training and SVR

Each sentence is scored with the three features explained above. The features are given weights by a support vector regression model, following the methodology described in (Bysani et al., 2009). We train the regression model using the ROUGE-2 similarity of the sentences with human models as the objective to maximize. Data from TAC-2010 is used as the training corpus, and the trained regression model is used to predict the saliency scores of each sentence in the TAC-2011 test set.

3.3 Sentence Re-ranking

After each sentence has been scored, the maximal marginal relevance (MMR) (Carbonell and Goldstein, 1998) algorithm is used to re-rank and extract the best sentences to generate a 100-word summary. In our implementation, the MMR of a sentence s is computed as:

$$MMR(s) = Score(s) - R2(s, S)$$

where $Score(s)$ is the score predicted by the regression model, S is the set of sentences already selected to be in the summary from previous iterations, and $R2$ is the predicted ROUGE-2 score of the sentence under consideration (s) with respect to the selected sentences (S).

3.4 Post-Processing

There are many extraneous text fragments in the corpus that are uninformative. These include news agency headers and the reporting date of the articles, among others. These are removed automatically during post-processing from the summaries with the use of a modular post-processing system that matches regular expressions.

Table 3 provides the evaluation results of a baseline summarizer, `Generic`, when using only the above discussed generic features on the test dataset. We also provide the results of two

baseline systems commonly used in TAC for comparison. `FirstSent` returns the top sentences from the most recent article until the summary length (100 words) is reached, and `MEAD` is the output of *MEAD*, a popular open-source summarizer[1].

Configuration	ROUGE-2	ROUGE-SU4
`Generic`	0.13392	0.16513
`FirstSent`	0.06410	0.09934
`MEAD`	0.08682	0.11749

Table 3: ROUGE scores for baseline summarizer with generic features and common TAC baselines.

The ROUGE scores indicate that putting these generic features together surpassed the baseline systems by a huge margin, and is a competitive configuration used to compare with in the remaining parts of this paper.

4 Category Specific Information

In the guided summarization task, summaries are generated for each topic, where each topic belongs to one or more categories. The purpose for providing this manually-given classification is so that the summaries can focus on the content related to the aspects associated with the category. We want to leverage this knowledge of the category of a topic to improve generated summaries.

In this extractive summarization scenario, we formulate the summarization task as supervised regression, where the system learns to score the saliency of sentences. The idea behind CSI is to exploit information which is specific to a particular category, and use this as a guide to the saliency of sentences from the source documents. One such possible category-specific information could be how words are used within the category's topics. For a category such as *Accidents*, we may expect to see words like "died", "collision" in the associated source documents more commonly than we would in a general piece of English text. For multi-document summarization, we hypothesize that the word frequency statistics will be similar for document sets within the same category and will be different than those across document sets from different categories. For example, a set of news articles on "Borneo Ferry Sinking" may share similar word statistics with another set of news articles reporting "Minnesota Bridge Collapse" as these two sets belong to the category of *Accidents*. However, the word statistics will have a different distribution when compared to a set of news articles on "Pet Food Recall" (*Health*) as they are from different categories.

To find out if there is indeed a difference in word frequencies across each of the categories, we independently performed an analysis of the word usage in each category. To quantify this difference, we applied the log-likelihood ratio test (LLR) (Dunning, 1993). The LLR of a word w across two categories c_1 and c_2 is defined as:

$$LLR(w) = 2 \times \sum_{i \in c_1, c_2} \left(a_i \times \ log \left(\frac{a_i \times F}{b_i \times f(w)} \right) \right)$$

where a_i is the frequency of word w and b_i is the total frequency of all words in category c_i. F is the total frequency of all words, and $f(w)$ is the frequency of w across all categories. A

[1] `http://www.summarization.com/mead/`

word with a high LLR value implies that it co-occurs in both categories surprisingly often, or surprisingly rarely.

We obtained a list of words with high LLR value (99th percentile; 0.1% level; value = 6.63) for each category with respect to all other categories. For illustration, the top ten words for each of the five categories are shown in Table 4.

Category	Words
Accidents	bridge, bangladesh, crane, weather, spill, cyclone, survivor, earthquake, oil, crash
Attacks	attack, school, police, gunman, terrorist, shoot, condemn, fbi, molest, nuclear
Health	food, safety, children, recall, sleep, cancer, organ, heart, blood, risk
Endangered Resources	water, turtle, coral, ivory, global, conserve, warm, decline, poach, tuna
Investigations	charge, trial, guilty, investor, testify, plead, robbery, taylor, former, conspiracy

Table 4: Top ten words listed in decreasing order of LLR values in each of the TAC categories.

The table shows that almost all of the words are semantically related to their corresponding categories. For example, the first word for the category *Attacks* is actually "attack", while that for the category *Endangered Resources* is "water". We expect that a good summary will contain a fair amount of these category-specific words. To validate this, we examine the densities of these words in both the model summaries and all of the document sets that belong to a category. Here, density is computed as the ratio of the sum of the term frequencies of all the words found in the list to the total term frequency of the category. If a word is used more frequently in a model summary compared to a more general document set, we would expect a higher density value for the model summary.

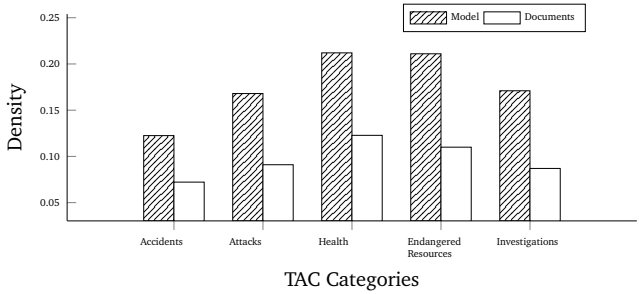

Figure 2: Comparison of density of category-specific words across model summaries and document sets.

The word densities for both the model summaries and document sets for each category are plotted in Figure 2. It shows that the words identified by the LLR criterion are indeed used more often in the model summaries than in the document sets. This shows that a good summary will

contain more category-specific words, and thus gives solid evidence for our intuition that the difference in word usage across each category is a useful guide in generating a good summary.

4.1 Category-Specific Features

Having determined the efficacy of category-specific word usage, we design two features, category relevance score (CRS), and category KL-divergence score (CKLD), to model and exploit this property.

Category Relevance Score (CRS) computes the importance of a word with respect to a category, using the frequency statistics of the word in constituent topics and topic documents of the category. As every topic in the category is related, the topic frequency of a word is directly proportional to its categorical relevance. Similarly, the larger the number of documents a word appears in within the category, the more relevant it is to the category. CRS is the linear interpolation of frequency scores at topic (TLF) and document level (DLF). The score of a sentence s in category c, is calculated as:

$$CRS_c(s) = \frac{\sum_{w \in s}(\beta \times TLF_c(w) + (1-\beta) \times DLF_c(w))}{|s|}$$

where $TLF_c(w)$ and $DLF_c(w)$ are computed as:

$$TLF_c(w) = \frac{|\{t : w \in t, \ \ \forall t \in c\}|}{|T_c|}$$

$$DLF_c(w) = \frac{|\{d : w \in d, \ \ \forall d \in c\}|}{|D_c|}$$

where t and d represent topic and document, respectively, and T_c and D_c are the sets of topics and documents in category c, respectively. The value of β was determined empirically, optimally set to 0.7. This setting highlights that topic-level influence is more important that of the document level.

Category KL-Divergence Score (CKLD) is a differential measure that calculates the importance of a word using KL Divergence. Also known as information divergence, it quantifies the information gain between two probability distributions. Category KLD (CKLD) measures the divergence of probability distribution of a word in the current category (c) to its distribution in the whole corpus (C). The greater the divergence from C, the more informative the word is for category c. The CKLD value of a sentence s in category c is given as:

$$CKLD_c(s) = \sum_{w \in s} \left(p_c(w) \times log \frac{p_c(w)}{p_C(w)} \right)$$

where $p_c(w)$ is the probability of word w in category c and $p_C(w)$ is the probability of word w in the corpus.

The key difference between CRS and CKLD is that CRS tries to promote words which are important to all the topics within a category, while CKLD seeks words which are unique in terms of word usage in a category. In other words, CRS is an *intra-category* measure, while CKLD is an *inter-category* measure. The distinction between these two is subtle but important. Table 5 shows the top five words in descending order of CRS and CKLD in each category.

Consider two words such as "report" and "Madoff" for the category of *Investigations*. The word "report" ranks top for CRS in this category and appears in three categories, while "Madoff" ranks top for CKLD and only appears in *Investigations*. CKLD will be able to detect if these two words are used differently from how they are used in the other categories, which explains the fact that most words in the list appear only in one category. In this example, the word "Madoff" is a person name which is likely important only in some topics in *Investigations* but not in other categories. On the other hand while "report" is important to the *Investigations* category (it appears in seven out of eight topics in this category), it is also found important in two other categories (*Accidents* and *Attacks*). We hypothesize that these intra- and inter-category aspects of CRS and CKLD will be complementary to each other, which we will validate in the experiment section.

Category	CRS	CKLD
Accidents	official, people, report, news, accident	crane, bridge, construction, java, people
Attacks	attack, report, killed, state, police	attack, pirate, police, school, israel
Health	product, research, company, increase, time	food, toy, sleep, vitamin, product
Resources	conserve, world, protect, manage, country	coral, water, tuna, elephant, turtle
Investigations	report, charge, people, killed, family	madoff, taylor, alvarez, prosecutor, charge

Table 5: Top five words listed in decreasing order of CRS and CKLD, for each category.

4.2 Experiments

To evaluate the efficacy of the proposed category-specific importance features (*i.e.*, CRS and CKLD), we add them to the baseline summarizer described earlier. Table 6 shows the ROUGE measures of the various summarizer configurations when tested on the TAC-2011 dataset. `Generic+CRS` uses the CRS feature alongside the generic features described in the previous section (*i.e.*, sentence position, sentence length, and INDF). Likewise `Generic+CKLD` uses the CKLD feature in addition to the generic features, and `SWING` which is essentially `Generic+CRS+CKLD` uses both CRS and CKLD. We also include the results achieved by two other top-performing systems, `CLASSY` (Conroy et al., 2011) and `POLYCOM` (Zhang et al., 2011), at TAC-2011 for comparative purposes.

Configuration	ROUGE-2	ROUGE-SU4
`SWING`	0.13796	0.16808
`Generic+CRS`	0.13702	0.16788
`Generic+CKLD`	0.13525	0.16649
`CLASSY`	0.12780	0.15812
`POLYCOM`	0.12269	0.15974

Table 6: ROUGE scores over TAC-2011 dataset. Results for `CLASSY` and `POLYCOM` are reported after the jackknifing procedure, as released by the shared task organizer.

The table shows that adding either one of the category-specific features to `Generic` outperforms the two top-performing summarizers on both ROUGE-2 and ROUGE-SU4. When comparing `Generic+CRS` and `Generic+CKLD`, `Generic+CRS` slightly outperforms `Generic+CKLD` with 0.00177 for ROUGE-2 and 0.00139 for ROUGE-SU4. This is explained by the fact that CRS

captures intra-category importance of words which focuses on word usage within a topic of a specific category. As TAC systems are to summarize a single topic (as opposed to a whole category), it is reasonable that CRS provides more improvement when we look at the ROUGE scores on the topics. We expect that if systems were asked to instead summarize categories, CKLD would yield a larger improvement as CKLD captures inter-category importance of words which would be more pertinent to this hypothetical task.

When both category-specific features are used (*i.e.*, SWING), the performance for both ROUGE-2 and ROUGE-SU4 are higher than that for Generic+CRS and Generic+CKLD. This validates our hypothesis that both features are complementary to each other as they measure word statistics from different angles (*i.e.*, intra- vs. inter-category). Two-tailed student's t-test verifies that SWING significantly outperforms Generic, CLASSY, and POLYCOM (p-value < 0.05).

4.2.1 Chunk-sensitive CSI Scoring

Up to this point, we have assigned sentence-wide CSI scores; the sentence score aggregates the CSI scores of all words in the sentence. However consider the word "bridge" from the category of *Accidents* — "bridge" can be part of a NP chunk (*e.g.*, *The bridge across the road...*), or part of a VP chunk (*e.g.*, *Let's bridge our differences...*). When found in a NP chunk, we can (casually) associate the use of the word with accidents. For example traffic accidents can happen on bridges, or bridges can collapse. When found in a VP chunk however, this association is lost. It is unfair then to regard a sentence as being more salient to the category *Accidents* if it contains the word "bridge" outside of a NP chunk.

We postulate that there is a need to first determine the word's role within a sentence, before deciding if it contributes to the saliency of the sentence. To verify this, we build variants of our scorer that ignores the CSI scores of word occurrences when they appear in chunks outside of a target chunk type.

To implement this, we parse all the input sentences from the source documents using the OpenNLP constituent grammar parser[2]. From the parses, we identify the constituent noun phrases (NP), verb phrases (VP) and prepositional phrases (PP). Instead of computing the CSI value of every word in the sentence, only the words found in a particular syntactic chunk (*i.e.*, one of NP, VP, and PP) are used to compute its score. The ROUGE evaluation results of the experiments are shown in Table 7.

Configuration	ROUGE-2	ROUGE-SU4
NP	0.13934	0.16836
VP	0.1354	0.16602
PP	0.13494	0.16592
All	0.13796	0.16808

Table 7: ROUGE scores of SWING when CSI computation is restricted to specific syntactic chunks. "All" denotes the non-chunk specific system, where results are repeated from Table 6.

By restricting CSI scores to word occurrences found only within NP chunks, we obtain a statistical significant improvement ($p < 0.05$) on the ROUGE-2 score. This result suggests that it is indeed useful to also consider the function of a word within a sentence.

[2] http://opennlp.sourceforge.net/projects.html

We note that restricting scoring to either just VP or PP chunks reduced performance significantly when compared to the baseline on the other hand. We suspect that word usage within VP and PP chunks could be more generic, and thus do not convey additional notions of saliency. It will be insightful to investigate this further in future work.

4.2.2 Clustering Accuracy

So far, we definitively demonstrated the utility of CSI features in guided summarization. However, the previous experiments made use of gold-standard, human-assigned categories for each topic, provided manually by the TAC organizers. In more typical multi-document summarization scenarios, such gold-standard categorization is unavailable. Might CSI features still be useful when such categorization is generated using less-than-perfect automatic categorization? To answer this, we set out to measure the effect that the quality of category assignments have on CSI feature efficacy.

We start by placing all the topics into one large cluster, ignoring the original human-assigned categories. Various automated clustering algorithms are then run to cluster the topics. The summarizer is then provided with these automatic clustering results to compute summaries as per the pipeline previously discussed.

Since our focus in this experiment is to measure the robustness of the CSI features, a simple clustering method suffices. We used a simple approach in which a bag-of-words feature is used for the clustering, considering only words from the first sentence of each document. This is reasonable as the first few sentences of a news article often give a good indication of the content to follow in the rest of the article.

We experiment with three clustering algorithms of K-Means, X-Means and Expectation Maximization (EM), using different numbers of clusters. All experiments were carried out using the *WEKA* (Hall et al., 2009) package and used only the simple bag-of-words feature to construct clusters. Evaluation results of the clustering algorithms are shown in Table 8 along with p-values from the two-tailed Student's t-test when compared with SWING that used the gold-standard clusters provided by TAC. Each configuration in the table uses the automatic clustering results assigned by the corresponding clustering algorithm while computing the relevant CSI scores.

Clustering Method	Size	ROUGE-2	p-value
EM	3	0.13547	0.156
	4	0.13659	0.158

Table 8: ROUGE scores of SWING when paired with different clustering schemes. *p-values* are with respect to results obtained when SWING is paired with human-assigned categories from the TAC datasets.

From Table 8, we see that while all automatic clustering algorithms report a drop in ROUGE compared to the use of gold-standard categories, the difference in the scores were generally not

statistically significant. This is a positive result as it shows that our CSI features can be useful even if perfect categorization results are not available; automatic clustering can be employed to create the necessary input to calculate CSI features.

The drop in performance is expected: since CSI features measure information specific to a category, noisy clusters produced by the automatic algorithms are more likely to be less well-defined than the human assigned gold-standard categories. Any category-specific information will be diluted, and thus features seeking to exploit this information will be adversely affected.

Results among the clustering methods were inconclusive. Variation in the methods employed and the number of clusters used led to mixed results that did not point towards a clear direction to favor.

5 Analysis

To gain insight on how category specific information affects our system, we manually examined the improvements SWING made over Generic. In the test topics, we found that the CSI version selected alternative sentences in 14 out of the 44 topics, roughly 1/3 of all summaries. The categories *Accidents*, *Attacks*, and *Investigations* have 3 replacements each while *Health* and *Endangered Resources* have 1 and 4 replacements, respectively. Less important a phenomenon is that the summary sentences were re-ordered in 10 instances, resulting in minor changes in ROUGE scores, as the last sentence is trimmed to keep the summary length to 100 words. The changes made by CSI in the selection are thus frequent, altering some summaries in a substantial way, made evident by the change in ROUGE score.

To illustrate the utility of leveraging on category specific information, differences between both systems for a topic in *Accidents* category are provided in Figure 3. The '—' sign represents that the sentence is excluded and '+' sign shows that the sentence is included in SWING. The first sentence that was replaced has more category specific words like "warning", "earthquake", "killed", "people". The original sentence only contains words such as "death", "buried". The new sentence thus offers more information content.

Generic:
— *The death toll could rise as thousands are still buried in debris and many are reported missing.*
— *Therefore, the relevant sectors and personnel should pay attention to disaster prevention.*
SWING:
\+ *Chinese authorities did not detect any warning signs ahead of Monday's earthquake that killed more than* ***8,600 people****.*
\+ *Xinhua said* ***8,533 people*** *had died in Sichuan alone, citing the local government.*

Figure 3: Difference in summaries for the topic "Earthquake in Sichuan", from the category *Accidents*.

When we compute CSI scores for sentences, one shortcoming is that we do not look at whether sentences have redundant category-specific information and whether all aspects of the category are covered by the selected sentences. For example, we observed that the second replaced sentence repeats the information already found in previous sentences of the summary. However it still gets selected into the summary due to the presence of more category specific words.

In the future, we plan to use category specific statistics in a more organized way to remove category-specific redundancy (akin to MMR) and to include all aspects of information in the summary.

Numerical information in a topic, such as casualties, temporal markers, monetary damages can also conflict within documents in a set on a topic, as they are compiled by different sources and at different points of time. For example, the number of casualties (**bolded** in summaries) is specified as 8,533 and more than 8,600 in different sentences from different sources. While any of these sentences could be selected into a summary due to similar content words, the corresponding model summary has only the most updated information (12,000 people). As a result the evaluation scores are dropped although the summarizer picks an informative sentence. This highlights the need to normalize such numerical information in the summaries which are important in categories like accidents and attacks where quantitative information is key.

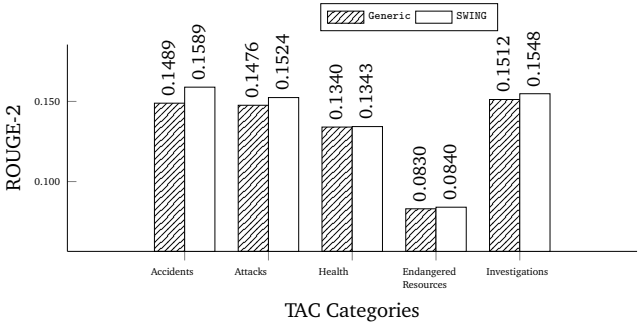

Figure 4: ROUGE-2 scores for each category for `Generic` and `SWING`.

We further observed that the difficulty in summarizing a topic may vary by category. We show ROUGE-2 performance by category in Figure 4, revealing that the topics in *Health* and *Endangered Resources* are the most difficult to summarize. We believe that the larger presence of subjective aspects (*How, Why, Threats*) in both of these categories increases the difficulty for automatic summarizers to recognize relevant information. The topics in the other three categories are easier to summarize: we note that the improvements on *Accidents* and *Attacks* with the CSI features are more pronounced than in the remaining categories. When we look at the aspects defined by TAC for both *Accidents* and *Attacks*, we notice that seven of their aspects overlap, as shown in Table 9. This suggests that the more general aspects a category has, the easier it is to compute its category-specific information. In our future work, we plan to look at how we can utilize general versus specific aspects to improve our model of CSI.

Conclusion

We have shown that using category-specific information (CSI) can significantly improve the performance of topic oriented summaries. We model CSI by creating two features: category relevance score (CRS), an intra-category measure; and category KL-divergence score (CKLD), an inter-category measure. Simple to compute and requiring no external knowledge or corpus, the combined use of both CRS and CKLD significantly improved automated ROUGE scores, leading to a basic extractive summarization system that leads the state-of-the-art.

Category	Aspects
Accidents and Natural Disasters	WHAT, WHEN, WHERE, WHY, WHO_AFFECTED, DAMAGES, COUNTERMEASURES
Attacks	WHAT, WHEN, WHERE, PERPETRATORS, WHY, WHO_AFFECTED, DAMAGES, COUNTERMEASURES

Table 9: Aspects for categories *Accidents* and *Attacks* defined in TAC. Seven aspects overlap in these two categories.

To probe more deeply, we assessed how to improve CSI features by limiting its calculation to word occurrences that occur within NP chunks. We also showed that automatically acquired category information (through clustering) still yields improved results, even when the artificially induced categories are noisy. Finally we performed a micro-analysis of the effect of CSI, studying the changes in sentence selection in the test dataset. This process showed that the incorporation of CSI changed selection selection significantly. The analysis also yielded insights about future directions for extractive sentence selection.

The use of CSI can be incorporated with sophisticated sentence post-processing that is a focus of current summarization research. As such, we see CSI as a foundational contribution that we urge other summarization platforms to adopt. To aid this adoption, we have open-sourced our package for the research community to use[3].

Improved Temporal Relation Classification using Dependency Parses and Selective Crowdsourced Annotations

ABSTRACT
We study the problem of classifying the temporal relationship between events and time expressions in text. In contrast to previous methods that require extensive feature engineering, our approach is simple, relying only on a measure of parse tree similarity. Our method generates such tree similarity values using dependency parses as input to a convolution kernel. The resulting system outperforms the current state-of-the-art.

To further improve classifier performance, we can obtain more annotated data. Rather than rely on expert annotation, we assess the feasibility of acquiring annotations through crowdsourcing. We show that quality temporal relationship annotation can be crowdsourced from novices. By leveraging the problem structure of temporal relation classification, we can selectively acquire annotations on problem instances that we assess as more difficult. Employing this annotation strategy allows us to achieve a classification accuracy of 73.2%, a statistically significant improvement of 8.6% over the previous state-of-the-art, while trimming annotation efforts by up to 37%.

Finally, as we believe that access to sufficient training data is a significant barrier to current temporal relationship classification, we plan to share our collected data with the research community to promote benchmarking and comparative studies.

KEYWORDS: temporal relations, information extraction, crowdsourcing, convolution kernels, clause structure, dependency parsing.

1 Introduction

We study the problem of temporal information extraction; specifically, we seek to establish when an event has taken place relative to a time expression. We refer to this task as *event-temporal* relationship classification. We adopt the same definitions for event and time expressions used in TimeML[1]. Consider the sentence[2]:

> Two top aides to Netanyahu , political adviser Uzi Arad and Cabinet Secretary Danny Naveh, left for Europe on *Sunday* , apparently to investigate the Syrian issue , the newspaper said. (1)

In Sentence 1 "*Sunday*" is a time expression, while the various underlined words such as "said" are events. A pictorial summary of the timeline of the events as they are described in the sentence is shown in Figure 1. The time expression "*Sunday*" is marked on the timeline to represent an instance in time. The spans of the arrows representing each of the events denote the temporal relation between the three events and the time expression. In this case "left" happens in the same time span denoted by "*Sunday*". The other two events (i.e. "investigate" and "said") do not coincide with the "*Sunday*" marker and take place after the time span denoted by "*Sunday*".

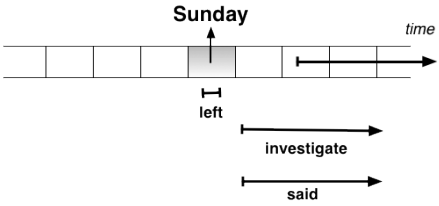

Figure 1: Temporal relationships between events and a time expression in Sentence 1.

Knowing such temporal relations are useful for downstream natural language processing applications. For example, Harabagiu and Bejan (2005) attempt to identify relationships between entities and time expressions to improve their question answering system. They combine knowledge of the relations between answer candidates and temporal expressions with semantic inference to derive exact answers to temporal questions. Temporal relations are also a recent focus in information extraction. In the temporal slot-filling task of the Knowledge Population Track featured in the Text Analysis Conference (Ji et al., 2011), the shared task required systems to add temporal information to extracted information. Such information would enable inference on such knowledge bases to be extended to event ordering and perhaps help to identify temporal contradictions.

Recognizing the value of temporal relations, the community has organized shared tasks to spur research efforts in this area. In our work, we adopt the community-standard TempEval-2 task definition and dataset (Verhagen et al., 2010). This dataset consists of 959 training instances for the *event-temporal* relationship classification task, and a testing set of 138 instances. A summary of the various *event-temporal* relationships annotated in the dataset is shown in Table 1.

Event-Temporal Relationship	Relative temporal ordering
OVERLAP	Event happens *within* time expression
BEFORE	Event happens *before* time expression
AFTER	Event happens *after* time expression
BEFORE-OR-OVERLAP	Event happens either *before* or *within* time expression
OVERLAP-OR-AFTER	Event happens either *within* or *after* time expression
VAGUE	Unable to assign a relation

Table 1: Event-temporal relationships in the TempEval-2 dataset.

State-of-the-art approaches to this problem make extensive use of careful feature engineering to model both surface lexical cues as well as information about the syntactic relations between parts of the sentences, focusing on the words that comprise the events and time expressions. Both feature types manifest a wide array of values, making data sparsity a concern. Current state-of-the-art systems achieve only about 65% accuracy, where the low performance has indeed been partially attributed to data sparsity (Yoshikawa et al., 2009).

There are several techniques to address sparse data. We adopt two in this paper, both of which lead to improved performance. First, we simplify the input features and classification methodology. Specifically, we use a support vector machine provisioned with only two features: dependency parse similarities of the time expression and the path from the event to time expressions. By limiting our input features, we obtain denser judgments which enhance the quality of the decision boundary. Second, we can enlarge our annotated dataset. To this end, we exploit annotations obtained from novices via crowdsourcing. We show that augmenting the TempEval-2 dataset with crowdsourced information improves classification performance slightly. However, we can further boost performance by selectively acquiring annotations for difficult and under-represented categories of instances. Pairing both techniques together allow us to achieve an 8.6% improvement in accuracy over the current state-of-the-art, which is statistically significant.

After first reviewing the related work, the remainder of this paper sequentially details these two key contributions of our temporal classification work. In the first half, we detail our approach for temporal relation classification. In the second half, we discuss our approach to selectively annotate important problem instances via crowdsourcing.

2 Related Work

There has been a good amount of research on temporal relationship classification, culminating in recent shared tasks in TempEval-1 (Verhagen et al., 2007) and TempEval-2 (Verhagen et al., 2010). In fact, the *event-temporal* relationship classification problem we focus on is exactly Task C in TempEval-2. Other temporal information extraction tasks include *event-event* relationship classification, which involves determining which of two events took place earlier. Top performing teams attempting Task C made use of supervised machine-learning, including conditional random fields (Kolya et al., 2010), Markov logic (UzZaman and Allen, 2010; Ha et al., 2010), and maximum entropy classification (Derczynski and Gaizauskas, 2010). Enlarging the problem, Yoshikawa et al. (2009) proposed building an inference model which jointly predicts *event-temporal*, *temporal-document creation time* and *event-event* temporal

relationships within a given sentence. While the system performed comparably to other systems in TempEval-1, such a joint model greatly enlarges the problem complexity as the search space is a Cartesian product of the three separate problems.

All of the above systems employed similar features which we categorize into three feature types: 1) lexical cues, such as signal words and part-of-speech tags, 2) context, including the attributes of the event and time expressions and 3) the grammatical structure of the sentences, obtained by processing automatic parses. Possibly since they use similar features, the top performing systems all perform similarly, achieving around 65% accuracy in their judgments. We note that the feature types employed can take on many different values and thus represent a large potential feature space. Given that the TempEval-2 dataset comprises of only 959 instances, we believe the learned models suffer from sparse data, and can improve from the incorporation of additional data.

Many researchers have looked at ways to reduce the annotation effort required to build a sizable temporal dataset. Setzer et al. (2003) proposed making use of a set of inference rules to identify useful unlabeled instances for annotation. If the equivalence of an unlabeled instance to an already labeled instance can be shown, the unlabeled instance is discarded. Similarly, we are proposing a systematic way in which unlabeled instances can be left out of the data acquisition process. But instead of making use of pre-identified inference rules, our proposal is fully automatic and exploits the dependency parse structure of unlabeled instances without prior curation of hand-written rules.

In a bid to balance the cost of data acquisition with the need for more annotated data, the organizers of TempEval-3 (UzZaman et al., 2012), to be held at SemEval-2013 propose augmenting a manually annotated dataset of 100K word tokens with around 500K semi-automatically annotated instances. At the time of this writing, the semi-automatically annotated instances have yet to be released.

In recent times, crowdsourcing has been a popular method employed to collect linguistic annotations. Munro et al. (2010), for example, lists some linguistic projects which have benefitted from crowdsourcing. To the best of our knowledge however, there is no existing literature on the adaptation of crowdsourcing for temporal datasets.

3 Convolution Kernels using Dependency Parse Trees

What features and model should we adopt to create a robust temporal relation classifier that takes full advantage of the small amount of annotated training data?

Given the sparsity of values in the features used by previous work, our approach is to reduce the dimensionality of the input feature space, to make the feature space more dense. While we concur with the prior work that the relation between the events and time expression are important, we feel that the current approaches to model this information can be simplified. Such structural relations are perhaps best captured by parse tree paths. Intuitively, if the parse tree of a testing instance is similar to one from a training instance, we may guess that the training instance's type of temporal relation would also hold for the previously unseen testing instance.

To compute the similarity between two parse trees, a typical approach is to engineer flat representations of the parse structure through feature engineering. This process is time consuming and often requires good knowledge of the problem structure to decide which

features are more discriminative than others. Convolution kernels (Collins and Duffy, 2001) on the other hand model this form of structure similarity well. Convolution tree kernels take as input tree structures and calculate a degree of similarity between the two trees. In its simplest form, similarity is computed by recursively counting the number of identical subtrees that appear in both input instances. With this structural similarity measure, we can do away with the need to "flatten" the structure with hand-devised representations. For these reasons, we use a support vector machine (SVM) as our supervised classification model, adopting a convolution kernel as its kernel function (Moschitti, 2006).

A second issue is then to decide the type of parse tree to employ. Most previous work centered around the use of constituent grammar parses. In fact, the only other work that also adopts a convolution kernel approach to temporal relation classification (Mirroshandel et al., 2011) also uses constituent grammar parses. However, as constituent parses create internal phrasal nodes for every semantic constituent, such parse trees are often deep and overly detailed. Paths in such trees are fine-grained, capturing nuances (*e.g.*, intervening finite verb phrase nodes), and as such, may not generalize well when used to compute tree or path similarities.

To remedy this, we employ dependency parses instead of constituent parses. Dependency parses are generally more compact than constituent grammar parses because they have no immediate phrasal nodes. This translates into a more compact feature space. Bearing in mind that one of the problems we are trying to overcome is that of data sparsity, we find that dependency parses are generally more useful than constituent parses for this task.

We compute two features based on dependency parses:

1. ***Dependency path from event to time expression.*** Starting from a full dependency parse of a sentence, we identify the vertices representing the event and time expressions. We locate the shortest path between these two vertices and use this sub-tree as a feature.
2. ***Dependency parse of the time expression.*** Time expressions can range from single word tokens to multi-word phrases, with vastly different semantics. For example, *Friday*, *last Friday* and *next Friday* convey very different meanings. To capture this, we extract a sub-tree from the full dependency parse consisting of all the vertices and edges related to the time expression and use this as a feature.

3.1 Evaluation

How does our simplified, two input feature SVM compare against the prior work on the TempEval-2 dataset?

Table 2 gives the performance of our classifier which we will refer to as `SVMConvoDep` vis-a-vis the top performing systems in TempEval-2. We adopt the same *accuracy* metric used in the TempEval-2 task, which is the number of correct answers divided by the number of answers. We also list macro-averaged precision, recall, and F_1 measures. We find macro-averaged measures more appropriate than micro-averaged ones for this task. As will be explained later, the dataset has a skewed distribution of labels, with `OVERLAP` forming the majority label. Micro-averaged measures give more weight to the most common label in such skewed datasets, but we feel that it is important for systems to be able to perform well across all the temporal labels.

To the best of our knowledge, our classifier outperforms all previous temporal relation classifiers. While this performance gain is probably not statistically significant (as we have no access to the participating systems' individual judgments, it is impossible to check for statistical significance),

we feel that these are impressive results as our classification input is decidedly simple (just two subtrees derived from dependency parses as features).

System	Accuracy (%)	Precision	Recall	F_1

4 Enlarging the Dataset through Crowdsourcing

Our next proposal to solve the data sparsity problem is to enlarge the dataset available. Developing a large, suitably annotated dataset is expensive – both in terms of time and monetary cost. Recent work in natural language processing suggests that crowdsourcing annotations from the untrained public can provide annotated data at similar annotation quality as expert annotators, but for a fraction of the cost (Sheng et al., 2008; Hsueh et al., 2009). However we are unsure if these results are applicable to a temporal dataset which is inherently complex (Setzer and Gaizauskas, 2000) and require a better understanding of the target language.

To find out, we set up a crowdsourcing task on CrowdFlower. We chose CrowdFlower as our crowdsourcing platform, as it has access to a large user base (it uses Amazon Mechanical Turk to find workers), but adds an extra validation layer to attempt to address quality concerns, as this has been an issue in many applications of crowdsourcing in natural language annotation tasks (Mason and Watts, 2009; Callison-Burch and Dredze, 2010).

4.1 Task Setup

Each annotation instance consists of a single sentence. We pre-process the sentence to highlight one event expression and one time expression found within it. Annotators were tasked to choose from five (`OVERLAP`, `AFTER`, `BEFORE`, `NOT-RELATED`, `BAD-SENTENCE`) possible temporal relationships between the marked event and time expression. An additional choice for `BAD-SENTENCE` was included to allow annotators to indicate if there had been problems with our automatic pre-processing. Such instances (67 in our study) were discarded.

We required that at least 3 judgments be made for each annotation, and majority voting was then used to decide on a final label for each annotation. To ensure the quality of the judgments we had obtained, we made use of a validation facility provided by CrowdFlower. Pre-annotated gold instances were mixed together with unlabeled instances. These gold instances were used to validate the annotations made by each annotator. Annotators were not informed which were the gold instances. During the annotation process, annotators who failed to label these gold instances correctly were stopped from proceeding with the task, and the annotations they made were discarded.

Raw Data. To ready a set of unlabeled instances for annotation, we crawled news articles on several news web sites, including *Wall Street Journal*, *New York Times*, *CNN*, and *Channel News*

Asia from 2 June to 8 July 2012. We made use of the sentence splitting module from the Apache OpenNLP[3] library to obtain individual sentences from these news articles. We built a CRF-based event and time expression extractor (`CRFEventTimexExt`) which is able to automatically identify event and time expressions in each of the collected sentences. For event extraction, we made use of part-of-speech (POS) tags as a feature. For time expression extraction, we made use of a compiled lexicon of the days of a week and months of a year on top of POS tags. The performance of our extractor is compared against top participating systems in TempEval-2 in Table 3. We include only the results of systems which are able extract both event and time expressions as it is not required for systems to be able to do both in TempEval-2.

System	Event			Time		
	Precision	Recall	F_1	Precision	Recall	F_1
`CRFEventTimexExt`	0.81	0.82	0.82	0.76	0.62	0.68
Edinburgh	0.75	0.85	0.80	0.85	0.82	0.84
TIPSem	0.81	0.86	0.83	0.92	0.80	0.85
TRIPS	0.55	0.88	0.68	0.85	0.85	0.85
TRIOS	0.80	0.74	0.77	0.85	0.85	0.85

Table 3: Comparison of event and time expression identification with TempEval-2 systems. Performance of TempEval-2 systems are cited from Verhagen et al. (2010).

We are able to turn in competitive F_1 scores for event expression extraction, but less so for time expression extraction due mainly to poor recall. We find the precision scores of 0.81 and 0.76 for event and time expression identification respectively sufficiently high as this is part of pre-processing. Incorrectly identified event and expressions can be labeled as so by annotators, and these precision scores will minimize the occurrences of such mistakes. To address the problems with recall, we can always collect more sentences to increase the number of time expressions we have for annotation.

4.2 Experiments

We first want to test how a similarly sized crowdsourced annotation compares with the manual, expert annotations from TempEval-2. For this reason, we extracted an initial batch of 1,000 tuples (close in size to the TempEval-2's training data of 959 instances) of event and time expressions from the sentences we had crawled. We collected annotations for each of the tuples on CrowdFlower. We refer to this dataset as `d-1000`. We compared the distribution of the labels within this collected set with the TempEval-2 training and testing sets in Table 4.

The skewed distribution in the TempEval-2 datasets are similarly observed in the collected dataset, with the `OVERLAP` label taking up more than 50% of the whole dataset.

We trained a new classifier using the same features as `SVMConvoDep` with the crowdsourced annotations `d-1000`. The performance of this trained classifier, `CF-1000`, on the TempEval-2 testing set is shown in Table 5. In the table we have also included macro-averaged precision, recall and F_1 measures.

`CF-1000` did not do as well as `SVMConvoDep` in terms of accuracy. While its F_1 score is slightly higher, the difference is not statistically significant. This is not surprising for two reasons. First

Dataset	Size	Distribution of label (%)			
		OVERLAP	BEFORE	AFTER	Others
TempEval-2 training set	959	53.8	18.0	23.0	5.2
TempEval-2 testing set	138	55.1	14.5	19.6	10.9
d-1000	1000	70.0	12.2	17.8	0.0

Table 4: Distribution of labels in different datasets.

the annotators recruited for the annotation task are not domain experts, and we can expect mistakes in the annotations obtained. Second, SVMConvoDep is trained on the TempEval-2 training set. This dataset is prepared in similar fashion together with the TempEval-2 testing set we are evaluating on. We will expect the two datasets to share more similar attributes and characteristics than the d-1000 set that we had collected. The content of the TempEval-2 datasets and ours span a different time period, are sourced from different sources, and possibly drawn from different domains and categories.

We tried to combine the TempEval-2 training set with d-1000. With this combined dataset, we trained another classifier CF-1000+TE. The performance of this classifier is also reported in Table 5. We get improved results in both accuracy and F_1 scores. This improvement is significant, with $p < 0.05$ when tested with the paired Student's t-test.

System	Accuracy (%)	Precision	Recall	F_1
SVMConvoDep	67.4	0.828	0.512	0.523
CF-1000	65.2	0.578	0.535	0.525
CF-1000+TE	71.7	0.726	0.598	0.615

Table 5: Classifier performance on TempEval-2 testing set.

There are two important conclusions that we can draw from these results. First, the difference in performance between SVMConvoDep and CF-1000 is slight. So while the the novices recruited via crowdsourcing may not have been domain experts, they are able to generate a dataset that is comparable to an expert-curated one.

Then, the improvement to the performance of CF-1000+TE shows us that despite the possible differences in time span, source, and categorization of d-1000 from the TempEval-2 dataset as we have suggested, there is value to the crowdsourced dataset. Doubling the amount of training data available by putting d-1000 and the TempEval-2 training set together rewards performance.

5 A Smarter Way

With crowdsourcing, the costs associated with generating temporal datasets are lowered. Yet we want to do this efficiently with minimal wastage. In this section, we explain how we can selectively acquire annotations to reduce the costs involved without affecting the efficacy of the data collected.

Motivation. We recognize that it is often not easy to decide on the relationship between an event and time expression. For example let us go back and take a look at Sentence 1.

Within the sentence there are several event expressions. For the sake of this discussion we focus on just two of them: 1) "left", and 2) "said". One immediate observation is that time

expressions are commonly adjuncts (in this case, a prepositional phrase (PP)) that attach to a verb phrase (VP). This implies that time expressions often directly modify only the head it is attached to. In such cases, it is usually easy to identify the temporal relationship between the event and time expression. Looking at "left" and "*Sunday*", it is quite straightforward to determine that they take place within the same time span.

However, it gets significantly more difficult when we look at "said" and "*Sunday*". We have to read through more of the sentence to build up an understanding of the relation between "left", "investigate", and "said" before we can conclude that "said" takes place after "*Sunday*".

Our key insight to more efficient data acquisition is to leverage this observation. We postulate that it is more useful if we can gather annotations for complex instances instead of easier ones.

Definitions. We define a few terms that we will use in the rest of this paper. For the *event-temporal* relationship classification problem, the input is a collection $\mathbb{S}$ of sentences. Each sentence s is composed of one or more word tokens, i.e. $s = w_1 w_2 \ldots$. Let s^* be the set of all possible subsequences of s. For each s, we can define a set of unigram word tokens $\epsilon_s = \{w, w \in s\}$ that are event expressions. We can also define a set $\Theta_s = \{\theta, \theta \in s^*\}$ which includes all the time expressions within s. The problem then is to define some function $f : s, e, t \rightarrow R, s \in \mathbb{S}, e \in \epsilon_s, t \in \Theta_s$ where R is the temporal relationship between the event expression e and time expression t.

Building on our observation, we want to be able to partition a set of unlabeled instances so that the more complex instances are separated from the easier ones. We propose building such a partitioning scheme around the ordering of the elements in ϵ_s given a time expression $t \in \Theta_s$.

To do this, we first build a dependency parse[4] of the input sentence s, where each $w_i \in s$ forms a vertex within the dependency parse tree. A portion of the dependency parse tree for Sentence 1 is shown in Figure 2.

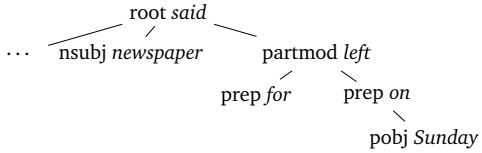

Figure 2: Excerpt of the dependency parse for Sentence 1.

In the figure, the governing dependency relation of a word is shown as a vertex. The associated word is also shown in *italics* to illustrate which part of the sentence this parse is about.

For a given dependency parse and a target time expression t, we can define a total order O_t on ϵ_s. O_t is defined by arranging each $w \in \epsilon_s$ in ascending order of their respective distances from the time expression vertex. Distance in this case is defined as the number of edges that needs to be traversed to reach the time expression vertex.

Imposing the total order O_t on ϵ_s gives us a totally ordered set, i.e. $(O_t, \epsilon_s) = \{e_0, e_1, \ldots\}$. From this, for every input sentence s and its associated event (e) and time expressions (t), we can place the tuple $< s, e, t >$ into a partition $\mathscr{P}_i$, where i is the index of e within (O_t, ϵ_s).

[4]We make use of Stanford dependencies (Klein and Manning, 2003).

Referring to Sentence 1 as an illustration, we thus place <"left", "*Sunday*"> in $\mathscr{P}_0$ because "left" is the nearest event expression to "*Sunday*" in the dependency parse in Figure 2. <"said","*Sunday*"> will be placed in $\mathscr{P}_1$ as "said" is the next nearest event expression. For convenience, we will also be referring to $\mathscr{P}_i$ as the set of Level-*i* instances.

This partitioning scheme is premised on the intuition that it requires more effort to understand the temporal relationship between event and time expressions which are both structurally and semantically further away from each other. Higher level instances thus should be more complex than their lower level peers.

Following this scheme, we separated the TempEval-2 testing set into different partitions based on our prescribed methodology. A breakdown of the performance of `SVMConvoDep` on each of the partitions $\mathscr{P}_i$ is shown in Table 6. Accuracy drops steadily from Level-0 instances to Level-2 instances. This provides support for our intuition that higher level instances are harder to classify accurately.

Given that there are only 10 Level-3 instances and 1 Level-4 instance, the variance in measurements can potentially be very wide. There are too few Level-3 and Level-4 instances for their results to be analyzed reliably.

System	Accuracy (%)				
	Level-0 (59)	Level-1 (47)	Level-2 (21)	Level-3 (10)	Level-4 (1)
`SVMConvoDep`	84.5	66.0	42.9	30.0	100.0

Table 6: Breakdown of performance on partitions of TempEval-2 testing data. The number of instances for each partition is indicated in parentheses.

Given the high prediction accuracy on Level-0 instances, we argue that it is not necessary to obtain more annotations for them. Instead we should focus on the higher level instances. By opting not to annotate additional Level-0 instances, substantial cost savings can be made, as seen from Table 7. In the table we present a breakdown of the relative size of each partition to its entire dataset. `d-full` is a set of 8,851 tuples of event and time expressions that we have extracted from the same set of sentences we had crawled earlier. As seen from the table, Level-0 instances consistently form a large part of the various datasets. Not annotating Level-0 instances will directly lead to a cost savings of at least 37%.

Dataset	Relative size of partition (%)			
	Level-0	Level-1	Level-2	Others
TempEval-2 Training Set	40.9	35.2	15.1	8.8
TempEval-2 Testing Set	41.4	34.3	15.7	8.6
`d-full`	37.0	34.3	17.5	11.2

Table 7: Breakdown of partition sizes of different datasets.

5.1 Experiments

To study the effectiveness of our recommendations, we collected annotations for all the tuples in `d-full` via CrowdFlower in a similar way to what we had done earlier. From this `d-full` collection of 8,851 annotations, we removed all Level-0 instances to create a subset of 5,576 annotations which we will call `d-nolevel0`.

Using d-full and d-nolevel0, we trained two new classifiers CF-Full and CF-NoLevel0 respectively. Table 8 shows the performance of these two new classifiers with that of SVMConvoDep when tested with the TempEval-2 testing set.

From the results, we note that CF-NoLevel0 is able to deliver a significant performance gain of about 8.6% over SVMConvoDep ($p < 0.05$) even though it only made use of part of the full dataset we had collected. Further, it is able to match the performance of CF-Full which was trained over all collected instances (d-full). The performances of CF-NoLevel0 and CF-Full are not significantly different.

System	Accuracy (%)	Precision	Recall	F_1
SVMConvoDep	67.4	0.828	0.512	0.523
CF-NoLevel0	73.2	0.659	0.643	0.639
CF-Full	73.2	0.660	0.647	0.641

Table 8: Accuracy on TempEval-2 testing set.

These results are illuminating. We see that our proposed partitioning scheme is able to reliably identify unlabeled instances that will not be able to contribute to better classifier performance. By focusing our annotation effort only on more complex instances, we bring down data acquisition costs by a large amount (37%) while retaining classifier performance.

6 Analysis and Discussion

6.1 Selective Data Acquisition

We try to probe deeper into the performance of both CF-NoLevel0 and CF-Full. We want insight into why the former works as well as the latter, despite the large reduction in training data.

Table 9 shows a more concise breakdown of the precision, recall and F_1 scores of both classifiers when tested with the TempEval-2 testing set. We see that both classifiers turn in similar performance across all three labels. Performance for the OVERLAP label is better, possibly because there are more training instances for it in the training dataset.

Classifier	OVERLAP			BEFORE			AFTER		
	P	R	F_1	P	R	F_1	P	R	F_1
CF-NoLevel0	0.72	0.96	0.82	0.56	0.45	0.5	0.70	0.52	0.60
CF-Full	0.72	0.95	0.81	0.57	0.40	0.47	0.70	0.60	0.64

Table 9: Performance measures on TempEval-2 testing set broken down by individual labels.

Table 10 illustrates the distribution of the AFTER and BEFORE labels in the first three partitions of the test data. The labels make up a larger part of the annotations at Level-1 and Level-2 than at Level-0.

Putting the pieces of the puzzle together, it is likely that the training instances in Level-0 are more useful for the OVERLAP label than the other two. CF-NoLevel0 is already able to classify these instances quite well, so not having access to Level-0 training instances does not affect it adversely.

We break down the performance of the classifiers on each partition of the test data in Figure 3. As expected, without access to Level-0 training instances, CF-NoLevel0 is slightly outperformed

Label	Distribution of labels (%)		
	Level-0	Level-1	Level-2
AFTER	10.1	21.2	23.6
BEFORE	5.1	13.7	16.1

Table 10: Distribution of labels in each partition.

(but not statistically so) by `CF-Full` for Level-0 test instances. Interestingly, the performance of `CF-NoLevel0` for Level-2 and Level-3 instances are also behind that for `CF-Full`. This suggests that having additional Level-0 training instances can have an effect on classifier performance for Level-2 and Level-3 test instances. In future work we will like to investigate why this is the case.

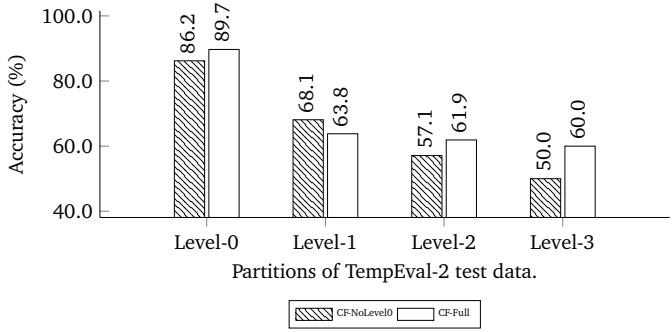

Figure 3: Breakdown of performance across different partitions.

6.2 Common Errors

We are also interested to investigate what more can be done to push system performance towards its upper-bound. Typically, such a theoretic upper-bound is derived from the inter-annotator agreement for the training set. The inter-annotator agreement for the annotations we have collected for `d-full` is 78.8%. Considering that the participants of the crowdsourcing exercise are not domain experts, the actual upper-bound could be higher. However this value is a good starting point for our analysis.

The best performing classifier we have presented in this work has an accuracy of 73.2%. There is still room for improvement towards our pessimistic upper-bound estimate. We study the misclassifications made, building a confusion matrix for `CF-NoLevel0`. Studying the matrix in Table 11, we observe two large clusters of errors.

Skewed dataset. First, `BEFORE` and `AFTER` instances are often mis-classified as `OVERLAP`. Reflecting on this, we believe the skewed training dataset where `OVERLAP` instances form a majority is one of the reasons why.

Considering the lower recall scores we get for `BEFORE` and `AFTER` labels, the mis-classifications are likely a direct result of a lack of suitable training instances within the training dataset to better identify `BEFORE` and `AFTER` instances.

Actual Label	Predicted label		
	OVERLAP	BEFORE	AFTER
OVERLAP	78	2	1
BEFORE	7	9	4
AFTER	13	0	14

Table 11: Confusion matrix for CF-NoLevel0.

Looking closer, we see that the performance on BEFORE instances is slightly lower than the performance for AFTER instances. We relate this to the smaller number of training instances available for the BEFORE label as seen from Table 10.

In future work it will be useful to verify if increasing the number of training instances available can help to improve the recall of the classifier for instances of these two labels, thereby eradicating this cluster of errors.

Feature design. The next major cause of mistakes is the misclassification of BEFORE instances as AFTER. Studying the mis-labeled instances, we realized this is because the features that we have used neglected to consider modal or copula modifications to the event expressions. For example, take a look at sentence 2[5]. The relationship between "added" and "*early November*" should have been BEFORE but was incorrectly classified as AFTER. The relevant portions of the dependency parse extracted as a feature for this instance is shown in Figure 4.

He added that final guidelines to be published in *early November* will determine whether the bank is in compliance . (2)

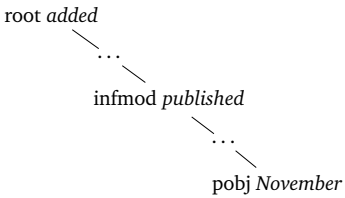

Figure 4: Dependency parse of Sentence 2.

The dependency parse feature that we extract is the shortest path between the vertices for "added" and "*November*". The key to interpreting the temporal relationship in this example however is the copula modifier "*to be*" in front of "published".

Without capturing these modifiers, the sentence will appear to read as "He added that final guidelines published in *early November* will determine . . . ". In this reading, "added" takes place AFTER the time span indicated by "*early November*", which explains the mis-classification by our classifier.

It will be useful following this analysis to study if including the auxiliary modifiers of event expressions into our parse features can help improve classifier performance.

[5]Extracted from document wsj_0527 of the TempEval-2 dataset.

Conclusion

In our study, we target the the main problem which we believe is hampering better performance for *event-temporal* relationship classification — lack of sufficient training data. We adopt a two-prong approach to tackle this problem: 1) by simplifying the feature space with the use of dependency parses as features to a convolution kernel support vector machine, and 2) by leveraging on crowdsourcing to get more data to support supervised machine learners.

We show that the classifier design we adopted is competitive when pitted against classifiers which make use of far more complex mechanics and features. With this as a starting point, we went on to expand the training data that is available for use via crowdsourcing. Despite the complexity of the annotation task, novice annotators are able to generate a dataset that helps improve classifier performance significantly.

Building on our insight of the clausal structure inherent to event and time expressions, we suggest an effective way to selectively acquire annotations. Our proposal reduces the amount of data to be annotated by up to 37% without sacrificing classifier performance. We achieved a classification accuracy of 73.2%, which represents a 8.6% improvement over our very competitive baseline.

ABSTRACT
Accurate recovery of predicate-argument dependencies is vital for interpretation tasks like information extraction and question answering, and unbounded dependencies may account for a significant portion of the dependencies in any given text. This paper describes a categorial grammar which, like other categorial grammars, imposes a small, uniform, and easily learnable set of semantic composition operations based on functor-argument relations, but like HPSG, is generalized to limit the number of categories used to those needed to enforce grammatical constraints. The paper also describes a novel reannotation system used to map existing resources based on Government and Binding Theory, like the Penn Treebank, into this categorial representation. This grammar is evaluated on an existing unbounded dependency recovery task (Rimell et al., 2009; Nivre et al., 2010).

1 Introduction

Accurate recovery of predicate-argument dependencies is vital for interpretation tasks like information extraction and question answering, and unbounded dependencies may account for a significant portion of the dependencies in any given text. Many current interpretation models are based on PCFGs, trained on syntactic annotations from the Penn Treebank (Marcus et al., 1993). These often recover dependencies as a post-process to parsing, and often are not able to retrieve unbounded dependencies if they are optimized on syntactic representations that leave these dependencies out.

Categorial grammars, on the other hand, have well-defined unbounded dependency representations based on functor-argument relations in a small and easily-learnable set of composition operations. Such grammars — in particular, Combinatory Categorial Grammar (CCG) (Steedman, 2000; Clark and Curran, 2007) — do well on unbounded dependency recovery tasks (Rimell et al., 2009) but not as well as models based on Head Driven Phrase-structure Grammar (HPSG) (Pollard and Sag, 1994; Miyao and Tsujii, 2005), given the same training. This may be attributed to implicit tradeoffs in many categorial frameworks that minimize the number of composition operations at the expense of large numbers of possible categories for each lexical item, which may lead to sparse data effects in training. HPSG models, in contrast, maintain a relatively large number of composition operations and a relatively small set of possible lexical categories, which are then used in a wider set of contexts.

Can categorial grammars, which have well-studied semantic representations and are well suited for interpretation, obtain better performance on a general unbounded dependency extraction task if it adopts an HPSG-like strategy of re-using types in various contexts? This paper describes a categorial grammar which, like HPSG, is generalized to limit the number of categories used to those needed to enforce grammatical constraints, but like other categorial grammars, imposes a small, uniform, and easily learnable set of semantic composition operations based on functor-argument relations. The paper also describes a novel reannotation system used to map existing resources based on Government and Binding Theory, like the Penn Treebank, into this categorial representation. This grammar is evaluated by training a state-of-the-art latent-variable parser on a version of the Penn Treebank reannotated into this generalized categorial grammar representation, and testing on an existing unbounded dependency recovery task (Rimell et al., 2009; Nivre et al., 2010).

The remainder of this paper is organized as follows. Section 2 describes related work on modeling unbounded dependencies and reannotation of syntax, Section 3 describes a generalized categorial grammar which provides transparent predicate-argument dependencies and generalizes similar categories across contexts, Section 4 describes how syntactically-annotated corpora can be reannotated into this framework, and Section 5 describes an evaluation of this system on an existing unbounded dependency recovery task.

2 Related Work

This section describes related work in unbounded dependencies and syntax reannotation.

2.1 Unbounded Dependencies

This paper describes a general-purpose reannotation system and its application to the specific task of reannotating local argument-passing treatments of long-distance dependencies in a generalized categorial grammar. Unbounded dependencies are dependencies between constituents

and points of attachment that have other constituents syntactically intervening. For example, the sentence *What does the First Amendment protect?* has a preposed constituent *what* that functions as a direct object of the transitive verb *protect*. The long distance between the source and destination of this type of dependency, paired with the relatively low probability of their occurrence in the language, and the fact that filler-gap annotations in syntactic resources such as the Penn Treebank are often stripped out, makes it very difficult for parsers to recognize this type of dependency correctly. While difficult to parse, this type of dependency is vital to the meaning of the sentence and of great importance in applications such as question answering and information extraction.

Rich grammar formalisms such as CCG (Steedman, 2000) have been shown to provide very accurate syntactic dependency extraction. This is thought to be because these formalisms explicitly model long-distance filler-gap dependencies inherent in relative clauses and interrogatives (Gildea and Hockenmaier, 2003). But formal systems like CCG, especially as reflected in reannotated Treebanks like CCGbank (Hockenmaier, 2003), comprise analyses of many phenomena: right node raising, light verbs, subject control, object control, coordinating conjunctions, etc., among which filler-gap constructions are just one component. Some of these analyses may be more easily automatically learnable (and thus more robust) than others. For example, CCG analyzes filler-gap constructions using essentially the same mechanism as right-side complementation, turning gaps into right-seeking functors using a special backward crossed composition combinator when gaps are not at the right periphery of constituents that contain them (Steedman, 2000). This distinction between peripheral and non-peripheral filler-gap constructions, and this merging of filler-gap constructions with right-side complementation, may produce different data densities in training corpora and make certain phenomena harder or easier to learn than, say, an HPSG-style analysis (Pollard and Sag, 1994), which treats all filler-gap constructions the same, but distinguishes constituents containing gaps from constituents awaiting complements.

Naturally, empirical questions about alternative syntactic analyses such as these cannot be resolved by fitting to syntactically annotated corpora, since the syntactic analyses do not agree. This paper therefore addresses the question of how to empirically distinguish between analyses of individual phenomena, or between entire formal systems, on the basis of learnability in a down-stream unbounded dependency recovery task. In particular, this paper describes a method for implementing syntactic analyses of various phenomena through automatic reannotation rules, which operate deterministically on a corpus like the Penn Treebank (Marcus et al., 1993) to produce a corpus with desired syntactic analyses. This reannotated corpus is then used to define a probabilistic grammar which is automatically annotated with additional latent variable values (Petrov and Klein, 2007) to introduce distinctions based on distributions of words and syntactic categories that increase the probability of the corpus (and improve the accuracy of parsing on held-out data), but do not affect the calculation of dependency structure. Dependency structures can then be extracted from parse trees produced by this grammar in a deterministic post-process, and mapped to the dependency representation used by Rimell et al. (2009) for evaluation.

2.2 Reannotation

The reannotation process described in this paper is similar in purpose to efforts to convert Penn Treebank annotations into other grammar formalisms, e.g. CCG (Hockenmaier, 2003) and HPSG (Miyao et al., 2004). These reannotation processes consist of multiple phases for

head-finding, binarization, and relabeling. However, unlike the Hockenmaier or Miyao et al. processes, the rule set described in this paper is intended to be modified and reused by researchers interested in manipulating analyses of individual phenomena (like distinguishing or consolidating filler-gap and right-node raising constructions) to test the generality and learnability of alternative syntactic representations on some down-stream task such as recovering unbounded dependencies. As such, the reannotation rules used in this process are defined to apply in a single top-down pass, pulling arguments and modifiers out of constituents until only a lexical head remains at the bottom. This single-pass architecture allows the rules for reannotating various linguistic phenomena to be relatively modular, so that they can be independently manipulated and evaluated.

The reannotation rules described in this paper are also similar to reannotation rules in the 'wsjsed' system (Blaheta, 2002), but that system was evaluated as an error-correction tool, rather than for making theoretically-motivated changes to syntactic analyses.

The reannotated grammar described in this paper exploits the rich traces and function labels in the Treebank that are typically ignored in parsing. These annotations are transformed into a categorial grammar representation of filler-gap constructions that makes use of 'gap' arguments, similar to the 'slash' arguments used in HPSG. Other approaches also exploit the trace and function labels of the Penn Treebank. Campbell (2004) proposed recovering trace information in a post-process following parsing. In contrast, the sample reannotation described in this paper incorporates filler-gap annotations into the corpus on which the parser is trained. Collins (1997), connected fillers with gaps and introduced a 'TRACE' category into the training data. Since this annotation does not change the constituent structure of the corpus, the addition of this gap annotation did not result in improved parsing results for Collins' gap-annotating model (model 3) as compared to the non-gap-annotating model (model 2). However, these are the kind of unbounded dependencies that need to be recovered in the evaluation described in this paper.

3 Generalized Categorial Grammar

This paper explores the use of a generalized categorial grammar which has the transparent predicate-argument dependencies of traditional categorial grammars (based on function application), but is generalized to allow arbitrary sets of type-constructing operators. An extended set of type-constructing operators and a corresponding set of inference rules are then used to group syntactically-interchangeable signs — for example, those with peripheral and non-peripheral gaps or those occurring in post-nominal and predicative contexts — into equivalent categories.

A generalized categorial grammar (Lambek, 1958; Bach, 1981; Oehrle, 1994) is a tuple $\langle U, O, R, X, M \rangle$ of a set U of primitive category types, a set O of type-constructing operators, a set R of inference rules, a set X of vocabulary items, and a mapping M from vocabulary items to complex types. The set of primitive category types U specify various linguistic forms for descriptions of entities or eventualities, corresponding to different clause types,[1] e.g.:

V: finite verbal (*they knew it*)
I: infinitive verbal (*them to know it*)
B: base-form verbal (*them know it*)
L: participial verbal (*them known it*)
A: adjectival/predicative (*them knowing it*)
R: adverbial (*them knowingly*)

[1]This system of categories may be viewed as a simplification of a tectogrammatical type system such as that of Mihalicek and Pollard (2010), weakened to be representable as a context-free grammar.

G: gerund (*them knowing it*)
N: nominal form (e.g. *their knowledge of it*)
D: determiner (*their knowledge of it's*)
O: genitive (*of their knowledge of it*)
E: embedded infinitive (*for them to know it*)
C: complementized finite (*that they know it*)
Q: interrogative (*did they know it*)
S: complete utterance (*know it*)

The set of type-constructing operators O specify various kinds of arguments:[2]

-a: initial argument
-b: final argument
-c: initial conjunct
-d: final conjunct
-g: filler-gap argument
-h: held argument for right node raising
-i: interrogative pronoun argument
-r: relative pronoun argument

Using this set of primitive category types U and type-constructing operators O, a set of complex categories C can be defined such that:

1. every U is in C
2. every $C \times O \times C$ is in C
3. nothing else is in C

Mapping M defines associations from vocabulary items $x \in X$ to meaning functions and associated categories of the form '$(\lambda ...) : u\varphi_1...\varphi_v\psi$', where '$(\lambda ...)$' is a meaning function and '$u\varphi_1...\varphi_v\psi$' is a category consisting of output category $u \in U$, a sequence of argument categories $\varphi_1, ..., \varphi_v \in \{\textbf{-a}, \textbf{-b}, \textbf{-c}, \textbf{-d}\} \times C$, and an optional non-local argument category $\psi \in (\{\textbf{-r}, \textbf{-i}\} \times C) \cup \{\epsilon\}$. Since this model will be used to generate predicate-argument relations but not scoping relations, these meaning functions are constrained to describe simple existentially-quantified variables over instances of entities or eventualities, connected by a set of numbered argument relations. These meaning functions map instances of entities or eventualities i, j, k to truth values based on whether the described argument relations hold between these referents. These argument relations are defined as numbered functions $(v\,i){=}j$ from eventuality or predicate instances i to argument instances j identified by the number of the function v. The '0' function identifies j as i's predicate concept (so '0' maps entity or eventuality instances to instances of concepts associated with words in X), the '1' function identifies j as i's first argument (e.g. its subject), the '2' function identifies j as i's second argument (e.g. its direct object), and so on.[3] A graphical representation of the predicate-argument relations generated by this system for the sentence *The person who officials say stole millions,* is shown in Figure 1. This is similar to the semantic dependency representations of Mel'čuk (1988) and Parsons (1990).

The meaning functions associated with most words specify just the predicate concept (which is here defined to match the word x):

$$x \;\mapsto_M\; (\lambda_i\,(0\,i){=}x) : u\varphi_1...\varphi_v \tag{1a}$$

[2] The **-a** and **-b** operators may be viewed as equivalent to the forward and backward slash, respectively, of Lambek (1958) or Bar-Hillel (1953) categorial grammars, except that they are not used to represent gap arguments or conjuncts. The **-g** operator is similar to the vertical or neutral slash of Kubota and Levine (2012), used to represent gap arguments. The **-c** and **-d** operators for conjuncts, the **-h** operator for rightward raising, and the **-r** and **-i** operators for relative and interrogative pronoun referents are novel extensions to the system.

[3] More sophisticated meaning functions are possible, but are not necessary for evaluating the accuracy of unbounded dependency recovery.

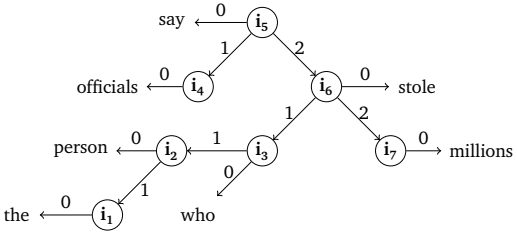

Figure 1: Graphical representation of predicate-argument dependencies for the sentence *The person who officials say stole millions.*

Meaning functions for relative pronouns (Equation 1b) and interrogative pronouns (Equation 1c) introduce additional arguments k, using operators **-r** or **-i** for the referent of the antecedent of a relative or interrogative pronoun respectively:

$$x \;\mapsto_M\; (\lambda_{k\,i}\,(0\,i){=}x \wedge (v\,i){=}k) : u\varphi_1 ... \varphi_{v-1}\text{-}\mathbf{r}c \tag{1b}$$

$$x \;\mapsto_M\; (\lambda_{k\,i}\,(0\,i){=}x \wedge (v\,i){=}k) : u\varphi_1 ... \varphi_{v-1}\text{-}\mathbf{i}c \tag{1c}$$

Inference rules are defined in terms of *composition functions* for arguments, modifiers, and conjuncts. These composition functions each take a meaning function g for an initial (left) child sign and a meaning function h for a final (right) child sign (each defining a set of entity or eventuality instances) and return a meaning function for the parent, which is itself a function from entity or eventuality instances i to truth values:

- Composition functions for arguments $f_{u\varphi_1 ... \varphi_v}$ connect the referent j of an initial (left) child function g as an argument of referent i of a final (right) child function h, or vice versa:

$$f_{u\varphi_1 ... \varphi_{v-1}\text{-}\mathbf{a}c} \stackrel{\text{def}}{=} \lambda_{g\,h\,i}\,\exists_j\,(v\,i){=}j \wedge (g\,j) \wedge (h\,i) \tag{2a}$$

$$f_{u\varphi_1 ... \varphi_{v-1}\text{-}\mathbf{b}c} \stackrel{\text{def}}{=} \lambda_{g\,h\,i}\,\exists_j\,(v\,i){=}j \wedge (g\,i) \wedge (h\,j) \tag{2b}$$

- Composition functions for initial and final modifiers (f_{IM} and f_{FM}) are category-independent and return the referent of the argument (j) rather than of the predicate (i):

$$f_{\text{IM}} \stackrel{\text{def}}{=} \lambda_{g\,h\,j}\,\exists_i\,(1\,i){=}j \wedge (g\,i) \wedge (h\,j) \tag{3a}$$

$$f_{\text{FM}} \stackrel{\text{def}}{=} \lambda_{g\,h\,j}\,\exists_i\,(1\,i){=}j \wedge (g\,j) \wedge (h\,i) \tag{3b}$$

- Composition functions for conjuncts are similar to composition functions for arguments,

except that they only count conjunct arguments, for $c, d \in C$:[4]

$$f_{c\text{-}\mathbf{c}d} \stackrel{\text{def}}{=} \lambda_{ghi}\, \exists_j\, (1\, i){=}j \wedge (g\, j) \wedge (h\, i) \tag{4a}$$

$$f_{c\text{-}\mathbf{d}d} \stackrel{\text{def}}{=} \lambda_{ghi}\, \exists_j\, (2\, i){=}j \wedge (g\, i) \wedge (h\, j) \tag{4b}$$

$$f_{\&} \stackrel{\text{def}}{=} \lambda_{ghi}\, \exists_{jk}\, j{=}(2\, i) \wedge (0\, i){=}(0\, j) \wedge (1\, j){=}k \wedge (g\, k) \wedge (h\, j) \tag{4c}$$

The set of *inference rules R* in the categorial grammar then apply these composition functions to compose and categorize super-lexical signs. These inference rules will use variables f, g, h over meaning functions, variables k over referents for possible values of gaps, variables $u \in U$ over primitive categories, variables $c, d, e \in U \times (\{\textbf{-a}, \textbf{-b}, \textbf{-c}, \textbf{-d}\} \times C)^*$ over categories with local arguments, and variables $\psi \in \{\textbf{-g}, \textbf{-h}, \textbf{-i}, \textbf{-r}\} \times C$ over non-local operators and argument categories:[5]

1. Inference rules for argument attachment apply functors of category c-**a**d or c-**b**d to initial or final arguments of category d. Non-local arguments k, using non-local operator and argument category ψ, are then propagated to the consequent from all possible combinations of antecedents, skipping over the composition function:

$$\frac{g{:}d \quad h{:}\,c\text{-}\mathbf{a}d}{(f_{c\text{-}\mathbf{a}d}\, g\, h){:}\,c} \quad \frac{g{:}d\psi \quad h{:}\,c\text{-}\mathbf{a}d}{\lambda_k\,(f_{c\text{-}\mathbf{a}d}\, (g\, k)\, h){:}\,c\psi} \quad \frac{g{:}d \quad h{:}\,c\text{-}\mathbf{a}d\psi}{\lambda_k\,(f_{c\text{-}\mathbf{a}d}\, g\, (h\, k)){:}\,c\psi} \quad \frac{g{:}d\psi \quad h{:}\,c\text{-}\mathbf{a}d\psi}{\lambda_k\,(f_{c\text{-}\mathbf{a}d}\, (g\, k)\, (h\, k)){:}\,c\psi} \quad \text{(Aa–d)}$$

$$\frac{g{:}\,c\text{-}\mathbf{b}d \quad h{:}d}{(f_{c\text{-}\mathbf{b}d}\, g\, h){:}\,c} \quad \frac{g{:}\,c\text{-}\mathbf{b}d\psi \quad h{:}d}{\lambda_k\,(f_{c\text{-}\mathbf{b}d}\, (g\, k)\, h){:}\,c\psi} \quad \frac{g{:}\,c\text{-}\mathbf{b}d \quad h{:}d\psi}{\lambda_k\,(f_{c\text{-}\mathbf{b}d}\, g\, (h\, k)){:}\,c\psi} \quad \frac{g{:}\,c\text{-}\mathbf{b}d\psi \quad h{:}d\psi}{\lambda_k\,(f_{c\text{-}\mathbf{b}d}\, (g\, k)\, (h\, k)){:}\,c\psi} \quad \text{(Ae–h)}$$

For example, to attach a verb to a direct object with or without a gap:

$$\frac{\dfrac{\text{read} \quad \text{a book about cars}}{\textbf{V-aN-bN} \qquad \textbf{N}}\ \text{Ae}}{\textbf{V-aN}} \qquad \frac{\dfrac{\text{read} \quad \text{a book about}}{\textbf{V-aN-bN} \qquad \textbf{N-gN}}\ \text{Ag}}{\textbf{V-aN-gN}}$$

2. Inference rules for modifier attachment apply initial or final modifiers of category u-**a**d to modificands of category c (again propagating non-local arguments ψ to the consequent from all combinations of antecedents, so as to skip over the composition function):

$$\frac{g{:}\,u\text{-}\mathbf{a}d \quad h{:}c}{(f_{\text{IM}}\, g\, h){:}\,c} \quad \frac{g{:}\,u\text{-}\mathbf{a}d\psi \quad h{:}c}{\lambda_k\,(f_{\text{IM}}\, (g\, k)\, h){:}\,c\psi} \quad \frac{g{:}\,u\text{-}\mathbf{a}d \quad h{:}c\psi}{\lambda_k\,(f_{\text{IM}}\, g\, (h\, k)){:}\,c\psi} \quad \frac{g{:}\,u\text{-}\mathbf{a}d\psi \quad h{:}c\psi}{\lambda_k\,(f_{\text{IM}}\, (g\, k)\, (h\, k)){:}\,c\psi} \quad \text{(Ma–d)}$$

$$\frac{g{:}c \quad h{:}\,u\text{-}\mathbf{a}d}{(f_{\text{FM}}\, g\, h){:}\,c} \quad \frac{g{:}c\psi \quad h{:}\,u\text{-}\mathbf{a}d}{\lambda_k\,(f_{\text{FM}}\, (g\, k)\, h){:}\,c\psi} \quad \frac{g{:}c \quad h{:}\,u\text{-}\mathbf{a}d\psi}{\lambda_k\,(f_{\text{FM}}\, g\, (h\, k)){:}\,c\psi} \quad \frac{g{:}c\psi \quad h{:}\,u\text{-}\mathbf{a}d\psi}{\lambda_k\,(f_{\text{FM}}\, (g\, k)\, (h\, k)){:}\,c\psi} \quad \text{(Me–h)}$$

For example, to attach an adverbial modifier with or without a gap:

$$\frac{\dfrac{\text{sleep} \quad \text{in Aix}}{\textbf{V-aN} \qquad \textbf{R-aN}}\ \text{Me}}{\textbf{V-aN}} \qquad \frac{\dfrac{\text{sleep} \quad \text{in}}{\textbf{V-aN} \qquad \textbf{R-aN-gN}}\ \text{Mg}}{\textbf{V-aN-gN}}$$

[4] The last of these (4c) introduces lexical and compositional relations for elided conjunctions in sequences of three or more conjuncts (e.g. between *creditors* and *investors* in the conjunction *creditors, investors, and employees*).

[5] A deductive system consists of inference rules of the form $\frac{P}{Q}R$, meaning premises or antecedents P entail conclusion or consequent Q according to rule or side condition R (Shieber et al., 1995). Additionally, this notation assumes adjacent premises arise from adjacent and similarly ordered sequences of observations.

3. Inference rules for conjunct attachment apply conjunctions of category c-**c**d or c-**d**d to conjuncts of category d (including repeated initial conjuncts):

$$\frac{g{:}d \quad h{:}\,c\text{-}\mathbf{c}d}{(f_{c\text{-}\mathbf{c}d}\ g\ h){:}\,c} \qquad \frac{g{:}d \quad h{:}\,c\text{-}\mathbf{c}d}{(f_{\&}\ g\ h){:}\,c\text{-}\mathbf{c}d} \qquad \frac{g{:}\,c\text{-}\mathbf{d}d \quad h{:}d}{(f_{c\text{-}\mathbf{d}d}\ g\ h){:}\,c} \qquad \text{(Ca–c)}$$

$$\frac{g{:}d\psi \quad h{:}\,c\text{-}\mathbf{c}d\psi}{\lambda_k(f_{c\text{-}\mathbf{c}d}\ (g\ k)\ (h\ k)){:}\,c} \qquad \frac{g{:}d\psi \quad h{:}\,c\text{-}\mathbf{c}d\psi}{\lambda_k(f_{\&}\ (g\ k)\ (h\ k)){:}\,c\text{-}\mathbf{c}d\psi} \qquad \frac{g{:}\,c\text{-}\mathbf{d}d\psi \quad h{:}d\psi}{\lambda_k(f_{c\text{-}\mathbf{d}d}\ g\ (h\ k)){:}\,c} \qquad \text{(Cd–f)}$$

For example, to combine three noun phrase conjuncts:

$$\dfrac{\text{creditors}\ \ \dfrac{\text{investors}\ \ \dfrac{\text{and}\ \ \text{employees}}{\mathbf{N\text{-}cN\text{-}dN}\quad\ \mathbf{N}}\ \text{Cc}}{\mathbf{N}\qquad\qquad\mathbf{N\text{-}cN}}\ \text{Cb}}{\mathbf{N}\qquad\qquad\mathbf{N\text{-}cN}}\ \text{Ca}$$

4. Inference rules for gap attachment hypothesize gaps as initial arguments, final arguments, or modifiers:[6]

$$\frac{g{:}\,c\text{-}\mathbf{a}d}{\lambda_k\,(f_{c\text{-}\mathbf{a}d}\ \{k\}\ g){:}\,c\text{-}\mathbf{g}d} \qquad \frac{g{:}\,c\text{-}\mathbf{b}d}{\lambda_k\,(f_{c\text{-}\mathbf{b}d}\ g\ \{k\}){:}\,c\text{-}\mathbf{g}d} \qquad \frac{g{:}c}{\lambda_k\,(f_{\mathrm{IM}}\ \{k\}\ g){:}\,c\text{-}\mathbf{g}d} \qquad \text{(Ga–c)}$$

For example:

$$\dfrac{\text{is sleeping}}{\mathbf{V\text{-}aN}}\ \text{Ga}\qquad \dfrac{\text{we}\quad\dfrac{\text{drove}}{\mathbf{V\text{-}aN\text{-}bN}}}{\mathbf{N}\qquad\mathbf{V\text{-}aN\text{-}gN}}\ \begin{matrix}\text{Gb}\\ \text{Ac}\end{matrix}\qquad \dfrac{\text{is sleeping}}{\mathbf{V\text{-}aN}}\ \text{Gc}$$

5. Inference rules for filler attachment apply gapped clauses to modificands or relative or interrogative phrases as fillers:

$$\frac{g{:}e \quad h{:}\,c\text{-}\mathbf{g}d}{\lambda_i\,\exists_j\,(g\ i)\wedge(h\ i\ j){:}e} \qquad \frac{g{:}d\text{-}\mathbf{r}e \quad h{:}\,c\text{-}\mathbf{g}d}{\lambda_{kj}\,\exists_i\,(g\ k\ i)\wedge(h\ i\ j){:}\,c\text{-}\mathbf{r}e} \qquad \frac{g{:}d\text{-}\mathbf{i}e \quad h{:}\,c\text{-}\mathbf{g}d}{\lambda_{kj}\,\exists_i\,(g\ k\ i)\wedge(h\ i\ j){:}\,c\text{-}\mathbf{i}e} \qquad \text{(Fa–c)}$$

For example:

$$\dfrac{\text{the car}\quad\text{we drove}}{\mathbf{N}\qquad\mathbf{V\text{-}gN}}\ \text{Fa}\qquad \dfrac{\text{which}\quad\text{we drove}}{\mathbf{N\text{-}rN}\qquad\mathbf{V\text{-}gN}}\ \text{Fb}\qquad \dfrac{\text{what}\quad\text{do we drive}}{\mathbf{N\text{-}iN}\qquad\mathbf{Q\text{-}gN}}\ \text{Fc}$$

6. Inference rules for relative pronoun attachment apply pronominal relative clauses of category c-**r**d to modificands of category e:

$$\frac{g{:}e \quad h{:}c\text{-}\mathbf{r}d}{\lambda_i\,\exists_j\,(g\ i)\wedge(h\ i\ j){:}e} \qquad \text{(R)}$$

For example:

$$\dfrac{\text{the car}\quad\text{which we drove}}{\mathbf{N}\qquad\mathbf{V\text{-}rN}}\ \text{R}$$

[6]Here, set notation is used in order to save space: $\{k\} = (\lambda_i\ i{=}k)$.

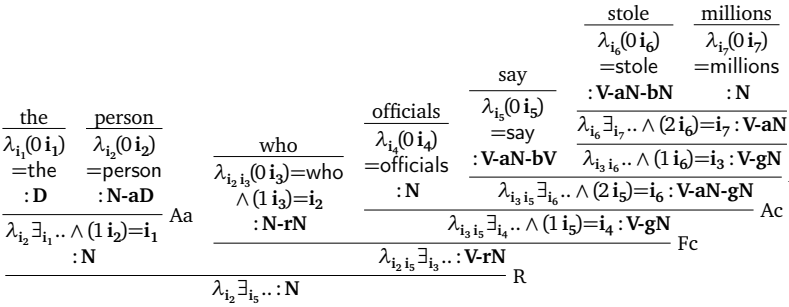

Figure 2: Example categorization of the noun phrase *the person who officials say stole millions*. This derivation yields the following lexical relations: $(0\,\mathbf{i}_1)$=the, $(0\,\mathbf{i}_2)$=person, $(0\,\mathbf{i}_3)$=who, $(0\,\mathbf{i}_4)$=officials, $(0\,\mathbf{i}_5)$=say, $(0\,\mathbf{i}_6)$=stole, $(0\,\mathbf{i}_7)$=millions, and the following argument relations: $(1\,\mathbf{i}_2)$=$\mathbf{i}_1$, $(1\,\mathbf{i}_3)$=$\mathbf{i}_2$, $(1\,\mathbf{i}_5)$=$\mathbf{i}_4$, $(2\,\mathbf{i}_5)$=$\mathbf{i}_6$, $(1\,\mathbf{i}_6)$=$\mathbf{i}_3$, $(2\,\mathbf{i}_6)$=$\mathbf{i}_7$. The semantic dependency relations for this sentence are represented graphically in Figure 1.

7. Inference rules for argument elision (including determiners of plural nouns) simply leave these arguments unspecified in the resulting meaning function:

$$\frac{g\colon c\text{-}\mathbf{a}d}{g\colon c} \qquad \frac{g\colon c\text{-}\mathbf{b}d}{g\colon c} \qquad \frac{g\colon c\text{-}\mathbf{a}d\psi}{g\colon c\psi} \qquad \frac{g\colon c\text{-}\mathbf{b}d\psi}{g\colon c\psi} \qquad \text{(Ea–d)}$$

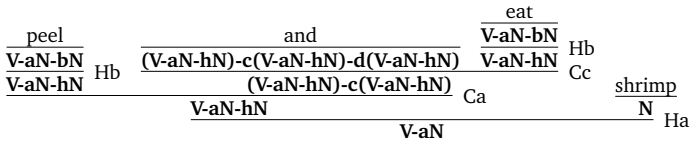
   For example, to elide determiners of plural nouns or optional direct objects:

$$\dfrac{\dfrac{\text{cars}}{\textbf{N-aD}}\,\text{Ea}}{\textbf{N}} \qquad \dfrac{\dfrac{\text{drive}}{\textbf{V-aN-bN}}\,\text{Eb}}{\textbf{V-aN}}$$

8. Inference rules for right node raising introduction and attachment treat right-node raising as a type of non-local argument using operator **-h**:

$$\frac{g\colon c\text{-}\mathbf{h}d \quad h\colon d}{\lambda_i\,\exists_j\,(g\;j\;i)\wedge(h\;j)\colon c} \qquad \frac{g\colon c\text{-}\mathbf{b}d}{\lambda_k\,(f_{c\text{-}\mathbf{b}d}\;g\;\{k\})\colon c\text{-}\mathbf{h}d} \qquad \text{(Ha–b)}$$

   For example:



An example derivation of the noun phrase *the person who officials say stole millions*, exemplifying F, G, and R rules, is shown in Figure 2; and an example derivation of the noun phrase *creditors, investors and employees of the company*, exemplifying C, E, and H rules, is shown in Figure 3. After all lambda expressions are applied to arguments in a derivation, each word is associated

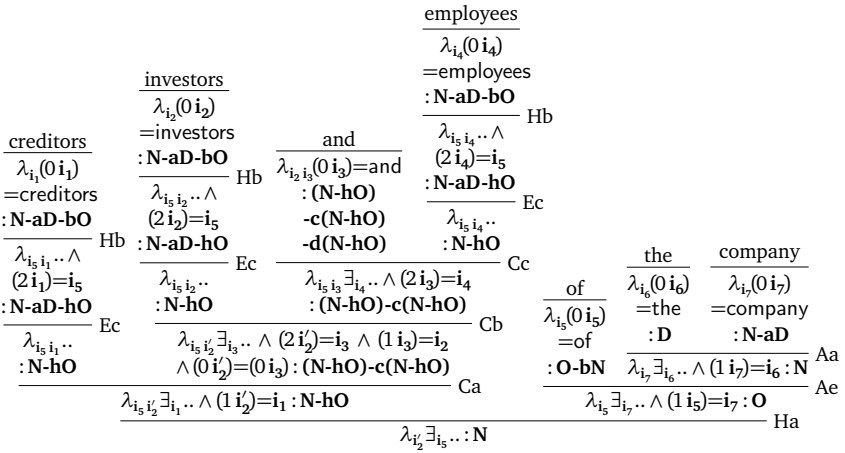


Figure 3: Example categorization of the noun phrase *creditors investors and employees of the company*. This derivation yields the following lexical relations: $(0\,\mathbf{i}_1)$=creditors, $(0\,\mathbf{i}_2)$=investors, $(0\,\mathbf{i}'_2)=(0\,\mathbf{i}_3)$=and, $(0\,\mathbf{i}_4)$=employees, $(0\,\mathbf{i}_5)$=of, $(0\,\mathbf{i}_6)$=the, $(0\,\mathbf{i}_7)$=company, and the following argument relations: $(2\,\mathbf{i}_1)=\mathbf{i}_5$, $(2\,\mathbf{i}_2)=\mathbf{i}_5$, $(2\,\mathbf{i}_4)=\mathbf{i}_5$, $(1\,\mathbf{i}'_2)=\mathbf{i}_1$, $(2\,\mathbf{i}'_2)=\mathbf{i}_3$, $(1\,\mathbf{i}_3)=\mathbf{i}_2$, $(2\,\mathbf{i}_3)=\mathbf{i}_4$, $(1\,\mathbf{i}_5)=\mathbf{i}_7$, $(1\,\mathbf{i}_7)=\mathbf{i}_6$.

with the variable of an existential quantifier. These existentially quantified variables can then be uniquely identified using numerical indices of words, and the numbered functions in lambda expressions $(v\,i)=j$ are interpreted as dependency relations assigning the v^{th} argument of i to be j.

This system has the attractive property that the same syntactic constraints can be assigned the same category in every context. This property is not shared by most categorial grammars: e.g. post-nominal and post-copular prepositional phrases often have different categories.

4 Mapping Treebank to a Generalized Categorial Grammar

The reannotation system described in this paper defines its target grammar in terms of a set of reannotation rules. These reannotation rules work within a script that traverses each bracketed sentence in a corpus by selecting each pair of matching brackets from the top of the tree to the bottom, then running a sed-like pattern substitution rule on each selection (see Figure 4). Such rules can implement local syntactic transformations, as well as certain non-local transformations like adding gap arguments to constituents containing a particular trace marker, for example. Reannotation of the categorial grammar evaluated in this paper requires about 150 such rules. These rules are modular and can be reused or modified to experiment with different syntactic analyses.

In order to make the trace and function labels in the Treebank accessible to a PCFG-based latent variable annotator, they must be incorporated into the syntactic categories of each tree and propagated from filler to gap constituents, creating a categorial grammar with local associations between parents and immediate children. First all trace annotations for interrogatives, relative

a) s/{(V-rN) <(WHNP)(-[0-9]+)([^ >]*)> (.*[-NONE- *T*\3].*)}/{\1 <N-rN\4> <V-gN\3 \5>}/;

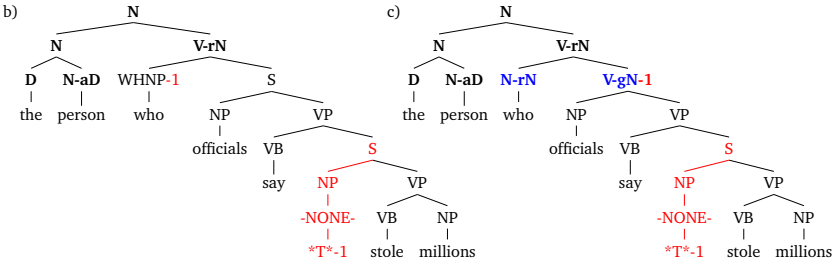

Figure 4: Sample sed-like reannotation rule introducing a gap tag at the top of a relative clause (a), and an application of this rule to the movement-based notation in the Penn Treebank (b) to produce a binary-branching categorial grammar derivation using gap arguments (c). Rules are applied to every constituent from the top of the tree down, using parentheses to delimit constituents above the current constituent, curly braces to delimit the current constituent, angle brackets to delimit child constituents, and square brackets to delimit constituents below children. Delimiters are then updated at every iteration.

clauses, and topicalizations are transformed into gap arguments: **-gN** (for noun phrase gaps), **-g(R-aN)** (for adverbial phrase gaps), and **-gS** (for e.g. topicalized sentential gaps), which follow the category label for each constituent. Similar transformations localize it-clefts (*it seems that...*), tough constructions (*tough to cut*), parentheticals (*he/she said*), and certain types of inversion (*'it rained,' she said*), also using the gap operator **-g**. This is similar to the treatment of filler-gap constructions used in HPSG (Pollard and Sag, 1994).

Then, specifiers of head projections are annotated as initial arguments, e.g. **-aN** for nominal subjects, and complements of head projections are annotated as final arguments: e.g. **-bN** for transitive verbs, prepositions, and certain adjectives, **-bV** for sentential complements, **-bN-bN** for ditransitive verbs, etc. The **-h** operator is then used to propagate directional dependencies in right node raising (*they peeled and ate shrimp*). These are similar to the 'subcat' feature in HPSG, or to the left and right slash in categorial grammar accounts of specification, complementation and right node raising.

Then, interrogative and relative pronouns (e.g. *what* and *which*) are distinguished with **-iN** and **-rN** arguments, respectively, in order to regularize typical contexts for filler-gap traces.

Conjuncts are assigned **-c** and **-d** arguments to distinguish composition functions for conjuncts from composition functions for ordinary arguments. This distinction makes it possible for ordinary arguments to be shared among conjuncts.

The transform rules are defined as recursive rewrites that progress down the Treebank trees, propagating **-a**, **-b**, **-c**, **-d**, **-g**, **-h**, **-i**, and **-r** arguments as they go. Figure 4 shows a single step in a reannotation of the noun phrase *the person who officials say stole millions.* This set of recursive rules obtains about 94% coverage of the training set, consisting of sections 2–21 of the Penn Treebank. Trees not completely transformed by these rules are excluded from training. Since the system is evaluated on unbounded dependency annotations as described by Rimell et al. (2009), it is not necessary to apply this transformation to the test set.

In many cases the conversion to this categorial grammar replaces Treebank category labels with more general specifications. For example, in most contexts, adjective phrases, prepositional phrases, and progressive and passive verb phrases are replaced with a predicative category **A-aN**. This allows an HPSG-, GPSG- or CCG-like treatment of conjunction of any of these kinds of phrases with any other, following Sag et al. (1985), Gazdar et al. (1985), and Komagata (2002). This generalized predicative category is also used for noun phrase modifiers, and for noun phrases following the copular *be*. This annotation is compatible with additional specification of categories for adjective phrases (following words like *become*), or gerund phrases (following words like *start*), but these contexts cannot be reliably identified by the current reannotation.

In other cases, the conversion to categorial grammar distinguishes categories that are conflated in the Treebank. For example, the Treebank 'SBAR' category is distinguished into adjectival relative clauses **V-rN**, embedded questions **V-iN**, embedded inflected sentences **C**, embedded infinitival sentences **E**, nominal clauses **N**, adjectival modifier phrases **A-aN**, and adverbial modifier phrases **R-aN** (e.g. *because* . . .). Treebank 'S' categories are similarly distinguished into inflected sentences **V**, infinitival sentences **I**, base form sentences **B**, adjectival sentences (small clauses) **A**, and participial sentences **L**.[7]

Also, like other categorial grammars, this transform leaves trees in binary branching (Chomsky normal) form.

5 Evaluation

To evaluate the reannotation system described in this paper, a version of the Penn Treebank was annotated with a generalized categorial grammar as described in Section 3. This required about 150 reannotation rules, with about 20 rules for each of noun phrases, verb phrases, prepositional phrases, adjectival phrases, and adverbial phrases, and about 50 rules for various sentence types. This reannotation was applied to Sections 02 to 21 of the WSJ portion of the Penn Treebank (Marcus et al., 1993). The resulting corpus then underwent three iterations of latent variable annotation, using the split-merge algorithm of Petrov et al. (2006).[8] Each iteration of this algorithm splits the categories in the training corpus randomly in two, runs the inside-outside algorithm (expectation maximization) on the resulting trees to maximize the probability of the training set, then merges those categories that contributed the least to the maximization. The categorial grammar type-constructing operators were then used to extract semantic dependency relations for each parsed sentence.

This evaluation used development and test sets from Rimell et al. (2009) for tuning the annotation mappings and testing, respectively. The de Marneffe et al. (2006) dependencies used in these sets are deterministically mapped to the comparable numeric relations used by the current system.[9] Thus, the dependencies 'nsubj' and 'nsubjpass' are mapped to a '1' relation, and 'dobj', 'pobj', and 'obj2' are mapped to a '2' relation. The dependencies 'advmod', 'prep', and 'nn' are also mapped to a '1' relation with the direction of the dependency reversed.[10]

[7] It is important to note that these rules allow the word *that* to be treated as a relativizer rather than a relative pronoun, as it is in other categorial grammars, such as CCG.

[8] Under the current system, this number of split-merge iterations was empirically shown to yield the same results on development data as five iterations of split-merge, which is the recommended number for maximum accuracy without overfitting according to Petrov and Klein (2007).

[9] This simplification of dependency labels to numbers can be losslessly reversed by looking at the categories of the involved predicates.

[10] One anonymous reviewer points out that this reversal of direction for modifier dependencies is similar to that described in dependency accounts of Tree Adjoining Grammars (Joshi, 1985; Candito and Kahane, 1998).

This system	52.7	**69.2**	68.4	69.0	**57.5**	26.4	**38.8**	**54.6**

Table 1: Unbounded dependency results compared to those of other systems studied by Rimell et al. (2009) and Nivre et al. (2010) over a variety of constructions: object extraction from relative clauses (Obj RC), object extraction from reduced relative clauses (Obj Red), subject extraction from relative clauses (Sbj RC), free relatives (Free), object wh-questions (Obj Q), right node raising (RNR), and subject extraction from embedded clauses (Sbj Embed). Evaluated parsers are C&C (Clark and Curran, 2007), Enju (Miyao and Tsujii, 2005), DCU (Cahill et al., 2004), Rasp (Briscoe et al., 2006), Stanford (Klein and Manning, 2003), MST (McDonald, 2006), Malt (Nivre et al., 2006a,b). This system used the Berkley parser (Petrov and Klein, 2007) run on the reannotated categorial grammar.

Due to differences between the de Marneffe et al. (2006) dependency representation and that of the current system, some deterministic modifications were required for evaluation against the Rimell et al. (2009) corpus.[11]

1. If the hypothesized target of a dependency is a conjunction, the dependencies to each of its conjuncts are hypothesized instead;

2. If the target of a dependency is a relativizer or a relative pronoun, the predicate it modifies is used in its place; and

3. If the source predicate of a dependency has a category of **O**, the predicate that depends on the hypothesized target is hypothesized as the target.

For example, in this categorial grammar analysis of the phrase *levels of health*, the word *of* heads a phrase of category **O**, with *health* as an argument, and *levels* depends directly on *health*, so the dependency that is evaluated is from *of* to *levels*. Finally, following Rimell et al. (2009), the current system counts both dependencies in a conjunction as having been captured if the first is correct and the conjunction is modelled correctly. If the source has the same type of relation to the target in the gold standard as was output by the current system, the dependency is counted as correct. The final results are tabulated in comparison to those in Rimell et al. (2009) and Nivre et al. (2010) in Table 1.[12]

[11] This automated scoring makes the evaluation less generous than the manual output interpretations given in Rimell et al. (2009) and Nivre et al. (2010), but has the advantage of being easily reproducible.

[12] Note that one of the other systems was a variant of C&C which was given additional training on QuestionBank (Judge et al., 2006). This extra training and the results obtained from it were not used in the experimental description in this paper because i) other systems were not trained on this data and ii) extra training examples may distort the prior model to reduce probability of non-questions, which may have an adverse effect on overall parsing accuracy.

6 Conclusion

This paper has presented a system for automatically reannotating syntactically-annotated corpora for the purpose of refining linguistically-informed phrase structure analyses of various phenomena. The paper has also presented a generalized categorial grammar reannotation developed using this system which combines the transparent predicate-argument structure of a categorial grammar with the categorial generality of an HPSG-like system. The system achieves unbounded dependency parsing accuracy favorably comparable to all the systems recently studied by Rimell et al. (2009) and Nivre et al. (2010) on this same task.

This system and the generalized categorial grammar reannotation rules (and other scripts needed to produce the reannotated corpus) are available at:
http://sourceforge.net/projects/modelblocks/

ABSTRACT

This paper presents an identification framework for extracting Tibetan base noun phrase (NP). The framework includes two phases. In the first phase, Chinese base NPs are extracted from all Chinese sentences in the sentence aligned Chinese-Tibetan corpus using Stanford Chinese parser. In the second phase, the Tibetan translations of those Chinese NPs are identified using four different methods, that is, word alignment, iterative re-evaluation, dictionary and word alignment, and sequence intersection method. We implemented and tested these methods on Chinese-Tibetan sentence aligned unlabelled corpus without Tibetan POS tagger and Treebank. The experimental results demonstrate these methods can get satisfactory results, and the best performance with 0.5283 precision is got using sequence intersection identification method. The identification framework can also be extended to extract Tibetan verb phrase.

Title and abstract in Chinese

基于汉藏句子对齐语料的藏文BaseNP识别框架

本文提出藏文BaseNP识别框架，它分两步完成。先通过句法分析得到汉语BaseNP。再为这些汉语BaseNP从汉藏句子对齐语料中识别出藏文对应短语。我们应用四种方法识别藏文BaseNP，分别是词对齐、迭代重估算法、词典和词对齐相结合的方法以及基于序列相交的方法。评价实验表明，没有藏文词性标注和树库的前提下，基于序列相交的方法性能最好。本文提出的框架可以用于藏文动词短语识别任务中。

1 Introduction

Shallow parsing identifies the non-recursive cores of various phrase types in text, possibly as a precursor to full parsing or information extraction (Abney, 1991). The paradigmatic shallow parsing problem is NP chunking, which finds the non-recursive cores of noun phrases called BaseNPs. It can help to solve many natural language processing tasks, such as information extraction, named entity extraction, machine translation, and text summarization and so on.

In general, researchers consider chunking as a kind of tagging problem or a sequence labelling task. Machine learning techniques are often applied to chunking. In Tibetan information processing, the shortage of Tibetan language resource leads to the fact that most of the techniques related text processing are still developing. Since 2003, research on Tibetan corpus, Tibetan word segmentation are reported. Although there is no public available Tibetan annotated corpus and Tibetan Treebank, we intend to extract Tibetan BaseNP using machine translation techniques based on our Chinese-Tibetan sentence aligned corpus. The research on Tibetan BaseNP is still in the initial stage. So far, there is no related report. In this paper, we will propose several methods for automatic identification of Tibetan base noun phrases.

The concept of BaseNP is initially put forward by (Church, 1998). In English, BaseNP is simple and non-recursive noun phrase which does not contain other noun phrase descendants. It cannot meet the needs in Tibetan information processing. Presently, different definitions of Chinese BaseNP are used on the basis of research field. According to our Chinese-Tibetan corpus, restrictive attribute phrase is in the scope of our BaseNP extraction. Observing that the Tibetan BaseNP is different from English, BaseNP in Tibetan can be recursively defined as follows, which is in accordance with the definition of Chinese BaseNP in (Zhao and Huang, 1998).

Definition 1: Tibetan base noun phrase (abbreviated as *BaseNP*)
BaseNP ::= *BaseNP* + *BaseNP*
BaseNP ::= *BaseNP* + *Noun*
BaseNP ::= *Determinative modifier* + *BaseNP*
BaseNP ::= *Determinative modifier* + *Noun*
Determinative modifier ::= *Adjective* | *Distinctive Adjectives (DA)* |*Nominalized Verb*| *Noun* |*Location* |*Numeral* + *Quantifier*

The Determinative modifiers have agglutinative relation with the heads.

The rest of this paper is organized as follows. Section 2 introduces related work of BaseNP chunking. Section 3 describes the outline of our framework. In Section 4, we propose four methods to automatically identify the Tibetan BaseNP which are very convenient to manual proofreading. In Section 5, we make an experiment to evaluate the four methods by three metrics, namely coverage, quasi-precision, and precision, then concludes this paper.

2 Related work

2.1 English BaseNP chunking

In 1991, Abney proposed to approach parsing by starting with finding correlated chunks of words (Abney, 1991). The pioneering work of Ramshaw and Marcus (1995) introduced NP chunking as a machine-learning problem, with standard datasets and evaluation metrics. Their work has inspired many others to study the application of learning methods to noun phrase chunking. Other chunk types have not received the same attention as NP chunks. At home and abroad, many statistical and machine learning methods are applied to the English BaseNP identification, and have achieved good recognition performance.

The task was extended to additional phrase types for the CoNLL-2000 shared task (Sang and Buchholz, 2000), which is the standard evaluation task for shallow parsing now. In this conference, many systems used the Machine learning methods, and among them, the most representative and effective one is Support Vector Machine (SVM) based method (Kudo and Matsumoto, 2000). Recently, some new statistical techniques, such as CRF (Lafferty et al. 2001), Winnow algorithm (Zhang, 2001) and structural learning methods (Ando and Zhang, 2005) have been applied to the BaseNP chunking task. Sha and Pereira (2003) considered chunking as a sequence labelling task and achieved good performance by an improved training method of CRF. Ando and Zhang (2005) presented a novel semi-supervised learning method on chunking and produced higher performance than the previous best results.

2.2 Chinese BaseNP chunking

Researchers apply similar methods of English BaseNP chunking to Chinese. Zhao and Huang (1998) made a strict definition of Chinese BaseNP in terms of combination of determinative modifier and head noun and put forward a quasi-dependency model to analyse the structure of Chinese BaseNP. There are some other methods to deal with Chinese phrase (not only BaseNP) chunking, such as HMM (Li et al., 2003), Maximum Entropy (Zhou et al., 2003), Memory-Based Learning (Zhang and Zhou, 2002) etc. Xu et al. (2006) propose a hybrid error-driven combination approach to chunking Chinese BaseNP, which combines TBL (Transformation-based Learning) model and CRF. In order to analyse the results respectively from the two (TBL-based and CRF-based) classifiers and improve the performance of the BaseNP chunker, an error-driven SVM based classifier is trained from the classification errors of the two classifiers. The hybrid method outperforms the previous works.

In general, the flexible structure of Chinese noun phrase often results in the ambiguities during the recognition procedure. Compared with English, internal grammatical structure of phrases is not rigorous; long noun phrase in Chinese is richer. Usage of Chinese word may serve with multi POS (Part-of-Speech) tags. Therefore, the chunker is puzzled by those multi-used words. Furthermore, there are no standard datasets and evaluation systems for Chinese BaseNP chunking as the CoNLL-2000 shared task, which makes it difficult to compare and evaluate different Chinese BaseNP chunking systems.

2.3 Tibetan chunking

In Tibetan information processing, the shortage of Tibetan language resource leads to the fact that most of the techniques related text processing are still developing. Recently, the focus of Tibetan information processing is gradually transferred from word processing to text processing. The Tibetan text processing started in the early 1990s, mainly analyse statically at the beginning. Since 2003, research on Tibetan syntactic chunks is reported.

Jiang (2003a) describes the basic types of syntactic chunks and their formal markers in modern Tibetan, and propose a scheme of automatic word-segmentation based on chunks according to the features of Tibetan syntactic structures. This paper finds the left and right boundaries of each chunk on the basis of pre-processing, setting up small tables of formal markers of each chunk, the verbal paradigm, special tables of homographs, etc, and goes on segmenting words with a dictionary and tagging within chunk. In (Jiang, 2003b), they discuss the automatic recognition strategies of nominalization markers in the modern Tibetan language. The purpose of identifying the nominalization markers is to make automatic word-segmentation within non-finite VP chunks. Due to the complexity of the formal features as well as distribution of the markers, the paper proposes the major recognition approach of the nominalization markers which distinguish between nominal markers and their homographic words. Huang et al. (2005) defines the nominal chunks of Tibetan according to the structures and syntax. Their identification strategy of nominal chunks depends mainly on the markers on the right boundary of the chunks. These previous works define the basic types of syntactic chunks and their formal markers. Identification of chunk is rule-based, including word order rule and syntactic rules of chunk. These papers just illustrate chunking result of several example sentences without experimental data.

The research on Tibetan BaseNP Chunking is, however, still at its initial stage. There is no public available Tibetan Treebank, even a POS tagger at present. In addition, there is no annotated Tibetan corpus available which contain specific information about dividing sentences into chunks of words of arbitrary types. Since we have large-scale Chinese-Tibetan sentence aligned corpus, public available Chinese parser, and word segmentation software etc., we can identify Tibetan BaseNP using these existing resources. Therefore, a Tibetan BaseNP identification framework based on Chinese-Tibetan sentence aligned corpus is proposed in the following.

3 Brief description of Tibetan BaseNP identification framework

The proposed Tibetan BaseNP identification framework consists of three main steps: pre-processing step, Chinese BaseNP extraction step, and Tibetan BaseNP identification step, which are in boldface in FIGURE 1(A). Chinese BaseNP extraction step and the Tibetan BaseNP identification step are the core of the identification framework.

In pre-processing step, sentence aligned Chinese and Tibetan corpus are word segmented and stored separately to the two documents, one sentence per line. Then words in sentence pairs are aligned using Giza++ toolbox (Och and Ney, 2003). FIGURE 1(B) shows the data flowchart of pre-processing.

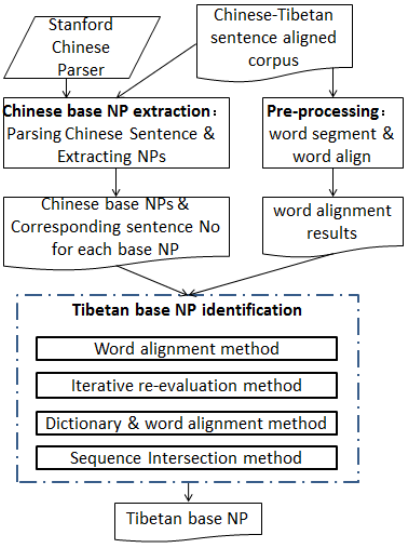

FIGURE 1 (A) – Flow chart of Tibetan BaseNP identification

(B) – Flow chart of pre-processing

In Chinese BaseNP extraction step, we use Stanford Chinese parser to parse all sentences in Chinese corpus from step 1; Extract all NP phrases from parsing results and note the sentence number in which there is a Chinese BaseNP.

The final step is Tibetan BaseNP identification. Aligned sentence pairs, their word alignment results and Chinese BaseNP extracted in step 2 is the input of Tibetan BaseNP identification. To determine the alignment for each Chinese BaseNP from step 2, different approaches within the dotted line in FIGURE 1(A) are proposed.

In the condition that there are no annotated Tibetan corpus, Treebank and Tibetan POS tagger, the framework regards the Tibetan BaseNP identification as translation problem, which confirms correct correspondence for those extracted Chinese BaseNP based on Chinese-Tibetan sentence aligned corpus. We assume that when a phrase in a source language is a BaseNP, its translation in target language is BaseNP too. The term "correspondence" is used here to signify a mapping between words in two aligned sentences. Specify that symbol '↔' is used to represent alignment. Any sentence-pair is symbolized by *SP*, and notated as $SP = CS \leftrightarrow TS$, where *CS* and *TS* stand for Chinese and Tibetan sentence respectively. A word sequence in *CS* is defined here as the correspondence of another sequence in *TS* if the words of one sequence are considered to represent the words in the other. In other words, Chinese-Tibetan BaseNP correspondence is an alignment at phrase-level.

Definition 2: Chinese-Tibetan BaseNP correspondence

$< C_{mi}, C_{mi+1}, \cdots, C_{mi+p} > \leftrightarrow < T_{nj}, T_{nj+1}, \cdots, T_{nj+q} >.$

On the left of alignment symbol is a Chinese BaseNP. Definition of Chinese BaseNP is the same to definition 1. On the right is its translation in Tibetan sentence of aligned sentence pair where Chinese BaseNP located, it conforms to definition 1 too. In this paper, Tibetan BaseNP consist of two or more words are taken into consideration, because of the task objectives.

In next section, we describe in detail how to identify Tibetan BaseNP correspondence to the extracted Chinese BaseNP. Different methods are evaluated, and we will select the method with best performance to generate referable Tibetan BaseNP, which is fully or partial correct, for further manual proofreading.

4 Tibetan BaseNP identification methods

Four different methods, that is, word alignment, iterative re-evaluation, dictionary and word alignment, and sequence intersection method are proposed to determine Tibetan correspondences for Chinese BaseNP. In the following, we elaborate the four methods.

4.1 Word alignment method

This subsection presents word alignment (WA, hereafter) method. In this method, phrase-level alignments are obtained on the basis of the optimal two-way word alignment results from Giza++. Outline of WA method is given below.

Step 1: Run Giza++ to get word alignment results of aligned sentence pair in Chinese-Tibetan corpus.

Step 2: For each Chinese BaseNP, get the word alignment results of located sentence pair and corresponding Tibetan sentence based on the sentence number it located.

Step 3: For each word in Chinese BaseNP, obtain the aligned Tibetan word according to word alignments using a heuristic. These Tibetan words constitute a Tibetan BaseNP for current Chinese BaseNP.

A number of different word alignment heuristics are implemented; in the end, grow-diag-final heuristic shows better performance than others on our aligned corpus. Consequently WA method with grow-diag-final heuristic is regarded as a baseline method.

4.2 Iterative re-evaluation method

This subsection describes iterative re-evaluation (IRE, hereafter) method, which is based on correlations of Chinese phrase and Tibetan words, to complete the identification of Tibetan BaseNP. It is an instance of a general approach to statistical estimation, represented by the EM algorithm (Dempster et al., 1977). Iterative re-evaluation algorithm assumes that a Chinese phrase has a corresponding probability with every Tibetan word; we call it relevancy (R). First, we assign an initial value to R, and then iteratively update the value of R based on correlations between Tibetan word

and Chinese phrase. If the absolute value of the difference between the latest updated two R value, the iterative process stops. Eventually we obtain satisfactory correlations of Chinese phrase and Tibetan words. We will describe the details of iterative re-evaluation algorithm in this section.

Relevancy of Chinese phrase and Tibetan words are used to identify the potential Tibetan BaseNP translation for each Chinese phrase. Tibetan words with higher relevancy should be within the translation of Chinese phrase. If we denote the relevancy of a Chinese phrase *c* and a Tibetan word *t* by $R(c,t)$, then we can calculate it with the following formula.

$$R(c,t) = \frac{W(c,t)}{\sum_{q \in V_F} W(c,q)} \qquad \text{satisfied} \quad \sum_{q \in V_F} R(c,q) = 1 \tag{4.1}$$

In formula(4.1), $W(c,t)$ represents weighted frequency (product of co-occurrence frequency and relevancy) of *c* and *t*. Every Chinese phrase *c* and every Tibetan word *t* has a weighted frequency. V_F indicates words set of Tibetan corpus.

Weighted frequency of Chinese phrase and Tibetan word is the key to the calculation of relevancy. Weighted frequency of *c* and *t* is defined as follow:

$$W(c,t) = \sum_{i=1}^{N} F(i,c,t) R(c,t) \tag{4.2}$$

In which *N* represents the number of sentence pairs in Chinese-Tibetan corpus. $F(i,c,t)$ indicates the number of simultaneous occurrence of *c* and *t* in i^{th} sentence pair. Equation (4.3) assumes that each Chinese BaseNP is initially equally likely to correspond to each Tibetan BaseNP. The weights $W_0(c,t)$ can be interpreted as the mean number of times that *c* corresponds to *t* given the corpus and the initial assumption of equivalent correspondences.

$$W_0(c,t) = \sum_{i=1}^{N} F(i,c,t) \frac{1}{\phi(i)} \tag{4.3}$$

Where $\phi(i)$ indicates the number of Tibetan words in i^{th} sentence pair.

Let *r* be the number of iterations, $P(c,t)$ and $W(c,t)$ for iteration *r* is formulated as in formula (4.4) and (4.5).

$$R_r(c,t) = \frac{W_{r-1}(c,t)}{\sum_{q \in V_F} W_{r-1}(c,q)} \tag{4.4}$$

$$W_r(c,t) = \sum_{i=1}^{N} F(i,c,t) R_{r-1}(c,t) \tag{4.5}$$

The procedure is then iterated using Equations (4.4) and (4.5) to obtain successively refined, convergent estimates of the probability that *c* corresponds to *t*. Experiment results shows that it works well when the iterative threshold is 0.001. It means that we can find Tibetan word *t* with highest corresponding probability to each Chinese phrase,

after several iterations. If $|R_r(c,t)-R_{r-1}(c,t)|<0.001$ then stop iterating.

IRE method can globally calculate the corresponding information, while Mutual Information is used to measure the relevance between Chinese phrase and Tibetan word in isolation without the information of other Tibetan words. For instance, if a few Tibetan words are correct translation for a certain Chinese phrase in a sentence pair, and its located sentence is long, it will lead to lower initial relevancy. However, after iteration, the weighted frequency will be increased due to the high co-occurrence frequency; and the proportion become greater in the sum of weighted frequency of all words, which makes the relevancy increased. Meanwhile, the proportion of weighted frequency of other words will decrease. In other words, relevancy of the error Tibetan correspondence will decrease. After each iteration, the difference between the correct and error Tibetan correspondence words gets bigger and bigger. This is the reason why we use IRE method.

4.3 Dictionary and word alignment method

To increase the overall performance of identification of Tibetan BaseNP, Dictionary and word alignment based (D&WA, hereafter) method are presented. Zhang et al. (2006) proposed a phrase alignment method. Their work obtains the translation head-phrase according to dictionary-based word alignment，and statistical translation boundary is determined based on the translation extending confidence.

Inspired by this research, we use the basic idea of head-phrase extension. The key problem is how to get the head-phrase and how to extend it to a correct Tibetan BaseNP. In other words, we decompose the identification of Tibetan BaseNP into head-phrase extraction and head-phrase extension steps. D&WA method use different way from (Zhang et al., 2006) in both steps.

4.3.1 Tibetan head-phrase extraction

Bilingual dictionary with 135,000 word pairs is used as an additional resource. Dictionary provides reliable alignments, but its coverage rate is low. Hence, we have modified the head-phrase extraction step in (Zhang et al., 2006). Our head-phrase extraction step is no longer solely dependent on Chinese-Tibetan dictionary. When there are no corresponding entries in bilingual dictionary for a Chinese word, we will use the word alignment result from intersect heuristic for current word, because intersect heuristic can achieve higher precision without any interference. Description of modified head-phrase extraction is as follows.

Firstly, for each word in a Chinese BaseNP, we search the bilingual dictionary and get the translation words list (TWL).

- If TWL is not null, judge whether one or more member of TWL occur in the corresponding Tibetan sentence of Chinese BaseNP, and mark the positions in Tibetan sentence.
- If TWL is null, directly use the word alignment correspondence from intersect heuristic, and mark the position in Tibetan sentence.

Then, continuous words between the most left and most right position from previous step constitute the head-phrase.

4.3.2 Tibetan head-phrase extension

The next step is the determination process of statistical translation boundary called head-phrase extension. Unlike (Zhang et al., 2006), D&WA method use commonly used Mutual information (MI) and t-value to determine left and right boundary of Tibetan BaseNP in the extension step. The formula is as follows:

$$MI(c,t) = \log \frac{P_r(c,t)}{P_r(c) \times P_r(t)} \tag{4.6}$$

$$t(c,t) \approx \frac{P_r(c,t) - P_r(c) \times P_r(t)}{\sqrt{\frac{1}{N} P_r(c,t)}} \tag{4.7}$$

Where *N* indicates the total number of sentences in bilingual corpus; *c* indicates Chinese phrase, *t* indicates Tibetan word; $P_r(c,t)$ denotes the co-occurrence probability of *c* and *t*. $P_r(c)$ and $P_r(t)$ denotes the occurrence probability of *c* and *t* respectively. For each Chinese BaseNP, we calculate MI and t-value between Tibetan words in corresponding sentence and reserve these values.

Suppose T is full or partial correspondence of Chinese BaseNP, it can symbolized as formula(4.8).

$$T = w_1 w_2 \cdots w_i \cdots w_n \tag{4.8}$$

Average Mutual Information and Average T-score between Chinese BaseNP c and T are based on formula(4.9) and formula(4.10).

$$AMI(c,T) = \frac{1}{n} \sum_{i=1}^{n} MI(c,W_i) \tag{4.9}$$

$$AT(c,T) = \frac{1}{n} \sum_{i=1}^{n} t(c,W_i) \tag{4.10}$$

Definition 4: head-phrase extension confidence.

For Chinese phrase Ph_C, the head-phrase of its translation in Tibetan sentence is denoted by $Ph_T(n)$, where *n* indicates the length of head-phrase; Extend to an adjacent Tibetan word of $Ph_T(n)$ and get $Ph_T(n+1)$, so the head-phrase extension confidence C_n defined as:

$$\begin{aligned} C_n = {} & \lambda_1 \left| AMI[Ph_C(n), Ph_T(n)] - AMI[Ph_C(n), Ph_T(n+1)] \right| \\ & + \lambda_2 \left| AT[Ph_C(n), Ph_T(n)] - AT[Ph_C(n), Ph_T(n+1)] \right| \end{aligned} \tag{4.11}$$

In which AMI and AT indicates the mean of *MI* and t-value in the scope of extended Tibetan BaseNP respectively.

In the extension step, word by word calculation of extension confidence in Tibetan sentence will be held, to both sides of head-phrase. For each extension-ready Tibetan word, note the head-phrase extension confidence C_n; if C_n is greater than the threshold, current Tibetan word is accepted as a member of Tibetan BaseNP, and extension continues; when C_n is less than the threshold extension stops. Statistical translation boundary for Chinese phrase Ph_C is obtained at the end of extension under head-phrase. FIGURE 2 shows the extension process in detail.

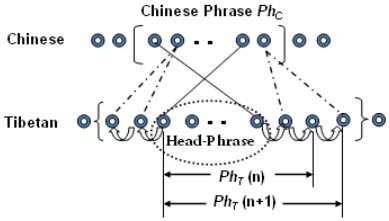

FIGURE 2 –Concept of head-phrase extension

In FIGURE 2, Chinese phrase Ph_C is in brackets; its final translation is in brace in Tibetan sentence. The extended $Ph_T(n+\omega), 0 \le \omega \le L-n$ is Tibetan BaseNP.

4.4 Sequence intersection identification method

Sequence intersection identification (SII, hereafter) method we proposed in this subsection is in accordance with the characteristics of Tibetan BaseNP. It uses intersection operation between Tibetan sentences and head-phrase extension strategy.

Analysis to the structure of Tibetan BaseNP indicates that, context based free translation style causes one Chinese phrase has different correct translation in Chinese-Tibetan sentence aligned corpus. Let's analyse the structure of following Example. "进出口货物收发货人" is "Shipper & Consignee as Declarant" in English. Three versions of Tibetan translation of "进出口货物收发货人" in Chinese-Tibetan sentence aligned corpus are given in TS1, TS2 and TS3.

TS1: ཕྱིར་གཏོང་ནང་འདེན་བྱ་རྒྱུའི་ཚོང་ཞོན་གཏོང་ལེན་བྱེད་མཁན

TS2: ཕྱིར་གཏོང་ནང་འདེན་བྱ་རྒྱུའི་ཚོང་ཞོན་ཐོབ་སྟོངས་ལེན་བྱེད་མཁན

TS3: ཕྱིར་གཏོང་ནང་འདེན་ཚོང་ཞོན་ཐོབ་སྟོངས་ལེན་མི་སྣ

During the intersection operation, "ཕྱིར་གཏོང་ནང་འདེན་" and "ཚོང་ཞོན་" is common string of TS1, TS2 and TS3. We can get "ཕྱིར་གཏོང་ནང་འདེན་བྱ་རྒྱུའི་ཚོང་ཞོན་" or "ཕྱིར་གཏོང་ནང་འདེན་ཚོང་ཞོན་" from different Tibetan sentences as head-phrase. Then we use head-phrase extension strategy to Tibetan sentence of sentence pair where "进出口货物收发货人" located and get TS1, TS2 or TS3. These different translations co-occur in our bilingual corpus. Moreover, the case is more common.

The extension step is the same as that we described in section4.3.2. The identification of Tibetan head-phrase in SII method is presented in this subsection.

4.4.1 Definition of sentence sequence intersection

Chinese-Tibetan bilingual corpus *CTBC* is composed of numerous aligned sentence pairs. Any sentence pair is notated as $SP = CS \leftrightarrow TS$, where *CS* and *TS* represent Chinese and Tibetan sentence respectively. Formula (4.12) and (4.13) give the expression of Chinese and Tibetan sentence as a word sequence.

$$CS = < C_1, C_2, \cdots, C_n > \tag{4.12}$$

$$TS = < T_1, T_2, \cdots, T_m > \tag{4.13}$$

Thus, SP can be expressed as words sequence form in formula (4.14) as below:

$$SP = CS \leftrightarrow TS = < C_1, C_2, \cdots, C_n > \leftrightarrow < T_1, T_2, \cdots, T_m > \tag{4.14}$$

Then, let's define sentence sequence intersection. Set $SP_r, SP_t \in CTBC$ are any two aligned sentence pairs. Representation of SP_r and SP_t in word sequence form is in formula (4.15) and (4.16).

$$SP_r = CS_r \leftrightarrow TS_r = < C_r, C_{r+1}, \cdots, C_{r+nr} > \leftrightarrow < T_r, T_{r+1}, \cdots, T_{r+mr} > \tag{4.15}$$

$$SP_t = CS_t \leftrightarrow TS_t = < C_t, C_{t+1}, \cdots, C_{t+nt} > \leftrightarrow < T_t, T_{t+1}, \cdots, T_{t+mt} > \tag{4.16}$$

Definition 3: Intersection of TS_r and TS_t

$$\begin{aligned} TS_r \cap TS_t = \{ & < T_{r+r1}, T_{r+r2}, \cdots, T_{r+rq} > = < T_{t+t1}, T_{t+t2}, \cdots, T_{t+tp} > \\ & | 0 \le r_1 < r_2 < \cdots < r_q \le n_r, 0 \le t_1 < t_2 < \cdots < t_p \le m_t \} \end{aligned} \tag{4.17}$$

In formula(4.17), the result of $TS_r \cap TS_t$ is a set of common substring of TS_r and TS_t. New subscripts $r_1, r_2 \cdots\cdots r_q$ and $t_1, t_2 \cdots\cdots t_p$ monotonously increase, they must be within the scope of original subscript n_r and m_t.

4.4.2 Identification of Tibetan BaseNP

SII method uses head-phrase extension like in the D&WA method. In head-phrase extraction step, SII method uses the idea of sentence sequence intersection, which is different from D&WA method.

Intuitively, if a Chinese BaseNP occurs in more than one sentence, denotes S_C, its Tibetan correspondence must occur in the aligned Tibetan sentences of S_C, denotes S_T; and sentences in S_T must have common substrings, denotes *TCS*, which is a set of multiword units including full or partial Tibetan correspondence. After sentence intersection, it is likely to get part of Tibetan BaseNP correspondence in terms of Tibetan tense, verb-endings, auxiliary word etc. Hence, one of the intersection parts must be regarded as head-phrase. It is to say, the preferred way to obtain translation of a Chinese BaseNP Q_i is searching for common substring of Tibetan sentences.

From above analysis, another form of sequence intersection for formula (4.17) is in formula(4.18).

$$TS_r \cap TS_t = T = \{T_1, T_2, \cdots, T_g\} \tag{4.18}$$

In(4.18), T is including T_j which is full or partial correspondence of Chinese BaseNP. Among these multiword units in T, we use selection function Ψ_j to determine the candidate. Commonly used mutual information (MI) and t-value statistical information are used to determine the candidate. Definition of Ψ_j for $T_j\ (1 \le j \le g)$ is given in formula(4.19).

$$\Psi_j = \lambda_1 \cdot AMI(Q_i, T_j) + \lambda_2 \cdot AT(Q_i, T_j) \tag{4.19}$$

Where *AMI* and *AT* are the means of *MI* and t-value between Chinese BaseNP Q_i and T_j respectively. $T_j\ (1 \le j \le g)$ with the highest Ψ_j is head-phrase of candidate Tibetan BaseNP. In the end, the Tibetan head-phrase is extended to BaseNP using the same extension process described in section4.3.2.

5 Experiments

5.1 Experimental corpus

The corpus used in this experiments is a domain-specific Chinese-Tibetan bilingual corpus in laws, regulations and official documents, which is the input of the Tibetan BaseNP identification. The original corpus is used to Chinese BaseNP extraction; we call it corpus1. It consists of 256,880 bilingual aligned sentence pairs including both long and short sentences. The size of Chinese corpus is 18,244 kilobytes; and that of Tibetan corpus is 58,650 kilobytes. We generate test corpus in TABLE 1 under random selection, to evaluate the proposed methods. TABLE 1 shows the basic information about the corpora. In TABLE 1, CS denotes Chinese sentence, TS denotes Tibetan sentence and SP denotes sentence pair.

First of all, Chinese sentences in corpus1 are parsed by Stanford parser, and NPs are extracted. The number of Chinese BaseNP in corpus1 is 422,146 without any pre-processing. After duplicate removal, it decreases to 255,249 which is shown in the last column of TABLE 1, where CBNP denotes Chinese BaseNP. The size of Chinese BaseNP from corpus1 is too large. In order to quantify the result, Tibetan BaseNP identification is tested on the small size of test corpus, because we need the manual reference for those Chinese BaseNPs at present. The number of Chinese BaseNP in test corpus is 394 before pre-processing. We take no account of one word NP. After filtration of one word NP and deletion of error parsed NP, we get 212 Chinese BaseNP from the test corpus.

Corpora	CS(KB)	TS(KB)	Number of SP	Number of CBNP
corpus1	18,244	58,650	256,880	255,249
Test corpus	37	149	378	212

TABLE 1 – Information about corpora

5.2 Evaluation

We define the Coverage, quasi-precision and precision to evaluate the experimental results.

$$Coverage = \frac{N_1}{N} \times 100\% \tag{5.1}$$

$$Quasi - Precision = \frac{N_2 + N_3}{N_1} \times 100\% \tag{5.2}$$

$$Precision = \frac{N_3}{N_1} \times 100\% \tag{5.3}$$

Where, N denotes the number of Chinese BaseNP for test. N_1 denotes the total number of Chinese BaseNP for which we obtain its correspondence. N_2 denotes the number of Chinese BaseNP which obtained partial correct correspondence . N_3 denotes the number of Chinese BaseNP which obtained full correct correspondence . We ask Tibetan scholar to provide us reference for Chinese BaseNP in size 212 for test, then automatically judge N_1, N_2, and N_3.

5.2.1 Different word alignment heuristics for WA method

A number of different word alignment heuristics are used in WA method. The options are:

- intersect
- union
- grow-diag-final-and
- grow-diag-final
- grow-diag

Different heuristic may show better performance for a specific language pair or corpus, the experimental results of Tibetan BaseNPs are shown in TABLE 2.

heuristic	Coverage	Quasi-precision	Precision
intersect	0.9292	0.7716	0.4975
union	1.0	0.7972	0.5165
grow-diag-final-and	0.9811	0.7692	0.5096
grow-diag-final	1.0	0.7972	0.5212
grow-diag	1.0	0.7972	0.5142

TABLE 2 –Results of WA method using different word alignment heuristics

TABLE 2 shows that, from the overall perspective, grow-diag-final heuristic outperforms others, and intersect heuristic gets the lowest performance.

On analysis, the reason for lower precision is as follows.

- Some of determinative modifier in Chinese noun phrases is verb in test set. The target language is Tibetan, which is morphologically rich language with ample variations in terms of tense, verb-endings, auxiliary word etc. These lead to discontinuous Tibetan translation.
- Chinese and Tibetan word segmentation is in different granularity.
- The quasi-precision of five heuristic is more even, however, there are some boundary interference like stop words in word alignment result all but intersect heuristic.
- Giza++is a tool based on statistics; therefore, it does not work so well on low frequency phrases.

The finding by analysis is that the word alignment result from heuristics except intersect heuristic interfered by tense, verb-endings, auxiliary word or stop word at the boundary. Yet the results from intersect heuristic consist of one or more Tibetan words without any interference. Hence we select the word alignment results of intersect heuristic in D&WA method to supplement to bilingual dictionary. It is proved that modification to automatic Tibetan BaseNP candidate under partial correspondence turns out to be effective than pure manual translation. Consequently, the best overall performance will be regarded as baseline method in next subsection.

5.2.2 Different methods for Tibetan BaseNP identification

The motivation of this paper is produce referable Tibetan BaseNP with best overall performance. To compare the four proposed Tibetan BaseNP identification method, WA methods with grow-diag-final heuristic is selected as baseline. TABLE 3 shows the results of four methods which are proposed in this paper for Tibetan BaseNP identification.

Methods	Coverage	Quasi-precision	Precision
WA method(Baseline)	1.0	0.7972	0.2453
IRE method	0.9764	0.8261	0.4203
D&WA method	0.9670	0.8732	0.4976
SII method	1.0	0.8821	0.5283

TABLE 3 –Results of different methods

The precision of IRE method is higher than baseline, because IRE method is able to filter some interference. However, precision of IRE method is influenced by some of the high frequency words and different granularity of Chinese and Tibetan words segmentation. Its coverage is medium due to correct correspondences to the low

frequency phrases. In D&WA method, Chinese-Tibetan word dictionary as auxiliary resource significantly increases the precision. Combination of dictionary and intersect heuristic word alignment improves the coverage of D&WA method. In SII method, we use intersection of Tibetan sentences to improve the coverage and quasi-precision. During intersection, some interference on boundary like verb-endings, auxiliary word are filtered; meanwhile, the step for head-phrase identification does not rely on statistics, so it works even on low frequency phrases. The overall result of SII method outperforms other proposed methods. Obviously, our test corpus is in small size, we are working on the further verification of the framework on large-scale Tibetan BaseNP identification.

Conclusion and perspectives

We are in the initial stage of identification of Tibetan base noun phrase. At present, you know, Tibetan POS tagger, Tibetan Treebank or annotated corpus is not available. On the basis of the existing resources of our group, we take the BaseNP identification as a translation problem. Four methods, namely word alignment, iterative re-evaluation, dictionary and word alignment, and sequence intersection method are applied to identify Tibetan BaseNP. We define the Coverage, quasi-precision and precision as metrics to evaluate the experimental results. As a result, the best one (SII method) achieves 1.0, 0.8821 and 0.5283 respectively on the test corpus. Compared with English or Chinese BaseNP identification work, the proposed methods doesn't get the best score, but the approach is very novel to Tibetan BaseNP identification. Due to the lack of resources like POS tagger and previous technology, the result is acceptable.

In the future, on one hand, we will improve the coverage to identify more potential BaseNP. Methods proposed in this paper need further validation in large-scale corpus. On the other hand, we will make more research on the Tibetan BaseNP templates using grammatical rules to produce a high quality results. It means that Tibetan parts-of-speech tagging is one of our future direction too.

Acknowledgments

We are grateful to three anonymous reviewers for their insightful comments that helped us improve the quality of the paper. We are thankful for Guancho Dorjie providing reference of Tibetan BaseNP in experiment part. ABSTRACT

Most Arabic Named Entity Recognition (NER) systems have been developed using either of two approaches: a rule-based or Machine Learning (ML) based approach, with their strengths and weaknesses. In this paper, the problem of Arabic NER is tackled through integrating the two approaches together in a pipelined process to create a hybrid system with the aim of enhancing the overall performance of NER tasks. The proposed system is capable of recognizing 11 different types of named entities (NEs): Person, Location, Organization, Date, Time, Price, Measurement, Percent, Phone Number, ISBN and File Name. Extensive experiments are conducted using three different ML classifiers to evaluate the overall performance of the hybrid system. The empirical results indicate that the hybrid approach outperforms both the rule-based and the ML-based approaches. Moreover, our system outperforms the state-of-the-art of Arabic NER in terms of accuracy when applied to ANERcorp dataset, with f-measures 94.4% for Person, 90.1% for Location, and 88.2% for Organization.

Title in Arabic

تنسيقٌ متتالٍ في التعرف على أنماط الأسماء العربية من خلال استخدام المنهج الهجين

Abstract in Arabic

تم بناء معظم أنظمة التعرف على أنماط الأسماء العربية من خلال تبني منهجية القواعد أو تبني المنهجية المبنية على تعلم الآلة، بما فيهما من نقاط قوة وضعف. في هذه الورقة، عملية التعرف على أنماط الأسماء في اللغة العربية يتم معالجتها من خلال دمج المنهجيتين معًا في تنسيقٍ متتالٍ لتشكيل المنهج الهجين في محاولة لتحسين أداء مهام التعرف على أنماط الأسماء. النظام المُقترح قادر على التعرف على 11 نوعًا مختلفًا من أنماط الأسماء بما في ذلك أسماء الأشخاص، والأماكن، والمنظمات، والتواريخ، والأوقات، والأسعار (الأموال)، والمقاييس (المقادير القياسية)، والنسب المئوية، وأرقام الهواتف، وردمك (الرقم الدولي المعياري للكتاب)، وأسماء الملفات. وقد تم إجراء تجارب مكثفة باستخدام ثلاث مصنفات مختلفة تُطَبّق تعلم الآلة لتقييم أداء النظام الهجين. تُظهر النتائج التجريبية تفوق المنهج الهجين على كلٍ من المنهج المبني على القواعد والمنهج المبني على تعلم الآلة. يتفوق نظامنا الهجين على أفضل الأنظمة المنشورة في الدوريات العلمية في مجال التعرف على أنماط الأسماء العربية من حيث الدقة عند تطبيق نظامنا على مجموعة البيانات "أنيركورب" بنتيجة معدلات توافقية قدرها: 94.4% في حالة أسماء الأشخاص، 90.1% في حالة أسماء الأماكن، و 88.2% في حالة أسماء المنظمات.

1 Introduction

Named Entity Recognition (NER) is the task of detecting and classifying proper names within texts into predefined types, such as Person, Location and Organization names (Nadeau and Sekine, 2007), in addition to the detection of numerical expressions, such as date, time, price and phone number. Machine Translation, Information Retrieval and Question Answering are good examples of Natural Language Processing (NLP) applications that employ NER as an important preprocessing step to enhance the overall performance. In the literature, three types of approaches are used to develop NER systems: rule-based approach, machine learning (ML) based approach and hybrid approach. The rule-based approach relies on handcrafted local grammatical rules, while ML-based approach takes advantage of the ML algorithms that utilize sets of features extracted from datasets annotated with NEs for building NER systems. The hybrid approach combines rule-based approach with ML-based approach together in a pipelined process to improve the overall performance of the system.

Arabic is the official language in the Arab world where more than 300 million people speak Arabic as their native language (Shaalan, 2010). Arabic is a Semitic language and one of the richest natural languages in the world in terms of morphological inflection and derivation. Interest in Arabic NLP has been gaining momentum in the past decade, and some of the tasks have proven to be challenging especially when it comes to Information Extraction due to the language's complex and rich morphology. NER for Arabic has received some attention recently, yet opportunities for improvement in performance are still available. A number of Arabic NER systems have been developed using two types of approaches: the rule-based approach, notably NERA system (Shaalan and Raza, 2008), and the ML-based approach, notably ANERsys 2.0 (Benajiba and Rosso, 2007). Rule-based NER systems rely on handcrafted grammatical rules written by linguists. Therefore, any maintenance applied to rule-based systems is labour-intensive and time consuming especially if linguists with the required knowledge and background are not available. On the other hand, ML-based NER systems utilize ML techniques that require large tagged datasets for training and testing. An advantage of the ML-based NER systems is that they are updatable with minimal time and effort as long as sufficiently large datasets are available. The lack of linguistic resources creates a critical obstacle when it comes to Arabic NLP in general and Arabic NER in particular.

In this paper, the problem of Arabic NER is tackled through integrating the ML-based approach with the rule-based approach to develop a hybrid system in an attempt to enhance the overall performance. To the best of our knowledge, only one recent Arabic NER system (Abdallah, Shaalan and Shoaib, 2012) has adopted the hybrid approach in order to recognize three types of named entities (NEs) including Person, Location and Organization. Abdallah et al. (2012) have used only one ML technique (i.e. Decision Trees) within their system. Our research aims to develop an Arabic hybrid NER system that has the ability to extract 11 different types of NEs including Person, Location, Organization, Date, Time, Price, Measurement, Percent, Phone Number, ISBN and File Name. We extend the ML feature space to include morphological and contextual information. We test three ML algorithms (Decision Trees, Support Vector Machines, and Logistic Regression), and our results show significant performance gains over the state of the art.

The proposed system is composed of two main components: a rule-based component and a ML-based component. The rule-based component is a reproduction of an Arabic rule-based NER

system (Shaalan and Raza, 2008) with modifications and additions in order to enhance the performance. The ML-based component utilizes the ML techniques that have been used successfully in similar NER for other languages to generate a classification model for Arabic NER trained on annotated datasets. The annotated datasets are presented to the ML-based component through a set of features. The feature set is selected to optimize the performance of the ML-based component as much as possible. Two types of linguistic resources are collected and acquired: gazetteers (i.e. predefined lists of NEs or keywords) and corpora (i.e. datasets). Extensive experiments are conducted to evaluate the proposed hybrid system on different dimensions.

The structure of the remainder of this paper is as follows. Section 2 provides some background on NER. Section 3 gives a literature review of NER. Section 4 describes the process followed for data collection. Section 5 illustrates the architecture of the proposed NER system and then describes in details the main components. The evaluation experiments and the results are reported and discussed in Section 6. Finally, a conclusion and proposed future work extension are provided.

2 Background

2.1 NER and NLP Applications

In the 1990s, at the Message Understanding Conferences (MUC) in particular, the task of NER was firstly introduced and given attention by the community of research. Three main NER subtasks were defined at the 6th MUC: ENAMEX (i.e. Person, Location and Organization), TIMEX (i.e. temporal expressions), and NUMEX (i.e. numerical expressions). Customized NER system may require more sub-divisions in one or more of the NER subtasks to fulfil the system goals and objectives, e.g. Location NEs may have sub-types as City, Country, River, Road, etc.

The role of NER within NLP applications differs from one application to another. Examples of NLP applications which find the functionalities of NER useful for their purposes are Information Retrieval, Machine Translation, Question Answering and Text Clustering (Cowie and Wilks, 1996).

- **Information Retrieval (IR).** IR is the task of identifying and retrieving relevant documents out of a database of documents according to an input query (Benajiba, Diab and Rosso, 2009a). There are two possible ways that IR can benefit from NER: 1) recognizing the NEs within the query, 2) recognizing the NEs within the documents to extract the relevant documents taking into consideration their classified NEs. For example, if the input query has the word "مايكروسوفت" maAykruwsuwft[1] "Microsoft", an Organization NE, any documents that include Microsoft is considered relevant and retrieved.
- **Machine Translation (MT).** MT is the task of translating a text into another natural language. NEs need special handling in order to be translated correctly. Hence, the quality of the NE translation component would become an integral part that enhances the performance of the overall MT system (Babych and Hartley, 2003). In the translation from Arabic to Latin languages, such as English, Person names (NEs) can also be found as regular words (non-NEs) in the language without any distinguishing

[1] We used Habash-Soudi-Buckwalter transliteration scheme (Habash, Soudi and Buckwalter, 2007)

orthographic characteristics between the two surface forms. For example, the surface word "وفاء" wafaA' can be used as an adjective that means trustfulness and loyalty, and also as a Person name.

- **Question Answering (QA).** QA application is closely related to IR but with more sophisticated results. A QA system takes questions as input and gives in return concise and precise answers. NER can be exploited in recognizing NEs within the questions to help identifying the relevant documents and then extracting the correct answers (Hamadene, Shaheen and Badawy, 2011; Molla, Zaanen and Smith, 2006). For instance, the NE "الشرق الأوسط" Alšarq AlÂwsaT "Middle East" may be classified as an Organization (i.e. Newspaper) or as a Location according to the context. Hence, the proper classification for the NE will help targeting the relevant group of documents that answer the given query.
- **Text Clustering (TC).** TC may exploit NER in ranking the resulted clusters based on a ratio of entities that is associated with each cluster (Benajiba et al., 2009a). This is reflected in enhancing the process of analyzing the nature of the clusters and also improving the clustering approach in terms of the selected features. For example, Time expressions along with Location NEs can be utilized as factors that give an indication of *when* and *where* the events mentioned in a cluster of documents have happened.

2.2 Arabic Language Characteristics

Applying NLP tasks in general and NER task in particular is very challenging when it comes to Arabic because of its particularities and unique nature. The main characteristics of Arabic that pose non-trivial challenges for NER task are as follows:

- **No Capitalization:** Capitalization is not a feature of Arabic script unlike the European languages where an NE usually begins with a capital letter. Therefore, the usage of the capitalization feature is not an option in Arabic NER. However, the English translation of Arabic words may be exploited in this respect (Farber, Freitag, Habash and Rambow, 2008).
- **The Agglutinative Nature:** Arabic language has a high agglutinative nature in which a word may consist of prefixes, lemma and suffixes in different combination, and that results in a very complicated morphology (AbdelRahman, Elarnaoty, Magdy and Fahmy, 2010).
- **No Short Vowels:** Short vowels, or diacritics, are needed for pronunciation and disambiguation. However, most modern Arabic texts do not include diacritics, and therefore, a word form in Arabic may refer to two or more different words or meanings according to the context they appear, creating a one-to-many ambiguity.
- **Spelling Variants:** In Arabic script, the word may be spelled differently and still refers to the same word with the same meaning, creating a many-to-one ambiguity. For example, the word جرام jrAm 'Gram' can also be written as غرام grAm with the same meaning.
- **Lack of Linguistic Resources:** There is a limitation in the number of available Arabic linguistic resources that are free for research purposes, and many of those available are not suitable for Arabic NER tasks due to the absence of NEs annotations in the datasets or the size of the datasets which may not be sufficiently large. The Arabic gazetteers are rare as well and limited in size. Therefore, researchers tend to build their own Arabic linguistic resources in order to train and evaluate Arabic NER systems.

3 Literature Review

NER revolves around two main goals: 1) the detection of NEs 2) the extraction of those NEs in the form of different predefined types. Three main approaches are used to fulfill those two goals: the rule-based approach, the ML-based approach and the hybrid approach.

3.1 Rule-Based NER

Rule-based NER systems depend on handcrafted linguistic rules to identify NEs within texts using linguistic and contextual clues and indicators (Shaalan and Raza, 2007). Such systems exploit gazetteers/dictionaries as auxiliary clues to the rules. The rules are usually implemented in the form of regular expressions or finite state transducers (Mesfar, 2007). The maintenance of rule-based systems is not a straightforward process since experienced linguists need to be available to provide the system with the proper adjustments (Petasis et al., 2001). Thus, any adjustment to such systems is labour intensive and time consuming.

Maloney and Niv (1998) have presented TAGARAB system which is one of the early attempts to tackle Arabic NER. It is a rule-based system where a pattern matching engine is combined with a morphological tokenizer to recognize Person, Organization, Location, Number and Time. The empirical results show that combining NE finder with a morphological tokenizer outperforms the individual NE finder in terms of accuracy when applied to random datasets from AI-Hayat.

Mesfar (2007) has developed an Arabic component under NooJ linguistic environment to enable Arabic text processing and NER. The component consists of a tokenizer, morphological analyzer and NE finder. The NE finder exploits a set of gazetteers and indicator lists to support rules construction. The system identifies NEs of types: Person, Location, Organization, Currency, and Temporal expressions. The system utilizes the morphological information to extract unclassified proper nouns and thereby enhance the overall performance of the system.

Another work adopting the rule-based approach for NER is the one developed by Shaalan and Raza called PERA (2007). PERA is a grammar-based system which is built for identifying Person names in Arabic scripts with high degree of accuracy. PERA is composed of three components: gazetteers, grammars and filtration mechanism. Whitelists of complete Person names are provided in the gazetteer component in order to extract the matching names regardless of the grammars. Afterwards, the input text is presented to the grammar, which is in the form of regular expressions, to identify the rest of Person NEs. Finally, the filtration mechanism is applied on NEs detected through certain grammatical rules in order to exclude invalid NEs. PERA achieved satisfactory results when applied to the ACE and Treebank Arabic datasets.

As a continuation of Shaalan and Raza (2007) research work, NERA system was introduced in Shaalan and Raza (2008; 2009). NERA is a rule-based system that is capable of recognizing NEs of 10 different types: Person, Location, Organization, Date, Time, ISBN, Price, Measurement, Phone Numbers and Filenames. The implementation of the system was in the FAST ESP framework, where the system has three components as the PERA system with the same functionalities to cover the 10 NE types. The Authors have constructed their own corpora from different resources in order to have a representative number of instances for each NE type.

Elsebai et al. (2009) have proposed a rule-based NER system that integrates pattern matching with morphological analysis to extract Person names from Arabic text. The pattern matching engine utilizes lists of keywords without using predefined lists of Person names. Zaghouani

(2012) has also introduced a rule-based system for Arabic NER (RENAR) to extract Person, Location and Organization NEs. The system is composed of three phases: 1) morphological preprocessing, 2) looking up known NEs and 3) using local grammar to extract unknown NEs. According to the empirical results, RENAR outperforms ANERsys 1.0 (Benajiba et al., 2007), ANERsys 2.0 (Benajiba and Rosso, 2007) and LingPipe[2] in extracting Location NEs when applied to ANERcorp dataset, while LingPipe outperforms RENAR in extracting Person and Organization NEs.

3.2 Machine Learning Based NER

ML-based NER systems take advantage of the ML algorithms in order to learn NE tagging decisions from annotated texts. The most common ML techniques used for NER are Supervised Learning (SL) techniques which represent the NER problem as a classification task and require the availability of large annotated datasets. Among the most common SL techniques utilized for NER are Support Vector Machines (SVM), Conditional Random Fields (CRF), Maximum Entropy (ME), Hidden Markov Models (HMM) and Decision Trees (Nadeau and Sekine, 2007).

Benajiba et al. (2007) have developed an Arabic NER system, ANERsys 1.0, which uses ME. The authors have built their own linguistic resources: ANERcorp (i.e. an annotated corpus) and ANERgazet (i.e. gazetteers). The features used by the system are lexical, contextual and gazetteers features. The system can recognize four types of NEs: Person, Location, Organization and Miscellaneous. The ANERsys 1.0 system used to have difficulties with detecting NEs that are composed of more than one token/word; hence Benajiba and Rosso (2007) developed ANERsys 2.0, which employs a 2-step mechanism for NER: 1) detecting the start and the end points of each NE, 2) classifying the detected NEs. Benajiba and Rosso (2008) have applied CRF instead of ME as an attempt to improve the performance. The feature set used in ANERsys 2.0 was used in the CRF-based system. The features are POS tags and base phrase chunks (BPC), gazetteers and nationality. The CRF-based system achieves higher results in terms of accuracy.

Benajiba et al., (2008a) have developed another NER system based on SVM. The features used are contextual, lexical, morphological, gazetteers, POS-tags and BPC, nationality and the corresponding English capitalization. The system has been evaluated using ACE Corpora and ANERcorp. The best results are achieved when all the features are considered.

A simplified feature set has been proposed by Abdul-Hamid and Darwish (2010) to be utilized in Arabic NER. They proposed a NER system based on CRF to recognize three types of NEs: Person, Location and Organization. The system considers only surface features (i.e. leading and trailing character n-gram, word position, word length, word unigram probability, the preceding and succeeding words n-gram and character n-gram probability) without taking into consideration any other type of features. The system is evaluated using ANERcorp and ACE2005 dataset. The results show that the system outperforms the CRF-based NER system of Benajiba and Rosso (2008).

Benajiba et al, (2008b) investigated the sensitivity of different NE types to various types of features, i.e. in Benajiba et al., (2008a). They build multiple classifiers for each NE type adopting SVM and CRF approaches. ACE datasets are used in the evaluation process. According to their results, it cannot be stated whether CRF is better than SVM or vice versa in Arabic NER. Each

[2] LingPipe is available on http://alias-i.com/lingpipe/

NE type is sensitive to different features and each feature plays a role in recognizing the NE in different degrees. Further studies (i.e. Benajiba et al., 2009a; 2009b) have confirmed as well the importance of considering language independent and language specific features in Arabic NER.

AbdelRahman et al. (2010) integrated two ML approaches to handle Arabic NER including CRF and bootstrapping pattern recognition. The feature set used with the CRF classifier includes word-level features, POS tag, BPC, gazetteers and morphological features. The system is developed to extract 10 types of NEs: Person, Location, Organization, Job, Device, Car, Cell Phone, Currency, Date and Time. The results show that the system outperforms LingPipe NE recognizer when both are applied to ANERcorp dataset.

3.3 Hybrid NER

The hybrid approach integrates the rule-based approach with the ML-based approach in order to optimize the overall performance (Petasis et al., 2001). The direction of the processing flow may be from the rule-based system to the ML-based system or vice versa.

To the best of our knowledge, there is only one hybrid NER system for Arabic which has been recently developed by Abdallah, et al. (2012). The hybrid system is capable of identifying Person, Location and Organization NEs. The rule-based component is a re-implementation of the NERA system (Shaalan and Raza 2008) using the GATE tool, while the ML-based component utilizes decision trees to build the NE classifier. Each token/word is represented with a vector of features including the rule-based decisions as a feature. The other features considered are word's length, POS tag, Noun flag (i.e. a binary feature to indicate whether POS tag is Noun or not), gazetteers, statement-end flag, prefix and suffix features. The experimental results show that the hybrid system outperforms the CRF-based NER system built by Benajiba and Rosso (2008) when applied to ANERcorp dataset.

The hybrid NER proves to be feasible and requires further investigations to enhance the scope and improve the overall performance. In this paper, we contribute to hybrid NER for Arabic both in width and depth. We handle the recognition of 11 types of NEs including Person, Location, Organization, Date, Time, Price, Percent, Phone Number, Measurement, ISBN and File Name with high degree of accuracy. We investigate three different ML approaches including Decision Trees (Orphanos, Kalles, Papagelis and Christodoulakis, 1999), SVM (Vapnik, 1995) and Logistic Regression (Hastie, Tibshirani and Friedman, 2009) along with different types of features (including contextual and morphological information) in different combinations to find the feature sets with the optimal performance.

4 Data Collection

Various linguistic resources are necessary in order to develop the proposed Arabic NER system with scope of 11 different categories of NEs. The linguistic resources are of two main categories: corpora and gazetteers. The corpora used in this research are a combination of licensed and free linguistics resources. The licensed linguistics resources[3] are Automatic Content Extraction (ACE) corpora and Arabic Treebank (ATB) Part1 v 2.0 dataset. While the free linguistic resource is: ANERcorp[4] dataset which is freely available for research purposes. In the literature, these

[3] Available for us under license agreement from the Linguistic Data Consortium (LDC)
[4] Available to download on http://www1.ccls.columbia.edu/~ybenajiba/downloads.html

linguistics resources are commonly used for evaluation and comparing with existing systems. We have also built our own corpus for training and evaluating certain types of NEs that were not sufficiently covered, including file names, phone numbers and ISBN numbers. The dataset files have been prepared and annotated using our tag schema and in XML format. Our tag schema includes 11 named entity tags; one for each NE type.

The ACE training datasets covered are Newswire (NW) and Broadcast News (BN). ANERcorp is an annotated dataset built by Yassine Benajiba (Benajiba et al., 2007). Arabic Treebank Part1 v. 2.0 dataset (Maamouri et al., 2003) has no NE annotations and originally designed to support POS tagging in Arabic NLP. Therefore in this research, the ATB dataset has been manually annotated in order to support the Arabic NER task. Our study indicates that the previously listed datasets indicate that they do not include annotation for NEs of types Phone Number, ISBN and File Name. In order to have a dataset with a representative number of NEs of certain types including Phone Number, ISBN and File Name, we acquired our own corpus from different internet resources and did the manual tagging ourselves. The total number of NEs in all datasets (i.e. the number of NE annotations that are used for training and testing purposes) is 23,929 as demonstrated in Table 1.

Dataset \ NE type		Per.	Loc.	Org.	Date	Time	Price	Measure.	Percent	Phone No.	File Name	ISBN
ACE 2003	BN	711	1292	493	58	15	17	28	35			
	NW	517	1073	181	20	1	3	14	3			
ACE 2004	BN	1865	3449	1313	357	28	105	51	54			
	NW				67	4	36	30	32			
ACE 2005	BN				154	20	163	60	42			
	NW				37	7	9	22	5			
ANERcorp		3602	4425	2025								
ATB Part1 v 2.0					431	80	168	330	75			
Our own corpus										136	160	126
Total		6695	10239	4012	1124	155	501	535	246	136	160	126

TABLE 1 – The Number of Named Entities in each Reference Dataset

Another type of linguistic resources used is the gazetteers, or dictionaries. The gazetteers for Person, Location and Organization are collected from Shaalan and Raza, (2008), while the gazetteers for the rest of the NE are prepared as part of this research. The total number of NEs/keywords in all gazetteers is 19,328.

5 The System Architecture

The Rule-based and ML-based NER approaches have their own strengths and weaknesses. In this paper, we propose a hybrid architecture that is significantly better than the rule-based or machine-learning systems individually. Figure 1 illustrates the architecture of the hybrid NER system for Arabic. The system consists of two pipelined components: rule-based and ML-based Arabic NER components. The processing goes through three main phases: 1) The rule-based NER phase, 2) The feature engineering phase, i.e. the feature selection and extraction, and 3) the ML-based NER phase.

5.1 The Rule-based Component

The rule-based component in our hybrid system is a reproduction of the NERA system (Shaalan and Raza, 2008) using GATE framework[5]. The rule-based component is built with the capability of recognizing the aforementioned 11 NEs. The percent NE type is introduced in this research and some rules are improved. The rule-based system consists of three main modules: Whitelists (or gazetteers), Grammar Rules (as a set of regular expressions), and a Filtration mechanism (blacklists of invalid NEs).

The GATE environment is used to build the rule-based component. The corpus with its documents is processed using different processing tools and resources such as a tokenizer, gazetteers and grammatical rules. Table 2 illustrates the number of gazetteers and rules implemented within each NE type. The system contains a total of 73 rules and 90 gazetteers.

	Per.	Loc.	Org.	Date	Time	Price	Measure	Percent	Phone No.	File Name	ISBN	Total
# of Gazetteers	11	20	8	12	10	8	7	3	7	3	1	**90**
# of Rules	9	20	9	7	8	4	3	1	7	3	2	**73**

TABLE 2 – The Number of Gazetteers and Rules in each NE Extractor

5.2 The ML-based Component

The ML-based component depends on two main aspects: feature engineering and selection of ML classifiers. The first aspect is the feature engineering which involves the selection and extraction of classification features. The features explored are divided into various categories: rule-based features (i.e. derived from the rule-based component's decisions), morphological features, POS features, Gazetteer features, contextual features, and word-level features. Exploring different types of features and arranging them in sets allow studying the effect of each feature set on the overall performance of the proposed system along different dimensions, including NE type and ML technique.

The second aspect concerns the ML classifier, or function, to be used in the training, testing and prediction phases. Three ML techniques have been explored and examined individually in order to reach a conclusion with regards to the best approach to work with in our hybrid NER system for Arabic. The three techniques are Decision Trees, SVM, and Logistic Regression. The first two techniques were chosen for their high performance in NER in general and Arabic NER in particular; whereas, the third technique is a new investigation that has never been used before in evaluating Arabic NER performance. In this research, WEKA[6], a comprehensive and efficient workbench with support for a large number of ML algorithms, is utilized as the environment of the ML task. The decision tree algorithm is applied using the J48 classifier, SVM with the LibSVM classifier, and Logistic Regression with the Logistic classifier.

[5] Available for free download on http://gate.ac.uk/
[6] The official website of WEKA : www.cs.waikato.ac.nz/ml/weka/

The 11 types of NEs are distributed among three groups according to their nature in which each group has a distinct feature set:

- 1st group: Person, Location and Organization NEs (aka ENAMEX)
- 2nd group: Date, Time, Price, Measurement and Percent NEs (aka TIMEX and NUMEX)
- 3rd group: Phone Number, ISBN and File Name NEs. Notice that the first two types of NE can be considered as NUMEX but they have been moved to this group intentionally because of the nature of their rules and patterns which is specific and limited.

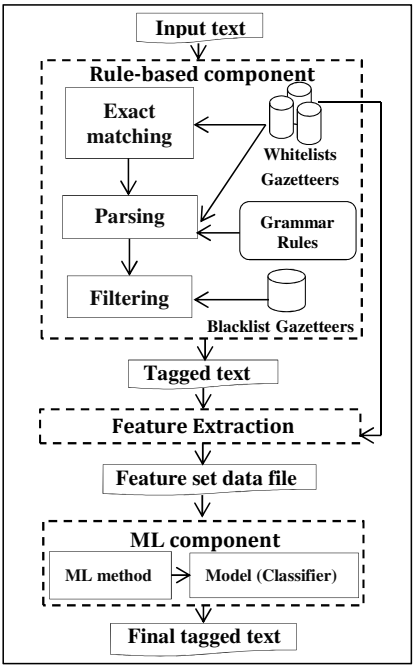

FIGURE 1 – The Architecture of the Hybrid NER System

The three groups of NEs have a generic set of classification features which are common among them, i.e. the following features are used across all three groups.

- *Rule-based features*: The NE type predicted by the rule-based component for the targeted word as well as the NE types for the two immediate left and right neighbors of the candidate word, i.e. NE type for a sliding window of size 5.
- *Morphological Features*: The set of 13 features generated by MADA[7] (Habash and Rambow, 2005).
- *POS tag*: part-of-speech tag of the targeted word estimated by MADA.

[7] MADA is Available for free download on http://www1.ccls.columbia.edu/MADA/MADA_download.html

- *Word length flag*: A binary feature to indicate whether the word length ≥ 3.
- *Dot flag*: A binary feature to indicate whether the word has adjacent dot.
- *Capitalization flag*: A binary feature to indicate the existence of capitalization information on the English gloss (translation) corresponding to the Arabic word.
- *NE type*: NE tag of the word is used along with other features for training the classification model. It is also used as a reference when calculating the accuracy scores. In the prediction phase, this feature (i.e. the NE type itself) is excluded from the selected feature set.

Besides, there are two distinct features that are used in the 1st group:

- *Nominal flag*: A binary feature to indicate whether POS tag is Noun (or Proper Noun).
- *Check Person/Location/Organization Gazetteers feature flags*: A binary feature to indicate whether the word (or left/right neighbour of targeted word) belongs to Person/Location/Organization Gazetteer(s).

Similarly, there are two distinct feature used with the 2nd group:

- *Check POS feature flags*: A binary feature to indicate whether POS tag is Noun_num (i.e. literal number word) (or Proper Noun).
- *Check Date/Time/Price/Measurement/Percent Gazetteers feature flags*: A binary feature to indicate whether the word (or left/right neighbour of targeted word) belongs to Date/Time/Price/Measurement/Percent Gazetteer(s).

Likewise, two distinct features are used with the 3rd group:

- *Nominal flag*: as described in the 1st group feature set.
- *Check Phone Number/ISBN/File Name Gazetteers feature flags*: A binary feature to represent indicate the word (or left/right neighbour of targeted word) belongs to Phone Number/ISBN/File Name Gazetteer(s).

6 Experimental Analysis

6.1 Experimental Setup

We conduct testing and evaluation experiments to test the rule-based component and compare it to the hybrid system. At the level of the hybrid system, experiments are subdivided at three dimensions: the NE type, the ML classifier used, and the inclusion/exclusion of feature groups, with the rule-based decision included as one of the feature groups as will be detailed in the following subsection. Each experiment includes a reference dataset, and an annotated dataset. The reference datasets are the initial datasets described with their tagging details in Section 4 including ACE corpora, ATB part1 v 2.0, ANERcorp and our own corpus. The reference datasets are fed into the rule-based component so that the outputs represent the annotated datasets which are exploited in the feature extraction phase to generate the feature set data files in order to be utilized by the ML-based component.

The performance of the rule-based component is evaluated using GATE built-in evaluation tool, so-called *AnnotationDiff*. This tool enables the comparison of two sets of annotations and the results are presented with the Information Extraction standard measures (i.e. precision, recall and f-measure). On the other hand, the ML approach uses three different functions (or classifiers) to

be applied to the annotated dataset, including decision trees, SVM and logistic regression approaches which are available in WEKA workbench via J48, LibSVM and Logistic classifiers respectively. In this research, 10-fold cross validation is chosen to avoid overfitting. The WEKA tool provides the functionality of applying the conventional k-fold cross-validation for evaluation with each classifier and then having the results represented in the aforementioned standard measures.

6.2 Experiments and Results

A number of experiments have been conducted to evaluate the performance of the proposed hybrid NER system when applied to different datasets in order to extract the various types of NEs applying each of the three different ML techniques. The experiments setting study the performance of the system when the contribution of all features is considered, contribution of pure ML-based features is considered, and after excluding the morphological features generated by MADA (Habash and Rambow, 2005; Roth et al., 2008), i.e. *asp, cas, enc0, gen, mod, num, per, prc0, prc1, prc2, prc3, stt, vox,* and *gloss*. In this way, the following three settings on the level of feature groups are examined:

1. All Features: all features are considered.
2. W/O RB: excluding the rule-based features (pure ML-based mode).
3. W/O MF: excluding the morphological features.

It should be noted that the baseline in all experiments is the performance of the pure rule-based component.

According to the empirical results illustrated in Table 3, the highest performance of our system in terms of Average F-measures when applied on ACE (2003-2004) NW and ANERcorp datasets to extract NEs of the 1st group (i.e. Person, Location and Organization) is achieved by J48 classifier when the 1st feature setting is used, while using J48 classifier with the 3rd setting leads to the highest performance in extracting NEs of the same group from ACE2003 BN dataset.

		ACE2003 NW	**ACE2003 BN**	**ACE2004 NW**	**ANERcorp**
		Avg. F-measure	Avg. F-measure	Avg. F-measure	Avg. F-measure
Rule-based (baseline)		0.6365	0.6087	0.4671	0.6745
J48	All Features	**0.8517**	0.8077	**0.7613**	**0.9090**
	W/O RB	0.8173	0.7633	0.7350	0.8357
	W/O MF	0.8487	**0.8203**	0.7447	0.9047
Libsvm	All Features	0.7953	**0.7653**	**0.7190**	**0.9007**
	W/O RB	0.7453	0.6307	0.6590	0.8100
	W/O MF	**0.7937**	0.7667	0.7117	0.8967
Logistic	All Features	**0.7953**	**0.7693**	**0.7170**	**0.8980**
	W/O RB	0.7577	0.6703	0.6447	0.7753
	W/O MF	0.7827	0.7620	0.7077	0.8857

TABLE 3 – The results of applying the proposed hybrid system on ACE2003 (NW & BN), ACE2004 (NW), and ANERcorp datasets in order to extract NEs of the 1st group

The results illustrated in Table 4 show that the highest performance in terms of Average F-measures when applied on ACE2003 BN, ACE2004 NW & BN, ACE2005 NW & BN and ATB Part1 v 2.0 datasets to extract NEs of the 2nd group (i.e. Date, Time, Price, Measurement and Percent) is achieved by J48 classifier when either the 1st or the 3rd feature setting is utilized, while using Logistic classifier with the 3rd feature setting leads to the highest performance in extracting NEs of the same group from ACE2003 NW dataset. The highest performance of our system in terms of Average F-measures when applied on our own corpus to extract NEs of the 3rd group (i.e. Phone Number, ISBN and File Name) is achieved by either the J48 classifier or the Logistic classifier when the 1st or the 3rd feature setting is utilized as shown in Table 5.

The experimental results show that the adaptation of the hybrid approach leads to the highest performance. It is worth noting that the results of the proposed hybrid system is very close to the results of the rule-based component when it comes to the numerical and temporal expressions, and the two approaches achieve the same results in recognizing NEs of the 3rd group. Therefore, the hybrid approach proves its suitability for the recognition of the three groups of NEs. Also, the decision trees function has proved its comparatively higher efficiency as a classifier in our Arabic hybrid NER system.

In comparison with the results achieved by ANERsys 1.0 (Benajiba et al., 2007), ANERsys 2.0 (Benajiba and Rosso, 2007), Arabic ML-based NER system using CRF (Benajiba and Rosso, 2008) and the hybrid NER system for Arabic developed by Abdallah et al. (2012) when applied on ANERcorp, our system performs demonstrably better as illustrated by Table 6. As it can be noticed, our hybrid system outperforms the other systems in terms of F-measure in extracting Person, Location and Organization NEs from ANERcorp dataset.

System \ NE Type	Person	Location	Organization
	F-measure	F-measure	F-measure
ANERsys 1.0	0.4669	0.8025	0.3679
ANERsys 2.0	0.5213	0.8671	0.4643
CRF-based system	0.7335	0.8974	0.6576
Abdallah et al. (2012)	0.928	0.8739	0.8612
Our Hybrid System (J48)	**0.944**	**0.901**	**0.882**

TABLE 6 – The results of ANERsys 1.0, ANERsys 2.0, CRF-based system (Benajiba and Rosso, 2008) and Abdallah et al. (2012)'s system compared to our hybrid system's highest performance when applied to ANERcorp dataset

Conclusion and Future Work

The hybrid approach is most recent which integrates rule-based with ML approaches. The integration is more intuitive and linguistically motivated as it conducts an Arabic NER pipeline that combines rule-based features with other features used in machine learning. The proposed hybrid system has achieved an overall improvement of the Arabic NER performance. It is capable of recognizing 11 different types of named entities including Person, Location, Organization, Date, Time, Price, Measurement, Percent, Phone Number, ISBN and File Name. A number of extensive experiments are conducted on three different dimensions including the named entity types, the feature set (divided into groups) and the ML technique to evaluate the performance of our Arabic NER system when applied on different datasets. The experimental results show that the hybrid approach outperforms the pure Rule-based approach and the pure ML-based approach. Our hybrid NER system for Arabic outperforms the state-of-the-art of the Arabic NER in terms of f-measure when applied to ANERcorp dataset with f-measure of 94.4% for Person named entities, f-measure of 90.1% for Location named entities, and f-measure of 88.2% for Organization named entities.

In future work, we intend to enhance the gazetteers and explore the possibility of improving the system with adding more lists. There is also a space for improving the grammatical rules implemented within the rule-based component through analyzing the hybrid system's output in a way to automate the enhancement process. We are also considering the possibility of using different ML techniques other than decision trees, SVM and logistic regression and how this will impact on the overall performance of the system.

Attribute Extraction from Conjectural Queries

Marius Paşca
Google Inc.
Mountain View, California
mars@google.com

ABSTRACT
Conjectural search queries (*is python case sensitive, is millennium stadium heated*) embody attempts by Web users to verify whether a particular property (*soluble in water?, case sensitive?, heated?*) does or does not apply to a particular instance (*iodine, python, millennium stadium*). This paper considers such queries to be a data source of attributes of open-domain classes. Conjectural attributes complement attributes encoded in human-compiled knowledge resources or automatically acquired from text by previous methods. They correspond to properties of interest to Web users, which are not necessarily stated in nominal form. Relevant properties of *Chemical elements*, *Programming languages* and *Stadiums* include whether they are *soluble in water*, *flammable* or *ductile*; *case sensitive, platform independent*, or *interpreted*; or *air conditioned, roof retractable* or *heated*, respectively. Experimental results show that relevant, conjectural attributes can be extracted from inherently-noisy queries, for a variety of open-domain classes of interest.

KEYWORDS: Class attributes, open-domain information extraction, Web search queries.

Proceedings of COLING 2012: Technical Papers, pages 2177–2190,
COLING 2012, Mumbai, December 2012.

Examples of Attributes Available in or Extracted from Various Sources, for a Sample of Classes
Food ingredients:
W: energy, dietary fiber, solubility in water
F: energy per 100g, availability, scientific name, solubility in water
D_1: species, pounds, cup, kinds, lbs, bowl
D_2: quality, part, taste, value, portion
Q_1: nutritional value, health benefits, glycemic index, varieties, calories
Q_C: gluten free?, safe?, healthy?, vegan?, halal?, fattening?, acidic?, good for skin?
Astronomical objects:
W: constellation, right ascension, spectral type, rotational velocity, orbital period, mean radius
F: category, constellation, age, periapsis, orbital period, mean radius
D_1: observations, spectrum, planet, spectra, conjunction, transit, temple, surface
D_2: surface, orbit, bars, history, atmosphere
Q_1: atmosphere, surface, gravity, diameter, mass, rotation, revolution, moons, radius
Q_C: bigger than earth?, close to the sun?, circumpolar?, capable of supporting life?
Religions:
W: fundamentals, texts, deities, sacred sites, schools, people
F: founding figures, beliefs, practices, texts, deities, sacred sites
D_1: teachings, practice, beliefs, religion spread, principles, emergence, doctrines
D_2: basis, influence, name, truths, symbols, principles, strength, practice, origin, god, defence
Q_1: basic beliefs, teachings, holy book, practices, rise, branches, spread, sects
Q_C: monotheistic?, a religion or a way of life?, peaceful?, older than hinduism?

Table 1: Examples of attributes already explicitly encoded in human-compiled knowledge resources (W=Wikipedia; F=Freebase) or extracted by various methods from text. Some of the entries in the table are also listed in (Van Durme et al., 2008) (D_1=from documents (Paşca et al., 2007), D_2=from documents (Van Durme et al., 2008), Q_1=from queries (Paşca, 2007), Q_C=from conjectural queries (this method))

1 Introduction

Motivation: Current efforts towards injecting structured knowledge into search results place a renewed emphasis on extracting, curating and serving open-domain knowledge. Resources such as Wikipedia (Remy, 2002) and Freebase (Bollacker et al., 2008) contain knowledge about classes (*Chemical elements*, *Programming languages* and *Stadiums*) and their instances (*iodine*, *python*, *millennium stadium*). Knowledge is often represented as properties or attributes of the instances, along with values for those properties. But even the largest human-curated knowledge resources may be missing at least some relevant knowledge, for some or all instances. For example, attributes representing the geographical coordinate or seating capacity are available in both Wikipedia and Freebase for many (e.g., for *millennium stadium*, *bc place*, *georgia dome*), albeit not all (e.g., *jenner park stadium*) instances of *Stadiums*. In contrast, information on whether particular *Stadiums* are *heated* or *roof retractable* is uniformly missing. Search queries such as *"is millennium stadium heated"*, *"is bc place heated"* and *"is the georgia dome heated"* suggest that such information is relevant to Web users. Populating the knowledge resource with the attribute *heated?*, for instances of *Stadiums*, would likely be more useful than, e.g., adding knowledge about whether they are *painted white*. More generally, identifying properties or attributes of interest to Web users but missing from the knowledge resource, helps allocate limited resource-development cycles to areas within the resource where their addition is most beneficial.

Contributions: This paper introduces a method for the acquisition of class attributes, from queries in the form *"<be> I A"* (e.g., *"is (georgia dome)$_I$ (heated)$_A$"*) or *"why <be> I A"* (e.g., *"why was the (tiger stadium)$_I$ (demolished)$_A$"*). Through such queries, Web users likely attempt to

verify whether - or why - a particular property (*demolished?*, *heated?*) applies to a particular instance (*tiger stadium*, *georgia dome*). In Table 1, attributes from conjectural queries are different in scope and style from attributes already encoded in human-compiled knowledge resources or attributes automatically acquired by previous methods. Examples include *good for skin?* for *Food ingredients*, *capable of supporting life?* for *Astronomical objects*, or *peaceful?* for Religions. Conjectural attributes cannot be easily captured by, and are therefore complementary to, attributes produced by previous methods, including methods targeting textual fragments in the form *"A of I"* (e.g., *"(seating capacity)$_A$ of (millennium stadium)$_I$"*) occurring in documents (Tokunaga et al., 2005) or queries (Paşca and Van Durme, 2007).

2 Extraction of Conjectural Attributes

Intuitions: The extraction of attributes from queries starts from the intuition that, if an attribute A is relevant for a class C, then users are likely to ask for the value of the attribute A, for various instances I of the class C (Paşca, 2007). The submission of fact-seeking queries such as *"what is the (seating capacity)$_A$ of (millennium stadium)$_I$"*, or the more compact *"(seating capacity)$_A$ of (millennium stadium)$_I$"*, is taken as evidence that *seating capacity* is a candidate attribute of the instance *Millennium Stadium*, and transitively a candidate attribute of the class *(Stadiums)$_C$* to which *Millennium Stadium* belongs. Attributes extracted from such queries are usually limited to noun phrases.

If an attribute A is relevant for a class C, then users are also likely to ask whether the attribute A does or does not apply to various instances I of the class C. The method introduced here takes advantage of other kinds of queries, namely conjectural, or truth-verification queries. Conjectural queries ask whether something is true or not. In comparison to fact-seeking queries, conjectural queries provide only weak evidence (conjectures) that the fact being asked about is true or not. Nevertheless, conjectural queries such as *"is (millennium stadium)$_I$ (heated)$_A$"* are taken as weak evidence that *heated?* is a candidate attribute of the instance *Millennium Stadium*, and transitively as stronger evidence a candidate attribute of the class *(Stadiums)$_C$*. Intuitively, the evidence supporting the candidate attribute is stronger for the class than it is for the instance. Users are likely to ask whether an attribute does or does not apply to an instance, based on prior knowledge that the attribute already applies to the class. If users submit the query mentioned earlier in this paragraph, it is likely because they are aware that *Stadiums* may or may not be *heated*, and would like to check whether a particular instance of *Stadiums* is. Collectively, queries asking whether an attribute applies to multiple instances of the same class are indirect evidence that the attribute does in fact apply to the class.

In addition to conjectural queries, the method also takes advantage of explanation-seeking queries, as a less frequent but more reliable source of evidence available in queries. Such queries ask for an explanation of why something is true. Queries such as *"why is (millennium stadium)$_I$ (heated)$_A$"* are intuitively more reliable sources of evidence that *Millennium Stadium*, in particular, and *Stadiums*, in general, are in fact *heated*, than queries like *"is (millennium stadium)$_I$ (heated)$_A$"* are.

Scope: Attributes extracted from conjectural queries cover multiple parts of speech, from single-word adjectives (*heated?*) and multiple-word descriptors (*open to the public?*) to noun phrases (*a retractable roof?*, *a 5 star stadium?*). On another dimension, conjectural attributes can capture properties that are objective or subjective. They include the more objective *on netflix?*, *a true story?*, *rated r?* for *Films*; but also the more subjective properties of whether *Films* are *weird?* or *funny?*. Anecdotal evidence of query frequency distribution in query logs suggests that Web users

Figure 1: Overview of extraction of conjectural attributes from Web search queries

are sometimes as interested in subjective attributes as they are in objective ones.

Referring back to Table 1, at least some of the conjectural adjectives have a nominal counterpart, which could in principle be extracted by existing extraction methods. The attribute *bigger than earth?* may be thought of as roughly equivalent to *size relative to earth*; *close to the sun?* to *distance to the sun*; *capable of supporting life* to *ability to support life*. However, even large query logs may not contain such noun phrases in the query format expected by previous methods. Moreover, some of the theoretical nominal counterparts of some conjectural attributes would be difficult to even identify manually, let alone extract with previous methods. It is less clear what the nominal counterparts are in the case of *fun?* for *Actors*, *peaceful?* for *Religions*, or *waterproof?* for *Cameras*. To summarize, conjectural attributes are arguably more diverse than attributes from existing resources or previously extracted from text.

Extraction from Queries: As illustrated in Figure 1, the proposed method takes as input a set of target classes, each of which is a set of instances; and a set of anonymized queries. Instances may be available as non-disambiguated items, that is, as strings (*python*) whose meaning is otherwise not available; or as disambiguated items, that is, as pointers to knowledge base entries with a particular, disambiguated meaning (*Python (programming language)*).

The method identifies the subset of input queries that are deemed to be conjectural queries. For this purpose, queries are matched against the patterns "*<be> I A*" and "*why <be> I A*", where I and A are a possible instance and an attribute. Other simple patterns were employed in previous

Actors, Aircraft, Animated characters, Association football clubs, Astronomical objects, Automobiles, Awards, Battles and operations of World War II, Chemical elements, Cities, Companies, Countries, Currencies by country, Digital cameras, Diseases and disorders, Drugs, Empires, Films, Flowers, Food ingredients, Holidays, Hurricanes in North America, Internet search engines, Mobile phones, Mountains, National Basketball Association teams, National parks, Newspapers, Organizations designated as terrorist, Painters, Programming languages, Religious faiths traditions and movements, Rivers, Skyscrapers, Sports events, Stadiums, Treaties, Universities and colleges, Video games, Wine

Table 2: Set of 40 Wikipedia categories used as target classes in the evaluation of attributes

work (Paşca and Van Durme, 2007) to extract attributes from text. Queries that match any of the patterns are deemed to be conjectural, but only if the query fragment corresponding to I can be matched to one of the instances of the input target classes. Queries do not need to end in a question mark, in order to be deemed conjectural. Depending on whether instances are non-disambiguated or disambiguated items, the matching from a query fragment to an instance from the input classes consists in either simple string matching; or disambiguation of I in the context of the query. When matching succeeds, the query fragment A is collected as a conjectural attribute for the instance I. In turn, attributes of a class are aggregated from attributes of individual instances of the class. The relative ranking among attributes of a class promotes attributes extracted from source queries that a) match many instances of the class, and few instances of any other classes; and b) have higher frequency in query logs.

3 Experimental Setting

Textual Data Sources: The experiments rely on a random sample of around 500 million fully-anonymized Web search queries in English. Each query is available independently from other queries, and is accompanied by its frequency of occurrence in the query logs.

Target Classes: The attributes extracted from queries are evaluated over a set of 40 target classes included in Table 2. In an effort to reuse experimental setup proposed in previous work, each of the 40 manually-compiled classes introduced in (Paşca, 2007) is mapped into the Wikipedia category that best matches it. For example, the evaluation classes *Actor*, *Mountain*, *Movie*, *Religion* and *TerroristGroup* from (Paşca, 2007) are mapped into the Wikipedia categories *Actors*, *Mountains*, *Films*, *Religious faiths traditions and movements* and *Organizations designated as terrorist* respectively. Note that the name of the Wikipedia category only serves as a convenience label for its target class, and is not otherwise exploited in any way during the evaluation. Instead, a target class consists in a sample set of Wikipedia articles selected from all articles listed under the respective category in Wikipedia, or listed under sub-categories of the respective category. For example, the target class *Automobiles* includes the Wikipedia articles titled *Chevrolet Tahoe*, *Jaguar XJ220* etc., as illustrated in Table 3. Due to noise within Wikipedia categories, spurious instances such as *Vibrating alert* (for *Mobile phones*) or *Veljko Rus* (for *Universities and colleges*) are occasionally present in the target classes, which makes the evaluation set more realistic than artificially clean. The resulting set of 40 target classes contains an average of 14,974 instances per class.

Extraction Parameters: A tagger links query fragments to their disambiguated, corresponding Wikipedia instances (i.e., to Wikipedia articles). The tagger is simplified to select the longest instance mentions in case of multiple, overlapping possible mentions. Depending on the sources of textual data available for training, any taggers (Cucerzan, 2007; Ratinov et al., 2011; Pantel et al., 2012) that disambiguate text fragments relative to Wikipedia entries can be employed.

The application of extraction patterns to disambiguated queries identifies matching source queries, which contain a Wikipedia instance and a candidate attribute. There are almost 1 million

Class: Examples of Instances
Actors: Bobby Todd, Chunky Pandey, Cody Estes, Emma Cleasby, Koen Crucke, Lauro Delgado, Leandra Leal, Leo Hallerstam, Lindsay Sloane, Margit Saad, Renu Saikia
Animated characters: Boris Badenov, Flying Dutchman (SpongeBob SquarePants), Kang and Kodos, Little Red-Haired Girl, Road Runner (video game), Strafe (Transformers), Subaru Sumeragi, Teletraan I, Zor (Robotech)
Astronomical objects: 65 Andromedae, Beta Lacertae, Dione (moon), Eta Corvi, Jewel Box (star cluster), Lacaille 8760, Messier 90, Mu Pegasi, Radio relics, S/2011 J 2
Automobiles: Chevrolet Tahoe, Ford CD2 platform, Jaguar XJ220, Lancia Dikappa, Mercedes-Benz Vario, Mitsubishi Mizushima, Rolls-Royce Phantom VI, Simca Esplanada, Tata Pixel
Awards: Academy Award, Dan Immerfall, Kalyna Roberge, Pulitzer Prizes, Justin Winsor Prize (library), Palme d'Or, Phajol Moolsan, Wallace Roney
Chemical elements: Aluminium, Bromine, Californium, Group 12 element, Group 7 element, Ilmenium, Lanthanum, Nebulium, Period 3 element, Polonium, Unbiunium, Yttrium, Zirconium
Companies: Consilient, Dorfan, Enercell, Fixafone, Gigaset Communications, Ingman, N3V Games, Quakers Yard and Merthyr Railway, Southeastern Airlines, TV Senado
Digital cameras: Fujifilm FinePix T-series, Fujifilm FinePix X100, General Imaging, Kodak DCS 300 series, Nikon Coolpix series, Nikon D60, Olympus E-400, Pentax K10D, Polaroid Z340
Diseases and disorders: Anthropophilia in animals, Bladder spasm, Hyperlysinemia, Inappropriate sinus tachycardia, Lymphoid Leucosis, Pantothenate kinase-associated neurodegeneration, Repetitive strain injury, Xwrits
Films: I Am Trying to Break Your Heart: A Film About Wilco, It Takes Two (1995 film), Mockingbird Don't Sing, Moster fra Mols, Prayers for Bobby, Roped, Strings (2004 film), Ten Thousand Years Older
Flowers: Acanthephippium mantinianum, Alcea, Dahlia 'Moonfire', Evergreen rose, Flower frog, Geranium caespitosum, Gilliflower, Hyacinth (plant), Iris douglasiana, Lavandula stoechas
Hurricanes in North America: 1856 Last Island hurricane, 1948 Miami hurricane, Effects of Hurricane Isabel in New York and New England, Hurricane Bertha (2008), Hurricane Charley, Hurricane Jova (2011)
Mobile phones: HTC Desire, LG Rumor, LG VX9400, Motorola A910, Nokia 1100, Nokia 7230, Nokia N71, Samsung S5560, Samsung SGH-T809, Samsung SPH-A460, Serene (phone), Vibrating alert
Mountains: Boulder Hills, Cerro San Luis Obispo, Lumiere Peak, Mount Erymanthos, Mount Shindainichi, Mynydd Mawr, Peters Mountain, Poroto Mountains, Remsspitze, Steel Peak, Stob Coire an Laoigh, Stoodley Pike
National Basketball Association teams: Chicago Bulls, Cleveland Cavaliers, Dallas Mavericks, Golden State Warriors, Houston Rockets, Indiana Pacers, Miami Heat, Philadelphia 76ers
National parks: Bu Gia Map National Park, Defileul Jiului National Park, Dooragan National Park, Great Basalt Wall National Park, Orang National Park, Tortuguero National Park
Newspapers: 7days, Chicago Sun-Times, Chojoongdong, Church Times, Corriere del Trentino, Government Gazette (Greece), L'Ordine Nuovo, Le Propagateur Catholique, Novato Advance, Seattle Medium, Venad Pathrika
Painters: Chester Harding (painter), Domingo Antonio Velasco, Gifford Beal, Giovanni Ambrogio de Predis, Lech Rzewuski, Ronnie Landfield, Tarcisio Merati, Tyler Vlahovich, Wolfgang Bauer (artist)
Programming languages: ALGOL 68, Brutus2D, C11 (C standard revision), CORC, Ease (programming language), GiNaC, IBM Basic assembly language, KANT (software), NESL, Obliq, RoboLogix, Rubinius
Religious faiths traditions and movements: Astral body, Chen Tao ("True Way"), Fudoki, Gnostic Mass, Ife, Lutheran Church in Singapore, Omnism, Pneumatic (Gnosticism)
Rivers: Arctic Red River, Deadwood River, Kuzumaru Dam, Ounce River, Pingo River, Presumpscot River, Reno (river), Sand Creek (Denver, Colorado), Viehmoorgraben, Zebracu River
Skyscrapers: 100 Montgomery Street, 15 Penn Plaza, 19 South LaSalle Street, 595 Market Street, EQT Plaza, Edelweiss (skyscraper), Transamerica Tower (Baltimore)
Wine: Acqui Terme, Cinque Terre, Costers del Segre, Elqui River, Los Palacios (Vino de la Tierra), Norte de Granada, Santorini, Sovana DOC, Vinho Verde, Wachau wine

Table 3: Examples of instances for a sample of target classes, where an instance is represented by the title of its Wikipedia article

such matching queries. In turn, Wikipedia instances are separately associated with the classes (Wikipedia categories) to which they belong, including the target classes described earlier. Transitively, attributes extracted from queries are thus associated to target classes. If an attribute co-occurs in the source queries with fewer than five, distinct instances of a class, then the attribute is deemed unreliable and therefore removed from the set of candidate attributes of the class.

Label	Value	Examples of Attributes
vital	1.0	Painters: famous when he was alive?
		Programming languages: compiled?
		Stadiums: covered?
okay	0.5	Painters: born in italy?
		Programming languages: useful?
		Stadiums: safe?
wrong	0.0	Painters: stolen?
		Programming languages: affectionate pets?
		Stadiums: good college?

Table 4: Correctness labels manually assigned to attributes extracted for various classes

Class	Precision of Extracted Attributes			
	%vital	%okay	%wrong	Score
Animated characters	64	32	4	0.80
Companies	84	0	16	0.84
Empires	68	20	12	0.78
Hurricanes in North America	52	44	4	0.74
Organizations designated as terrorist	56	8	36	0.60
Programming languages	96	4	0	0.98
Wine	44	4	52	0.46
...				
Avg-All-Classes	78	12	10	0.84

Table 5: Accuracy of attributes extracted from conjectural queries, over the set of 40 target classes

4 Evaluation Results

Attribute Accuracy: A sample of 25 attributes from each target class is manually assigned correctness labels. Following previously introduced methodology, an attribute is marked as *vital*, if it must be present amongrepresentative attributes of the class; *okay*, if it provides useful but non-essential information; and *wrong*, if it is incorrect (Paşca, 2007). When attributes are not *vital*, the choice between the labels *okay* vs. *wrong* often depends on whether the instances mentioned in source queries have been disambiguated to the correct entries in Wikipedia or not. To compute the precision score over a set of attributes, the correctness labels are converted to numeric values as shown in Table 4. Precision is the sum of the correctness values of the attributes, divided by the number of attributes.

Table 5 summarizes the resulting precision scores over the evaluation set of target classes. The scores vary from one class to another, for example 0.46 for *Wine* but 0.98 for *Programming languages*. The average score is 0.84, indicating that attributes extracted from conjectural queries have encouraging levels of accuracy. Table 6 shows examples of attributes extracted for some of the target classes, whereas Table 7 contains examples of source queries from which various attributes are extracted. Attributes extracted from *why*-prefixed source queries tend to be individually more reliable that attributes from *is*-prefixed queries. As noted earlier, this is because *why*-prefixed queries tend to request an explanation for something already known to be true to the questioner, instead of merely asking whether something is true or not.

Error Analysis: Erroneous attributes are extracted mainly due to two reasons. First, the presence of noisy instances in an input target class, illustrated earlier in Table 3, causes the extraction of attributes that may be relevant to individual instances but not to the class. For example, a significant number of instances in the target classes *Awards* and *Wine* are incorrect, because Wikipedia lists the categories *Award winners* and *Wine regions* as sub-categories of *Awards* and *Wine* respectively.

Class: Extracted Attributes
Association football clubs: playing today?, in debt?, a big club?, in the champions league?, in europe?, in fifa 12?, wearing black armbands?, for sale?, going to sign anyone?,..
Automobiles: a good car?, reliable?, front wheel drive?, a good first car?, rear wheel drive?, all wheel drive?, safe?, a girl car?, fast?, 4 wheel drive?, awd?, a sports car?, discontinued?, worth it?, a chick car?, good in snow?, good on gas?, parts expensive?, expensive to maintain?, discontinued?, being discontinued?,..
Awards: married?, famous?, a vegetarian?, overrated?, broke?, cancelled?, left handed?, based on a true story?, playing tonight?, having a baby?, appropriate for kids?, a good show?,..
Battles and operations of World War II: a success?, fought?, necessary?, a turning point?, an important battle?, important to the allies?, a failure?, in world war 2?, successful?, inevitable?, called that?, important to the us?, planned?,..

Table 7: Examples of source queries from which candidate attributes are extracted for various target classes

category-to-category edges from Wikipedia into a category taxonomy (Ponzetto and Strube, 2007; Ponzetto and Navigli, 2009) prior to assembling the target classes from categories. Second, the incorrect disambiguation of instances in queries causes attributes of a different instance with a similar name to be associated with the wrong class.

Conjectural Attribute → Possible Mappings to Equivalent Nominal Attributes	
Astronomical objects: bigger than earth? → size relative to earth^{A}, size^{P}, volume^{W,F,P}	Astronomical objects: capable of supporting life? → ability to support life^{A}
Astronomical objects: circumpolar? → ∅	Food ingredients: fattening? → energy^{W,F}, calories^{W,F}
Chemical elements: man made? → manufacturing process^{P}	Chemical elements: toxic? → toxicity^{P}
Chemical elements: soluble in water? → solubility in water^{W,F,P}	Chemical elements: a solid liquid or gas at room temperature? → phase^{W,F,P}
Chemical elements: conductive? → conductivity^{P}, electrical conductivity^{A}, electrical resistivity^{W,F}	Automobiles: reliable? → reliability^{P}
Automobiles: front wheel drive? → driveline^{F}	Automobiles: safe? → safety rating^{P}
Mobile phones: smartphone? → function as smartphone^{A}	Mobile phones: compatible with mac? → compatibility with mac^{P}
Cities: dog friendly? → dog friendliness^{A}	Cities: nice place to live? → attractiveness as a place to live^{A}
Cities: cheap? → cost of living^{P}	Companies: publicly traded? → stock symbol^{P}
Companies: fortune 500 company? → ∅	Companies: for sale? → availability for sale^{A}
Companies: a good place to work? → ranking^{P}, employee benefits^{P}	Films: on netflix? → availability on netflix^{A}, netflix title^{F}, providers^{P}
Films: sad? → genre^{F,P}	National parks: busy in may? → number of visitors in may^{A}, may visitors statistics^{A}, visitor statistics^{P}
National Basketball Association teams: losing money? → cash flow^{A}, financial statement^{P}, debt,	Newspapers: conservative? → preference for conservative views^{A}, political alignment^{W}, political bias^{P}
Newspapers: reputable? ? → reputation^{A}	Programming languages: case sensitive? → case sensitivity^{A}
Programming languages: obsolete? → ∅	Treaties: binding? → ∅

Table 8: Examples of mappings from conjectural attributes to their equivalent nominal attributes, if any. Nominal attributes present in Wikipedia, Freebase or among non-conjectural attributes extracted with previous methods (Paşca et al., 2007), are marked as W, F and/or P respectively; otherwise, they are marked A. A lack of equivalent nominal attributes is marked as ∅

Relation to Nominal Attributes: Table 8 reviews a sample of conjectural attributes, from the point of view of the availability of equivalent noun-phrase attributes into which conjectural attributes can be mapped. The nominal attributes would correspond to attributes available in human-compiled resources or that may be extracted by previous methods. Out of a sample of 200 conjectural attributes, 72% are manually found to have possible mappings into equivalent nominal attributes, of which 28% fully preserve the meaning (e.g., *safe?→safety rating*) but 44% only partially approximate the meaning (e.g., *bigger than earth?→volume*). When possible mappings to nominal attributes exist, whether fully or partially meaning-preserving, 18% (Wikipedia), 22% (Freebase) and 33% are present among the attributes available for instances of the respective classes in Wikipedia, Freebase or among the top 500 attributes returned by the method from (Paşca, 2007). About 31% of the conjectural attributes in the sample are found to not have a nominal equivalent, and an additional 28% have a possible nominal equivalent that is not present in any of the respective resources. Overall, the analysis suggests that conjectural attributes are not already captured by, and therefore complement, existing or previously extracted attributes.

Relation to Unary Attributes: To our knowledge, (Van Durme et al., 2008) is the only previous attribute extraction method allowing for the extraction of non-nominal attributes. It parses document sentences, leading to so-called unary attributes of classes, such as *trapped*, *dangerous*, and *unfortunate* for *Animals*. The attributes are collected from document sentences, roughly by identifying adjectival modifiers of mentions of the class (“*..the animals were trapped..*”, “*..the trapped*

Class	Extracted Attributes
Painter	D_U: famous, romantic, distinguished, celebrated, well-known, pre-raphaelite, flemish, dutch, abstract
	Q_C: famous when he was alive?, an important artist?, dead?, born in italy?, rich or poor?, left handed?
Animal	D_U: dead, trapped, dangerous, unfortunate, intact, hungry, wounded, tropical, sick, favourite
	Q_C: good with children?, aggressive?, smart?, dangerous?, hard to train?, endangered?, nocturnal?
Drug	D_U: dangerous, powerful, addictive, safe, illegal, experimental, effective, prescribed, harmful, hallucinatory
	Q_C: safe during pregnancy?, addictive?, dangerous?, over the counter?, a controlled substance?, legal?, effective?
Apple	D_U: red, juicy, fresh, bad, substantive, stuffed, shiny, ripe, green, baked
	Q_C: good for baking?, tart?, cooking apple?, sweet?, healthy?, good for canning?, biennial?, gmo?
Earthquake	D_U: disastrous, violent, underwater, prolonged, powerful, popular, monstrous, fatal, famous, epic
	Q_C: predicted?, destructive?, man made?, deadly?, devastating?, common?, normal?

Table 9: Comparison between unary attributes (D_U) extracted from documents as described in (Van Durme et al., 2008), and conjectural attributes (Q_C) extracted from queries as described in the current paper. To extract comparable attributes, the classes from (Van Durme et al., 2008), shown in the first column, are manually mapped into their equivalent Wikipedia categories *Painters*, *Animals*, *Drugs*, *Apple cultivars* and *Earthquakes* respectively

animals..”). In comparison to (Van Durme et al., 2008), our method takes noisy queries as input, rather than clean document sentences from reliable documents such as news articles. The comparison in Table 9, between attributes extracted for a sample of classes, highlights a few additional differences between the two methods. First, the attributes extracted in (Van Durme et al., 2008) seem to be limited to single-word adjectives, whereas conjectural attributes accommodate other phrases too. Second, the different intuitions behind the two methods determine what kind of attributes one would expect to see extracted. Unary attributes from (Van Durme et al., 2008) often capture transient states or events in which the respective classes are involved, like *Animals* being *trapped*, or *Apples* being *ripe* or *baked*. Such states or events may be relevant in the particular context of the document containing the source sentences. But they are not necessarily generally-relevant, context-independent properties that Web users would likely inquire about. Indeed, adding the property *trapped* for the class *Animals* to Wikipedia, and filling in its corresponding values for all instances (kinds) of *Animals*, would likely have little value. In contrast, conjectural attributes like *aggressive?* or *nocturnal?* are information-seeking, and often refer to permanent, context-independent rather than transient, context-dependent properties of the instances of the class *Animals*.

5 Related Work

A variety of methods address the more general task of acquisition of open-domain relations from text, e.g., (Zhu et al., 2009; Carlson et al., 2010; Fader et al., 2011; Lao et al., 2011). In order to acquire class attributes in particular, a common strategy is to first acquire attributes of instances, then aggregate or propagate (Talukdar and Pereira, 2010) attributes, from instances to the classes to which the instances belong. The identification of relevant instances within queries is related to the task of word sense disambiguation (Ponzetto and Navigli, 2010).

Data available within Web documents, from which attributes are extracted in previous work, includes unstructured (Tokunaga et al., 2005; Paşca et al., 2007), structured (Raju et al., 2008) and semi-structured text (Yoshinaga and Torisawa, 2007), layout formatting tags (Wong et al., 2008), itemized lists or tables (Cafarella et al., 2008). Another source of attributes is data in human-compiled encyclopedia (Wu et al., 2008; Cui et al., 2009), including infoboxes and category labels (Suchanek et al., 2007; Nastase and Strube, 2008; Wu and Weld, 2008) associated with

Wikipedia articles (Remy, 2002). The role of Web search queries, as an alternative textual data source to Web documents in open-domain information extraction, has been investigated in the tasks of attribute extraction (Paşca, 2007), as well as in collecting labeled (Sekine and Suzuki, 2007; Pennacchiotti and Pantel, 2009) or unlabeled sets of related instances (Jain and Pennacchiotti, 2010) and ranking of class labels already extracted from text (Billerbeck et al., 2010).

6 Conclusion

Collectively, queries that inquire whether an attribute applies to individual instances or not are evidence that the attribute in question does apply to classes to which the instances belong. The resulting conjectural attributes have encouraging accuracy, and complement attributes available in manually-compiled resources or automatically extracted with previous methods. Current work investigates the role of repositories of class labels (*heated stadiums*) extracted from text for various instances (*Millennium Stadium*), as an additional source of evidence towards extracting class attributes (*heated?*); and the acquisition of (mostly binary) values of conjectural attributes for individual instances.

ABSTRACT
This paper provides an explicit, formal analysis of two not only interesting but also frequent coordination phenomena: the coordination of unlike categories and the coordination of distinct grammatical functions possibly belonging to entirely different levels of structure. The proposed account of the former makes it possible to take full advantage of new generation valence dictionaries which encode information about the possibility of such non-standard coordination, creating new possibilities for existing grammar implementations. Furthermore, interactions with complex phenomena such as case assignment are taken into consideration, providing a solution which may be adopted for modelling similar phenomena in other languages. The other variety of coordination addressed in this paper sheds some new light on coordination and how it should be modelled. It demonstrates on the basis of attested data that coordination is subject to fewer constraints than previously assumed and provides an elegant linguistically-motivated solution employing currently available LFG mechanisms.

TITLE AND ABSTRACT IN POLISH

Kompleksowa analiza koordynacji składnikowej na potrzeby inżynierii lingwistycznej

Niniejszy artykuł przedstawia sformalizowaną analizę dwóch zarówno interesujących, jak i częstych zjawisk związanych z koordynacją: koordynację różnych kategorii oraz koordynację różnych funkcji gramatycznych, które mogą również należeć do zupełnie odmiennych poziomów struktury. Zaproponowana analiza pozwala na wykorzystanie w pełni możliwości stwarzanych przez słowniki walencyjne nowej generacji, które zawierają informacje o możliwości wystąpienia niejednorodnej koordynacji, co otwiera zupełnie nowe perspektywy przed istniejącymi już implementacjami gramatyk. Ponadto brane są pod uwagę interakcje ze złożonymi zjawiskami takimi jak nadawanie przypadka, które to rozwiązanie może zostać przystosowane do opisu podobnych zjawisk w innych językach. Drugi rodzaj koordynacji opisany w artykule rzuca nowe światło na koordynację i jej formalny opis: na podstawie autentycznych danych pokazano, że koordynacja podlega znacznie mniejszej liczbie ograniczeń, niż wcześniej sądzono, oraz zaproponowano eleganckie rozwiązanie o solidnych podstawach lingwistycznych, wykorzystujące obecnie dostępne mechanizmy LFG.

KEYWORDS: coordination, unlikes, formal grammar, parsing, Polish, LFG.

KEYWORDS IN POLISH: koordynacja, gramatyka formalna, parsowanie, polski, LFG.

Proceedings of COLING 2012: Technical Papers, pages 2191–2208,
COLING 2012, Mumbai, December 2012.

1 Introduction

During the last two decades of the previous millennium grammar engineering was solidly placed within the core of Natural Language Processing (NLP), as also witnessed by the number of papers devoted to this topic in COLING proceedings of 1980s and 1990s. While – in the age of inductive NLP – this theme has almost disappeared from major conferences, grammar engineering efforts, supported by new corpus-based methods, have continued, especially within the HPSG[1] and LFG[2] communities, where large-scale multilingual grammar engineering initiatives were set up: DELPH-IN (`http://www.delph-in.net/`) and PARGRAM (`http://pargram.b.uib.no/`). There has also been much progress during the last 15 years or so in the theoretical linguistic foundations of these efforts, with flourishing HPSG and LFG conferences and with analyses set up within these frameworks appearing in prestigious linguistic journals.

One of the topics that has received much attention in formal theoretical linguistics is coordination, a phenomenon which is not only theoretically challenging, but also – due to its textual frequency – crucial to grammar engineering. Unfortunately, as coordination remains difficult to describe accurately and exhaustively, this theoretical interest is not fully reflected in existing grammar implementations.

The aim of this paper is to present a comprehensive implementation of constituent coordination, a part of an ongoing effort to develop a wide-coverage LFG parser of Polish (Patejuk and Przepiórkowski, 2012b). Polish is a good test-bed for the task at hand, as it offers a wide range of interactions between coordination on one hand and various agreement, case assignment and valence phenomena on the other.

One aspect of coordination that has remained especially elusive in grammar engineering is the possibility to coordinate elements which are unlike in some sense. Polish offers a much wider range of unlike constituent coordination than has been discussed in NLP, including the so-called lexico-semantic coordination (Kallas 1993; Chaves and Paperno 2007; Gazdik 2010), i.e., the coordination of *very* unlikes, where coordinated items do not even represent the same grammatical function. While such cases go against any comprehensive analysis of coordination we are aware of, they are textually frequent and therefore should be taken into account in any wide-coverage grammar implementation effort.

Note that, for reasons of space, we do not provide here an analysis of non-constituent coordination, as in *give a teacher an apple and a policeman a flower* (Steedman, 2000, p.46).[3] This subtype of coordination has an elegant analysis in different versions of categorial grammars, while it remains troublesome for many other grammatical theories. Within LFG, a comprehensive analysis of non-constituent coordination is offered in Maxwell and Manning 1996. In fact, while the LFG analysis seems to cover roughly the same patch as categorial grammar analyses, Maxwell and Manning (1996) claim that it is superior,[4] as it provides more natural accounts of cases such as *You may call me directly or after 3pm through my secretary* and *She put a lamp on the table, and on the ledge a large antique punchbowl*, which are difficult because coordinated elements are not only non-constituents, but they also differ in the number and order of constituents. The analysis of the current paper may be extended to cover non-constituent

[1] Head-driven Phrase Structure Grammar; cf. Pollard and Sag 1987, 1994.
[2] Lexical-Functional Grammar, cf. Bresnan 1982 and Dalrymple 2001.
[3] Steedman 2000 calls this phenomenon *argument cluster coordination*.
[4] See Levine 2011, § 2.4, for a refutal of this claim.

coordination along the lines of Maxwell and Manning 1996.

2 Basics: Coordination of 'like' categories

The usual intuition behind implementations of coordination is that, wherever some phrase type XP (e.g., a nominal phrase) may occur, a coordination of XP-like elements (i.e., of nominal phrases) may occur instead. In LFG, this intuition is expressed via constituency rules:

(1) $\begin{array}{lcccc} \text{XP} & \rightarrow & \text{XP} & \text{Conj} & \text{XP} \\ & & \downarrow\in\uparrow & & \downarrow\in\uparrow \end{array}$

LFG makes a distinction between c(onstituent)-structure and f(unctional)-structure (among other linguistic levels). Annotations of elements of c-structure rules, such as $\downarrow\in\uparrow$, are used to construct corresponding f-structures. In this case, the two conjuncts are elements of the set representing the mother. For example, when used to parse the Polish sentence (2), the above rule constructs the set representation of the subject of the sentence, as in (3).[5]

(2) Idą Jan i Marysia.
walk.PL Jan.SG and Marysia.SG
'Jan and Marysia walk.'

(3) $\left\{\left[\text{PRED} \quad \text{'Jan'}\right], \left[\text{PRED} \quad \text{'Marysia'}\right]\right\}$

This simple example also illustrates the immediate weakness of the basic intuition given above: neither the singular *Jan*, nor the singular *Marysia* alone can directly replace the coordination *Jan i Marysia*, as this would lead to number disagreement with the plural verb. Because of such agreement facts, coordinate structures are represented in LFG as hybrid feature structures, which contain sets such as (3), but may also contain their own features (Dalrymple and Kaplan, 2000); a fuller representation of the subject of (2) would be (4).

(4) $\left[\begin{array}{l} \left\{\left[\begin{array}{ll} \text{PRED} & \text{'Jan'} \\ \text{NUM} & \text{SG} \end{array}\right], \left[\begin{array}{ll} \text{PRED} & \text{'Marysia'} \\ \text{NUM} & \text{SG} \end{array}\right]\right\} \\ \\ \text{NUM} \quad \text{PL} \end{array}\right]$

3 Basics: Coordination of 'unlike' categories

An influential paper that demonstrated that the assumption of 'likeness' of coordinated elements is too strong is Sag et al. 1985, set within GPSG.[6] Under their analysis, examples (5)–(7) are grammatical because both conjuncts satisfy the underspecified requirements which hold for the syntactic position they occupy.

(5) That was a rude remark and in very bad taste.

(6) We walked slowly and with great care.

(7) Pat became a republican and quite conservative.

[5] The attribute PRED stands for PREDICATE and represents the basic predicate-argument structure of a given element. Here both predicates 'Jan' and 'Marysia' have no arguments.

[6] Generalized Phrase Structure Grammar; cf. Gazdar et al. 1985.

(8) *Tracy has become a republican and of the opinion that we must place nuclear weapons in Europe.

For example, the verb BE, as in (5), only requires that its complement be predicative, [PRD +], and both conjuncts *a rude remark* and *in very bad taste* are [PRD +] (apart from being a noun phrase and a prepositional phrase, respectively). Similarly, the adjunct in (6) is specified as [MANNER +], and again both conjuncts, although categorially unlike, are [MANNER +]. On the other hand, the verb BECOME puts stronger restrictions on its complement: not only should it be predicative, but also nominal, [N +], in the sense that nouns and adjectives are nominal, while prepositions and verbs are not (they are marked as [N −]). Hence, (7), involving two predicative nominal conjuncts (a noun phrase and an adjectival phrase), is grammatical, while (8), involving a [N −] conjunct (the prepositional *of the opinion...*) is not.

In order for this analysis to work, the theory needs to implement a notion of feature structure subsumption. In GPSG such a notion is hardwired into the Head Feature Convention (cf. Sag et al. 1985, § 2.4). Attempts have also been made to carry over these subsumption-based insights into HPSG, but they require certain extensions of the formal apparatus assumed within HPSG; two such analyses are proposed in Sag 2002 and Yatabe 2004.

Despite the fact that LFG offers interesting analyses of various aspects of coordination (Maxwell and Manning 1996 on non-constituent coordination; Dalrymple and Kaplan 2000 and Dalrymple et al. 2009 on how coordination influences the representation of features such as person, gender and case; Dalrymple and Nikolaeva 2006, Kuhn and Sadler 2007, and Dalrymple and Hristov 2010 on the interaction between coordination and agreement), there is surprisingly little explicit discussion of coordination of unlike constituents. The assumption seems to be that, at the level of c-structure, there are no categorial constraints on conjuncts, i.e., instead of (1) above, the relevant rule would rather resemble (9) below (cf. Peterson 2004, p. 652).

(9) $\text{XP} \rightarrow \underset{\downarrow\in\uparrow}{\text{YP}} \quad \text{Conj} \quad \underset{\downarrow\in\uparrow}{\text{ZP}}$

In LFG, any appearances of categorial 'likeness' are a side effect of constraints imposed at the functional level of representation. For example, in Polish, subjects are typically nominative (but see below), a fact which may be expressed via (10).[7]

(10) $(\uparrow \text{SUBJ CASE}) =_c \text{NOM}$

In fact, on standard LFG assumptions, nothing more is required to ensure that *both conjuncts* in (2) are nominative. This is because LFG distinguishes between distributive features, such as CASE, and non-distributive features, such as NUM(BER) (Dalrymple and Kaplan, 2000). The former distribute over all elements of coordination, so the specification CASE = NOM for the outer hybrid feature structure in (11) results in CASE = NOM on all conjuncts within the set.

(11)
$$\left[\begin{array}{ll} \left\{\left[\begin{array}{ll}\text{PRED} & \text{'JAN'}\\ \text{NUM} & \text{SG}\\ \text{CASE} & \text{NOM}\end{array}\right], \left[\begin{array}{ll}\text{PRED} & \text{'MARYSIA'}\\ \text{NUM} & \text{SG}\\ \text{CASE} & \text{NOM}\end{array}\right]\right\} \\ \text{NUM} \quad \text{PL}\end{array}\right]$$

[7] The constraining equation, expressed by '$=_c$', *verifies* that the equality holds, rather than assigning a value, as in case of the operator '='.

Using these mechanisms, it is simple to implement in LFG an analysis similar to that of Sag et al. 1985. For example, part of the lexical entry of the verb BE might be: (↑ OBJ PRD) = +. Assuming that PRD[8] is a distributive feature, the requirement that the object be predicative will percolate to all conjuncts, without predetermining their categorial status, and thus accounting for (5).

4 Towards an LFG analysis of the coordination of unlikes

At the end of the paper, Sag et al. (1985) discuss cases of coordination of an NP with a clause (p. 165):

(12) Pat remembered the appointment and that it was important to be on time.

(13) That Himmler appointed Heydrich and the implications thereof frightened many observers.

The analysis they propose is far from elegant and it involves, *inter alia*, the assumption that such clauses are in a sense NPs. Apparently, they are attempting to avoid a disjunctive specification of the verb's argument, one that would state that, e.g., the object of the verb REMEMBER is either an NP or a clause (or a coordination of such elements).

When other languages are taken into consideration, it turns out that such disjunctive specifications are inevitable. For example, Kosek 1999, pp. 43–44, cites the following:

(14) Owinął dziecko w koc i ręcznikiem.
wrapped baby in blanket.ACC and towel.INST
'He wrapped the baby in a blanket and in a towel.'

(15) Nadajesz się do tej pracy i na dyrektora.
are fit for this job and for manager
'You are fit for this job and for a manager.'

Prepositional phrases involved in these examples must be headed by the specific prepositions W, DO and NA, and the NP in (14) must be in the instrumental case. It seems highly unlikely that the intuitive disjunctive specifications 'PP[*w*] ∨ NP[*inst*]' (for (14)) and 'PP[*do*] ∨ PP[*na*]' (for (15)) could be replaced by non-disjunctive specifications capturing putative commonalities between, for instance, PP[*w*] and NP[*inst*] (to the exclusion of other types of phrases).

It turns out that such disjunctive specifications are also problematic for LFG. The obvious way to formalise the requirements of the verb OWINĄĆ 'wrap', as in (14), would be:[9]

(16) (↑ OBL CASE) = INST ∨ (↑ OBL PFORM) = W

Unfortunately, the statement (16) does not have the intended meaning. Because of the distributivity of CASE (and, presumably, PFORM, which stands for 'prepositional form'), the statement, when applied to a coordinate complement, has the following effect: either all conjuncts are instrumental, or all conjuncts have the prepositional form W. Making (any of) these features non-distributive does not solve the problem, as it would only render the relevant constraints inapplicable to individual conjuncts.

[8] Not to be confused with 'PRED'.

[9] We use here '∨' to mark disjunction, instead of the '|' usual in the LFG literature; similarly, we explicitly mark conjunction with '∧' instead of leaving it implicit.

There is, however, a solution which does not require extending the formal apparatus of LFG, although it is based on a relatively rarely used LFG mechanism, namely, the so-called off-path constraints (Dalrymple, 2001, p. 148).[10]

Off-path constraints make it possible to restrict the path (or, more importantly, its part) used by other statements. For example, while the minimal feature structure satisfying (17) is that of (18), the statement (19), with an off-path constraint added to the attribute A, specifies (20).[11]

(17) $(\uparrow \text{A B C}) =_c +$

(18) $\begin{bmatrix} \text{A} & \begin{bmatrix} \text{B} & \begin{bmatrix} \text{C} & + \end{bmatrix} \end{bmatrix} \end{bmatrix}$

(19) $(\uparrow \text{A B C}) =_c +$
$(\leftarrow \text{D}) =_c \text{E}$

(20) $\begin{bmatrix} \text{A} & \begin{bmatrix} \text{B} & \begin{bmatrix} \text{C} & + \end{bmatrix} \end{bmatrix} \\ \text{D} & \text{E} \end{bmatrix}$

More formally, '←' denotes the f-structure which contains the attribute to which it is attached, while '→' denotes the f-structure which is the value of the attribute to which it is attached. Hence, (21) (i.e., with '←' above replaced by '→') specifies the structure in (22).

(21) $(\uparrow \text{A B C}) =_c +$
$(\rightarrow \text{D}) =_c \text{E}$

(22) $\begin{bmatrix} \text{A} & \begin{bmatrix} \text{B} & \begin{bmatrix} \text{C} & + \end{bmatrix} \\ \text{D} & \text{E} \end{bmatrix} \end{bmatrix}$

The last piece of puzzle necessary to successfully analyse coordination of unlikes in LFG is the standard possibility to require the existence of a certain feature (whatever its value) in a feature structure: for example, (↑ PRED), without any equality sign, requires that the feature PRED be present in the feature structure being described. Given that PRED is a distributive feature, this specification forces all conjuncts to contain PRED (i.e., they must be semantically non-vacuous).

Returning to the failed attempt to formalise a disjunctive constraint in (16), let us note that the problem occurs because the disjunction is understood too early: instead of being interpreted as "for every conjunct, either... or...", it means: "either for every conjunct..., or for every conjunct...". What is needed is a means of 'smuggling' the disjunction into conjuncts before it is interpreted. Off-path constraints provide a mechanism to achieve this.

The relevant statement, replacing (16), is given below:

(23) $(\uparrow \text{OBL} \quad \text{PRED}) \\ (\leftarrow \text{CASE}) =_c \text{INST} \vee (\leftarrow \text{PFORM}) =_c \text{W}$

(23) ensures that – in Polish – there are no semantically vacuous (expletive) oblique complements, i.e., each such complement has a PRED value. This part of the statement is trivial. The main import of the statement is given in the off-path constraint part: for each such PRED, either the value of the CASE attribute (at the same level as the PRED) is instrumental, or the value of PFORM (again, at the same level) is W. As a result, disjunction is interpreted independently for each conjunct.

[10] We would like to thank Mary Dalrymple for suggesting to us that off-path constraints could be used to account for the coordination of unlikes, namely, for Polish unlike category subjects. (The usual disclaimers apply.) Przepiórkowski and Patejuk 2012 presents this analysis – and an alternative account – in more detail.

[11] Note that off-path constraints are placed *below* the attribute to which they apply.

5 Interactions with case assignment

Polish is a morphologically rich language with 7 grammatical cases. While case values of some arguments are stable and do not change with the syntactic environment (such case values are said to be assigned lexically or inherently), other case values depend on the syntactic context, e.g., the presence of negation or the categorial status of the argument. The syntactic (or structural) case assignment facts may be partially summarised as follows:[12]

(24) a. **subjects** bearing structural case are in the nominative,

b. with the exception of numeral phrase subjects, headed by so-called governing numerals (see below), which are in the accusative;

(25) a. **objects** bearing structural case are in the accusative,

b. unless they are in the syntactic scope of sentential negation, in which case they are in the genitive (so-called Genitive of Negation, GoN).

It should be possible to model these facts in a straightforward way by case assignment statements such as the following (for (24) above):[13]

(26) $[(\uparrow \textsc{subj acm}) =_c \textsc{rec} \wedge (\uparrow \textsc{subj case}) =_c \textsc{acc}] \vee (\uparrow \textsc{subj case}) =_c \textsc{nom}$

In this statement, ACM represents *accommodability*, a lexical feature introduced for Polish by Bień and Saloni (1982) to distinguish numeral forms governing the genitive noun (the value of ACM in such cases is REC) from numeral forms agreeing with the following noun.

Although, again, (26) does not have the intended meaning (its effect is that either all conjuncts are accusative numeral phrases or they are all nominative), the following version does the trick:

(27) $(\uparrow \textsc{subj} \quad \textsc{pred} \quad) \\ [(\leftarrow \textsc{acm}) =_c \textsc{rec} \wedge (\leftarrow \textsc{case}) =_c \textsc{acc}] \vee (\leftarrow \textsc{case}) =_c \textsc{nom}$

Such statements are successful in handling coordinate arguments, as in the example below.[14]

(28) [Pan Mirosław] i [czternastu ludzi] pracowało dzień i noc.
Mr Mirosław.NOM.SG and fourteen.ACC.PL man.GEN.PL worked.3.SG.N day and night
'Mr Mirosław and fourteen men worked night and day.' (NKJP)

On the other hand, just as in English, some Polish verbs allow for either an NP or a clause (or their coordination) in an argument position (here: subject); a relevant example is given below:

(29) Jana dziwiło, [że Maria wybiera Piotra], i [jej brak gustu].
Jan.ACC puzzled.3.SG.N that Maria chooses Piotr and her lack of taste.NOM.SG
'(The fact) that Maria prefers Piotr and her lack of taste puzzled Jan.'
(Świdziński, 1992, 1993)

For such verbs, the following constraint holds:

[12] See Przepiórkowski 1999 for extensive justification. We limit our considerations to arguments of verbs here.

[13] Where necessary, square brackets are used for the purpose of grouping constraints.

[14] "NKJP" marks attested examples found in the National Corpus of Polish (`http://nkjp.pl/`; Przepiórkowski et al. 2010, 2012).

(30) (↑ SUBJ PRED)
[(← ACM) =$_c$ REC ∧ (← CASE) =$_c$ ACC] ∨
(← CASE) =$_c$ NOM ∨ (← COMP-FORM) =$_c$ ŻE

A similar account can be offered for syntactically case-assigned objects, which – for some verbs – may be alternatively realised as clauses. Consider the following examples:

(31) Doradził mu [wyjazd] i [żeby nie wracał].
advised him leave.ACC and that NEG come back
'He advised him to leave and not to come back.' Kallas (1993)

(32) (Wcale) nie doradził mu [wyjazdu] ani [żeby nie wracał].
not at all NEG advised him leave.GEN nor that NEG come back
'He did not advise him to leave nor not to come back.'

These examples illustrate the principles of structural case assignment in Polish referring to objects (see (25) above): verbs assign accusative case to nominal objects in the absence of negation, as in (31), while genitive is assigned if negation is present, see (32). This basic principle is formalised in (33).

(33) (↑ OBJ PRED)
[¬((OBJ ←) NEG) ∧ (← CASE)=$_c$ ACC] ∨
[((OBJ ←) NEG)=$_c$ + ∧ (← CASE)=$_c$ GEN]

However, in case of verbs such as DORADZIĆ 'advise', as in (32), another disjunct must be added, allowing for a clausal object:

(34) (↑ OBJ PRED)
[¬((OBJ ←) NEG) ∧ (← CASE)=$_c$ ACC] ∨
[((OBJ ←) NEG)=$_c$ + ∧ (← CASE)=$_c$ GEN] ∨
(← COMP-FORM) =$_c$ ŻEBY

Again, the distributive feature PRED is used as an anchor so that disjunctive off-path constraints are checked against each element of OBJ independently (so, each conjunct under coordination). Note that a combination of outside-in (used so far) and inside-out equations is employed in (33)–(34). The former designate a path leading downwards into the f-structure, the latter make it possible to construct a path leading in the opposite direction, namely to higher f-structures; '(OBJ ←)' creates a path starting from the f-structure designated by '←', leading to the one which contains OBJ. Paths constructed in this way may be used as designators in outside-in equations as in the first disjunct of (33)–(34) which requires that the particular OBJ f-structure be marked for accusative case and that there be no negation in the f-structure containing OBJ (see '¬((OBJ ←) NEG)'). The second disjunct uses the same mechanisms to ensure that a given OBJ f-structure be marked for genitive case and that there be negation in the f-structure which contains OBJ (see '((OBJ ←) NEG)=$_c$ +').[15]

6 Implications for valence lexicons

Any adequate account of coordination of unlike categories implies a certain organisation of the valence dictionary, i.e., a lexicon recording information about arguments of predicates. Such a

[15]This solution may be extended to handle optional GoN under transferred negation in verb chains. This is achieved using functional uncertainty in relevant off-path constraints.

lexicon should make it clear whether arguments in the same position can be coordinated.

Note that it is not enough to know that various categorial kinds of arguments bear the same grammatical function in relation to the predicate. For example, the Polish verb MÓWIĆ 'say, speak' takes as its (passivisable) object the following categories, among others: *oratio recta* (direct speech; marked as `or` below), prepositional phrase headed by O and requiring a locative phrase (`prepnp(o,loc)`), subordinate finite clause introduced by the complementiser ŻE (`cp(że)`), embedded question (`cp(intrel)`), etc. While various of these possible objects may be coordinated, apparently an *oratio recta* object cannot be coordinated with any other category. This calls for postulating two different subcategorisation frames: one involving an *oratio recta* object, and another involving other kinds of objects.

Valence dictionaries we are aware of, Polish or otherwise, do not include such 'coordinatability' information. However, a new valence dictionary, Walenty,[16] is being developed for Polish which encodes such information explicitly. In this valence dictionary, any frame allowing for the coordination of unlikes is accompanied by an attested example, usually from the National Corpus of Polish. Figure 1 shows a screenshot of the application assisting in the creation of this dictionary.

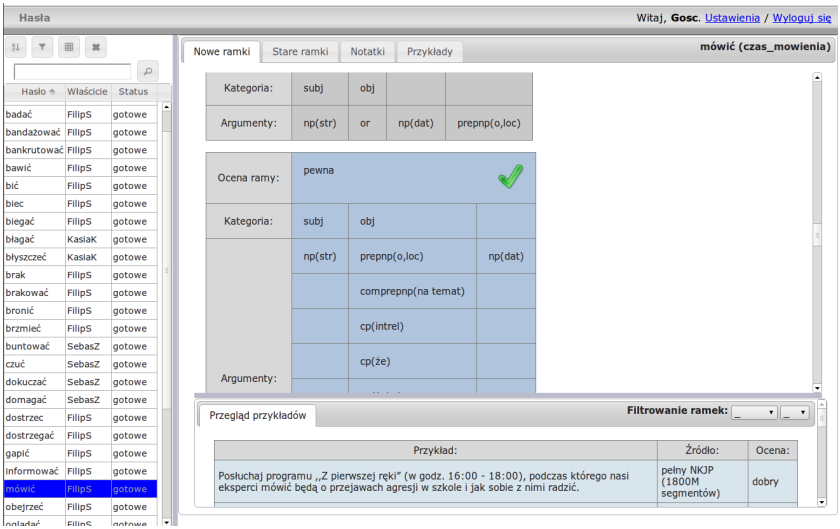

Figure 1: An application for creating Walenty, a new valence dictionary of Polish – a screenshot showing subcategorisation frames for MÓWIĆ 'say, speak': one involving an *oratio recta* object (near the top), and another involving an object which may be realised as a prepositional phrase, an embedded clause, etc. (in the bottom). An example from the National Corpus of Polish, illustrating the possibility to coordinate `prepnp(o,loc)` and `cp(intrel)` is provided at the very bottom.

[16] The preliminary version is available at: `http://clip.ipipan.waw.pl/Walenty`.

7 Coordination of very unlikes

Standard coordination of unlike categories involves elements which bear the same grammatical function. For example, in (12) above, both *the appointment* and *that it was important to be on time* correspond to the direct object of *remembered*. However, in some languages and under certain circumstances it is possible to coordinate elements bearing starkly different grammatical functions, as in Polish (35), involving coordination of the subject and the direct object of the verb *uczył* 'teach'.

(35) Kto i kogo będzie uczył?
who.NOM and who.ACC will teach
'Who will teach whom?' (NKJP)

To the best of our knowledge, such cases, called in English – after Mel'čuk 1988, p. 40 – *lexico-semantic coordination* or – as in Chaves and Paperno 2007, who provide a preliminary HPSG analysis – *hybrid coordination*, were first described for Russian (and in Russian) in Sannikov 1979, 1980, and for Polish (and in Polish) in Kallas 1993. Similar data are also discussed for French and Hungarian, and given the first LFG account, in Gazdik 2010 (only for *wh*-words, though).

Examination of Polish data reveals that such coordination is more robust than previously described in the literature. First of all, elements which enter lexico-semantic coordination are not only *wh*-phrases, as in (35), but also phrases containing a pronoun expressing an existential quantifier, a universal quantifier or phrases with n-words, as in (36), (37) and (38), respectively.

(36) czy komukolwiek, kiedykolwiek i do czegokolwiek przydał się poradnik
PART anybody.DAT anytime and for anything.GEN come in handy guide
'Has a(ny) guide ever come in handy to anybody for anything?' (NKJP)

(37) Obiecać można wszystko i wszystkim.
promise may everything.ACC and everyone.DAT
'One may promise everything to everyone.' (NKJP)

(38) nikogo i nic nie może tłumaczyć.
nobody.GEN and nothing.NOM NEG can excuse
'Nothing may excuse anybody.' (NKJP)

Second, as already evidenced in (38), and contra theoretical assumptions of the HPSG and LFG analyses mentioned above, the coordinated elements may be dependents of different predicates. This is more clearly illustrated in (39), where *skąd* 'where from' is an adjunct of the verb *otrzymujemy* 'receive' and *jakie* 'what kind' is a modifier of the noun *informacje* 'information'.

(39) Skąd i jakie otrzymujemy informacje?
whence and what receive information
'What information and where from do we receive?' (NKJP)

While coordinated elements may be dependents of different heads, the semantics of (35)–(39) is that of a single clause; for example, (35) may be translated into 'Who will teach whom?', and not into 'Who will teach (somebody) and whom will (somebody) teach?'. Moreover, when the conjunction is *i* 'and', it may often be omitted, without any obvious change of meaning:

(40) Kto kogo będzie uczył?
who.NOM who.ACC will teach
'Who will teach whom?'

This is reflected in the implemented LFG analysis, where the main c-structure rule handling lexico-semantic coordination is (41), where *type* is a parameter which may assume the following values: WH (question word; cf. (35) and (39)), ANY (existential quantifier; cf. (36)), ALL (universal quantifier; cf. (37)), NEG (n-word; cf. (38)).

(41) $\text{XPlexsem-mono}_{type} \rightarrow \underset{\uparrow=\downarrow}{\text{XPextr}_{type}} \; [, \; \underset{\uparrow=\downarrow}{\text{XPextr}_{type}}]^* \; \text{CONJ} \; \underset{\uparrow=\downarrow}{\text{XPextr}_{type}}$

According to this rule, the f-structure of each extracted phrase of a given type is identified with the f-structure of the mother. This is achieved using the '↑=↓' annotation on all conjuncts which treats them as co-heads: f-structure fragments built by particular conjuncts, see (42), are unified in one top-level f-structure, resulting in (43). The latter, once it is unified with the f-structure of the rest of the utterance, renders (44).

(42) a. $\left[\text{ADJ} \left\{\left[\text{PRED} \quad \text{'WHENCE'}\right]\right\}\right]$

b. $\left[\text{OBJ} \left[\text{ADJ} \left\{\left[\text{PRED} \quad \text{'WHAT'}\right]\right\}\right]\right]$

(43) $\begin{bmatrix} \text{ADJ} & \left\{\left[\text{PRED} \quad \text{'WHENCE'}\right]\right\} \\ \text{OBJ} & \left[\text{ADJ} \left\{\left[\text{PRED} \quad \text{'WHAT'}\right]\right\}\right] \end{bmatrix}$

(44) $\begin{bmatrix} \text{PRED} & \text{'RECEIVE}\langle\boxed{1},\boxed{2}\rangle\text{'} \\ \text{SUBJ } \boxed{1} & \left[\text{PRED} \quad \text{'PRO'}\right] \\ \text{OBJ } \boxed{2} & \begin{bmatrix} \text{PRED} & \text{'INFORMATION'} \\ \text{ADJ} & \left\{\left[\text{PRED} \quad \text{'WHAT'}\right]\right\} \end{bmatrix} \\ \text{ADJ} & \left\{\left[\text{PRED} \quad \text{'WHENCE'}\right]\right\} \end{bmatrix}$

The complete analysis, which is not given here in detail for lack of space (e.g., the definition of XP_{type} is omitted), also includes the rule (45) which, together with (46)–(47), encodes appropriate locality (or island) constraints on the provenance of coordinated phrases.[17] While (46) defines the set of grammatical functions which may be assigned to a given element, (47) defines the main extraction path of such elements: they may be extracted across any number of infinitival complements (XCOMP) and, below that, across any number of grammatical functions GF, but – crucially – not across finite sentential complements, etc.[18] Since each conjunct resolves its functional annotation independently, it is possible for every conjunct to bear entirely different grammatical function and depend on different heads, as in (42a) vs (42b).

(45) $\text{XPextr}_{type} \rightarrow \underset{(\uparrow \text{ PATH } \text{GF}^+)=\downarrow}{\text{XP}_{type}}$

(46) $\text{GF} \equiv \{\text{SUBJ} \,|\, \text{OBJ} \,|\, \text{OBJ}_\theta \,|\, \text{OBL} \,|\, \text{ADJ} \in\}$

(47) $\text{PATH} \equiv \text{XCOMP}^*$

Let us finish this section with the observation that there is a subtype of lexico-semantic coordination which is not amenable to the above analysis:

[17] The complete analysis is presented in Patejuk and Przepiórkowski 2012a.

[18] For *wh*-phrases (47) is extended to allow for extraction from sentential complements: $\text{PATH} \equiv \text{COMP}^* \; \text{XCOMP}^*$, to account for examples such as *Kto i kogo chciałeś, żeby zaprosił?* 'Who did you want to invite whom?', lit.: 'who and whom you-wanted that invite.FIN'.

(48) Nie wiadomo było, czy *(i) kiedy wróci.
NEG know was whether and when returns
'It was not clear whether and when (s)he would return.' (NKJP)

As indicated by the asterisk and the parentheses, this example is ungrammatical once the conjunction *i* is omitted. Moreover, the meaning of the embedded question is biclausal: 'It was not clear whether (s)he would return, and – if (s)he did – when (s)he would return.' Such cases, where the first conjunct in the lexico-semantic coordination is the question particle *czy*, are handled by the following c-structure rule:[19]

(49) $\text{XPlexsem-bi}_{wh} \rightarrow \underset{\downarrow\in\uparrow}{\text{PART}_{wh}} \; [, \; \underset{\downarrow\in\uparrow}{\text{XPextr}_{wh}}]^* \; \text{CONJ} \; \underset{\downarrow\in\uparrow}{\text{XPextr}_{wh}}$

The crucial difference between (41) and (49) is that f-structures of the conjuncts in the latter are not identified with the mother, but become elements of the set representation of the mother; cf. the representation of the conjuncts in (50) and the resulting coordination in (51).

(50) a. $\left[\text{CLAUSE-TYPE} \quad \text{INT}\right]$

b. $\left[\text{ADJ} \quad \left\{\left[\text{PRED} \quad \text{'WHEN'}\right]\right\}\right]$

(51) $\left\{\left[\text{CLAUSE-TYPE} \quad \text{INT}\right], \left[\text{ADJ} \quad \left\{\left[\text{PRED} \quad \text{'WHEN'}\right]\right\}\right]\right\}$

When (51) is unified with the rest of the utterance, a biclausal coordinate structure results, as illustrated in (52):

(52) $\left\{\left[\begin{array}{l}\text{PRED} \quad \text{'RETURN}\langle\boxed{1}\rangle\text{'} \\ \text{SUBJ} \; \boxed{1} \quad \left[\text{PRED} \quad \text{'PRO'}\right] \\ \text{CLAUSE-TYPE} \quad \text{INT}\end{array}\right], \left[\begin{array}{l}\text{PRED} \quad \text{'RETURN}\langle\boxed{1}\rangle\text{'} \\ \text{SUBJ} \quad \boxed{1} \\ \text{ADJ} \quad \left\{\left[\text{PRED} \quad \text{'WHEN'}\right]\right\}\end{array}\right]\right\}$

8 Towards evaluation

As mentioned in the Introduction, coordination is textually frequent, so any parser should be able to handle it. But exactly how frequent is it?

There are two balanced subcorpora within the National Corpus of Polish: one – let us call it NKJP1M – is manually annotated and contains around 1 million words, another one – NKJP250M – contains 250 million words tagged automatically. As shown in Table 1, depending on which subcorpus is used to gather statistics, between 37.5% and 38.7% of all sentences involve coordination, which amply justifies the claim advanced in the Introduction.

It is considerably more difficult to estimate how many of these coordinate structures involve unlike categories. Instead, let us concentrate on cases of lexico-semantic coordination, which are easier to find automatically. Of these, undoubtedly the most frequent – and the ones most readily noticed in the linguistic literature – are cases of coordination of *wh*-phrases, as in (35) and (39) above. This subtype of lexico-semantic coordination is especially important in NLP, for example, in question answering, where Polish users will naturally use such constructions.

[19] There are examples where the question particle is the last conjunct. Handling these requires simple modifications.

corpus	# of sentences	# of conjunctions	# of sentences containing conjunctions	% of sentences containing conjunctions
NKJP1M	85 663	44 841	32 147	37.5
NKJP250M	18 625 185	10 455 657	7 210 648	38.7

Table 1: The number of conjunctions and the percentage of sentences containing conjunctions in balanced subcorpora of the National Corpus of Polish.

In NKJP250M, there are 272 results of the query '`Kto [orth="i|lub|oraz|albo"] [orth!=co/i]`', where *kto* means 'who' (nominative), *i*, *lub*, *oraz* and *albo* are the most frequent conjunctions, and *co* means 'what' (nominative or accusative); the last part of this query ensures that structures like *Kto i co*, i.e., possibly involving two nominative phrases, are not among the reported results.[20] Compared to over 18 million sentences of NKJP250M, this number seems to be infinitesimal, but note that this is only one subtype of *wh*-lexico-semantic coordination; *Gdzie i...* 'where and...' occurs 157 times, *Komu i...* 'who.DAT and' occurs 47 times, etc.[21] These numbers are sufficiently large to show that this is not a marginal construction in Polish.

The LFG grammar of Polish (Patejuk and Przepiórkowski, 2012b), which includes the analysis of coordination sketched above, is implemented in the XLE system developed at PARC.[22] It is based on two previous implemented grammars of Polish: its c-structure is based on a DCG (Warren and Pereira, 1980) grammar used by the parser Świgra (Świdziński, 1992; Woliński, 2004, 2005), while its f-structure is inspired by an HPSG grammar (Przepiórkowski et al., 2002; Marciniak et al., 2003). The quality of the grammar is ensured in a two-fold way: using treebank testing, but also verifying the linguistic coverage against manually constructed testsuites.

The former takes the form of reparsing Składnica (Woliński et al., 2011), a treebank of Polish containing parses for sentences extracted from the manually annotated subcorpus of the National Corpus of Polish and parsed using Świgra. The treebank coverage of the LFG grammar amounts to 90%. Unfortunately, the current version of Składnica contains sentences which were relatively unproblematic for Świgra and for human annotators, i.e., it is skewed towards simple and short sentences. In particular, coordination is underrepresented in general (1869 out of 8227 sentences, or 22.7%, contain conjunctions), and no cases of lexico-semantic coordination were found by the authors.[23] The complete NKJP1M, from which Składnica draws its sentences, does contain instances of lexico-semantic coordination, e.g., *Kto i dlaczego boi się prywatyzacji?* 'Who and why is afraid of privatisation?'.

While Składnica currently contains good parses for 8227 sentences, it contains many more sentences for which human annotators could not identify a good parse among the trees

[20] The query syntax is described in more detail at `http://nkjp.pl/poliqarp/help/en.html`.

[21] Also note that such queries only find cases of coordination of two *wh*-phrases, while – as expected – it is possible to coordinate more of them, as in the attested (NKJP) *Gdzie, jak i za ile będą się bawić*, lit. 'Where, how and for how much will they have fun'. Since the first word is capitalised, such queries also do not target embedded questions.

[22] Maxwell and Kaplan 1996; `http://www2.parc.com/isl/groups/nltt/xle/`

[23] The treebank search engine available at `http://nlp.ipipan.waw.pl:8000/ui.xhtml` has been employed, and queries such as '`[base = /kto/ & orth = /K.*/]`' were given, which should find any capitalised form of the pronoun KTO 'who'. Out of 39 sentences beginning with a form of KTO, 57 beginning with a form of CO 'what', 22 beginning with KIEDY 'when', 21 beginning with DLACZEGO 'why' and 5 beginning with GDZIE 'where', none contained lexico-semantic coordination.

generated by the DCG grammar. It is hoped that extensions related to coordination, including the two described above, make it possible to parse sentences which have been rejected so far due to the limitations of the previous grammar and its valence dictionary, which did not take coordination of unlikes into consideration.

The other method of testing relies on constructed sentences: currently there are over 1200 items which provide a means of comprehensive grammar testing, making it possible to test a wide range of phenomena, ensuring proper handling of fundamental issues, but also giving an opportunity to test very sophisticated phenomena where complex interactions between various areas of the grammar are involved. Also, while treebank testing is limited to positive examples exclusively, there are numerous negative examples among constructed testsuite items. This testsuite is currently being extended with examples of unlike and lexico-semantic coordination, so no quantitative results can be cited here (they should be available by the time of COLING 2012), but the grammar correctly parses any sentences involving such difficult instances of coordination that we have come across.

Conclusion

While currently a niche activity in NLP, grammar engineering is actively pursued and finds high-profile applications, such as the use of the English LFG grammar in Microsoft's Bing search engine.[24] Since coordination is textually very frequent, any self-respecting grammar should allow for a comprehensive treatment of this phenomenon. The analysis presented above, taking into account not only run of the mill cases of coordination, but also coordination of unlike and very unlike constituents, is implemented within a large LFG grammar of Polish.

It must be stressed, however, that – although the details of the interaction of coordination with case assignment and other phenomena vary from language to language – the general mechanisms described in sections 4–7 seem to be applicable to any language. In particular, coordination of unlikes has been by now reported for many languages, syntactic case assignment mechanisms which interact with coordination can be observed in Slavic, Baltic and Finno-Ugric languages (to limit ourselves to European languages), and lexico-semantic coordination has been described for French, Hungarian, Romanian and a number of Slavic languages.

Due to space constraints, many aspects of the implementation of coordination in the LFG grammar of Polish have been omitted here. Probably the most important is agreement between the verb (or, more generally, a predicate) and its coordinated subject, but also the interesting phenomenon of single conjunct agreement. However, unlike coordination of unlikes, these phenomena already have established accounts in the LFG literature, e.g., Dalrymple and Nikolaeva 2006, Kuhn and Sadler 2007 and Dalrymple et al. 2009, and their standard analyses are implemented in the current grammar. The first stable version of the grammar will be made publicly available by the end of January 2013 at `http://zil.ipipan.waw.pl/LFG`.

ABSTRACT
Current state-of-the-art Statistical Machine Translation systems are based on log-linear models that combine a set of feature functions to score translation hypotheses during decoding. The models are parametrized by a vector of weights usually optimized on a set of sentences and their reference translations, called development data. In this paper, we explore a (common and industry relevant) scenario where a system trained and tuned on general domain data needs to be adapted to a specific domain for which no or only very limited in-domain bilingual data is available. It turns out that such systems can be adapted successfully by re-tuning model parameters using surprisingly small amounts of parallel in-domain data, by cross-tuning or no tuning at all. We show in detail how and why this is effective, compare the approaches and effort involved. We also study the effect of system hyperparameters (such as maximum phrase length and development data size) and their optimal values in this scenario.

TITLE AND ABSTRACT IN CZECH

Jednoduchá a efektivní optimalizace parametrů pro doménovou adaptaci statistického strojového překladu

Současné systémy statistického strojového překladu jsou založeny na logaritmicko-lineárních modelech, které pro hodnocení překladových hypotéz ve fázi dekódování kombinují sadu příznakových funkcí. Tyto modely jsou parametrizovány vektorem vah, které se optimalizují na tzv. vývojových datech, tj. množině vět a jejich referenčních překladů. V tomto článku se zabýváme (často a pro průmyslové nasazení relevantní) situací, kdy je třeba překladový systém natrénovaný na datech z obecné domény adaptovat na nějakou specifickou doménu, pro kterou jsou k dispozici paralelní data jen ve velice omezeném (či žádném) množství. Ukazujeme, že takové systémy mohou být vhodně adaptovány pomocí optimalizace parametrů za použití jen překvapivě malého množství paralelních doménově-specifických dat nebo tzv. křížovou optimalizací. Možností je také nepoužití optimalizace vůbec. Jednotlivé přístupy analyzujeme a porovnáváme jejich cekovou náročnost. Dále se zabýváme analýzou systémových hyperparametrů (např. maximální délkou frází a velikostí vývojových dat) a jejich optimalizací.

KEYWORDS: machine translation, domain adaptation, parameter optimization.

KEYWORDS IN CZECH: strojový překlad, doménová adaptace, optimalizace parametrů.

1 Introduction

Statistical Machine Translation (SMT) is an instance of a machine learning application and, in general, will work best if the data for training and testing are drawn from the same distribution (i.e. domain, genre, and style). In practice, however, it is often difficult to obtain sufficient amounts of in-domain data (in particular parallel data required for translation and distortion models) to train a well performing system for a specific domain.

Recently, Pecina et al. (2011) showed that just using in-domain development data for parameter tuning improves output quality of a Phrase-Based SMT (PB-SMT) system trained on general--domain data but applied to a specific domain. Although further additional improvements can be realized by using in-domain parallel and/or monolingual training data, parameter tuning on in-domain data requires only a relatively small set of parallel sentences, which is often easier to obtain. They report on a series of experiments carried out on the domains of Natural Environment (*env*) and Labour Legislation (*lab*) and two language pairs: English–French and English–Greek (both directions) and observe a substantial average relative improvement of 25% in terms of BLEU (Papineni et al., 2002) when switching from general-domain to in-domain tuning.

In this paper, we corroborate the results reported by Pecina et al. (2011), carrying out similar experiments on the domain of medical texts (*med*). In contrast to earlier work, we explain the improvements brought about by specific domain tuning by analysing the results in detail. In a nutshell: domain tuning for matching-domain training, tuning and test data results in feature vectors that trust (often long) translation table entries, while tuning with and for specific domains (while using generic training data) allows the MT system to stitch together translations from smaller bits and pieces with significantly more reordering, effectively undoing or "de--tuning" any previous optimizations. In a sense, this is natural: substantial divergence between test and training data means that in particular long and potentially high quality phrase pairs obtained in training may no longer be applicable to the test data and that this divergence can only be bridged by smaller translation units and more flexible recombination. Furthermore, our findings show that in the general-domain training and specific-domain test scenario, approaches that do not perform any parameter tuning (at all) or that tune on other specific development sets may in fact fare better than tuning on general-domain data. In addition, there is a question of how much specific-domain tuning data is in fact required to "de-tune" a general domain system to a specific domain. Finally, given the fact that a general-domain system can only use limited length translation units when translating specific-domain data, we explore limited length training and decoding.

After a brief overview of the log-linear model including its parameter optimization and an overview of the state-of-the-art in domain adaptation for SMT, we describe our experiments, present the results, the analysis, explore the resulting research questions with additional experiments, and conclude.

2 Phrase-Based Statistical Machine Translation

In PB-SMT, implemented e.g. in Moses (Koehn et al., 2007), an input sentence is segmented into sequences of consecutive words, called phrases. Each phrase is then translated into a target language phrase, which may be reordered with other translated phrases to produce the output.

Formally, the model is based on the noisy channel model. The translation **e** of an input sentence **f** is searched for by maximizing the translation probability $p(\mathbf{e}|\mathbf{f})$ formulated as a log-linear combination of a set of feature functions h_i and their weights λ_i:

$$p(\mathbf{e}|\mathbf{f}) = \prod_i^n h_i(\mathbf{e},\mathbf{f})^{\lambda_i}$$

Typically, the components include features of the following models: *phrase translation model*, which ensures that the source and target phrases are good translations of each other (e.g. direct and inverse phrase translation probability, direct and indirect lexical weighting, and phrase penalty), *language model*, which ensures that the translations are fluent, *reordering* (*distortion*) *model*, which allows to reorder phrases in the input sentences (e.g. distance-based and lexicalized reordering) and *word penalty*, which prevents the translations from being too long or too short. These models are trained on either parallel or monolingual training data.

The weights of the log-linear combination influence overall translation quality; however, the optimal setting depends on the translation direction and data. A common solution to optimise weights is to use Minimum Error Rate Training (MERT), proposed by Och (2003), which automatically searches for the values that minimize a given error measure (or maximize a given translation quality measure) on a development set of parallel sentences. Theoretically, any automatic measure can be used for this purpose; however, the most commonly used is BLEU (Papineni et al., 2002). The search algorithm is a type of coordinate ascent: considering n-best translation hypotheses for each input sentence, it updates the feature weight most likely promising to improve the objective and iterates until convergence. The error surface is highly non-convex and as the algorithm cannot explore the whole parameter space, it may converge to a local maximum; in practise, it often produces good results (Bertoldi et al., 2009).

3 Domain adaptation in Statistical Machine Translation

Domain-adaptation is a very active research topic within the area of SMT. Three main topics can be identified: (i) combination of in-domain and out-of-domain resources for training, (ii) training data selection, and (iii) acquisition of specific-domain data. Below we briefly review a selection of relevant work that falls into these topics.

The first attempt to perform domain adaptation was carried out by Langlais (2002), who integrated in-domain lexicons in the translation model. Koehn and Schroeder (2007) integrate in-domain and out-of-domain language models as log-linear features in Moses. Nakov (2008) combines in-domain translation and reordering models with out-of-domain models. Finch and Sumita (2008) use a probabilistic mixture model combining two models for questions and declarative sentences with a general model.

Training data selection is another approach to domain-adaptation. The assumption is that a general-domain corpus, if sufficiently broad, includes sentences that resemble the target domain. Eck et al. (2004) present a technique for adapting the language model by selecting similar sentences from available training data. Hildebrand et al. (2005) extended this approach to the translation model. Foster et al. (2010) weigh phrase pairs from out-of-domain corpora according to their relevance to the target domain.

Munteanu and Marcu (2005) extract in-domain sentence pairs from comparable corpora. Daumé III and Jagarlamudi (2011) attempt to reduce out-of-vocabulary terms when targeting a specific domain by mining their translations from comparable corpora. Bertoldi et al. (2009) rely on large in-domain monolingual data to create synthetic parallel corpora for training.

Table 1: Statistics of the training, development and test data sets from the domains used in the experiments including the number of sentence pairs, tokens, and vocabulary size (*voc*).

Pecina et al. (2011) exploit automatically web-crawled in-domain resources for parameter optimization and improving language models. Pecina et al. (2012) extend the work by using the web-crawled resources to also improve translation models.

4 Experimental setup

Our experimental setup follows and extends the one used in Pecina et al. (2011). In addition to the two evaluation domains (*env*, *lab*) used in that work, and in order to corroborate their earlier findings, we also carry out experiments on medical domain data (*med*).

4.1 Data

Our general-domain system is trained on the Europarl parallel corpus (Koehn, 2005, v5) extracted from the proceedings of the European Parliament and for the purposes of this work considered to contain general-domain texts (it covers a very broad range of topics and it is to a considerable extent spoken language). The general-domain development and test data used for parameter optimization and testing, respectively, are adopted from the WPT 2005[1] machine translation shared task. These sets were extracted from the same source as Europarl and contain 2,000 sentence pairs each.

The specific-domain development and test data for the *env* and *lab* domains were acquired by domain-focused web-crawling within the PANACEA project[2] and are available from the ELRA catalogue[3] under reference numbers ELRA-W0057 and ELRA-W0058. The entire acquisition procedure is described in detail in Pecina et al. (2011). The test sets consist of 2,000 sentence pairs each and the amount of sentence pairs in the development sets varies from 506 to 2,000.

Table 2: Results (in BLEU) of the systems tuned on general-domain and tested on the specific domains (*env*, *lab*, *med*) compared with the results on the general domain (*gen*); the figures in italics indicate the relative change (in percentage).

The *med* development and test data were extracted from the EMEA parallel corpus of texts from the European Medicines Agency, distributed as a part of the OPUS corpus (Tiedemann, 2009). A set of 3,500 parallel sentences in English, French, and Greek was randomly sampled from the sentence-aligned corpus data and manually checked for translation quality. Correct sentences were left untouched, sentences with minor errors were corrected, and those which required major corrections or were misaligned were discarded completely. We aimed at acquiring at least 3,000 correct sentence pairs: 2,000 for the test sets and the rest for the development sets. Finally, the test and development sets contained 2,000 and 1,064 sentence pairs respectively. All data sets used in our experiments contain one reference translation. Statistics are given in Table 1.

4.2 System description

Our MT system is based on the Moses PB-SMT system (Koehn et al., 2007). For training, all data sets are tokenized and lowercased using the Europarl tools. The original (non-lowercased) target side of the parallel data is kept for training the Moses recaser. The lowercased versions of the target side are used for training an interpolated 5-gram language model with Kneser-Ney discounting using the SRILM toolkit (Stolcke, 2002). Translation models are trained on the Europarl corpus, lowercased, and filtered on sentence level; we kept all sentence pairs having less than 100 words on each side and with length ratio within the interval $\langle 0.11, 9.0 \rangle$. The maximum length for aligned phrases is set to seven and the reordering models are generated using the following parameters: *distance, orientation-bidirectional-fe*. The resulting system combines 14 feature functions, listed below.

1. distance reordering score
2-7. lexicalised reordering scores
8. language model score
9. inverse phrase translation probability
10. inverse lexical weighting
11. direct phrase translation probability
12. direct lexical weighting
13. phrase penalty
14. word penalty

The corresponding parameters are optimized on the development sets by MERT. For decoding, test sentences are tokenized and lowercased. After translation, letter casing is reconstructed by the recaser and extra blank spaces are removed in order to produce human-readable text.

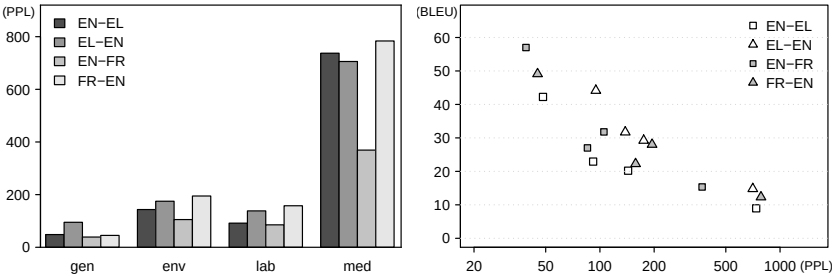

Figure 1: Perplexity (PPL) of the source side of the test sets given the language models trained on the source side of the training sets (left). Perplexity of the source side of the test data versus BLEU scores of the corresponding systems tuned on general-domain development data (right).

5 Experiments

Translation quality in our experiments is automatically evaluated using BLEU (Papineni et al., 2002) and all BLEU scores are reported as percentages.

5.1 Baseline system performance

Performance of the baseline system trained and tuned on the general-domain data and tested on the same domain varies from 42.24 to 57.00 (row 1 in Table 2). Applying the baseline general--domain system on the specific-domain data leads to significant degradation of translation quality (Banerjee et al., 2010; Wu et al., 2008). Pecina et al. (2011) reported an average decrease of 44.3% when the general-domain system was applied to the *env* and *lab* domains (see rows 2–3 in Table 2). Our experiments on the *med* domain show even more pronounced decrease: e.g. in case of the English–French translation, BLEU drops from 49.12 to 12.32; for English–Greek the change is from 42.24 to 8.96; other translation directions produce similar results. The average decrease for all directions on the *med* domain is 73.33% relative – the domain divergence between the training and test data from this domain is even more pronounced than in the case of the other two domains. The average decrease taken over all translation directions and all the domains is 53.97% relative.

5.2 Measuring domain divergence

From the results presented above, it is evident that the translation quality of a particular test set depends on the extent to which its domain differs from the domain of the training data. Quality is maximal when the domains match and decreases when the test data diverges from the training data. To quantify this observation, we measure cross perplexity of the test data given the training data. For each domain and translation direction, a language model of the same order as the maximum phrase length (7) used in the SMT systems is trained on the source side of the training data and applied to the source side of the test data. The results are presented in Figure 1 (left).

As expected, the perplexity of the general domain test sets is the lowest. It ranges from 40 to 90 depending on the language. In case of the *env* and *lab* domains, perplexity is slightly higher: on the *env* data it ranges from 100 to 190 and on the *lab* data from 80 to 160. Not surprisingly,

test	*dev*	*English–French*		*French–English*		*English–Greek*		*Greek–English*	
env	*gen*	28.03	*0.00*	31.79	*0.00*	20.20	*0.00*	29.23	*0.00*
	env	35.81	*+27.76*	39.04	*+22.81*	26.18	*+29.60*	34.16	*+16.87*
lab	*gen*	22.26	*0.00*	27.00	*0.00*	22.92	*0.00*	31.71	*0.00*
	lab	30.84	*+38.54*	33.52	*+24.15*	28.79	*+25.61*	37.55	*+18.42*
med	*gen*	12.32	*0.00*	15.33	*0.00*	8.96	*0.00*	14.79	*0.00*
	med	18.47	*+49.92*	24.42	*+59.30*	14.57	*+62.61*	18.10	*+22.38*
average			*+38.74*		*+35.42*		*+39.28*		*+19.22*

Table 3: The effect (measured by BLEU) of general-domain (*gen*) and in-domain (*env*, *lab*, *med*) tuning. The figures in italics indicate relative improvement (in percentage) obtained from using in-domain development data for optimization (with respect to tuning on general-domain data).

the perplexity scores obtained on the *med* domain are substantially higher; for most language directions they exceed 700. The only exception is the French–English test set, for which the score is as low as 370. This higher drop is consistent across the other domains (compare the yellow bars with other language pairs in Figure 1, left) and in line with the higher decrease of translation quality for this domain in terms of BLEU (see Section 5.1).

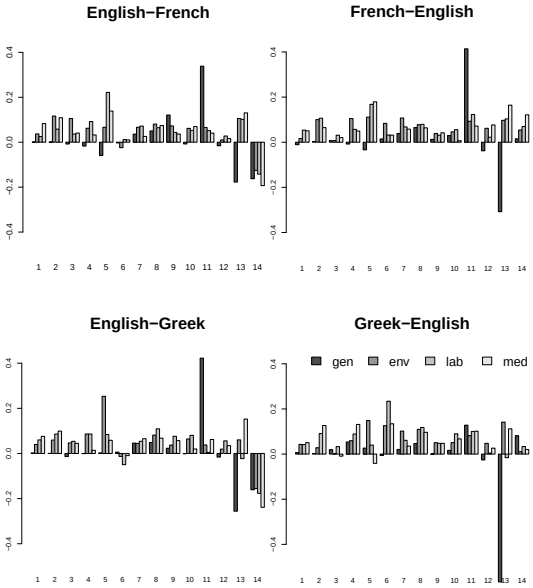
To complete the picture, we directly compare the perplexity scores with the translation quality measured by BLEU and provide a plot in Figure 1 (right). It is quite obvious that the perplexity scores on the logarithmic X axis (PPL) are highly correlated (inversely) with the BLEU scores on the Y axis. Higher perplexity indicates lower translation quality. This finding is in line with previous research on translation confidence estimation (Specia et al., 2011; He et al., 2010).

5.3 Parameter tuning on specific-domain development data

The baseline systems trained and tuned on general-domain data perform much worse on specific domains. Pecina et al. (2011) reported that a surprisingly significant amount of loss can be recovered by tuning on in-domain development data. The average relative improvement measured on the *env* and *lab* domains reported in this work was 25.5%. Our results, including those on the *med* domain, confirm the previous findings (see Table 3). The average relative improvement of BLEU e.g. in English–French translation is 38.74%. Similar improvements are obtained on French–English and English–Greek. Slightly lower improvements were achieved on Greek–English, 19.22% on average. The overall average increase of BLEU is 33.16% relative. Given that the development sets contain only several hundred sentence pairs each, such improvement is remarkable.

5.4 Analysis of model parameters

The only component that changes when the system is tuned on in-domain data are the weights of the feature functions in the log-linear model optimized by MERT. The reordering, language, and translation models all remain untouched (trained on general-domain data). Recall that the parameter space searched through by MERT is large and the error surface highly non-convex, therefore the resulting weight vectors might not be globally optimal and there might be other (i.e. different) weight vectors which perform equally well or even better. For this reason, the actual parameter values are not usually investigated. However, our experiments (Figure 2, left) show that the parameter values and their changes observed when switching from general--domain to specific-domain tuning are in fact highly consistent, indicating interesting trends.



EN–FR	*gen*	*env*	*lab*	*med*

Figure 2: Visualization of model weights of the four systems in the twelve evaluation scenarios; the black bars refer to model weights of the systems tuned on general-domain (*gen*) development sets while the grey bars refer to the model weights of the systems tuned on specific-domain development sets (*env*, *lab*, *med*) (left). Cosine similarity of the system feature vectors (right).

First, we analyse parameters of the systems tuned on the general-domain data (black bars):

1. The high weights assigned to h_{11} (*direct phrase translation probability*) indicate that the phrase pairs in the systems' translation tables apply well to the development data which are from the same domain as the training data; a high reward is given to translation hypotheses consisting of phrases with high translation probability (i.e. good general--domain translations).
2. The low negative weights assigned to h_{13} (*phrase penalty*) imply that the systems prefer hypotheses consisting of fewer but longer phrases.
3. Reordering in the hypotheses is not rewarded (weights of the reordering models h_1–h_7 are assigned values around zero). In some cases (e.g. for English–French and French–English), reordering is even slightly penalized (some weights of h_1–h_7 are negative).
4. The weight of h_{14} (*word penalty*) is negative for translations from English and slightly positive for translations to English. This reflects the fact that translation from English prefers shorter hypotheses and translation to English prefers longer hypotheses.

test	*dev*	*EN–FR*	*FR–EN*	*EN–EL*	*EL–EN*	*Average*
gen	*gen*	4.37	3.46	3.76	2.35	3.49

	def	2.33	2.12	2.12	2.03	2.15
	env	2.16	1.77	2.17	1.54	1.91
lab	*gen*	2.82	2.45	2.97	2.43	2.67
	def	2.24	2.09	2.30	2.21	2.21
	lab	2.05	1.83	2.46	2.30	2.16
med	*gen*	2.00	1.71	1.74	1.43	1.72
	def	1.62	1.52	1.47	1.41	1.51
	med	1.54	1.20	1.38	1.21	1.33

Table 4: Average phrase lengths in translations of all test sets (in all directions) by systems tuned on general (*gen*) and specific domains (*env*, *lab*, *med*) and with the default weights (*def*).

Now, we compare these findings with the systems tuned on the specific domains (grey bars).

1. The weights of h_{11} (*direct phrase translation probability*) decrease rapidly, in some scenarios this weight is very close to zero. The translation tables do not provide enough good quality translations for the specific domains and the best translations of the development sentences consist of phrases with varying translation probabilities.
2. Hypotheses consisting of few (and long) phrases are not rewarded anymore (weights of h_{13} are higher); in most cases they are penalized and hypotheses consisting of more (and short) phrases are allowed or even preferred.
3. In almost all cases the reordering feature weights (features h_1–h_7) increased substantially and for specific-domain data the model significantly prefers hypotheses with altered word order (which is consistent with the two preceding observations).
4. Language model weights (h_8) do not change substantially, its importance remains similar on general-domain and specific-domain data.

These findings are highly consistent across domains and language pairs. The weight vectors of the systems tuned on specific-domain data are quite similar but differ substantially from the parameters obtained by tuning on general-domain. This observation can be quantified by measuring cosine similarity (see Figure 2, right) as proposed by Hopkins and May (2011). Lower scores, as in the first rows/columns of each table, indicate low similarity of the vectors – specific-domain tuned weights differ a lot from the general-domain tuned ones; and vice versa – specific-domain tuned parameters are quite similar when compared to each other.

5.5 Analysis of phrase-length distribution

From the analysis presented above, we conclude that a PB-SMT system tuned on data from the same domain as the training data strongly prefers to construct translations consisting of long phrases. Such phrases are usually of good translation quality (local mistakes of word alignment disappear), fluent (formed by consecutive sequences of words), and recurrent (frequent in data from the same domain); therefore they form good translations of the input sentences and are preferred during decoding. This is, of course, a positive behaviour when the system translates sentences from the same domain. However, if this is not the case and the input sentences contain no or very few longer phrases from the translation tables, the system is not able to construct good translations from shorter phrases.

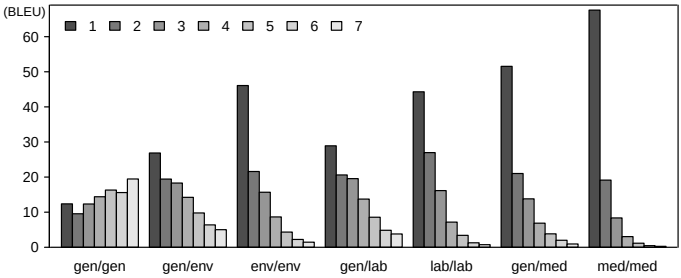

Figure 3: Phrase-length distribution in English–French translations by systems tuned and tested (*dev*/*test*) on various combinations of general (*gen*) and specific (*env*, *lab*, *med*) domains.

To support this hypothesis we analyse the phrase length distribution actually seen in the translation of the test sets. The average phrase lengths estimated for various combinations of tuning and test domains and all language pairs are shown in Table 4. The highest values are observed for translations of general-domain test sets by systems tuned on the same domain: 3.49 on average across all language pairs. The scores for systems trained on general and tuned and tested on specific-domain data are significantly lower and range from 1.21 to 3.00, depending on the domain and language pair. Figure 3 presents complete phrase-length distribution in English–French translations by systems tuned and tested on various combinations of general and specific domains. Generally, a higher divergence of the test domain from the training domain leads to shorter phrases being used in translation. However, when the systems tuned on general-domain are applied to specific domains, the average phrase lengths are consistently longer than for specific-domain tuning. The systems are tuned to prefer long phrases (Table 4) but the translation quality is lower (Table 3). This situation can be interpreted as overtraining, the model overfits the training (and tuning) data and on different data fails to form the best possible translations (given the translation, reordering, and language models).

5.6 Overfitting reduction

The optimal solution in case of such overfitting is to employ a sufficient amount of specific--domain development data, effectively tuning the system to using shorter phrases (see Figure 3). However, if such tuning data is not available (which is quite a realistic scenario in many applications) we explore the following alternatives: simply side-step parameter tuning (no tuning at all), or tune on a different domain, or use smaller amounts of development data, or reduce the maximum phrase length in decoding. All these methods work surprisingly well and are discussed in the following subsections.

5.6.1 No parameter tuning

Essentially, there are two options how to set the weight vectors without tuning. Either we can use the default weights set by Moses ($h_{1,\ldots,7} = 0.3$, $h_8 = 0.5$, $h_{9,\ldots,13} = 0.2$, $h_{14} = -1$) or a flat vector ($h_{1,\ldots,14} = 1$). We explored both options and the results are given in Table 5 (see the rows denoted *def* and *flat*, respectively, in the development data column). In all scenarios, both options outperform the systems trained and tuned on general-domain data. In some cases (e.g. English–Greek translations in all the specific domains), the results are very close

Table 5: Translation quality (in BLEU) of the general-domain systems tuned and tested on various domains. The figures in italics indicate relative improvement (in percentage) over the system tuned on general domain. The figures in bold denote the best performing combination for each test domain and translation direction and those which are not significantly different (Koehn, 2004, $p = 0.05$).

to those of systems tuned on specific-domain data. The overall average relative improvement of the systems with default parameters over the systems tuned on general domain is 24.75% (compare with 33.16% obtained from specific-domain tuning). The average phrase length in translations produced by such systems falls between the scores of general-domain-tuned and specific-domain-tuned systems (see rows with *def* in the development data column in Table 4). The systems with the flat weight vectors achieve an average relative improvement of 21.70%. However, they outperform the systems with the default parameters always when the translation direction is to English; the systems with the default parameters are better when translating from English.

5.6.2 Cross-domain tuning

It seems that the problem of the overfitted general-domain models and their poor performance on specific domains can be reduced by "diverting" the systems away from the general domain they are tuned to translate – but not necessarily towards a particular specific domain. To analyse this hypothesis we perform "cross-domain" tuning, i.e. tuning on specific domains different from the test domains. The results are shown in Table 5 (see the rows where the test and development domain do not match). In all scenarios the cross-domain tuned system performs better than the un-tuned ones. In a few cases the systems tuned on a cross domain perform even better than the in-domain ones: e.g. the EN–FR system tuned on the *lab* domain and tested on the *env* and *med* domains or the EL–EN system tuned on the *env* domain and tested on the *lab* domain, however, in most such cases the improvement is not statistically significant. The overall average relative gain over the systems tuned on general domain is 27.62% (compare with 24.75% obtained from no tuning and 33.16% from in-domain tuning).

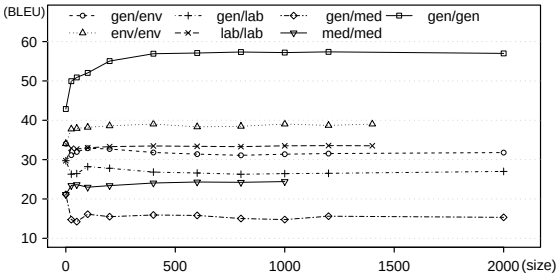

Figure 4: Translation quality (BLEU) of French–English systems tuned on data of varying size.

Similar results were observed also on mixtures of two domains (e.g. tuned on *lab+env* and tested on *med*). In general, we can conclude that cross-domain tuning is a reasonable solution when no in-domain development data is available (and the domains differ in a similar way).

5.6.3 Tuning on small development data

In the previous two scenarios we did not use any specific-domain development data for tuning, but were able to get very close to the performance of the systems tuned on a specific domain. Specific-domain parallel data is scarce, for many domains not available at all and must be prepared by manual translation of monolingual in-domain sentences. We investigate how much development data is needed. The only technical requirement is that MERT, the parameter optimization method, must converge in a reasonable number of iterations. For this reason, typical development sets contain about 1,000 – 2,000 sentence pairs (compare e.g. the size of development sets provided for the WMT[4] translation shared tasks). We vary the amount of sentences in our development sets, tune the systems, test their performance on the test sets and plot learning curves to capture the dependency of translation quality (in terms of BLEU) against gradually increasing the size of development data.

The general shapes of the curves are consistent across all translations (and domains) and thus we provide the curves for the English–French translation direction only (see Figure 4). Increasing the size of development sets is beneficial only in case the domains of development and test data are the same. The curve of the system tuned and tested on the general domain reaches a plateau for about 500 sentence pairs. In case of in-domain tuning for specific domains, the plateau is reached much earlier. Usually, as few as 100–200 sentence pairs are enough to get optimal results. This is encouraging, as tuning on specific-domains yields best results and fortunately requires only very limited amounts of bilingual data (and expense). Development sets of more than 400–600 sentences pairs do not improve translation quality at all and make the tuning process take longer. The systems tuned on the general domain and tested on specific domain do not benefit from the development data at all. The relatively high BLEU scores achieved with no tuning (zero development data size) decrease with increasing size of the development sets.

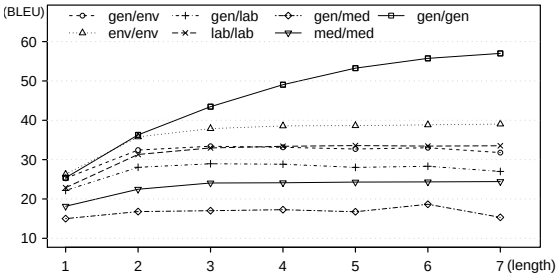

Figure 5: Translation quality (BLEU) of French–English systems with varying max phrase length.

5.6.4 Limiting phrase length

In the last experiment presented in this paper we limit the maximum phrase length allowed during training and decoding and study how system performance changes. The systems tuned on general-domain prefer longer phrases which, however, do not occur frequently in the specific--domain test sets. Our baseline systems, trained and tuned on general domain with maximum phrase length set to seven, translate general-domain test sets with an average phrase length of 3.49 (see Table 4). However, for the systems tuned and tested on in-domain data, this score is as low as 1.80. Figure 5 illustrates how the translation quality changes when the maximum phrase length varies from one to seven. The only case when longer phrases improve translation quality is for the systems trained, tuned and tested on the same (general) domain. In all other cases, the results for phrases up to three words long are as good as for longer phrases. If the domain of the test data does not match the domain of training and tuning data, the maximum phrase length set to three is enough in all scenarios. Longer phrases lead to degradation of translation quality and increase time for training and decoding, as well as memory requirements for building and storing the translation models. A similar result was reported already by Koehn et al. (2003). They observed that limiting the maximum length of a phrase to only three words achieved top performance. However, current state-of-the-art SMT systems usually benefit from longer phrases than three (see e.g. the top curve in Figure 5 which refers to a general-domain system applied to a general-domain test set), and our result applies only to scenarios where the training and test domains do not match; in that case setting the maximum phrase length to three is sufficient.

6 Conclusions

In this work, we have analysed domain adaptation of PB-SMT by tuning parameters of the underlying log-linear model. We confirmed the observation from previous research that systems trained and tuned on general domain perform poorly on specific domains. This finding is not very surprising, but the amount of loss and the fact that it is observed consistently in many evaluation scenarios was unexpected. We found that perplexity of the source side of the test data given the source side of the training nicely correlates with the translation quality.

Further, we confirmed that tuning the systems trained on general domain on specific target domain data recovers a (often) spectacular amount of the loss. We carried out a detailed analysis of the model parameters and phrase length distribution in translations of the test data and found that a system trained and tuned on general domain strongly prefers long and few

phrases in the output translations and therefore underperforms on specific domains where such phrases do not occur frequently. By contrast, the same systems tuned on specific-domain data form output translations from shorter phrases, allow more reordering and perform significantly and consistently better on specific domain data.

We investigated possible solutions for (common) scenarios when no or very little in-domain data is available for parameter tuning. Skipping tuning, i.e. using the default model parameters, performs surprisingly well and always outperforms systems tuned on general domain. Based on this observation, this should be preferred over general domain tuning if the test domain differs substantially. Cross-domain tuning on a different set also offers a good solution when no in-domain development data is available, especially when the domains differ in a similar way (e.g. measured by perplexity). This step has the effect of disassembling the original general-domain system towards shorter phrases and it does not matter much which different development set to use.

The analysis of learning curves of the tuning process showed that in-domain tuning of the general-domain systems requires about 100–200 sentence pairs to achieve decent translation quality (in terms of BLEU, the gain obtained from tuning on more data was negligible). We also experimented with limiting the maximum phrase length of decoding. The results showed that setting this parameter to three is sufficient for translating data from specific domains; longer phrases in this case do not improve translation quality and increase computational requirements of the translation systems. The last two results (limiting phrase length and using sufficient amounts of development data) have efficiency implications of paramount importance in industrial application scenarios.

ABSTRACT
In most summarization approaches, sentence ranking plays a vital role. Most previous work explored different features and combined them into unified ranking methods. However, it would be imprecise to rank sentences from a single point of view because contributions from the features are onefold in these methods. In this paper, a novel supervised aggregation approach for summarization is proposed which combines different summarization methods including LexPageRank, LexHITS, manifold-ranking method and DivRank. Human labeled data are used to train an optimization model which combines these multiple summarizers and then the weights assigned to each individual summarizer are learned. Experiments are conducted on DUC2004 data set and the results demonstrate the effectiveness of the supervised aggregation method compared with typical ensemble approaches. In addition, we also investigate the influence of training data construction and component diversity on the summarization results.

KEYWORDS: Multi-document summarization, supervised aggregation framework.

Proceedings of COLING 2012: Technical Papers, pages 2225–2242,
COLING 2012, Mumbai, December 2012.

1 Introduction

Multi-document summarization aims to generate a compressed summary by extracting the major information from a collection of documents sharing the same or similar topics. With the massive explosion of information on the web, e.g., news, blogs and microblogs, multi-document summarization, as an effective solution for information explosion, provides improved mechanisms for understanding documents and reducing information overload. Therefore it has attracted considerable attention recently.

Generally speaking, summarization can be categorized into two types: extractive summarization and abstractive summarization. Extractive summarization generates summary directly by choosing sentences from original documents while abstractive summarization requires formulating new sentences according to the text content. Although abstractive summarization could be more concise and understandable, it usually involves heavy machinery from natural language processing (Hahn and Mani, 2000). In this paper, we mainly focus on extractive multi-document summarization.

In extractive summarization tasks, sentence ranking is the issue of most concern (Wei et al., 2009). A number of methods have been proposed in the literature from different aspects to rank sentences. Feature-based approaches rank sentences by exploring combination of different features of sentences such as term frequency, sentence position, length and etc. Graph-based ranking approaches aim to design different strategies to rank sentences using random walk model to capture relations between sentences, i.e., LexPageRank (Erkan and Radev, 2004), TextRank (Mihalcea and Tarau, 2004) and DivRank (Mei et al., 2010). Nowadays, some machine learning algorithms have also been applied in summarization for learning optimal feature weights automatically, for instance, some leaning to rank models (Svore et al., 2007; Jin et al., 2010; Shen and Li, 2011) have been introduced in summarization tasks.

Most previous work concentrated on exploring different features, and the features were combined in unified ranking strategies for summarization. However, to identify the importance of sentences from a single point of view would be difficult (Wong et al., 2008) because contributions from the features are onefold in these methods. To address this problem, it is natural to propose an ensemble approach which combines different summarization methods to rank the sentences. Ensemble methods have been used in a variety of applications including web search, spam detection and collaborative filtering. Specific to ranking problems, ensemble ranking or ranking aggregation methods have been widely studied in many different tasks especially in information retrieval. However, there are limited work attempts on applying ensemble methods to summarization. In (Wang and Li, 2010) and (Wang and Li, 2011), a weighted consensus method was proposed to aggregate multiple summarization methods. Although the ensemble method used in these work outperforms individual summarizers and some other combination methods, there exists a serious drawback in unsupervised methods: because the assignment of weights to different summarizers is based on the consensus, contribution from some summarizer containing inferior ranking results may lead to an inaccurate final result.

In order to deal with the drawbacks in unified ranking strategies and unsupervised aggregation methods, we propose a supervised aggregation framework for summarization in this study. Taking a summarization task as a ranking problem, we combine several different summarizers, learn the weights assigned to each summarizer with human labeled data and then rank sentences according to their combined scores. This aggregation approach generates promising results by aggregating several different summarization methods. Experiments on DUC2004

data set have been conducted and the results demonstrate the effectiveness of the proposed supervised summarization aggregation method which outperforms typical ensemble schemes under various evaluation metrics. In addition, the influence of schemes to construct training data and component diversity on the summarization results has also been investigated.

The rest of this article is organized as follows. We briefly review the related work in Section 2 and the supervised aggregation framework for summarization is introduced in Section 3. We present the supervised aggregation summarization method implementation in Section 4 and experiments are discussed in Section 5. Finally, we draw a conclusion of this study.

2 Related work

The related work will be introduced from two aspects, first we describe some representative summarization methods and then the typical work about rank aggregation are presented briefly.

2.1 Multi-document summarization

Multi-document summarization is a process to generate a summary by reducing documents in size while retaining the main characteristics of the original documents. In order to archive this goal, different features and ranking strategies have been studied.

Traditional feature-based ranking methods explored different features of sentences to score and rank the sentences. One of the most popular feature-based methods is centroid-based method (Radev et al., 2004). Radev et al. implemented MEAD as a cetroid-based summarizer by combining several predefined features including TF*IDF, cluster centroid and position to score the sentences. Lin and Hovy (Lin and Hovy, 2002) used term frequency, sentence position, stigma words and simplified Maximal Marginal Relevance (MMR) to build the NeATS multi-document summarization system. High frequent words were proved crucial in reflecting the focus of documents (Nenkova et al., 2006) and You Ouyang et al. studied the influence of different word positions in summarization (Ouyang et al., 2010).

Graph-based ranking algorithms nowadays are successfully applied in summarization and LexPageRank (Erkan and Radev, 2004) is the representative work which is based on the PageRank algorithm (Page et al., 1999). Graph-based ranking algorithms take global information into consideration rather than rely only on vertex-specific information, therefore have been proved successful in multi-document summarization. Some methods have extended the traditional graph-based models recently including multi-layer graph incorporated with different relationship (Wan and Yang, 2008), multi-modality graph based on the manifold-ranking method (Wan and Xiao, 2009) and DivRank (Mei et al., 2010) introducing the time-variant matrix into a reinforced random walk to balance prestige and diversity.

Topic model has also been exploited in summarization recently. The query Latent Dirichlet Allocation (qLDA) model was proposed in (Tang et al., 2009), and this model takes into account the query information to extract query-oriented summaries. HIRESUM model (Haghighi and Vanderwende, 2009) was presented based on hierarchical Latent Dirichlet Allocation (hLDA) to represent content specificity as a hierarchy of topic vocabulary distributions. Celikyilmaz and Hakkani-Tur also utilized a hLDA-style model to devise a sentence-level probabilistic topic model and a hybrid learning algorithm for extracting salient features of sentences to generate summaries (Celikyilmaz and Hakkani-Tur, 2010).

To date, various machine learning methods, including unsupervised and supervised methods, have been developed for extractive summarization by learning to summarize documents automatically. For instance, Shen et al. proposed a conditional random field (CRF) based method which treats summarization task as a sequence labeling problem (Shen et al., 2007). The structural SVM approach was explored in (Li et al., 2009) to enhance diversity, coverage and balance of summary simultaneously. Learning to rank (Li, 2011) methods that are widely studied in information retrieval community have been applied in summarization (Svore et al., 2007; Jin et al., 2010; Shen and Li, 2011). These studies have used different learning strategies to rank sentences for summarizing documents.

In order to identify the importance of sentences from multiple aspects, aggregation methods can be used in summarization to combine results from different summarizers. However, aggregation methods for summarization are seldom been discussed in previous work. An exception is proposed in (Wang and Li, 2011), in this study a weighted consensus summarization based on optimization was applied in summarization by aggregating four different summarization methods.

2.2 Rank aggregation

Rank aggregation is aimed at combining results of objects from multiple ranking functions to generate a better one and it has been applied into a variety of applications including information retrieval and collaborative filtering. In general, rank aggregation can be categorized into two types: order-based and score-based (Liu et al., 2007). Order-based aggregation method takes order information as input from individual rankers and score-based method utilizes ranking scores from component rankers.

In most existing unsupervised rank aggregation methods, the final ranking decisions depend on majority voting. Median rank aggregation (Van and Erp, 2000) sorts entities based on the medians of their ranks in all the ranking lists. To treat different ranking lists with different weights, Klementiev, Roth and Small proposed an unsupervised aggregation algorithm named ULARA (Klementiev et al., 2007) to learn the weights of ranking lists online by optimizing the weighted Borda count. However, as mentioned in the Introduction, a serious drawback exists in unsupervised aggregation methods, that some inferior rankers may influence the overall performance.

In order to improve the quality of ranking aggregation, some supervised learning methods have also been proposed. The work in (Liu et al., 2007) incorporated labeled data into a supervised rank aggregation method to minimize disagreements between ranking results and labeled data. (Chen et al., 2011) proposed a semi-supervised rank aggregation approach and the work minimizes the weight disagreements of different rankers to learn the aggregation function. In the semi-supervised case, the preference constraints on several item pairs were incorporated and the intrinsic manifold structures of items are also taken into account. In (Hoi and Jin, 2008), a different semi-supervised method was proposed, which learns query-dependent weights by exploring the underlying distribution of items to be ranked and assigns two similar retrieved items with similar ranking scores.

Since ranking sentences plays an important role in summarization tasks, we can regard each result from an individual system as a ranking of sentences (Wang and Li, 2011). Then, aggregation methods can also be applied to summarization to combine multiple ranking results into an aggregation ranking to generate the combined results. However, aggregation meth-

ods for summarization are seldom been discussed in the literature. (Wang and Li, 2010) and (Wang and Li, 2011) are attempts and, in their work, a weighted consensus method was proposed for summarization and an unsupervised iteration method was applied to solve the optimization problem. Different from the unsupervised aggregation method used in these work, this paper proposes a supervised aggregation framework for summarization which combines different summarization methods and learns weights automatically with human labeled data.

3 Supervised summarization aggregation framework

In this section, we first state the problem by describing the general framework of aggregation method for summarization and then the proposed supervised summarization method is introduced in details.

3.1 Problem statement

First we consider the general framework of summarization aggregation that combines results from multiple summarizers, and each summarizer can produce a score list for sentences of a document cluster. An illustration of the framework is given by Figure 1. Suppose we have M document clusters $\{c_1, c_2, ..., c_M\}$ in the training data and the ith document cluster contains N_i sentences $\{s_1^i, s_2^i, ..., s_{N_i}^i\}$. Each sentence s_j^i is associated with a label l_j^i to denote whether it will be chosen as a summary sentence and the labels are categorized into three types as follows.

$$l_j^i = \begin{cases} +1 & \text{summary;} \\ 0 & \text{possible summary;} \\ -1 & \text{non-summary.} \end{cases} \quad (1)$$

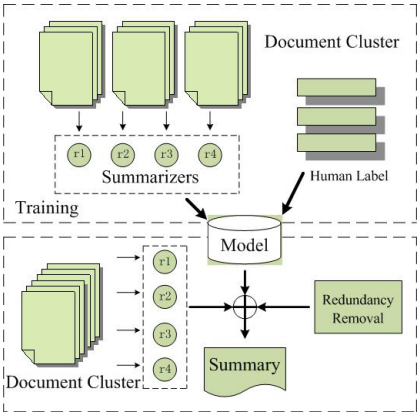

Figure 1: The framework of supervised aggregation for summarization.

Let $\mathscr{R} = \{r_1(\cdot), r_2(\cdot), ..., r_K(\cdot)\}$ denotes the set of K summarization methods and each method can produce a score list. The task of summarization aggregation is to combine the score lists

given by methods in $\mathscr{R}$ to produce better ranking results than any individual summarizer. In this study, we express the aggregation in a linear combining method and the combined ranking function can be denoted as

$$f(s) = \sum_{k=1}^{K} w_k r_k(s), \tag{2}$$

where w_k is the weight assigned to the kth individual summarization method. Thus, to learn the combination weights w_k $(k = 1, 2, ..., K)$ is pivotal in the aggregation method.

For simplicity, the aggregation score of sentence s_j^i can be rewritten in a matrix form:

$$f(s_j^i) = \mathbf{x}_j^i \mathbf{w}, \tag{3}$$

where $\mathbf{w} = [w_1, w_2, ...w_K]^T$ is the combination weights vector. $\mathbf{x}_j^i$ is a K-dimensional vector for representing the ranking scores computed by K different summarizers and denoted as

$$\mathbf{x}_j^i = [x_{j,1}^i, x_{j,2}^i, ..., x_{j,K}^i] = [r_1(s_j^i), r_2(s_j^i), ..., r_K(s_j^i)]. \tag{4}$$

3.2 Method description

In the supervised ranking aggregation method, we apply Ranking SVM (Joachims, 2002) directly. Ranking SVM trains the ranking model by decomposing a ranking list into the ordered pairs of items. In the document cluster c_i, given two sentences s_j^i and s_k^i with their score vectors $\mathbf{x}_j^i$ and $\mathbf{x}_k^i$, the training example can be built as the form $(\mathbf{x}_j^i - \mathbf{x}_k^i, z_{jk}^i)$ and the training label z_{jk}^i is defined as:

$$z_{jk}^i = \begin{cases} +1 & \text{if } s_j^i \succ s_k^i; \\ -1 & \text{if } s_k^i \succ s_j^i. \end{cases} \tag{5}$$

where $s_j^i \succ s_k^i$ denotes that sentence s_j^i is ranked higher than s_k^i. By defining the new training examples, the mathematical formulation of Ranking SVM is shown below, where the linear scoring function introduced in Formula (2) is used:

$$\begin{aligned} \min_{w} \quad & \frac{1}{2}\|\mathbf{w}\|^2 + C \sum_{i=1}^{M} \sum_{j=1}^{N_i} \sum_{k=j+1}^{N_i} \xi_{jk}^i \\ s.t. \quad & z_{jk}^i (\mathbf{w} \cdot (\mathbf{x}_j^i - \mathbf{x}_k^i)) \geq 1 - \xi_{jk}^i, i = 1, 2, ..., M, \\ & \xi_{jk}^i \geq 0, j < k \ \ and \ \ j, k \in [1, 2, ..., N_i]. \end{aligned} \tag{6}$$

where function complexity regularizer $\|\mathbf{w}\|^2$ is introduced to guarantee the generalization capacity and ξ_{jk}^i is the slack variables. C is a parameter that allows trading-off margin size against training error. Authors in (Hoi and Jin, 2008) pointed out that the above optimization problem has a drawback in training efficiency because the number of training pairs is quadratic of the number of items. Following their improved approach which can decrease the number of constraints significantly, we first build a relevance matrix A^i for ith document cluster to replace

above training labels, and the elements in the matrix are defined as follows.

$$A^i_{j,k} = \begin{cases} +1 & \text{if } l^i_j = 1 \text{ and } l^i_k = -1; \\ -1 & \text{if } l^i_j = -1 \text{ and } l^i_k = 1; \\ 1/2 & \text{if } l^i_j = 1 \text{ and } l^i_k = 0; \\ -1/2 & \text{if } l^i_j = 0 \text{ and } l^i_k = 1; \\ 0 & \text{otherwise.} \end{cases} \tag{7}$$

where l^i_j represents the label assigned to sentence s_j in the document cluster c_i and is defined in Formula (1).

Furthermore, a ranking matrix R is defined to denote the ranking results generated by the set of summarizers. For document cluster c_i, matrix $R^{i,j}$ stands for the ranking results output by summarizer $r_j(\cdot), j = 1, 2, ..., K$. Specifically, $R^{i,j}_{k,l} = 1$ if sentence s^i_k obtains higher score than s^i_l by $r_j(\cdot)$, and 0 otherwise. Next the matrix is normalized by a column-based normalization to be a transition matrix $\tilde{R}^{i,j}$, i.e. $\sum_{k=1}^{N_i} \tilde{R}^{i,j}_{k,l} = 1$.

After introducing the relevance matrix A and ranking matrix R, the original Ranking SVM shown in Formula (6) can be reformulated as:

$$\begin{aligned} \min_{w} \quad & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{M}\xi_i \\ s.t. \quad & sim([A^i]^T, [\sum_{j=1}^{K} w_j \tilde{R}^{i,j}]) \geq 1 - \xi_i, , i = 1, 2, ..., M, \\ & \xi^i_{jk} \geq 0, j < k \ \ and \ \ j, k \in [1, 2, ..., N_i]. \end{aligned} \tag{8}$$

where $sim(\cdot,\cdot)$ is a function that measures the similarity between two matrices: the transposition of relevance matrix A^i and the combined ranking matrix $\sum_{j=1}^{K} w_j \tilde{R}^{i,j}$. In the experiments, we follow (Hoi and Jin, 2008) by using trace function to measure the similarity of the two matrices. Compared with Formula (6), the number of constraints is significantly decreased from $\mathcal{O}(MN_i^2)$ to $\mathcal{O}(M)$.

4 Supervised summarization aggregation method implementation

4.1 Construction of training data

In order to apply supervised aggregation approach in summarization, we need to construct the training set in the form $\{(s^i_1, l^i_1), (s^i_2, l^i_2), ..., (s^i_{N_i}, l^i_{N_i})\}$ where s^i_j is the jth sentence in the document cluster c_i and l^i_j is the label assigned to the sentence. To capture the features contained in suboptimal sentences, we label sentences using three categories mentioned in Section 3.1: summary (+1), possible summary (0) and non-summary (-1).

Given a document cluster c which includes N sentences $\{s_1, s_2, ..., s_N\}$ and the corresponding human generated summary set $H = \{H_1, H_2, ..., H_m\}$ (H_i is the human summary generated by the ith linguist), we compute the score $score(s|H)$ for each sentence s in document cluster c to measure whether it can be chosen as the summary sentence. Motivated by ROUGE evaluation methods (Lin and Hovy, 2003), our scoring methods compute the combination of

multiple n-grams (1-gram and 2-gram are used in this study) probabilities of each sentence to be recognized as a summary sentence based on the human summary set.

First we compute the probability of an n-gram t under a human summary H_i as:

$$p(t|H_i) = tf(t)/|H_i|, \tag{9}$$

where $tf(t)$ is the frequency of t in H_i and $|H_i|$ is the number of n-grams (n is corresponding to the length of t) in H_i. In the data set, several human summaries are provided for each document cluster, and both average and maximum schemes introduced in (Ouyang et al., 2007) can be utilized[1]. The average scheme to obtain the probability of t under all human summaries is described as:

$$p_{avg}(t|H) = \sum_{H_i \in H} p(t|H_i)/|H|, \tag{10}$$

where $|H|$ is the number of summaries in the human summary set. And for maximum scheme the computation method is defined as:

$$p_{max}(t|H) = \max_{H_i \in H} p(t|H_i) \tag{11}$$

Motivated by the ROUGE evaluation metrics, we take into account both 1-gram and 2-gram to calculate the final score for each sentence in the following formula.

$$Score(s|H) = \alpha \sum_{t_{1-gram} \in s} p(t_{1-gram}|H) + (1-\alpha) \sum_{t_{2-gram} \in s} p(t_{2-gram}|H), \tag{12}$$

where α is used to control the ratios of these two types of n-grams in computing scores. Since 1-gram based ROUGE score has been shown to agree with human judgment most (Lin and Hovy, 2003), in our experiments α is set empirically to be 0.7.

4.2 Individual summarization methods

To evaluate the proposed supervised aggregation method for summarization, we introduce four typical summarization approaches (i.e., LexPageRank, LexHITS. Manifold-ranking, and DivRank) in the system implementation. In this section, we briefly describe these approaches which all have been proved effective in summarization task.

1. LexPageRank
   LexPageRank (Erkan and Radev, 2004) is a graph-based summarization method by introducing PageRank into summarization, which computes sentence scores by making use of the voting or recommendations between sentences. Sentences are used as nodes in the graph and the computational process can be described as:

$$PR(s_i) = \lambda \cdot \sum_{j:j \neq i} PR(s_j) \cdot w_{ji} + \frac{(1-\lambda)}{|S|}, \tag{13}$$

   where $PR(s_i)$ is the score of sentence s_i and $|S|$ denotes the number of sentences in a document cluster. w_{ji} represents the weight (e.g., cosine similarity) between sentence s_j and s_i and λ is the damping factor to control the probability to walk to a random sentence.

[1]The experimental comparison of two schemes will be described in Section 5.3.2

2. LexHITS
   Similar to LexPageRank, HITS (Kleinberg, 1999) algorithm can be applied in summarization task as well and correspondingly is named LexHITS. In LexHITS, sentences denote both authority nodes and hub nodes and the iteration process is written as follows.

$$\begin{aligned} Auth^{(T+1)}(s_i) &= \sum_{j:j\neq i} w_{ij} \cdot Hub^{(T)}(s_j) \\ Hub^{(T+1)}(s_j) &= \sum_{i:i\neq j} w_{ji} \cdot Auth^{(T)}(s_i) \end{aligned}, \tag{14}$$

   where $Auth^{(T)}(s_i)$ and $Hub^{(T)}(s_i)$ represent the authority score and hub score of sentence s_i at the Tth iteration, respectively. w_{ij} denotes the weight between sentence s_i and s_j same as Formula (13). Then sentences are ranked according to their authority scores.

3. Manifold
   Manifold-ranking based method (Zhou et al., 2004) is a universal ranking algorithm and can capture the underlying manifold structure of data. Authors in (Wan et al., 2007) used manifold-ranking approach for summarization. First the similarity matrix W is built and the element w_{ij} denotes the weight between sentence s_i and s_j like the settings in LexPageRank and LexHITS. Then normalize W by $\tilde{W} = D^{-1/2}WD^{-1/2}$ in which D is the diagonal matrix with (i,i)-element equal to the sum of the ith row of W. By incorporating a n-dimensional vector y, the score of each sentence can be iterated as:

$$MF^{(T+1)}(s_i) = \alpha \sum_{j:j\neq i} \tilde{w}_{ij} MF^{(T)}(s_j) + (1-\alpha)y_i, \tag{15}$$

   where $MF^{(T)}(s_i)$ denotes the manifold-ranking score of sentence s_i at the Tth iteration and $\tilde{w}_{ij}$ is the element in the normalized matrix $\tilde{W}$. α is a parameter between 0 and 1.

4. DivRank
   DivRank (Mei et al., 2010) belongs to the time-variant random walk process family which incorporates a variable to record the number of times of nodes having been visited. DivRank can balance prestige and diversity simultaneously by decreasing the visiting times of certain nodes. The iteration process of DivRank can be described as follows:

$$DR^{T+1}(s_i) = (1-\lambda)p^*(s_i) + \lambda \sum_{j:j\neq i} \frac{w_{ji} \cdot N^T(s_i)}{D^T(s_j)} DR^T(s_j), \tag{16}$$

   where $DR^T(s_i)$ denotes the DivRank score of sentence s_i at the Tth iteration and $p^*(s_i)$ represents the prior value of sentence s_i. $N^T(s_i)$ is the number of times the walk has visited s_i up to time T and $D^T(s_j) = \sum_{k:k\neq j} w_{kj} N^T(s_k)$. Similarly, w_{ji} is the weight between sentence s_j and s_i and denotes the transition probability from s_j to s_i.

4.3 Aggregation methods

Aiming to compare the proposed supervised aggregation method with other aggregation methods, we implement several aggregation methods using different ensemble strategies in the experimental studies including average scores, Round Robin (RR), unsupervised learning algorithm for rank aggregation (ULARA), and Weighted consensus summarization (WCS). A brief description of these aggregation methods is presented in this section.

1. Average Score (Avg_Score)
   This method normalizes the raw scores generated by different summarization systems between 0 and 1, and then uses the average score $Avg\_Score(s) = \frac{\sum_{k=1}^{K} score_k(s)}{K}$ to rank the sentences. In the formula, K is the number of summarization systems and $score_k(s)$ is the score of sentence s from kth summarization system.

2. Round Robin (RR)
   Refer to (Wang and Li, 2011), RR chooses the first sentence produced by the first summarizer and then the first sentence by the second summarizer. After all the first sentence are selected in the first round, the second round chooses the second sentences in the same way until reaching the summary length limit.

3. ULARA
   Unsupervised learning algorithm for rank aggregation (ULARA) is proposed in (Klementiev et al., 2007). ULARA applied a linear combination of the individual ranking approaches to form the aggregation result by rewarding ordering agreement between different rankers. By minimizing the weighted variance-like measures, the optimal weights assigned to component rankers are obtained.

4. Weighted Consensus Summarization (WCS)
   WCS algorithm (Wang and Li, 2011) utilizes a weighted consensus scheme to combine the results from individual summarizers. In this algorithm, the contribution from each summarization system is determined by its agreement with other systems. By minimizing the weighted distance between the consensus ranking and the individual ranking lists generated by different summarization systems, the weights that will be assigned to individual summarizers are obtained.

5. Supervised Summarization Aggregation Method (SSA)
   SSA is the supervised aggregation method for summarization described in Section 3.

In the experiments, we study the summarization performance of the implemented individual and aggregation systems, and compare the proposed supervised summarization aggregation method with other combination methods.

4.4 Redundancy removal

In order to choose more informative but less redundant sentences as the final summary, a redundancy removal step is conducted to impose the diversity penalty. In the experiments, we use the diversity penalty algorithm proposed in (Wan et al., 2007) to remove redundant sentences by introducing a penalty degree factor ω. The algorithm is described briefly in Algorithm 1.

5 Experiments

5.1 Data set

To evaluate the summarization results empirically, we use DUC2004[2] data set since generic multi-document summarization is one of the fundamental tasks in DUC2004. The data set

[2]http://duc.nist.gov/

Algorithm 1 Redundancy Removal Algorithm

1: Initialize set $S_A = \emptyset$, $S_B = \{s_1, s_2, ..., s_n\}$, and every sentence s_i in set S_B has a score $score(s_i)$ which initially is computed by the score function $r(\cdot)$;
2: Sort sentences in set S_B according to their scores in descending order;
3: Choose sentence s^* with the highest score in set S_B and move it from S_B to S_A;
4: **for** $s_j \in S_B$ **do**
5: $score(s_j) = score(s_j) - \omega \cdot w_{ji} \cdot r(s_i)$
6: **end for**
7: Go to step 2 and iterate until S_A reaches the length limit of a summary or $S_B = \emptyset$.

provides 50 document clusters and every generated summary is limited to 665 bytes. In the experiments, we randomly choose 40 document clusters as training data and the remaining 10 clusters are used as the testing data. For consistency, all the evaluation results are based on the testing set.

5.2 Evaluation methods

ROUGE (Lin and Hovy, 2003) (Recall Oriented Understudy for Gisting Evaluation) is widely applied for summarization evaluation by DUC. Therefore, we use the ROUGE toolkit[3] to evaluate the summarization results. It evaluates the quality of a summary by counting the overlapping units between the candidate summary and model summaries. ROUGE implements multiple evaluation metrics to measure the system-generated summarization such as ROUGE-N, ROUGE-L, ROUGE-W and ROUGE-SU. ROUGE-N is an n-gram recall measure computed as follows:

$$ROUGE-N = \frac{\sum_{S \in ref} \sum_{n-gram \in S} Count_{match}(n-gram)}{\sum_{S \in ref} \sum_{n-gram \in S} Count(n-gram)} \quad (17)$$

where n represents the length of n-gram, and $Count_{match}(n-gram)$ is the maximum number of n-grams co-occurring in the candidate summary and reference summaries. $Count(n-gram)$ is the number of n-grams in the reference summaries.

The ROUGE toolkit can report separate scores for 1, 2, 3 and 4-gram and among these different metrics, unigram-based ROUGE score (ROUGE-1) has been shown to correlate well with human judgments. Besides, longest common subsequence (LCS), weighted LCS and skip-bigram co-occurrences statistics are also used in ROUGE. ROUGE can generate three scores, i.e. recall, precision and F-measure, for each of the methods. In the experimental results we show three of the ROUGE metrics: ROUGE-1 (unigram-based), ROUGE-2 (bigram-based), and ROUGESU4 (extension of ROUGE-S, which is the skip-bigram co-occurrences statistics) metrics.

5.3 Evaluation results

5.3.1 Performance comparison

The proposed supervised summarization aggregation method is compared with different aggregation schemes including average score, round robin, ULARA, and WCS which are introduced in Section 4.3. In order to analyze the improvement of the aggregation method, we also list the

[3]ROUGE version 1.5.5 is used in this study, and it can be found on the website http://www.isi.edu/licensed-sw/see/rouge/

performance of all the individual methods. Besides, we also use Lead method as the baseline. The lead baseline takes the first sentences one by one in the last document in a document set, where documents are assumed to be ordered chronologically. Table 1 shows the comparison results (F-measure) on DUC2004 data set in ROUGE-1, ROUGE-2 and ROUGE-SU4 along with corresponding 95% confidence intervals and Figure 2 gives an illustration of the comparison on ROUGE-1 metric (LexPR is short for LexPageRank shown in the figure).

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Lead	0.31861 (0.30886 - 0.32820)	0.06814 (0.06102 - 0.07631)	0.10554 (0.09953 - 0.11208)
LexPageRank	0.36211 (0.35081 - 0.37384)	0.07808 (0.07027 – 0.08675)	0.11982 (0.11311 - 0.12717)
LexHITS	0.35285 (0.33981 - 0.36551)	0.06911 (0.06137 – 0.07675)	0.11485 (0.10771 - 0.12233)
Manifold	0.37809 (0.36785 - 0.38866)	0.08046 (0.07220 – 0.08890)	0.12577 (0.11952 - 0.13224)
DivRank	0.37442 (0.36076 - 0.38693)	0.08255 (0.07400 – 0.09058)	0.12503 (0.11721 - 0.13248)
Avg_Score	0.37814 (0.36716 - 0.38914)	0.08690 (0.07900 – 0.09520)	0.12823 (0.12155 - 0.13490)
RR	0.36809 (0.35489 - 0.38028)	0.08095 (0.07255 – 0.08984)	0.12412 (0.11672 - 0.13141)
ULARA	0.37971 (0.36720 - 0.39183)	0.09010 (0.08186 - 0.09837)	0.13163 (0.12399 - 0.13880)
WCS	0.38227 (0.37019 - 0.39334)	0.09133 (0.06669 - 0.11785)	0.13285 (0.11178 - 0.15798)
SSA	**0.39766** (0.36761 - 0.42835)	**0.09528** (0.07186 - 0.12093)	**0.13939** (0.11906 - 0.16217)

Table 1: Overall performance comparison on DUC2004

From the comparison results, it can be seen that the proposed supervised summarization aggregation (SSA) method can outperform all the other ensemble methods and individual summarization approaches on all the three metrices. This comparison indicates that by incorporating human labeled data, supervised aggregation method has an advantage over unsupervised ensemble methods, i.e., when identifying the reliability of score list from a single summarizer, human labeled data could serve as an precise guidance. Moreover, almost all the aggregation methods perform better than individual summarization systems except the round robin method and this result is consistent with the comparison in (Wang and Li, 2011). For one thing, the results demonstrate that generally ensemble methods can effectively enhance the performance since these methods make the best of individual summarization methods which rank sentences from different aspects. For another, the poor performance of round robin method may result from that simply choosing the sentence with highest score in every round ignores the relationship among different score lists and the inaccuracy or overlap of the top sentences can lead to the poor effect as well.

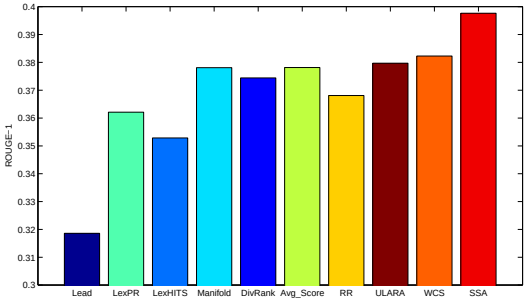

Figure 2: The comparison results of all the methods.

5.3.2 Influence of training data construction schemes

As mentioned in Section 4.1, there are two schemes to construct the training data (i.e., *average* and *maximum*). Average scheme chooses the average probability of an n-gram under all human summaries as the measure and maximum scheme applies the maximum probability value to represent the probability of an n-gram under all human summaries.

From the comparison shown in Table 2, we observe that the maximum scheme performs better than the average one. By analyzing the definition of two schemes, *maximum* tends to assign sentences with a higher value when compared with the *average* scheme and therefore it can choose more potential summary sentences into positive training set and produce better results.

Schemes	ROUGE-1	ROUGE-2	ROUGE-SU4
maximum	0.39766	0.09528	0.13939
average	0.39394	0.09306	0.13859

Table 2: Results of different schemes on DUC2004

5.3.3 Influence of component diversity

In the experimental study, we exploit four different summarization methods which are proven effective in summarization and they rank sentences from different aspects by utilizing diverse strategies. Therefore differences in algorithms and implementation make the ensemble process can comprehensively take into consideration multiple ranking strategies.

The LexPageRank summarization method scores sentences by making use of the voting or recommendations between sentences, and thus the global information of all the sentences can be in full use. LexHITS method assigns each sentence two properties, i.e., hub and authority, which can take into account the mutual relationship between sentences and provide a better view of the relationships embedded in the sentences. Manifold-ranking based method is based on a universal ranking algorithm and can capture the underlying manifold structure of data,

thus some implicit relationships between sentences are exploited. DivRank can be regarded as an expand version of LexPageRank which incorporates a variable to record the number of times of nodes having been visited. Through this improvement, the diversity and prestige of sentences to be chosen can be guaranteed simultaneously.

In this set of experiments, we further investigate the influence of different combinations of component methods[4]. We use the proposed framework to combine any three of all summarization methods and compare the results with the combination scheme using all the four methods. Table 3 shows the comparison results.

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
LH+MF+DR	0.39394	0.09306	0.13859
LPR+MF+DR	0.39393	0.09397	0.13834
LPR+LH+DR	0.38829	0.08172	0.12807
LPR+LH+MF	0.39383	0.09355	0.13916
All	0.39766	0.09528	0.13939

Table 3: Comparison results of different component combinations on DUC2004

From the table, it can be seen that different component summarization methods have less impact on the results in general and this may due to the small number of testing data. However, from the little fluctuation we can observe that aggregating all the individual methods can perform the best results. It is worth mentioning that the performance of LPR+LH+DR is relatively poor, and this result may owe to losing the Manifold-ranking based method which performs best among all the four methods.

Conclusion and perspectives

In this paper, we propose a supervised aggregation summarization framework by combining the results from four typical multi-document systems including LexPageRank, LexHITS, Manifold-ranking method and DivRank. To evaluate the proposed appraoch, we compare it with several combination methods, e.g., average score, round robin, unsupervised learning algorithm rank aggregation (ULARA) and weighted consensus summarization (WCS). And the experimental results on DUC 2004 data set demonstrate the effectiveness of our proposed framework. In addition, irrespective of the specific individual summarization methods used in this study, the supervised aggregation framework for summarization can also incorporate some more delicate and effective summarizers and generate more promising summary.

In this study, we investigate the supervised summarization aggregation approach to learn weights automatically by incorporating human labeled data. Since labeled sentences would be time-consuming and costly, in the future we will explore semi-supervised method which can decrease the amount of labeled data required. Moreover, more effective individual summarization approaches would be exploited and added into the ensemble method.

ABSTRACT
Name ambiguity is a major problem in information retrieval: The name "Metropolis" may refer to a movie, a physicist, or Superman's hometown. Recent work resolves ambiguity in natural language text by linking name mentions against the corresponding Wikipedia concept (Wikification). Standard methods comparing a single mention with the corresponding Wikipedia concept can potentially be improved by simultaneously considering all mentions in the input document. We propose a novel multiple assignment process based on a collective search over an inverted index that exploits the coherence of Wikipedia concepts. Based on this coherence, we compute the best fitting candidate concept for each mention and combine it with context information in a second search step. Using additional attributes an SVM then re-ranks the result of this search and estimates if a concept is not covered in Wikipedia. We give a unified view over the different performance measures used in other state-of-the art approaches and evaluate our approach on five benchmark corpora. On these corpora, our method has the most stable performance yielding similar or better results compared to other approaches.

KEYWORDS: Concept and Entity Disambiguation, Wikification, Natural Language Processing, Search and Ranking.

Proceedings of COLING 2012: Technical Papers, pages 2243–2258,
COLING 2012, Mumbai, December 2012.

1 Introduction

A major aim of search engines is the retrieval of information about concepts which may be any existing object, e.g. person, thing, notion, etc., with a designation or name. In natural language text however, many concepts share the same name and one concept may be referenced by different names. Consequently, a search based on pure string matching often yields many irrelevant results, such as a web page on Superman's hometown when indeed the user seeked information on the physicist Metropolis. Concept disambiguation which assigns the correct sense to the mention of a concept in a given context, can reduce the number of irrelevant results or group results by sense. The disambiguation of concept mentions is required in applications such as semantic search, but also many other areas like knowledge base construction or data base curation.

Recent work, for example (Ratinov et al., 2011), resolves name ambiguity by linking the name mention against the corresponding Wikipedia article, thus often terming the problem *Wikification*. For that, a name mention together with the features of its neighboring context is compared to the corresponding features of the Wikipedia article. If the difference between these features is small, a Wikipedia concept is linked to the mention and thus the name's ambiguity considered as resolved. A large number of features have been evaluated for concept disambiguation. Starting with simple bag-of-word descriptions more advanced features were developed characterizing the sense of surrounding words, e.g. topic model indices (Pilz and Paass, 2011). But often, approaches remained *local* and did not exploit the *global* coherence of candidate concepts.

In this paper we follow the *global* approach by simultaneously considering all mentions of an input document and jointly exploiting relations between potential concepts. We present a novel measure for concept coherence. We encode this information in a search index allowing fast and comprehensive access to the relational information present in large knowledge bases such as Wikipedia. One deficit of most current concept disambiguation methods is that they do not thoroughly handle the case when a concept mention is not covered by Wikipedia (nil-concepts). We use an SVM classifier to fine-tune the assignment and to detect nil-concepts. We discuss the various evaluation measures presented in other papers and apply our algorithm to five benchmark corpora. While fast and memory efficient, our algorithm yields similar or better results than its competitors and has the most stable performance of the compared methods.

2 Related Work

Concept disambiguation is closely related to the task of word sense discrimination (Schuetze, 1998), but in addition links the concepts to entries in a reference knowledge base which is often Wikipedia. Standard or *local* approaches like Cucerzan (2007) build word and feature vectors over the words occurring in a context window around the concept mention m and cluster them using similarity measures such as cosine similarity. Bunescu and Pasca (2006) correlate context words with Wikipedia categories to formulate a word-taxonomy kernel. This is used in a Ranking SVM which generates a ranked list of plausible Wikipedia concepts for a given context of a name mention m. Pilz and Paass (2011) showed that topic model indices instead of bag-of-word approaches provide a more informative context representation with better generalization properties.

Recent work on concept disambiguation follows a more *global* approach, where all concept mentions in a document are disambiguated collectively using a coherence measure that is usually

derived from the graph built over an existing knowledge base. Kulkarni et al. (2009) formulate concept assignment as an optimization problem that assigns concepts to mentions such that the mention-concept compatibility and global concept-concept coherence is maximal. They solve the problem using local hill-climbing and linear program relaxations, yielding favorable results on the **MSNBC** corpus (Cucerzan, 2007) as well as their own dataset **IITB**. Han et al. (2011) propose a graph-based collective concept linking method which can model and exploit the global interdependence between different assignment decisions. Ratinov et al. (2011) present the disambiguation model GLOW, a global approach that employs the normalized Google distance (Milne and Witten, 2008) as well as pointwise mutual information to measure the relatedness between concepts. To refine the assignment decision they additionally exploit the conditional probability that a concept belongs to a mention based on Wikipedia link information. Hoffart et al. (2011b) introduced AIDA which employs YAGO2 (Hoffart et al., 2011a) as an entity catalog and a rich source of entity types and semantic relationships among entities. They build a graph containing mentions from the input text and candidate concepts from the reference set as nodes. The edges are weighted capturing context similarities as well as coherence between Wikipedia concepts. Using a greedy algorithm they identify a dense sub-graph that contains exactly one mention-concept edge for each mention, yielding the most likely disambiguation.

We propose an approach that is based on a search index. The usefulness of search indices for concept resolution was also observed by Song and Heflin (2011) who present an efficient and scalable system for concept resolution on structured data. Opposed to our objective which is concept resolution in unstructured data, exploitable attributes are very different and often carry an inherent distinctive function. In the sequel, we give the details of our approach and compare it to a representative selection of four recent works showing that it is the most stable method yielding similar or better results on different benchmark corpora. Although all prior work shows improved results on benchmark corpora, none of them handles nil-concepts thoroughly. For specific tasks this might be appropriate, but in a more general setting this means a drastic simplification as most entities (e.g. persons) are *not* covered by Wikipedia.

3 Disambiguation as a Search Problem

We study the task of Wikification, i.e. concept disambiguation using Wikipedia as a reference knowledge base. We use the English version of Wikipedia[1] and represent it in the Lucene[2] search index **Wiki** that allows efficient search over the concepts contained in Wikipedia.
We resolve the ambiguity of a *mention* m in a text document through its assignment to a *unique concept* $c(m)$ described in Wikipedia, i.e. $c(m) \in \mathbf{Wiki} = \{c_1, ..., c_{|\mathbf{Wiki}|}\}$. If the true concept for m is not covered by an article in Wikipedia, then $c(m) \in \mathbf{C}_0$, the set of nil-concepts that we do not distinguish. Basically, **Wiki** contains all Wikipedia concepts apart from meta pages. We also excluded disambiguation pages since we assume that an assignment to such a page does not solve the task of name disambiguation. Furthermore, the varying usage of Wikipedia mark up language led to un-processable documents that are also not contained in **Wiki**. Thus, in the following, we distinguish between linkable concepts contained in the index $c \in \mathbf{Wiki}$, nil-concepts c_0 originally not covered by Wikipedia and ignored or missing concepts $\tilde{c}_0 \notin \mathbf{Wiki}$.

We assume the input to be a natural language text document with a collection of mentions $\mathbf{M} = \{m_1, \ldots, m_k\}$ to disambiguate. In the case of the benchmark corpora, these mentions are given. In other real-world applications, they can be provided by an automatic annotator, such

[1] Downloaded on September 1th, 2011.
[2] An open source search engine for large scale text collections, `http://lucene.apache.org/`

as a noun phrase or named entity recognizer (NER). Note that we do not restrict the mentions to named entities (persons, locations, etc) but also treat general concepts such as *bank* or *tree*.

To improve the individual disambiguation performance for each m_i, we simultaneously consider all mentions $\mathbf{M}$ to determine the best fitting *candidate concepts* $bestFit(m_i)$. We propose a disambiguation process that uses the search index **Wiki** to generate candidate concepts, as well as a supervised SVM classifier to adjust the ranking of these candidates and to detect nil-concepts c_0. This process consists of the following steps that are described in more detail in the following sections:

Step 1 Run a **collective search** using an **ensemble query** with terms from all mentions $m_1, \ldots, m_k$ to create sets of **potential candidates** $\mathbf{C}_i \subset$ **Wiki** for each m_i (Alg. 1.1-1.10).
Step 2 Compute the **cross coherence** over all candidates in the sets $\mathbf{C}_1, \ldots, \mathbf{C}_k$ to find related concept sets (c.f. Eq. 4), Alg.1.11-1.13).
Step 3 Determine the $bestFit_i \in$ **Wiki** for each mention m_i, based on the maximum cross coherence of each candidate in $\mathbf{C}_i$ (c.f. Eq. 6, Alg. 1.15).
Step 4 For each m_i combine the attributes of m_i and $bestFit_i$ into one query and search **Wiki**, which yields a set of improved concepts $\mathbf{C}_i^* \subset$ **Wiki** (Alg. 2.2-2.12).
Step 5 Apply an **SVM** classifier to all $\mathbf{C}_1^*, \ldots, \mathbf{C}_k^*$ for **re-ranking** and **nil-concept detection**, resulting in the final predicted concept $\hat{c}_i \in \mathbf{C}_i^* \cup \mathbf{C}_0$ for each m_i (c.f. Sec. 4.2, Alg. 2.17).

3.1 Concept Attributes in the Wiki index

Using the information stored in the article itself as well as Wikipedia's hyperlink graph, we enhance the representing concept $c \in$ **Wiki** with the searchable fields outlined in this section.

Name fields Special attention is given to name fields, since for unambiguous mentions the name is often sufficient for linkage. Each concept has a unique `titleLong` field which contains the title of the associated Wikipedia article. From this, we generate additional fields. The `title` field stores the part of `titleLong` that is not used as a disambiguation term (usually a qualifying term in parentheses). Abbreviations are generated via a simple heuristic and stored in separate `abbreviation` fields. As an example, the index concept representing the Wikipedia article *Michael Jordan (footballer)* has the fields: (`titleLong`, "Michael Jordan (footballer)"), (`title`, "Michael Jordan"), (`abbreviation`, "MJ"), (`abbreviation`, "M. Jordan") etc.

Furthermore, we add the redirect information from the Wikipedia redirect dump to the corresponding index concepts. In general, redirects provide a large resource of synonyms. In some cases, however, they can also be misleading, since they do not necessarily compose equivalence relations. For instance, *Ulrich Merkel* is a redirect for German chancellor *Angela Merkel*, but actually is the latter's spouse. Still, we consider all redirects without pre-processing, since a more well defined redirect scheme would already require a disambiguation step. The index concept for *Angela Merkel* is hence enriched with the field (`redirect`,"Ulrich Merkel").

Inspired by Ratinov et al. (2011), we create `meantBy` fields that, similar to redirects, provide concept names that may not be found in the article text itself. In a pre-processing step, we iterate over all articles in Wikipedia and analyze the pairs (c, m) of link target concept c and associated anchor text m. For each pair (c, m) we record the frequency of occurrence $\#(c, m)$ and estimate the concept-mention probability $p(c|m)$ through

$$p(c|m) \approx \frac{\#(c, m)}{\sum_{c_i \in \mathbf{Wiki}} \#(c_i, m)}. \quad (1)$$

For instance, we obtain $p(Japan|\text{"Japan"}) \approx 0.97$. Note that these are not true probabilities, since due to parsing errors or too aggressive stemming, we may observe that $\sum_i p(c_i|m) \neq 1$.

Lucene ranks the search results for a query according to a product of the following factors: the term frequency of the term x in the document, its inverted document frequency *idf(x)*, a weight factor *boost(x)* and the document's length norm (Hatcher et al., 2010). For the final index creation, we use the above probabilities as *boosts* on the `meantBy` fields: the index concept for *Japan* has the field (`meantBy`,"Japan", 0.97), where the field's searchable content is the surface form "Japan" and the field's boost is the estimated probability value $p(c|m) = 0.97$. To keep memory consumption as low as possible, we create an auxiliary index to retrieve these values efficiently.

In the following we refer to the above fields as *name* fields. Name fields allow queries of the form (`title`, m), (`redirect`, m) or (`meantBy`, m). In our experiments, we will show results when additional context information is ignored and only name fields are used for disambiguation.

Context fields Assuming that each concept is thoroughly depicted in the article's main text, we use this context (except stop words) in a designated `context` field. This allows us to place queries of the form (`context`,"w"), where "w" may be the mention itself or any other key word extracted from the input document.

Type fields For all **Wiki** concepts that can be automatically aligned with YAGO (Suchanek et al., 2008), we add the type information extracted from YAGO, such as person, location, etc.. If the mention text has been tagged as a named entity by a NER, we can use this additional meta information to place a more distinctive query, for example a query (`type`,"person").

Both context and type fields can be queried separately, and we will show the influence of context and type usage in our experiments.

Link fields Relational information is an important factor for concept resolution and Wikipedia's link structure provides a straightforward resource to model relations among concepts. We store all outlinks $\{c \rightarrow c'\}$ of a Wikipedia concept in the fields (`linkText`,"m") of the respective index concept c, where "m" is the anchor text used for the outlink target concept c'. These fields are used to compute the relatedness among concepts (c.f. Eq. 3) but also queried in the collective search step of our disambiguation algorithm (Alg. 1.1-1.2).

3.2 Mention-specific Attributes

To create specific disambiguating attributes for each mention m_i, we first extract the mention's *name*, *type* and *context* attributes from the input document.

Name and type attributes Having collected all mentions from the input document, we keep the name (i.e. the surface form) and if present, the type information as attributes for each m_i. We then run a *mention expansion* that searches for mentions that are token-wise contained in previous mentions. If the type of two mentions is the same, the shorter mention is expanded to the longer one. For example, if $\mathbf{M}$ ={("Al Gore", per), ("Gore", per), ("Gore Bay", loc)}, the result of mention expansion is $\mathbf{M}$ ={("Al Gore", per), ("Al Gore", per), ("Gore Bay", loc)}. If the NER did not identify the type of "Gore", we still assume that it refers to the person "Al Gore", since the abbreviation of person names is much more common compared to the abbreviation

of location names. In our experiments, we found that the expansion of mention names has a positive impact on disambiguation performance.

Context attributes We use both local as well as document level context information. The local context is a $[2,2]$ noun-window around the mention without stop words. Additionally, we extract tf-idf ranked key words from the document text and keep the 20 words with highest tf-idf value as document key words. This set is then localized for each m_i: from the joint set of local context words and document key words, we keep only those words that appear at least once in the text of an index concept whose title matches m_i. In the same way, we compute key words from the headline of the input document, assuming that headline information is especially important.

Topic information Additionally to the pure word-based context information, we use an LDA topic model (Blei and Lafferty, 2009) to infer the most likely topic distribution of the input document. The LDA model was trained with $Z = 500$ topics on the **CoNLL** training corpus (c.f. Sec. 5) where words are the surface forms of the named entities appearing in the documents. We then apply this topic model to the input document giving local context words of mention m_i a five-fold weight. This yields a specific topic distribution $topic(m_i)$ for each mention m_i.

Name, type and context attributes of the input mentions can be matched to the according index fields using specific queries. Topic information is used for relatedness computation as well as a distinct feature for the Ranking SVM.

4 Disambiguation via Search and Ranking

Having defined the components of our search index and the input to our system, we explain the search process for Wikification in this section. The first part of our disambiguation procedure is to *jointly* treat all mentions $m_1, \ldots, m_k$ in the input document to generate a *bestFit* candidate for each m_i. The algorithm for this is depicted in Alg. 1

4.1 bestFit concepts from collective search using ensemble queries

Our assumption is that Wikipedia articles containing many of the input mentions are likely to be of a similar content as the input document. From the *outlink target concepts* these articles provide, we can automatically generate good disambiguation candidates concepts (**step 1**).

To retrieve these candidate concepts, we create an *ensemble query* that jointly treats the names of all mentions m_i and thus exploits the co-occurrence of mentions as link texts (see Alg. 1.1). This query then contains one query term (`linkText`, m_i) per mention m_i. Using this query, a search in **Wiki** then yields a ranked list of concepts $\mathbf{C}_{coll}$ that *collectively* contain the input mentions m_i as values in their `linkText` fields (Alg. 1.2). Lucene ranks each concept $c_{coll} \in \mathbf{C}_{coll}$ with a score s_L, based on the number of matches c_{coll} has on the fields (`linkText`, m_i). The higher the ranking of c_{coll}, the more mentions the concept c_{coll} contains as link text.
We keep the top 30 concepts in $\mathbf{C}_{coll}$ from which we extract the collection of outlink targets $\mathbf{C}_{\rightarrow}$. Next, we endow each outlink target concept $c \in \mathbf{C}_{\rightarrow}$ with a weight $w(c)$ that is the sum over the concepts' scores in which it appears as an outlink target, i.e. $c_{coll} \rightarrow c$ (Alg. 1.4):

$$\forall c \in \mathbf{C}_{\rightarrow}: \quad w(c) = \sum_{c_{coll} \in \mathbf{C}_{coll}} \delta_c s_L(c_{coll}), \quad \delta_c = \begin{cases} 1 & \text{iff } c_{coll} \rightarrow c, \\ 0 & \text{else.} \end{cases} \tag{2}$$

Since the collection $\mathbf{C}_{\rightarrow}$ may contain a huge number of concepts appearing only once as an outlink target, we keep only the top 100 candidate concepts in $\mathbf{C}_{\rightarrow}$, that have the highest weights $w(c)$.
Next, we need to relate the elements in the candidate concept set $\mathbf{C}_{\rightarrow}$ to the input mentions. More specifically, we analyze for each $c \in \mathbf{C}_{\rightarrow}$ if either the title or the redirect of c contains the text of mention m_i. If so, we add c to the candidate set $\mathbf{C}_i$ for mention m_i (Alg. 1.7 ff). Note that one c can then be contained in multiple candidate sets. The result of the collective search is the collection $\{\mathbf{C}_i\}_{i=1}^{k}$, where each $\mathbf{C}_i$ is a set of candidate concepts for mention m_i.

Our intuition is that concepts mentioned jointly in an input document should be related. To model the relatedness between Wikipedia concepts, we follow the approach of Milne and Witten (2008) who define the normalized Google distance (NGD) of two concepts c_i and c_j as

$$\mathrm{NGD}(c_i, c_j) = \frac{\log\Big(|\{c' \rightarrow c_i\} \cap \{c' \rightarrow c_j\}|\Big) - \log\Big(\max(|\{c' \rightarrow c\}|, |\{c' \rightarrow c_j\}|)\Big)}{\log(|\{c' \rightarrow \cdot\}|) - \log\Big(\min(|\{c' \rightarrow c_i\}|, |\{c' \rightarrow c_j\}|)\Big)}, \tag{3}$$

where $\{c' \rightarrow c_i\}$ is the collection of all concepts c' that link to c_i (i.e. the inlinks of c_i) and $|\{c' \rightarrow \cdot\}|$ is the total number of links in Wikipedia. In the case that the concepts c_i and c_j share no inlinks, i.e. $\{c' \rightarrow c_i\} \cap \{c' \rightarrow c_j\} = \emptyset$, we define $\mathrm{NGD}(c_i, c_j) = 0$.

Using the above NGD, we can measure the relatedness of two candidate concepts. To account for the collective fitness of a set of candidates, we introduce *cross coherence* which basically states how well a concept $c_{ij} \in \mathbf{C}_i$ *fits* to the other candidate concepts $\{\mathbf{C}_l\}_{l=1}^{k}$. More formally, we define the cross coherence of a candidate concept c_{ij} and a collection of concepts $\{\mathbf{C}_l\}_{l=1}^{k}$ as

$$\text{cross coherence}(c_{ij}, \{\mathbf{C}_l\}_{l=1}^{k}) = \frac{1}{k} \sum_{\substack{i'=1 \\ i' \neq i; \mathbf{C}_i \neq \mathbf{C}_{i'}}}^{k} \frac{1}{|\mathbf{C}_{i'}|} \sum_{\substack{c' \in \mathbf{C}_{i'} \\ c_{ij} \neq c'}} \Delta\mathrm{NGD}(c_{ij}, c'), \tag{4}$$

with k the number of mentions in the document, i the index of mention m_i and j the index over the candidate concepts for m_i. The second sum is the average NGD (Eq. 3) of c_{ij} to the concepts in another candidate set $\mathbf{C}_{i'}$ which is again averaged over all candidate sets by the first sum. Cross coherence can be interpreted as the average distance of a concept to a collection of concepts and has range $[0, 1]$, where 0 denotes a *completely unrelated* concept. We compute cross coherence in **step 2** (Alg. 1.11-1.13) to determine the relatedness of candidates extracted in the previous **step 1**.

The factor Δ in Eq. 4 serves as an additional relatedness weighting between two concepts. While both Milne and Witten (2008) and Ratinov et al. (2011) used the standard NGD with $\Delta = 1$, we analyze three additional weighting schemes. The scheme $\Delta_{\cos}\mathrm{NGD}$ weighs the NGD via the cosine distance $\cos(c_i, c_j)$ between the term vectors of two article texts. Additionally, we introduce $\Delta_{topics}\mathrm{NGD}$ that uses the thematical distance between two article link text collections. More specifically, we use a LDA topic model to infer the topic probability distribution over the words contained in a concept's outlink collection $\{c \rightarrow c'\}$ (for more details on the topic model, see 3.2). We define Δ_{topics} as the Hellinger distance between two concepts' outlink text topic probability distributions:

$$\Delta_{topics}(c_i, c_j) = 1 - \sum_{z=1}^{Z} \sqrt{topic_z(c_i) \cdot topic_z(c_j)}, \tag{5}$$

where $topic(c_i)$ and $topic(c_j)$ are the topic probability distribution vectors for the link texts of the concepts c_i and c_j and Z is the number of topics in the LDA model. The subtraction from 1 assures that $\Delta_{topics} = 0$ iff $topic(c_i) = topic(c_j)$ and is required to maintain the interpretation of cross coherence as a distance. The last relatedness measure we analyze is cosine distance without NGD.

In **step 3**, we compute the final result of the collective search procedure, i.e. the *bestFit* concepts. We define the *bestFit* candidate concept for each mention m_i by the product of the weight $w(c)$ (computed in **step 1**) and c's cross coherence value (computed in **step 2**):

$$bestFit_i = \arg\max_{c \in \mathbf{C}_i} (w(c) \cdot \text{cross coherence}(c)). \tag{6}$$

When the concept-mention association in **step 1(c)** yields no result, no *bestFit* candidate can be assigned. Note that if we used the triple of $w(c)$, cross coherence(c) and $p(c|m)$, high-prior candidates are likely to dominate, even if their coherence is low.

Algorithm 1: Collective search for *bestFit* candidate generation

Input: List of mentions $\mathbf{M} = \{m_1, \ldots, m_k\}$
Output: A $bestFit_i$ candidate for each $m_i \in \mathbf{M}$, i.e. $\{(m_1, bestFit_1), \ldots, (m_k, bestFit_k)\}$
1.1 $query = (\texttt{linkText}, name(m_1)) \wedge \ldots \wedge (\texttt{linkText}, name(m_k))$ // **step 1(a)**: create ensemble query using all m_i
1.2 $\mathbf{C}_{coll}$ = search **Wiki** using *query*
1.3 $\mathbf{C}_{\rightarrow} = \bigcup_{c_{coll} \in \mathbf{C}_{coll}} \{c_{coll} \rightarrow c'\}$ // collect outlink target concepts from collective search result $\mathbf{C}_{coll}$
1.4 **for** $c \in \mathbf{C}_{\rightarrow}$ **do** // **step 1(b)**: compute concept weights
1.5 compute concept weight according to Eq. 2
1.6 keep only top 100 link target concepts in $\mathbf{C}_{\rightarrow}$
1.7 **for** $m_i \in \mathbf{M}$ **do** // **step 1(c)**: relate concepts to mentions
1.8 initialize candidate set $\mathbf{C}_i = \emptyset$
1.9 **for** $c \in \mathbf{C}_{\rightarrow}$ **do**
1.10 add c to candidate set $\mathbf{C}_i$ if `title` or `redirect` of c contains mention text m_i
1.11 **for** $i = 1, \ldots, k$ **do** // **step 2**
1.12 **for** $c_{ij} \in \mathbf{C}_i$ **do**
1.13 compute cross coherence according to Eq. 4
1.14 **for** $m_i \in \mathbf{M}$ **do** // **step 3**
1.15 find *bestFit* concept according to Eq. 6
1.16 **return** $\{(m_1, bestFit_1), \ldots, (m_k, bestFit_k)\}$

4.2 Combining Search Results and Supervised Learning

The final disambiguation algorithm Alg. 2 has two steps (**step 4** and **5**). First, we run a search on **Wiki** to create ranked sets of candidate concepts $\mathbf{C}_1^*, \ldots, \mathbf{C}_k^*$ with one set $\mathbf{C}_i^* \subset$ **Wiki** per mention m_i. Second, a pre-trained SVM is applied to re-rank this output and detect nil-concepts. The result is the disambiguated list of input mentions, where each mention m_i is associated with a unique concept $\hat{c}_i \in$ **Wiki** $\cup \mathbf{C}_0$, i.e. $\{(m_1, \hat{c}_1), \ldots, (m_k, \hat{c}_k)\}$.

In the search part (**step 4**), we restrict the size of each $\mathbf{C}_i^*$ (i.e. the number of search results) to 5, which we experimentally found to be sufficient. Initially, we also require each concept $c_i^* \in \mathbf{C}_i^*$ to have at least 5 inlinks. This *inlink prior* aims at filtering out rarely referenced concepts. Then we run separate searches using only the `titleLong`, `title` and `redirect` fields of the index documents to find direct matches between mention m_i and concepts $c \in$ **Wiki** (Alg. 2.3). If such a match $\tilde{c}$ has been found, we give an additional query boost for the attributes of $\tilde{c}$, that is the title of $\tilde{c}$ is used as an additional query term with a five times higher weight than the other

query terms. For the *bestFit* concept we proceed analogously.
If either $\tilde{c}$ or $bestFit_i$ has a lower number of inlinks than initially assumed, the inlink prior is adapted automatically (Alg. 2.6). Alternatively, if the maximum returned score of the first search (Alg. 2.10) is less than a threshold $\tau = 1$, we re-run the search without the prior constraint (Alg. 2.12). After prioritisation on the results from direct and collective search, we add each mention's individual attributes to account for type and context information. In our experiments, we evaluate searches of different coverage, more specifically searches using

- name attributes, i.e. we add queries only on name fields (Alg. 2.7)
- name and type attributes, i.e. we extend the query using the mention's type (Alg. 2.8)
- name, type and context attributes, i.e. we additionally query context fields (Alg. 2.9).

Using this comprehensive query, the search result in **Wiki** is a either a set of ranked concepts $\mathbf{C}_i^*$ or an empty set, in which case the search did yield no result. We collect all concept sets $\mathbf{C}_i^*$ into an overall set $\{\mathbf{C}_i^*\}_{i=1}^k$ on which we apply a linear ranking SVM (**step 5**). Each concept c_i^* is represented by a vector of features that are computed both from the index ranking $s_L(c_i^*)$ as well as in relation to the input mention. We use the ranking in different feature representations: $s_{L,\log}(c_i^*) = \log s_L(c_i^*)$, $s_{L,norm}(c_i^*) = \frac{s_L(c_i^*)}{\sum_{c_i^{*'} \in \mathbf{C}_i^*} s_L(c_i^{*'})}$, $s_{L,rank}(c_i^*) = \frac{s_L(c_i^*)}{\arg\max\ s_L(c_i^* \in \mathbf{C}_i^*)}$. Additional features are the concept-mention probability $p(c_i^*|m_i)$, the cross coherence of c_i^* computed as in 4 but now in relation to the improved concept set $\{\mathbf{C}_i^*\}_{i=1}^k$, the Hellinger distance over the topic distributions $topic(m)$ and $topic(c_i^*)$. As proposed by Bunescu and Pasca (2006), we use a feature f_0 for nil-concepts c_0 that is required for the automatic detection of these nil-concepts.

We train the Ranking SVM on the **CoNLL train** corpus which is annotated with Wikipedia concepts as well as nil-concepts. Positive and negative examples are extracted in the same way as we generate disambiguation candidates. For instance, a positive example is the correct candidate c_i^* for a mention m_i and the negative examples are all other $c_i^* \in \mathbf{C}_i^*$ for that mention. Additionally, if not already present when the search did yield no result, we add a candidate c_0 for each mention whose only feature is f_0.

In the final **step 5** we use the trained SVM to re-rank the index output (Alg. 2.17). While the index search often provides a reliable candidate, implicit features such as coherence, concept-mention probability and topic similarity are only partially graspable by **Wiki** and may induce a SVM re-ranking.

5 Benchmark Corpora

Recent work published a variety of benchmark corpora for Wikification, most of them consisting of English newspaper articles from different time periods. Table 1 gives an overview of the corpora treated in this paper. The major difference between these corpora is the annotation scheme. Cucerzan, Ratinov et al., Milne and Witten and Kulkarni et al. treated mentions of all types on **MSNBC**, **ACE**, **AQUAINT**[3] and **IITB**[4] respectively. Hoffart et al. considered only named entity mentions in the **CoNLL** corpus[5]. Additional to differing mention types, there are also annotation differences that render comparison difficult. For instance, in **CoNLLb** the mention "Taiwan" is linked to *Republic of China*, while in **ACE** it is linked to *Taiwan*. We also observed

[3] **MSNBC**, **AQUAINT** and **ACE** are publicly available and described in detail in (Ratinov et al., 2011).
[4] **IITB** is publicly available and described in detail in (Kulkarni et al., 2009).
[5] **CoNLL** is publicly available and described in detail in (Hoffart et al., 2011b), we consider **CoNLL testb** called **CoNLLb** in the following.

Algorithm 2: Disambiguation algorithm

Input: List of mentions $\mathbf{M} = m_1, \ldots, m_k$, where each m_i has name, type, context & *bestFit* attributes.
Output: List of disambiguated mentions $\mathbf{M} = \{(m_1, \hat{c}_1), \ldots, (m_k, \hat{c}_k)\}$

2.1 **for** $m_i \in \mathbf{M}$ **do** // **step 4**
2.2 $p_{in} = 5$ // initialize inlink prior
2.3 $\tilde{c} = \text{directMatch}(m_i)$ // c.f. Sec. 4.2
2.4 **if** $\tilde{c} \neq \emptyset$ **then** add boosted query terms for attributes of $\tilde{c}$
2.5 **if** $bestFit_i \neq \emptyset$ **then** add boosted query terms for attributes of $bestFit_i$
2.6 $p_{in} = \min\left(p_{in}(\tilde{c}), p_{in}(bestFit_i), p_{in}\right)$ // reduce prior on inlinks
2.7 *query*.addNameQuery(name(m_i)) // add name attributes to the query terms
2.8 **if** *type* **then** *query*.addTypeQuery(type(m_i)) // add type attributes to the query terms
2.9 **if** *context* **then** *query*.addContextQuery(context(m_i)) // add context attributes to the query terms
2.10 $\mathbf{C}_i^* =$ search **Wiki** using *query* and inlink prior p_{in}
2.11 **if** $\max_{c_j^* \in \mathbf{C}_i^*} s_L(c_j^*) \leq \tau$ **then**
2.12 $\mathbf{C}_i^* =$ search **Wiki** using *query* without inlink prior
2.13 **if** $\mathbf{C}_i^* \neq \emptyset$ **then** $\{\mathbf{C}_i^*\} \cup \mathbf{C}_i^*$ **else** $\{\mathbf{C}_i^*\} \cup c_0$ // add $\mathbf{C}_i^*$ to concept set $\{\mathbf{C}_i^*\}$ or add c_0 if the search yields no results
2.14 **for** $i = 1, \ldots, k$ **do**
2.15 **for** $c_{ij}^* \in \mathbf{C}_i^*$ **do**
2.16 compute cross coherence$(c_{ij}^*, \{\mathbf{C}_l^*\}_{l=1}^k)$ according to Eq. 4 and set other features (c.f. Sec. 4.2)
2.17 $\hat{c}_i = \arg\max_{c_{ij}^* \in \mathbf{C}_i^*} \text{SVM rank}(c_{ij}^*)$ // **step 5**: rank candidates by trained SVM for final concept prediction
2.18 **return** $\mathbf{M} = \{(m_1, \hat{c}_1), \ldots, (m_k, \hat{c}_k)\}$

corpus	#documents	#Wikipedia concepts (unique)	$\#c_0$	$\#c \in$ **Wiki**	$\#\tilde{c}_0 \notin$ **Wiki**	$\varnothing\lvert\mathbf{M}\rvert$ per doc.
MSNBC	20	658 (279)	97	640	18	37.75
ACE	36	257 (185)	49	254	3	8.5
AQUAINT	50	727 (572)	0	702	25	14.54
CoNLLb	228	4363 (1527)	0	4317	46	19.13
IITB	104	11185 (3755)	0	9439	1746	107.54

Table 1: Benchmark corpora with number of documents, the number of (unique) Wikipedia concepts and nil-concepts c_0, the number of linkable concepts $c \in$ **Wiki**, the number of Wikipedia concepts $\tilde{c}_0$ missing in **Wiki** and the average number of mentions per document.

some inconsistencies in the **CoNLL** training corpus that are presumably due to inter-annotator disagreement (20%) or candidate selection: while the phrase "European Union" is linked to the appropriate Wikipedia concept, it's acronym "EU" is linked to c_0. While Hoffart et al. neglected nil-concepts for evaluation on **CoNLLb**, these inconsistencies might be harmful for the SVM training of our approach. Moreover, **CoNLLb** contains many news articles about sport events. These are often not truly natural language texts, but more table-like. These variations make it challenging to apply the same system to different corpora.

For all corpora we proceed as follows: given the input mention, we first check if the ground truth concept is linkable, i.e. contained in our index. If this is not the case, but the mention is linked to some $c \neq c_0$, we change the ground truth to $\tilde{c}_0$ which is always considered during evaluation. Since we also resolve redirects, the number of distinct concepts in Tab. 1 may differ from the one published in the respective paper. Note that the overall number of mentions remains unchanged. The procedure is the same for concepts that do no longer exist in Wikipedia.
For a consistent set of named entity tags, we run the Apache OpenNLP NER[6] on all corpora.

6 Performance Measures for Wikification

In the following, we discuss different Wikification evaluation techniques. While in many areas performance measures are defined by the task at hand and used thoroughly by most authors, this is not the case in the field of concept disambiguation or Wikification. Consequently, published results are often hard to comparable.

Following Milne and Witten (2008), Ratinov et al. used **Bag-of-Titles** (**BOT**) evaluation which compares the predicted set of titles (i.e. concepts) with the ground truth set of concepts, ignoring duplicates in either set, and further utilizes standard Precision, Recall, and F1. For discussion, we take the example from Ratinov et al. (2011). Let the ground truth be $truth =$ {("China", *People's Rep. of China*), ("Taiwan", *Taiwan*), ("Jiangsu", *Jiangsu*}, with $truth_{BOT} =$ {*People's Rep. of China*, *Taiwan*, *Jiangsu*}. Assume the system predicts {("China", *People's Rep. of China*), ("China", *History of China*), ("Taiwan", c_0), ("Jiangsu", *Jiangsu*)}, with associated BOT $pred_{BOT} =$ {*People's Rep. of China*, *History of China*, *Jiangsu*}. According to Ratinov et al., both Precision and Recall for $pred_{BOT}$ are 0.66. Consequently, the nil prediction c_0 for *Taiwan* is not counted as a false positive, since we already observe *History of China* as a false positive, with two true positives from *People's Rep. of China* and *Jiangsu* resulting in $P = 0.66$.

The first remarkable point is the ignorance of duplicate concepts which obscures both erroneous as well as correct predictions: if a concept appears 5 times in the ground truth annotation, and the disambiguation model fails to resolve it correctly, the number of false negatives is only 1 in BOT, whereas it would be 5 if all instances were considered. Analogously this holds for the number of true positives. Second, nil predictions are not counted as false positives, which renders Precision less comparable. In our implementation of BOT, we assume that the sequential input order is taken into account.

The performance measure used by Hoffart et al. (2011b) is **Mean Average Precision** (**MAP**) which is defined as $MAP = \frac{1}{m}\sum_{i=1}^{m} p@\frac{i}{m}$, where $p@\frac{i}{m}$ is the Precision at a specific Recall level. Here, the model output is ranked according to the model's confidence s, i.e. mention-concept pairs with high model confidence are ranked at leading positions, pairs with low confidence at late positions. Consider the following prediction $\{s(m_3, c_3) = 0.9, s(m_2, c_2) = 0.8, s(m_1, c_1) = 0.2\}$, that is sorted by some confidence s instead of order of appearance. If c_1 is an incorrect prediction, the associated Precision values are $\{p@1 = \frac{1}{1}, p@2 = \frac{2}{2}, p@3 = \frac{2}{3}\}$. According to the above definition, the MAP of this example is $\frac{1+1+2/3}{3} = \frac{8}{9}$. If in contrast, we followed the sequential input order, the MAP would be $\frac{0+1/2+2/3}{3} = \frac{7}{9}$. Note that the interpretation of Recall differs from that in BOT since it is related to the position in the output list and not the number of false negatives. In terms of BOT, the performance result for this example is $P = R = \frac{2}{3}$.

Assuming that incorrect predictions have in general a low confidence, MAP shuffles erroneous predictions to the end of the ranked output list. Then the sum is dominated by correct predictions (high confidence) at the top of the ranking, which are propagated through the whole list. This is of great importance, if the number of mentions in a document is especially large. In our implementation of MAP, the model confidence is represented by the SVM's prediction, i.e. the instance's hyperplane offset.

The most crucial difference between current systems is the treatment of covered and uncovered concepts. Hoffart et al. decided to ignore nil-concepts during evaluation and hence roughly 20% of the mentions. To compare our method with AIDA, we follow this restriction when applying our method on **CoNLLb** and ignore nil-concepts for this corpus as well. Using the

AIDA online version that treats nil-concepts, we can evaluate this system on the other corpora. Kulkarni et al. also used a different evaluation scheme (KUL_{F1}) that is comparable to BOT but takes incorrect nil predictions into account. For more details, we refer to the respective paper.

7 Evaluation

As most alternative approaches rely on different versions of large-scale knowledge bases, it is practically not feasible to re-implement every competitor system. GLOW is publicly available, but we decided against using it, since we could not reproduce the results published in (Ratinov et al., 2011) and assumed that there was a crucial difference we could not solve[7]. Hence we compare our system to the figures reported by Ratinov et al. (2011) both for GLOW as well as the M&W system (Milne and Witten, 2008). For comparison with AIDA, we used the online interface $AIDA_{web}$ which was kindly provided to us by the authors[8] and run on all corpora. To give a unified view, we report the results for our system in all performance measures outlined in the previous section.

We ran initial experiments on all corpora to evaluate the effect of the mention expansion described in Sec. 3.2 and found that it increased $F1_{BOT}$ on all corpora by about 2%, when only the mention's name was considered in the search. We report the effect of different *search coverages* and show that in many cases results can be improved when we extend searches relying only the expanded mention name by additional type and context information. For all coverages, we show the effect of *bestFit* configurations: weighting NGD with Δ_{topics}, $\Delta_{\cos}$ and replacing NGD by the cosine distance over article texts. The influence of the topic feature computed from the Hellinger distance (Eq. 5) of $(topics(m_i), topics(c))$ is reported as well since it is computationally the most expensive SVM feature.

Tables 2 to 6 show the results obtained for the different configurations of our system. The corresponding performance figures of of GLOW, M&W and $AIDA_{web}$ are given in the text. For **MSNBC** (Tab. 2), the best configuration of our system (complete coverage, topics, *bestFit* candidate via $\Delta_{\cos}NGD$) achieves a $F1_{BOT}$ of 89.95%, which is 15% higher than that of GLOW (74.88%) and 20% higher than for M&W (68.49%). Also, the MAP of our system is with 96.81% more than 25% higher than that of $AIDA_{web}$ (69.52%). We found that the same configuration

⌀ cross coherence		0.402	0.208	0.134	0.262

Table 5: MAP of our system on **CoNLLb** for different configurations (all values in %).

also yields the best result on **ACE** (Tab. 3). On this corpus, our system achieves a $F1_{BOT}$ of 89.01%, which outperforms GLOW (77.25%) and M&W (72.67%) by more than 12%. Also, the MAP of our system is with 94.33% about 9% higher than that of $AIDA_{web}$ (86.14%).
For **AQUAINT** (Tab. 4), the best configuration of our system is complete search coverage and using the topic feature in SVM ranking. Here, *bestFit* candidate generation did not increase performance. We argue that this is due to the rather low average cross coherence over the ground truth concepts. Without the usage of collective information, our system achieves a $F1_{BOT}$ of 86.81%, which outperforms GLOW (83.94%) and M&W (83.61%) by 3%. Note that even the slightly worse results using collective search are higher. Also, the MAP of our system is with 91.97% about 30% higher than that of $AIDA_{web}$ (58.61%). For all of the above corpora, we found that not using the SVM for candidate re-ranking and nil-concept detection reduces the $F1_{BOT}$ of our system between 5 and 10%, which shows the usefulness of a supervised classifier.
For **CoNLLb** (Tab. 5), the best configuration of our system is the complete search coverage, the topic feature in SVM ranking, and *bestFit* candidate generation via Δ_{topics}NGD. This corpus has the highest avg. cross coherence over the ground truth concepts. Our system achieves a MAP of 89.32% (with corresponding $F1_{BOT}$= 82.16%), which is only slightly better than the figures published for AIDA (89.05%) but about 4% higher than that of $AIDA_{web}$ (85.66%). Without SVM application, the MAP of our system would be reduced to 86.70%. This indicates the necessity of features that are not graspable by **Wiki** but available in SVM candidate re-ranking.
We found that on **IITB** (Tab. 6), the best results can be achieved when we use only name and type based queries in combination with *bestFit* candidate selection via Δ_{topics}NGD. Although we found that this corpus has the lowest avg. cross coherence over the ground truth concepts, the collective search increases performance. We argue that this result is due to the very high number of mentions per document, which has a diminishing effect on the avg. cross coherence. Our system achieves a KUL_{F1} of 75.26%, which is 5% better than the result published by Kulkarni et al. (2009) (69.69%). Note that the performance of $AIDA_{web}$ on **IITB** is only MAP=43.62%, whereas the corresponding MAP of our system is 90%. We are aware that the performance reported by Han et al. (2011) is with KUL_{F1}=78.95% about 4% higher than that of our system. Still, even though our system was not tuned on specific data sets, we achieve a high performance on all of the 5 different benchmark corpora. We argue that this makes our system the most stable compared to other approaches both in terms of generalizability and applicability.

search coverage	no *bestFit*	*bestFit* via NGD	*bestFit* via Δ_{topics}NGD	*bestFit* via $\Delta_{\cos}$NGD	*bestFit* via $\cos(c_i, c_j)$

⌀ cross coherence		0.224	0.087	0.041	0.112

Table 6: KUL_{F1}/MAP on **IITB** for different method configurations (all values in %).

To summarize, we observe for all corpora a positive correlation between the avg. cross coherence of ground truth concepts and the effect of the collective search. The influence of confidence sorting in MAP becomes obvious on **MSNBC** and **ACE**: while F1_{BOT} differs only by 1%, the associated MAP value can differ by 4%. This can be the case, when the average number of mentions per document differs (8.5 on **ACE** and 37.75 on **MSNBC**).

The concept-mention probability $p(c|m)$ is a very strong feature as often the name is sufficient for disambiguation. This is most obvious on **IITB**, where the incorporation of context features even decreased performance. We also found that this prior-like attribute can mislead the SVM re-ranking on **CoNLLb**. This corpus contains many sport statistics that, for instance, mention countries participating in a match. As an example, even though the *bestFit Japan National Football Team* is correct due to high cross coherence, the SVM re-ranked the output to *Japan*, since the concept-mention probability $p(\textit{Japan}|\text{"Japan"}) = 0.97$ is much higher than $p(\textit{Japan National Football Team}|\text{"Japan"}) = 0.0063$. While Hoffart et al. (2011b) thus did not always use this feature, we could not find an appropriate threshold for our system.

Especially for **CoNLLb** we found that our system suffered from annotation scheme differences. While our system links mentions like "British" to concepts such as *English language* or *British people*, the ground truth concept in **CoNLLb** is always *United Kingdom*. An investigation showed that these annotations are often correct but in general depend on the gusto of the annotator. Also, we observed for **IITB** that many ground truth concepts are disambiguation pages. These are not contained in our index and thus treated as $\tilde{c}_0$. For example, we observed a document on sports mentioning the word "fitness" which was linked to the disambiguation page *Fitness* by the **IITB** annotators. While our system predicted the suitable concept *Physical Fitness*, this was still treated as an error since we relinked the disambiguation page *Fitness* to $\tilde{c}_0$.

Conclusion

In this paper we described a novel algorithm for concept disambiguation through concept assignment to Wikipedia articles. We exploit the coherence of Wikipedia concepts and take into account a variety of features to perform the assignment. The algorithm also estimates if a concept is not covered by Wikipedia. It turned out that the collective search is more efficient, if the average coherence between the concepts is higher.

We analyzed different evaluation criteria and discussed their relative strengths and weaknesses. We evaluated various configurations of our approach on five benchmark corpora and compared the results to four competitor systems. For some benchmark data sets our system is dramatically better than the other approaches, while for other corpora the differences are not so pronounced. We observed that these benchmark corpora are not error free, which can limit their usability. Except for one case our system always has better performance figures than the competitor systems and therefore can be considered as a stable alternative ready for practical application. In future work we will consider the assignment of concepts not described in Wikipedia.

Abstract
We study the perception of situational power in written dialogs in the context of organizational emails and contrast it to the power attributed by organizational hierarchy. We analyze various correlates of the perception of power in the dialog structure and language use by participants in the dialog. We also present an SVM-based machine learning system using dialog structure and lexical features to predict persons with situational power in a given communication thread.

Keywords: Computational Sociolinguistics, Social Networks, Power Analysis, Dialog Acts, Dialog.

Title and Abstract in German

Wer ist (wirklich) der Chef?
Situative Macht in schriftlichen Dialogen

Wir untersuchen, wie situative Macht in schriftlichen Dialogen wahrgenommen wird. Situative Macht ist Macht, die nicht beständig ist, sondern nur zielbedingt während einer (vielleicht längeren) Interaktion existiert. Unsere Studie beruht auf Geschäftsemails. Wir kontrastieren situative Macht mit der Macht, die durch die organisatorische Hierarchie entsteht. Wir identifizieren verschiedene Korrelate der Wahrnehmung situativer Macht in der Dialogstruktur und im Sprachgebrauch der Dialogteilnehmer. Wir stellen ausserdem einen SVM-basierten maschinellen Lernalgorithmus vor, der Dialogstruktur und Wörter in den Emails benutzt, um Dialogteilnehmer mit situativer Macht zu identifizieren.

1 Introduction

Within an interaction, there is often a power differential between the interactants. This differential is often drawn from a static source external to the interaction, such as a formal or informal power structure or hierarchy. Most computational studies (Creamer et al., 2009; Bramsen et al., 2011; Gilbert, 2012) that analyze power within interactions have used such an external power structure (namely, a corporate hierarchy) as the definition of the power differential. However, the power differential may also be dynamic and specific to the situation of the interaction. We define a person to have **situational power** if there is another person such that he or she has power or authority over the first person in the context of a situation or task. Such situational power may not always align with the external power structures, if one exists. For example, a Human Resources department employee within an organization will have power over an office manager when the interaction is about enforcing some HR policy. But the direction of power will be reversed if the interaction is about allocating office space for a new hire. Neither of these directions of power may be captured in the organizational hierarchy chart. In some cases, the situational power may even be in the opposite direction to the power relation reflected in the hierarchy — e.g., a subordinate organizing an office event.

Although power is a difficult concept to define, it is often recognizable from an interaction. As we show in this paper, one of the primary ways power is recognized in dialog is by the manner in which people participate in the dialog. Power relations sometimes constrain how one behaves when engaging in dialog; in some other cases, they enable one to constrain another person's behavior. And in some cases, the dialog behavior becomes a tool to express and even pursue power. By dialog behavior, we mean the choices a discourse participant makes while engaging in dialog. It includes choices with respect to the message content, like lexical choice or degree of politeness. It also includes choices participants make in terms of dialog structure, such as the choice of when to participate with how much and what sort of contribution, the number of questions to ask and which of those questions to answer. These manifestations may differ depending on whether the power differential is entirely hierarchical or situational or a mix of both - hierarchical power may be inert in a particular interaction, but situational power is a rather active form of power.

In this paper, we focus on situational power, how an outsider perceives it and what attributes of the interaction contributes to that perception. More specifically, we focus on why a dialog participant is perceived to have situational power within an interaction. Another related problem is whether a participant is perceived to have situational power over a *specified person* or not. We do not address it in this paper. We first analyze the notion of situational power in detail and find that its perception is subjective. We then define a set of features describing the choices participants make, including the dialog structure and the verbosity of dialog participants, and study how they correlate with the perception of situational power. We build a system to detect participants with situational power using a supervised machine learning approach. The main findings of this study are: a) situational power is a very different form of power than the power ascribed by hierarchy; b) the perception of situational power correlates with dialog structure as well as content-based features. The contributions of this paper also include an automatic situational power tagger based on dialog structure and content features. This study is conducted on email threads; however, we do not use any aspects of written dialog that are specific to email. Hence, we expect the methodology we use and the insights we gain to be applicable to other genres of online social media such as online discussion forums.

The rest of the paper is structured as follows: Section 2 presents related work in this field. Section 3 presents the data and describes various annotations present in the data, including situational power

annotations. Section 4 compares the perception of situational power with hierarchical power. Section 5 defines the problem formally and Section 6 describes all dialog structure and verbosity features we used. Section 7 presents statistical significance measures of these features with respect to persons perceived to have situational power. Section 8 presents the machine learning experiments conducted on the data and discusses results. We finally conclude and discuss future work.

2 Related Work

Most definitions of power in the sociology literature — e.g., (Dahl, 1957; Emerson, 1962; Bierstedt, 1950) — include "an element indicating that power is the capability of one social actor to overcome resistance in achieving a desired objective or result" (Pfeffer, 1981). The five bases of power proposed by French and Raven (1959) (Coercive, Reward, Legitimate, Referent, and Expert) and their extensions are widely used in sociology to study power. Wartenberg (1990) makes the distinction between two notions of power: power-over and power-to. Power-over refers to hierarchical relationships between interactants, while power-to refers to the ability to exercise power an interactant possesses (maybe temporarily) and can use within the interaction. Our notion of situational power roughly corresponds to Wartenberg's notion of power-to, while the power attributed to an interactant by an organizational hierarchy can be considered an instance of power-over. Both can be considered special cases of French and Raven's notion of legitimate power.

It has long been established that there is a correlation between dialog behavior of a discourse participant and how influential he or she is perceived to be by the other discourse participants (Bales et al., 1951; Scherer, 1979; Brook and Ng, 1986; Ng et al., 1993, 1995). Specifically, factors such as frequency of contribution, proportion of turns, and number of successful interruptions have been identified as being important indicators of influence. Reid and Ng (2000) explain this correlation by saying that "conversational turns function as a resource for establishing influence": discourse participants can manipulate the dialog structure in order to gain influence. This echoes a starker formulation by Bales (1970): "To take up time speaking in a small group is to exercise power over the other members for at least the duration of the time taken, regardless of the content." Simply successfully claiming the conversational floor represents a feat of power. The previous work just discussed was conducted entirely on spoken dialog. In this paper, we show that the core insight — conversation is a resource for power — carries over to written dialog. This means that we can predict powerful people from studying the discourse structure. However, some of the characteristics of spoken dialog do not carry over straightforwardly to written dialog, most prominently among them the important issue of interruptions: there is no interruption in written dialog. Our work draws on findings for spoken dialog, looking at correlates for written dialog.

We now turn to the computational literature. Several studies have used Social Network Analysis (Diesner and Carley, 2005; Shetty and Adibi, 2005; Creamer et al., 2009) or email traffic patterns (Namata et al., 2007) for extracting social relations from online communication. These studies use only meta-data about messages: who sent a message to whom when. For example, Creamer et al. (2009) find that the response time is an indicator of hierarchical relations; however, they calculate the response time based only on the meta-data, and do not have access to information such as thread structure or message content, which would actually verify that the second email is in fact a response to the first. In fact, using NLP to deduce social relations from online communication is relatively a new area which has only recently become an active area of research (Bramsen et al., 2011; Gilbert, 2012; Danescu-Niculescu-Mizil et al., 2012).

Bramsen et al. (2011) and Gilbert (2012) address the same problem we are trying to solve: identifying social power relationships from online written communication. They both also use the Enron email

corpus for their experiments. Using knowledge of the actual organizational structure, Bramsen et al. (2011) create two sets of messages: messages sent from a superior to a subordinate, and *vice versa*. Their task is to determine the direction of power (since all their data, by design in the construction of the corpus, has a power relationship). They approach the task as a text classification problem and build a classifier to determine whether the set of all emails (regardless of thread) between two participants is an instance of up-speak or down-speak. Similarly, Gilbert (2012) considers a message to be *upward* only when every recipient of that message outranks the sender. Any message that is not an *upward* message is labeled *non-upward*. This formulation is slightly different from that of (Bramsen et al., 2011) which considers only those messages that have a power relationship upward or downward. Gilbert (2012) extracts a list of phrases that signal *upward* messages using penalized logistic regression model. While the objectives of both these studies and our work are the same, there are major differences. Firstly, our focus is on situational power and how it is perceived by an outsider, while they focus on power from the organizational hierarchy. We show in Section 4 that the perception of situational power is not aligned with the organizational hierarchy. Secondly, our data unit is a naturally occurring thread, not data units assembled by the researchers, and a thread may or may not include a person who has power. Also, we focus on the structure of the dialog (which we can do since our unit is a thread, as opposed to a single message or an arbitrary aggregation of single messages).

Danescu-Niculescu-Mizil et al. (2012) study the notion of language coordination — a metric that measures the extent to which a discourse participant adopts another's language — in relation with various social attributes such as power, gender, etc. They perform their study on Wikipedia discussion forums and Supreme Court hearings. They also look into situational power; however they define situational power in terms of the dependence between interactants: "x may have power over y in a given situation because y needs something that x can choose to provide or not". They model this dependence "using the exchange-theoretic principle that the need to convince someone who disagrees with you creates a form of dependence." We adopt a broader definition of situational power based on context and perception. Strzalkowski et al. (2010) are also interested in power in written dialog. However, their work concentrates on lower-level constructs called *Language Uses* which will be used to predict power in subsequent work. They model power using notions of topic switching, exploiting mainly complex lexical features. Peterson et al. (2011) focus on formality in Enron email messages and relates it to social distance and power.

3 Data

3.1 Corpus

We use the email corpus presented in (Prabhakaran et al., 2012a) which contains manual annotations for various types of power relations between participants. In this study, we focus only on Situational Power (SP) and leave the other types of power for future work. The corpus contains 122 email threads with a total of 360 messages and 20,740 word tokens. This set of email threads is chosen from a version of the Enron email corpus with some missing messages restored from other emails in which they were quoted (Yeh and Harnly, 2006). Most emails are concerned with exchanging information, scheduling meetings, and solving problems, but there are also purely social emails. Table 1 presents some statistics on participants and messages in the corpus. We define an active participant of a given thread as someone who has sent at least one email message in the thread.

Apart from the thread level annotations for different types of power, the corpus also contains utterance level annotations for overt displays of power. The same corpus has been previously annotated with dialog act annotations (Hu et al., 2009). We utilize these annotations in our study

Statistic	Count / Mean (SD)
Number of email threads	122
Number of participants	1033
Ave. Participants / thread	8.47 (13.82)
Number of active participants	221
Ave. Active participants / thread	1.81 (0.73)
Number of messages	360
Ave. Messages / thread	2.95 (2.24)
Ave. Messages / active participant	1.45 (1.01)
Number of word tokens	20,740
Situational Power (SP)	81

Table 1: Corpus statistics

and will describe them in more detail in the following sections. We give an example thread and corresponding situational power annotations in Table 2. The example shows annotations for overt display of power (ODP) which will be explained in Section 3.1.2. The email body also contains dialog act annotations which will be explained in Section 3.1.3.

3.1.1 Situational Power Annotations

Person_1 is said to have situational power over person_2 if person_1 has power or authority to direct and/or approve person_2's actions in the current situation or while a particular task is being performed, based on the communication in the current thread. Situational power is independent of organizational hierarchy: person_1 with situational power may or may not be above person_2 in the organizational hierarchy (or there may be no organizational hierarchy at all). For more details on the situational power annotations, see (Prabhakaran et al., 2012a), where we explain these annotations in more detail with examples and describe instructions given to the annotator.

In our example thread, the annotator judged *William* to be possessing situational power over *Barry* and *Barry* over *Stephanie*: in both cases, a task is assigned to another person, even if the language used is more direct in the case of *Barry* delegating his task to *Stephanie*.

3.1.2 Overt Display of Power (ODP) annotations

An utterer can choose linguistic forms in her utterance to signal that she is imposing constraints on the addressee's choice of how to respond, which go beyond those defined by the standard set of dialog acts. For example, if the boss's email is "Please come to my office right now", and the addressee declines, he is clearly not adhering to the constraints the boss has signaled, though he is adhering to the general constraints of cooperative dialog by responding to the request for action. This roughly captures the "restriction of an interactant's action-environment", suggested as one of the key elements to identify exercise of power in interactions by Wartenberg (1990). An utterance is defined to have an **overt display of power (ODP)** if it is interpreted as creating additional constraints on the response beyond those imposed by the general dialog act. Syntactically, an ODP can be an imperative, a question, or a declarative sentence. The presence of an ODP does not presuppose that the utterer actually possess social power: the utterer could be attempting to gain power. Out of the 1734 utterances in our corpus, 86 were annotated to have an expression of ODP. In our example thread, utterances M2.2 and M2.6 were labeled as instances of ODP.

From: William S Bradford To: Barry Tycholiz CC: Michael Tribolet Subject: Gas Inventories Time: 2001-09-24 10:45:00 ——————————————— M1.1. Barry, [Conventional] M1.2. Situational Power	William S Bradford –> Barry Tycholiz
	Barry Tycholiz –> Stephanie Miller
Overt Display of Power	M2.2, M2.6

Table 2: Example thread and annotations; note that the dialog act for M1.2 appears to be incorrectly labeled as Inform, instead of Request-Action or perhaps Request-Information (we did not change any dialog act labels)

For a further discussion of the annotation of ODP, see (Prabhakaran et al., 2012b), where we further define the notion of ODP, give inter-annotator agreement numbers, and present initial work on building an automatic classifier for ODP.

3.1.3 Dialog Act annotations

The corpus we used also contains manual dialog act annotations as described in Hu et al. (2009). We use these annotations to model the dialog structure of the communication thread. Each message in the thread is segmented into Dialog Functional Units (DFUs). A DFU is a contiguous subset of a turn (i.e., in our corpus, of an email message) which has a coherent communicative intention. Each DFU is assigned a Dialog Act (DA) label which is one of the following: **Request for Action**, **Request for Information**, **Inform**, **Inform-Offline**,[1] **Conventional**, and **Commit**.

In addition, DFUs are interlinked by three types of links to reflect the dialog structure. These links capture the patterns of local alternation between an initiating dialog act and a responding one. A **forward link** (Flink) is the analog of a "first pair-part" of an adjacency pair, and is similarly restricted to specific speech act types. All Request-Information and Request-Action DFUs are assigned Flinks. The responses to such requests are assigned a **backward link** (Blink). If an utterance can be interpreted as a response to a preceding DFU, it gets a Blink even where the preceding DFU has no Flink. The preceding DFU taken to be the "first pair-part" of the link is assigned a **secondary forward** link (SFlink).

3.2 How Subjective is the Perception of Situational Power?

In this section, we investigate how subjective the perception of situational power is. We performed an independent study of annotator perceptions on a subset of 47 threads from the corpus. We trained two additional annotators — AnnA and AnnB — using the same annotation manual described in (Prabhakaran et al., 2012a) and compared the annotations they produced for situational power on the selected threads. Both AnnA and AnnB are undergraduate students, one from the Arts Department and the other from the Engineering Department.

The cognitive process behind labeling a participant to have situational power is not a binary decision the annotator makes for each participant. Annotators read the entire thread before performing the annotations. They are also asked to provide, in free-form English, a short "power narrative" which describes their perception of the overall power structure among the discourse participants of that thread. Annotators build a fairly consistent mental image of a power narrative — an outline of the power structure between the participants — based on various indicators from across the thread. Their annotations about situational power are based on this power narrative. Evaluating agreement on such a task is not trivial. For the purposes of this study, we port this task into a binary decision task of identifying whether participant X has situational power or not. There were 289 participants in the selected 47 threads. AnnA found 19 of these participants to have situational power while AnnB found only 13 to have situational power, 8 of which were also found by AnnA. We obtained a κ value of 0.472 which is only a moderate agreement. The fact that we don't obtain a higher agreement could be due to many reasons. Firstly, in porting the task to a binary labeling task, we are unnecessarily penalizing the annotators by introducing instances to represent judgments that the annotator never actually made. For example, if an email invite to a party was sent to 50 recipients, the annotator will not have considered each single recipient individually and made a choice about

[1] Sometimes, the Inform act refers to a previous act of communication that did not happen in the email thread itself. Such cases are marked as Offline.

him or her. However, these 50 recipients will be added as data points in our κ calculation, thereby increasing the expected agreement and decreasing the κ value. Another reason could be just that the task by itself is subjective. The indicators that are noticed by each annotator may underspecify how they can be interpreted in the power narrative (and subsequently the situational power annotation). The annotator's choices will then vary depending on the annotator's familiarity with corporate culture, or with other individual characteristic of the annotators.

We investigated the annotations further to confirm this. We found that there were many instances where different valid power narratives could be built based on the same email thread. For example, in our example thread, the message from Bill (first message) could be interpreted in isolation as a request from a peer or even a subordinate. However, if you take into consideration that Barry delegated the task to Stephanie upon receiving the message from Bill, the first message could be considered as Bill assigning a task to Barry. Either judgment is valid depending on the power narrative that one builds around the interaction within the thread. The original annotation in (Prabhakaran et al., 2012a) adopted the latter narrative whereas both AnnA and AnnB adopted the former. In our investigation of cases where AnnA and AnnB disagreed, we found many cases where both scenarios (person *X* having power and not having power) are plausible based on the annotators' power narrative.

The original annotations that were in the corpus are the perception of one particular annotator. We obtained similar moderate (>0.3) agreement between AnnA and AnnB and the original annotations for the subset of threads that were triply annotated. The moderate agreement suggests that there must be some core indicators of situational power that we could obtain by combining multiple perceptions. We leave that to future work. For the rest of this paper, we rely on the original annotations for the perception we are modeling. In Section 8.3, we explicitly address the issue of whether the original annotator's perceptions are internally consistent.

4 Are they really the bosses?

We explore how the perception of situational power compares with the organizational hierarchy. For this purpose, we utilize the gold organizational hierarchy for Enron released by (Agarwal et al., 2012). It contains relations between 1,518 employees, and 13,724 dominance pairs (pairs of employees such that the first dominates the second in the hierarchy, not necessarily immediately). We labeled a participant to have hierarchical power within a thread if there exist a dominance pair in the gold hierarchy where he/she is dominating over any other participant in the same thread.

According to the gold hierarchy, 113 out of the 1033 participants in our corpus have hierarchical power within the interaction. But only 12 of them (10.6%) were perceived to have situational power by our annotator. In other words, bosses act bossy rather rarely. Also, a total of 107 participants were judged to have situational power. The 12 of those who also had hierarchical power amounts to only 11.2% of them. In other words, you don't have to be the boss to be bossy.

The above findings are particularly important since most previous computational approaches have concentrated on modeling power purely in hierarchical terms. These findings show the importance of thinking beyond hierarchy and about other types of power.

5 Problem Definition and Approach

Now we move on to finding correlates in the interaction that could help predict participants with situational power. Given a communication thread $\mathcal{T}$ and an active participant $\mathcal{X}$, we would like

to predict whether $\mathscr{X}$ has situational power over some person $\mathscr{Y}$ in the thread.[2] In this paper, we restrict ourselves to features relative to messages sent by the participant $\mathscr{X}$. Hence, we consider each active participants in the thread as a data point and extract features with respect to them. There were 221 active participants in our corpus out of which 81 were annotated to have situational power. Our approach is to build a binary classifier predicting whether or not $\mathscr{X}$ has situational power based on features with respect to $\mathscr{X}$ in the context of the given thread $\mathscr{T}$.

6 Feature Sets

In this section, we describe six sets of features we use to capture the way interactants participate in dialog. The first four sets of features — dialog act (DAP), dialog link (DLC), positional (PST) features and verbosity (VRB) — relate to the whole dialog and its structure, whereas lexical (LEX) features and overt display of power (ODP) are features related to the form and content of individual messages. PST, VRB, and LEX are readily derivable from the data, while we use the gold annotation for DAP, DLC, and OSP.

6.1 Dialog act features - DAP

We have six features: **ReqAction**, **ReqInform**, **Inform**, **InformOffline**, **Conventional**, and **Commit**, denoting the percentage of each of these dialog act labels aggregated over all messages sent by the participant within the thread.

6.2 Dialog structure link features - DLC

We use counts of various types of dialog structure links between DFUs as features. We use absolute counts here rather than relative counts since there is no obvious maximal number of links against which to compare. **Flink**, **SFlink** and **Blink** denote the total number of Flinks, SFlinks and Blinks in messages sent by the participant. **Clink** denotes the number of Blinks by other people connected back to DFUs in messages sent by the participant. This includes both Flinks and SFlinks that are connected. **Dlink** denotes the number of Flinks by the participant that were not connected back via Blinks by other people ("dangling Flinks"). These are requests with no responses. **DlinkRatio** denotes Dlinks as a percentage of the number of Flinks by the participant.

6.3 Positional features - PST

We use features that denote the placement of the participant's messages relative to the thread. **Initiator** is a binary feature denoting whether the participant was the initiator of the thread. We used two other features: **FirstMsg** and **LastMsg**, to denote the position where the participant sent his/her first and last message, normalized by the total number of messages in the thread.

6.4 Verbosity features - VRB

We use features denoting how verbose the participant is within the thread. **MsgCount** denotes the number of messages sent by the participant. **MsgRatio** denotes the proportion of messages sent by the participant compared to the total number of messages in the thread. **TokenCount** denotes the number of tokens used by the participant. **TokenRatio** denotes the proportion of tokens used by the participant compared to the total number of tokens in the thread. **TokenPerMsg** denotes the average number of tokens per messages sent by the participant.

[2] The related problem to predict if person $\mathscr{X}$ has situational power over a specified person $\mathscr{Y}$ is not addressed in this paper.

Set	Features	SP
DAP	ReqAction	$\mathbf{0.07/0.01_{0.01}}$
	ReqInform	$0.10/0.12_{0.70}$
	Inform	$0.56/0.63_{0.10}$
	InformOffline	$0.003/0.005_{0.62}$
	Conventional	$0.25/0.23_{0.35}$
	Commit	$0.001/0.003_{0.51}$
DLC	Flink	$\mathbf{0.98/0.59_{0.03}}$
	SFlink	$\mathbf{0.49/0.24_{0.02}}$
	Blink	$0.72/0.59_{0.40}$
	Clink	$\mathbf{0.83/0.44_{7.1E-3}}$
	Dlink	$0.64/0.39_{0.08}$
	DlinkRatio	$\mathbf{0.33/0.21_{0.05}}$
PST	Initiator	$\mathbf{0.68/0.48_{3.3E-3}}$
	FirstMsg	$\mathbf{0.13/0.24_{1.1E-3}}$
	LastMsg	$0.41/0.36_{0.21}$
VRB	MsgCount	$\mathbf{1.68/1.32_{0.03}}$
	MsgRatio	$0.54/0.50_{0.18}$
	TokenCount	$\mathbf{113.04/74.19_{0.02}}$
	TokenRatio	$\mathbf{0.62/0.47_{2.1E-3}}$
	TokensPerMsg	$73.22/54.76_{0.07}$
ODP	ODPCount	$\mathbf{0.78/0.14_{6.0E-8}}$

Table 3: Statistical significance measures; values with $p \leq 0.05$ are boldfaced

6.5 Lexical features - LEX

The LEX feature set contains lexical features extracted from the content of messages sent by the participant. We aggregated all messages sent by the participant in the thread and extracted ngram counts for word lemmas. We experimented with **Unigram** counts, **Bigram** counts and a combination of both. We found that unigram counts performed better than the other two. Higher order ngrams were found to decrease the performance of the system.

6.6 Overt Display of power - ODP

We used a feature **ODPCount** to denote the number of instances of ODP in messages sent by the participant. For this study, we used the gold ODP tags (as we use the gold dialog annotations).

7 Statistical Significance Study

In this section, we present the statistical significance study of dialog features with respect to persons with situational power. We consider two populations of people who participated in the dialog – $\mathscr{P}_p$, those judged to have situational power and $\mathscr{P}_n$, those not judged to have situational power. Then,

for each feature, we performed a two-sample, two-tailed t-test comparing means of feature values of $\mathscr{P}_p$ and $\mathscr{P}_n$. Table 3 presents means of each feature value for both populations $\mathscr{P}_p$ and $\mathscr{P}_n$ (as mean($\mathscr{P}_p$)/mean($\mathscr{P}_n$)) along with the p-value associated with the t-test as the subscript. For p-values less than 0.05, we reject the null hypothesis and consider the feature to be statistically significant. We have highlighted the statistically significant features in Table 3.

7.1 Significant Features

We find many features to be statistically significant, which suggests that situational power is reflected in the dialog structure and content of messages. For example, persons with situational power tend to utter requests for action (ReqAction) significantly more than those without. They have significantly more connected links (Clink, SFlink); but the ratio of dangling links is also significantly higher for them, probably because they issue significantly more forward links (Flink). They also tend to be the initiators of the thread (Initiator) or start participating in the thread closer to the beginning (FirstMsg). They talk more within a thread (TokenRatio) and send significantly more (MsgCount) and longer (TokensCount, TokensPerMsg) messages. They also have significantly more instances of overt displays of power (ODPCount) than others.

7.2 Multiple Test Correction

The statistical measures presented in the previous section are exploratory in nature, presenting tests on all features, to gain a better understanding of their interaction with the situational power. We do not draw theoretical conclusions from the specific combination of interactions that are found statistically significant. Hence, we did not apply any corrections for multiple tests in statistical significance for individual features in the previous section. However, on applying the Bonferroni correction to adjust the p-value for the number of tests performed (threshold = 0.05/21 = 0.0024), three features (one each from PST (FirstMsg), VRB (TokenRatio) and ODP (ODPCount)) still remain statistically significant. Hence the global null hypothesis that the dialog structure and language use do not interact with situational power would still be rejected.

8 Automatic Situational Power Tagger

In this section, we present machine learning experiments to predict persons with situational power using features described in Section 6. We train a binary classifier to predict whether a participant has situational power or not.

8.1 Machinery

We used the ClearTK (Ogren et al., 2008) framework for extracting features and developing the classifier under the Apache UIMA framework. We used ClearTK's built-in tokenizer, POS tagger, lemmatizer and SVMLight (Joachims, 1999) wrapper. We balanced our dataset by up-sampling minority class instances in the training step. This has proven useful previously in cases of unbalanced datasets (Japkowicz, 2000). All results presented below have been obtained after balancing the training folds in cross validation; the test folds remain unchanged.

8.2 Experiments

Since we defined sets of dialog features (DAP, DLC, PST and VRB) in Section 6 based on separate aspects of communication they capture, we assume that these feature sets are reasonably coherent and individual features within a set interact with each other more strongly than with features from

Feature set	Features	P	R	F
Random		36.7	49.4	42.1
AlwaysTrue		36.7	100.0	53.6
VRB	TokenRatio, MsgRatio	43.9	70.4	54.0
PST	FirstMsg	45.1	67.9	54.2
DAP	ReqInform, Inform-Offline, Conventional, Commit	40.9	75.3	53.0
DLC	Blink, Flink, Clink, SFlink	49.6	**75.3**	59.8
LEX	Unigrams	54.9	55.6	55.2
ODP	ODPCount	**71.2**	51.9	**60.0**
BEST	DLC, ODP	59.4	70.4	64.4

Table 4: Cross validation results (P: Precision, R: Recall, F: F-measure) VRB: Verbosity, PST: Positional, DAP: Dialog acts, DLC: Dialog links, LEX: Lexical, ODP: Overt display of power

other feature sets. So, first we find the best performing subset of features for each feature set by exhaustive search within the set. The small cardinality of these feature sets (max of 6 for DAP and DLC) makes exhaustive search computationally feasible. For LEX, we found the best performing feature set to be Unigrams (Section 6.5), and ODP contains only one feature - ODPCount. Once we have the best subset of each feature set, we do another round of exhaustive search combining best performers of each set to find the overall best performing feature subset. We tried various feature selection methods such as information gain, which did not improve results. We believe this is because these methods rank each feature individually, and thus important interactions between features are not captured.

We used 5-fold cross validation on the data to evaluate the prediction performance for different feature subsets. The corpus was divided into 5 folds at the thread level. Active participants from 4 folds were used to train a model which was then tested on active participants in the 5th fold. We did this with all five configurations and all the reported results in this paper are micro-averaged results across 5 folds. We report (R)ecall, (P)recision and (F)-measure ($\beta = 1$). We experimented with a linear kernel and a quadratic kernel; the latter performed better. All results presented in this paper are obtained using a quadratic kernel.

8.3 Results

Table 4 shows cross validation results for each set of features. We present two baseline measures - **Random** and **AlwaysTrue**. In the Random baseline, we predict an active participant to have situational power at random. In AlwaysTrue baseline, we always predict an active participant to have situational power. The table 4 lists the best performing feature subset and corresponding precision/recall/f-measure for each set of features. As described in Section 8.2, the BEST feature set is found by doing exhaustive search on all combinations of best performers of VRB, PST, DAP, DLC, LEX and ODP.

The best performing individual feature sets are ODP and DLC, both at or near 60.0 F-measure. The random and AlwaysTrue baselines yield F-measures of 42.1 and 53.6, respectively. The best performers of all feature sets except DAP outperformed these baselines. The simple ngram based model obtained an F-measure of 55.2. While ODP results in a high precision (71.2) model, DLC yields a high recall (75.3) model; combination of both gave the best performing system with an

F measure of 64.4. The best performing single feature was ODPCount, which by itself gave an F measure of 60.0. The results we obtained are in line with the findings from the statistical significance study presented in Section 7. For example, DAP contained the least significant features while ODP contained the most significant feature. The tagger also performed worst when only DAP features were used and best when ODP was used. We assessed the statistical significance of F-measure improvements over baseline, using the Approximate Randomness Test (Yeh, 2000; Noreen, 1989).[3]. We found the improvements to be statistically significant (p = 0.001).

For the best performing feature set — DLC+ODP — we obtained a mean F-measure (macro-average) of 64.92 with a standard deviation of 8.82 (please note that Table 4 reports micro-averaged F-measure: 64.4). The low standard deviation suggests that the model built in this setting will obtain comparable performances for new unseen data. This also means that the data from which it was trained on the different folds of the cross-validation is sufficiently consistent to learn a model with predictive power. Put differently, our annotator's perception of situational power is coherent.

Conclusion and Future Work

In this paper, we studied the perception of situational power within written interactions. We have shown that situational power is not aligned with the organizational hierarchy. We have also shown that the perception of situational power correlates with various dialog structure and linguistic features. We presented an automatic situational power tagger to detect persons with power in written interactions. The methodology presented in this study can be applied to other forms of written interactions like discussions in online forums and blogs. We expect to find similar patterns of correlation in other genres.

As future work, we intend to study power relations between pairs of participants. It would be interesting to see how dialog features correlate with the other direction of power; that is from a submitter to an exerciser of power. Also, our current approach of aggregating features at the participant level is prone to noise. For example, let $\mathscr{X}$,$\mathscr{Y}$,$\mathscr{Z}$ be active participants such that $\mathscr{X}$ has power over $\mathscr{Y}$, who has power over $\mathscr{Z}$. When we aggregate features with respect to $\mathscr{Y}$, we are introducing noise from the part of communication between $\mathscr{X}$ and $\mathscr{Y}$. Extending our work to the person pair level would prevent this noise.

Our predictions are done using some gold features. Some features we used (verbosity, position) are readily derivable from the text; but others require processing. We will investigate using automatic taggers (such as a dialog act tagger and link predictor (Hu et al., 2009), an ODP tagger (Prabhakaran et al., 2012b)) to extract these features to predict power. However, one main contribution of this paper is to show the interaction between these dimensions of the dialog (like dialog structure and ODP) and situational power, which is an important first step towards solving the problem. Finally, in future work we will further study the manner in which different annotators interpret ambiguous threads in their power narratives, and identify different levels of certainty of situational power.

ABSTRACT

Bilingual lexicon construction (BLC) from comparable corpora is based on the idea that bilingual similar words tend to occur in similar contexts, usually of words. This, however, introduces noise and leads to low performance. This paper proposes a bilingual dependency mapping model for BLC which encodes a word's context as a combination of its dependent words and their relationships. This combination can provide more reliable clues than mere context words for bilingual translation words. We further demonstrate that this kind of bilingual dependency mappings can be successfully generated and maximally exploited without human intervention. The experiments on BLC from English to Chinese show that, by mapping context words and their dependency relationships simultaneously when calculating the similarity between bilingual words, our approach significantly outperforms a state-of-the-art one by ~14 units in accuracy for frequently occurring noun pairs and similarly, though in a less degree, for nouns and verbs in a wide frequency range. This justifies the effectiveness of our dependency mapping model for BLC.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE, CHINESE

应用依存映射从可比较语料库中抽取双语词表

从可比较语料库中抽取双语词表的基本思想是，双语相似的词语出现在相同的语词上下文中。不过，这种方法引入了噪声，从而导致了低的抽取性能。本文提出了一种用于双语词表抽取的双语依存映射模型，在该模型中一个词语的上下文结合了依存词语及其依存关系。这种结合方法为双语词表构建提供了比单一的词语上下文更为可靠的信息。我们还进一步展示了在没有人工干预的情况下可以产生和利用这种双语依存关系。从英文到中文的双语词表构建实验表明，通过在计算双语词语相似度时同时映射词语及其依存关系，同目前性能最好的系统相比，我们的方法显著提高了精度。对于经常出现的名词，精度提高了14个百分点；对于较大频率范围内的名词和动词，性能也提高了，尽管程度较小。这说明了依存映射模型对双语词表构建的有效性。

1 Introduction

Bilingual lexicons play an important role in many natural language processing tasks, such as machine translation (MT) (Och and Ney, 2003; Gong et al., 2011) and cross-language information retrieval (CLIR) (Grefenstette, 1998). Traditionally, bilingual lexicons are built manually with tremendous efforts. With the availability of large-scale parallel corpora, researchers turn to automatic construction from parallel corpora and achieve certain success (Wu and Xia, 1994). However, large-scale parallel corpora do not always exist for most language pairs. Therefore, researchers turn their attention to either pivot languages or non-parallel but comparable corpora.

Using pivot languages in BLC was pioneered by Tanaka and Umemura (1994). Thereafter, various studies have been done to take advantage of multiple paths (Mann and Yarowsky, 2001) and even multiple pivot languages (Mausam et al., 2009) between the source and target languages. Since such automatically constructed lexicons usually contain noisy and polysemous entries, corpus-based occurrence information has been widely used to help rank the candidate target words (Schafer and Yarowsky, 2002; Kaji et al., 2008; Shezaf and Rappoport, 2010).

Alternatively, extracting bilingual lexicons from comparable corpora assumes that words with similar meanings in different languages tend to occur in similar contexts, even in non-parallel corpora. Rapp (1999) and Fung (2001) proposed a bilingual context vector mapping strategy to explore word co-occurrence information. Both studies rely on a large, one-to-one mapping seed lexicon between the source and target languages. Koehn and Knight (2002) investigated various clues such as cognates, similar context, preservation of word similarity and word frequency. Garera et al. (2009) proposed a dependency-based context model and achieved better performance than previous word-based context models. Recent studies concentrate on automatic augmentation of the seed lexicon either by extracting identical words between two closely related languages (Ficšer and Ljubešić, 2011) or by aligning translation pairs from parallel sentences, which is mined in advance from a comparable corpus (Morin and Prochasson, 2011). The problem with above method is that they only consider the words involved in the contexts and ignore other rich information therein, such as syntactic relationships, thus usually suffering from low performance especially when they are applied to two distinct languages such as English and Chinese. For example, our preliminary experiment with the dependency-based model (Garera et al., 2009) shows that English source word "profit" matches wrongly with Chinese target word "企业" (enterprise), instead of the correct one "利润", due to the higher similarity score with the former than that with the latter. Further exploration shows that the word "企业" has a much higher frequency than the word "利润" in the adopted corpus, thus tends to have a higher similarity score due to richer (nevertheless noisy) contexts. We also find that some relevant contextual words with both target words, such as "实现" (realize) and "成本" (cost) etc., share the same or corresponding dependency relationships with "利润" (profit), i.e. *dobj* and *conj*, but not with "企业" (enterprise).

In order to take advantage of this observation, this paper proposes a bilingual dependency mapping model for BLC from a comparable corpus by extending the scope of a word's context from mere neighbouring words to both dependent words and their dependency relationships. The basic idea underlying our model is that bilingual similar words tend to occur within similar

bilingual contexts involving not only dependent words but also their relationships, and the similarity between bilingual words can be better calculated by considering the mappings of both context words and their relationships. Furthermore, while the mappings of bilingual words may suffer from the data sparseness problem due to the availability of only a small scale of given seed lexicon, the mappings of dependency relationships can be reliably generated from the seed lexicon without human intervention, making our method easily adapted to other language pairs and domains. Finally, the weights of different dependency mappings can be automatically learned using a simple yet effective perceptron algorithm.

The remainder of this paper is organized as follows. Section 2 reviews the related work. Section 3 introduces our comparable corpus and a strong baseline. Section 4 details our dependency mapping approach while the experimentation is described in Section 5. Finally, Section 6 draws the conclusion with future directions.

2 Related work

In this section, we limit the related work to BLC from comparable corpora between English and Chinese. For others, please refer to the general introduction in Section 1.

Due to distinct discrepancies between English and Chinese, BLC from comparable corpora between these two languages is challenging. Fung (2000) extracted word contexts from a comparable corpus, and calculated the similarity between word contexts via an online dictionary. Particularly she analyzed the impact of polysemous words, Chinese tokenization and English morphological information. Zhang et al. (2006) built a Chinese-English financial lexicon from a comparable corpus with focus on the impact of seed lexicon selection. Haghighi et al. (2008) proposed a generative model to construct lexicons for multiple language pairs, including English-Chinese, via canonical correlation analysis, which effectively explores monolingual lexicons in terms of latent matching.

In particular for BLC without any external lexicon, Fung (1995) focused on context heterogeneity in Chinese and English languages, which measures how productive the context of a word is, instead of its absolute occurrence frequency. She suggested that bilingual translation words tend to share similar context heterogeneity in non-parallel corpora. Specifically, she calculated the similarity between two bilingual words using the ratios of unique words in the right and left contexts. Yu and Tsujii (2009) proposed the notion of dependency heterogeneity, which assumes that a word and its translation should share similar modifiers and heads in comparable corpora, no matter whether they occur in similar contexts or not. In this sense, our approach is similar to theirs. However, while their distance measure of dependency heterogeneity is limited to three easily-mapping common relationships between two languages, namely SUB, OBJ and NMOD, we further generalize to automatic mappings of any bilingual dependency relationships. Another difference is that our method considers dependent words and their relationships simultaneously.

3 Corpus and baseline

This section introduces the comparable corpus and the bilingual seed/test/development lexicons used in this paper for evaluation as well as a state-of-the-art baseline for BLC.

3.1 Comparable corpus

In this paper, we generate a comparable corpus from the parallel Chinese-English Foreign Broadcast Information Service (FBIS) corpus, gathered from the news domain. This bilingual corpus contains about 240k sentences, 6.9 million words in Chinese and 8.9 million words in English. Similar to the way adopted in (Garera et al., 2009; Haghighi et al., 2008), we couple the first half of Chinese corpus and the second half on the English side as our comparable corpus.

For corpus pre-processing, we use the Stanford POS tagger (Toutanova and Manning, 2000) and syntactic parser (Marneffe et al., 2006) to generate the POS and dependency information for each sentence in both Chinese and English corpora. Particularly, English words are transformed to their respective lemmas using the TreeTagger package (Helmut, 1994).

3.2 Bilingual lexicons for evaluation: seed, test and development

In the literature, different scales of bilingual seed lexicons have been used. For example, Rapp (1999) and Fung (2000) used large-scale dictionaries of 10-20k word pairs while other studies (Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009) used only small dictionaries of about 100-1000 word pairs.

In this paper, we adopt a small scale one. In particular, we use the GIZA++ package (Och and Ney, 2000) to extract the most frequently occurring 1000 word pairs as the bilingual seed lexicon (denoted as L_s) and the subsequent 500 noun pairs (denoted as LN_t) as the primary bilingual test lexicon. This way of generating the test lexicon for nouns has been commonly used in previous studies (Koehn and Knight, 2002; Haghighi et al., 2008; Garera et al., 2009). Besides, we frame a secondary test lexicon (denoted as LA_t) including 200 nouns, verbs and adjectives respectively, which spread evenly in the four ranges of 1001-2000, 2001-3000, 3001-4000 and 4001-5000. The goal of LA_t is to evaluate the adaptability of our method to words with different categories in a wide frequency range.

Different from other studies on context-based BLC which use the seed lexicon only for bilingual word projection, we set aside a bilingual development lexicon L_d of nouns, verbs and adjectives (denoted as LN_d, LV_d and LJ_d) respectively for fine-tuning our BLC system. This bilingual development lexicon is constructed by randomly selecting 200 nouns, 200 verbs and 100 adjectives[1] in the bilingual seed lexicon. Obviously we have $L_d = \{LN_d \bigcup LV_d \bigcup LJ_d\} \subset L_s$.

3.3 Baseline

As a state-of-the-art baseline, Garera et al. (2009) extracted the words from the dependency tree with a fixed window size of ±2 as the context. That is, given a word w in a sentence, all the words corresponding to its immediate parent (-1), immediate children (+1), grandparent (-2) and grandchildren (+2) are extracted as features to constitute a context vector. Specifically, each feature in the vector is weighted by its point-wise mutual information (PMI) with the word w, defined as:

$$PMI(w,c) = \log_2 \frac{N(w,c) * N}{N(w) * N(c)} \quad (1)$$

[1] In the bilingual seed lexicon there are about 500, 300, 200 English and Chinese noun, verb and adjective pairs respectively.

where *N(w, c)* is the co-occurrence frequency of word *w* and its context word *c*, *N(w)* and *N(c)* are the occurrence frequencies of the words *w* and *c* respectively, *N* is the number of all word occurrences in the corpus. Since PMI is usually biased towards infrequent words, we multiplied it with a discounting factor as described in (Lin and Pantel, 2002):

$$\frac{N(w,c)}{N(w,c)+1} \times \frac{\min(N(w),N(c))}{\min(N(w),N(c))+1} \tag{2}$$

Then, the pair-wise similarity scores between source word w_s and candidate target words w_t are computed using the cosine similarity measure as follows:

$$Sim_{DW}(w_s,w_t) = COS(W_s,W_t) = \frac{\sum_i W_s^i \times W_t^i}{\sqrt{\sum_i W_s^i} \times \sqrt{\sum_i W_t^i}} \tag{3}$$

where W_s and W_t are the dependent word vectors of source word w_s and candidate target words w_t respectively, W_s^i and W_t^i are the discounted PMI values of the *i*th features f_s^i and f_t^i, s.t. $(f_s^i, f_t^i) \in L_s$. We call Formula (3) the dependent word similarity as it is calculated solely on dependent words in the contexts.

Finally, all the candidate target words are ranked in terms of their dependency word similarity scores with source word w_s, and the top one $\hat{w}_t$ is selected as the translation word:

$$\hat{w}_t = \arg\max_{w_t \in GEN(w_s)} Sim_{DW}(w_s,w_t) \tag{4}$$

Where $GEN(w_s)$ is a function that enumerates a set of candidates for source word w_s. Here, as our goal is to build a lexicon of nouns occurring frequently in the source text, one reasonable assumption is that their translation counterparts also occur frequently in the target text. Therefore, in order to reduce the computation cost we limit the candidate words for source word w_s, $GEN(w_s)$ to the most frequently occurring nouns with the number set to 10 times of the size of the lexicon.

4 BLC via dependency mappings

In this section, we first present the dependency mapping model for BLC and then detail on how to manually and automatically generate dependency mappings via a given development lexicon.

4.1 Dependency mapping model

Following Garera et al. (2009) and Yu and Tsujii (2009), we further postulate that the mapping of dependency relationships can hold between two translation words in comparable corpora. It is worth noting that one dependency relationship in one language may not always be directly mapped to the same relationship in another language and there are even cases where one relationship may map to multiple relationships in another language (cf. Fig. 1).Generally, we can enumerate the mappings of dependency relationships between English and Chinese, either by crafting manually or generating automatically. Suppose that we already have such dependency mappings between English and Chinese at hand, denoted as Ψ. Compared with the baseline procedure in Subsection 3.3, bilingual lexicon construction via dependency mappings can be revised by generating dependency mapping context vectors, in which each feature combines a dependent word and its relationship. Here, the window size is fine-tuned to ±1 (using the

development lexicon LN_d) with the relationship direction not considered. Formally, the weight of each feature can be recast via PMI as:

$$PMI(w,ct) = \log_2 \frac{N(w,ct) * N}{N(w) * N(ct)} \quad (1')$$

where *ct* denotes the combination of the dependent word and its relationship. Similarly, this PMI value is also discounted according to Formula (2).

Likewise, the dependency mapping similarity between source word w_s and target candidate word w_t is calculated using the cosine similarity as follows:

$$Sim_{DM}(w_s, w_t) = COS(D_s, D_t) = \frac{\sum_i D_s^i \times D_t^i}{\sqrt{\sum_i D_s^i} \times \sqrt{\sum_i D_t^i}} \quad (3')$$

where D_s and D_t are the dependency mapping vectors of source word w_s and candidate target words w_t respectively, D_s^i and D_t^i are the discounted PMI values of the ith features f_s^i and f_t^i whose involved words are translation pairs in the seed lexicon and whose involved dependency types are bilingually mapped in Ψ, i.e. $(f_s^i.word, f_t^i.word) \in L_s$ and $(f_s^i.type, f_t^i.type) \in \Psi$.

Obviously, we can rank the candidate target words in terms of their dependency mapping similarity scores with the source word and select the top one as the translation word. However, this often leads to the data sparseness problem since the combination of a dependent word and its relationship occurs much less frequently than a dependent word alone. Therefore, the dependent word similarity and dependency mapping similarity are interpolated linearly for candidate ranking as follows:

$$Sim_T(w_s, w_t) = \alpha \times Sim_{DW}(w_s, w_t) + (1-\alpha) \times Sim_{DM}(w_s, w_t) \quad (5)$$

Where $Sim_T(w_s, w_t)$ denotes the overall similarity score between the words w_s and w_t, and α is a coefficient to balance these two similarity measures and can be fine-tuned using the development lexicon L_d.

4.2 Manually crafting dependency mappings

Considering the number of dependency relationships in both English and Chinese, e.g. 53 dependency relationships in Stanford encoding scheme, there are potentially thousands of possible mappings between these two languages. Fortunately, the distribution of various dependency relationships is severely skewed. Table 1 lists the statistics for the dependency relationships whose percentages are greater than 2% in the descending order, where the left three columns denote the English relationships, their short descriptions and percentages as well as the Chinese statistics on the right three columns. These statistics are obtained from 5000 most frequently occurring nouns in our English and Chinese corpora.

It shows that the top 8 types (*prep*, *conj*, *nsubj*, *nn*, *amod*, *dobj*, *dep* and *poss* for English and *nn*, *conj*, *dobj*, *assmod*, *nsubj*, *rcmod*, *amod* and *dep* for Chinese) account for 87.2% and 94.2% of total dependency relationships for English and Chinese respectively. This means when we consider dependency mappings between English and Chinese, we can safely ignore other relationships whose percentages are less than 2%. Furthermore, since the *dep* one in both English and Chinese denotes general dependency relationship that can not be nicely fitted into other more

specific ones, the mapping between *dep* and any other ones are not considered subsequently in this paper.

EN Rel.	Short Description	%	CN Rel.	Short Description	%
prep	prepositional modifier	35.7	nn	noun modifier	32.0
conj	conjunction	11.8	conj	conjunction	13.1
nsubj	nominal subject	9.3	dobj	direct object	11.8
nn	noun modifier	8.6	assmod	associative modifier	11.4
amod	adjectival modifier	8.1	nsubj	nominal subject	9.6
dobj	direct object	7.6	rcmod	relative clausal modifier	8.0
dep	general dependency	3.6	amod	adjectival modifier	4.5
poss	possessive modifier	2.5	dep	general dependency	3.8
Total		87.2	Total		94.2

TABLE 1 –Statistics on dependency relationships for English and Chinese nouns

Using linguistic knowledge from both English and Chinese languages, we manually craft 10 dependency mappings Ψ_M between these two languages, as shown in Fig. 1.

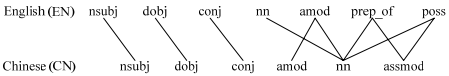

FIGURE 1 – Bilingual dependency mappings between English and Chinese

From the figure we can see that while some mappings, such as *nsubj* (EN) to *nsubj* (CN) and *dobj* (EN) to *dobj* (CN), capture common grammatical relationships in both languages, others, such as *poss* (EN) to *assmod* (CN), indicate the differences across the two languages. Particularly interesting is that *nn* (CN) can map to four relationships, namely *nn*, *amod*, *prep_of* and *poss* (EN) while *nn* (EN) has only one correspondence *nn* (CN). This indicates that *nn* (CN) is much more productive and ambiguous than *nn* (EN). This scenario can be illustrated by possible mapping of example Chinese phrase "中国银行" (*nn*) to English phrases "China Bank" (*nn*), "Chinese Bank" (*amod*), "Bank of China" (*prep_of*) , and "China's Bank" (*poss*), though only the third is correct while all the others are merely grammatically reasonable.

4.3 Automatically generating dependency mappings

While manually crafting dependency mappings between two languages do serve our purpose, its limitation exists in the need for bilingual knowledge and the lack of flexibility. One alternative is to automatically generate bilingual dependency mappings via a development lexicon. The idea behind is that not only the bilingual words with similar dependent words and dependency relationships tend to pair each other (cf. Section 4.1), but also the bilingual dependency relationships between similar dependent words and their context words tend to map to each other. Fig. 2 illustrates an algorithm to derive bilingual dependency mappings via a development lexicon.

In this figure, Ψ_A denotes the set of bilingual dependency mappings to be automatically generated while D_s and D_t are the respective dependency mapping vectors for source word s_i and target word t_i respectively.

Input: $L_d = \{(s_i, t_i)\}_{i=1}^{N}$

Output: Ψ_A

Initialize: $\Psi_A = NULL$

1. for i =1…N
2. extract D_s and D_t for s_i and t_i
3. for each feature f_s^j and f_t^j in D_s and D_t
4. if $(f_s^j.word, f_t^j.word) \in L_s$ then
5. add this mapping and its count to Ψ_A
6. end if
7. end for
8. end for
9. calculate the percentage for each mapping in Ψ_A
10. keep the top 30 most frequent mappings in Ψ_A

FIGURE 2 –Algorithm for automatically generating bilingual dependency mappings

Table 2 shows the derived bilingual dependency mappings from English to Chinese along with their percentages. Compared with Fig. 1, we can see that all the 10 manually crafted mappings (marked in italics fonts) in Ψ_M can be found in the top 30 automatically generated mappings Ψ_A, with 8 in top 10. This implies high consistency between Ψ_A and Ψ_M. A natural question one may ask is: are those extra mappings in Ψ_A but not in Ψ_M noisy for BLC?

No	EN-CN map.	%	No	EN-CN map.	%	No	EN-CN map.	%
1	*prep_of-nn*	7.3	11	nsubj-nn	1.7	21	prep_of-dobj	0.9
2	*nn-nn*	7.0	12	dobj-nn	1.6	22	nn-conj	0.9
3	*amod-nn*	6.2	13	conj-assmod	1.5	23	dobj-rcmod	0.8
4	*conj-conj*	5.5	14	nsubj-dobj	1.4	24	nsubj-assmod	0.8
5	*dobj-dobj*	5.4	15	*poss-nn*	1.4	25	amod-conj	0.8
6	conj-nn	4.9	16	prep_of-conj	1.2	26	amod-rcmod	0.8
7	*amod-amod*	3.2	17	amod-assmod	1.1	27	nn-assmod	0.8
8	*prep_of-assmod*	3.1	18	prep_for-nn	1.0	28	conj-dobj	0.8
9	*nsubj-nsubj*	2.5	19	dobj-nsubj	1.0	29	*poss-assmod*	0.7
10	prep_in-nn	2.4	20	prep_in-assmod	1.0	30	dobj-conj	0.7

TABLE 2 – Top 30 dependency mappings mined via the development lexicon

To answer this question is by no means a trivial task. Although we are quite sure that some of the mappings in Ψ_A are irrelevant such as *nsubj-assmod*, for others it's difficult to determine their relevancy with BLC from the linguistic perspective, just as we are not sure whether there are other useful mappings missing in Ψ_M. Therefore, we adopt an ablation testing strategy to progressively remove those mappings whose removal lead to better performance using the development lexicon L_d. Fig. 3 illustrates the algorithm, where P^i in Line 2 denotes the performance achieved on the development lexicon L_d using previous mappings Ψ_A^{i-1} and P_j in Line 4 denotes the performance on L_d using mappings Ψ_A^{i-1} minus the jth mapping. The output of this algorithm $\hat{\Psi}_A$ maximizes the performance on the development lexicon L_d.

Input: Ψ_A and L_d

Output: $\hat{\Psi}_A$

Initialize: $\Psi_A^0 = \Psi_A$

Steps:

1. for i =1… $|\Psi_A|$
2. calculate P^i using Ψ_A^{i-1} on L_d
3. for each mapping m_j in Ψ_A^{i-1}
4. calculate P_j using $\Psi_A^{i-1} - \{m_j\}$ on L_d
5. end for
6. $\hat{m} = \arg\max_{m_j} P_j$
7. $\Psi_A^i = \Psi_A^{i-1} - \{\hat{m}\}$
8. end for
9. $\hat{\Psi}_A = \arg\max_{\Psi_A^{i-1}} P^i$

FIGURE 3 –Algorithm for filtering the noisy mappings in Ψ_A

4.4 Weight learning via perceptron

While coefficient α in Formula (5) can be determined empirically using a development lexicon, it equally weighs different mappings. We argue that this may not be optimal since different mappings may have different contributions to BLC. That is, different mappings should have different weights to exploit such difference. Thus, Formula (5) can be recast as follows:

$$Sim_T(w_s, w_t) = \alpha^0 \times Sim_{DW}(w_s, w_t) + \sum_{i=1}^{|\Psi|} \alpha^i Sim_{DM}^i(w_s, w_t) \quad (5')$$

In this paper, we propose a simple perceptron algorithm to optimize those weights for different mappings using the development lexicon. Generally, the perceptron algorithm is guaranteed to find a hyper-plane that classifies all training points, if the data is separable. Even the data is non-separable as in most practical cases, the variants of perceptron (Freund and Schapire, 1999; Collins and Duffy, 2002), such as averaged perceptron (AP) or voted perceptron (VP), can generalize well.

Input: training examples (s_i,t_i)

Output: w

Initialize: w= w^0

Steps:

1. for i = 1…T
2. for j =1…N
3. Calculate $\hat{t}_j = \arg\max_{t \in GEN(s_j)} \Phi(s_j, t) \times w$
4. If $\hat{t}_j != t_j$ then $w = w + \Phi(s_j, t_j) - \Phi(s_j, \hat{t}_j)$
5. $u_{i,j} = w$
6. end for
7. end for
8. output $w = \sum_{i,j} u_{i,j} / NT$

Figure 4 – Perceptron algorithm for weight learning

Fig. 4 shows our averaged perceptron algorithm, where

- d, the number of features in a vector, is set to the order of the mapping set plus 1 for the dependency word similarity.
- Φ is a function which maps each bilingual word pair (s, t) to a feature vector $\Phi(s,t) \in R^d$.
- $w \in R^d$ is a weight vector for different mappings, and its initial value w^0 is set to the occurrence ratio for each mapping as in Table 2.

Here, the function Φ calculates the dependent word similarity score (cf. Formula (3)) and the similarity scores for each dependency mapping in Ψ (cf. Formula (3')), $u_{i,j}$ stores the weight vector in the ith iteration given the jth training example, and T denotes the number of iterations over the development lexicon[2].

5 Experimentation

This section systematically evaluates our approach for English-Chinese BLC. In this paper, precision (P) and mean reciprocal rank (MRR) are used as our evaluation metrics, as done in the literature (Koehn and Knight, 2002; Garera et al., 2009; Yu and Tsujii, 2009), where precision is the average accuracy within the top n (n=1 here) most similar words while MRR is the average of the reciprocal ranks for all the test words:

$$precision = \frac{count_{top1}}{N_w} \tag{6}$$

$$MRR = \frac{1}{N_w}\sum_{i=1}^{N_w}\frac{1}{rank_i} \tag{7}$$

where $count_{top1}$ is the number of correct translation words on the top one ranking, and $rank_i$ denotes the rank of the correct translation word for the ith test source word, and N_w is the total number of the test source words (e.g., 500).

5.1 Performance on the development noun lexicon LN_d

In order to determine the optimal subsets in automatic mappings Ψ_A and manual mappings Ψ_M respectively, we conduct ablation tests on the development lexicon LN_d (cf. Fig. 3) using proportional weights (PR) or automatic weights learned by the AP algorithm (cf. Fig. 4). Fig 6 depicts the MRR performance scores for 4 combinations, i.e. Auto-PR, Auto-AP, Manual-PR and Manual-AP. For Ψ_A, x-axis denotes the top 30 mappings (cf. Table 2) while for Ψ_M we present the data from the 20th iteration as there are only 10 mappings (cf. Fig. 1). At each iteration, the mapping whose removal causes the biggest performance increase is removed and the MRR score is measured using the remaining mappings. The integer numbers in Table 2 indicate the mappings to be removed at the corresponding iteration. Please note that the first iteration corresponds to all dependency mappings in Ψ_A or Ψ_M and the last one corresponds to the baseline without any dependency mapping. The figure shows that:

[2] T is experimentally tuned to 200 since the average perceptron algorithm converges after 200 iterations on the development lexicon LN_d.

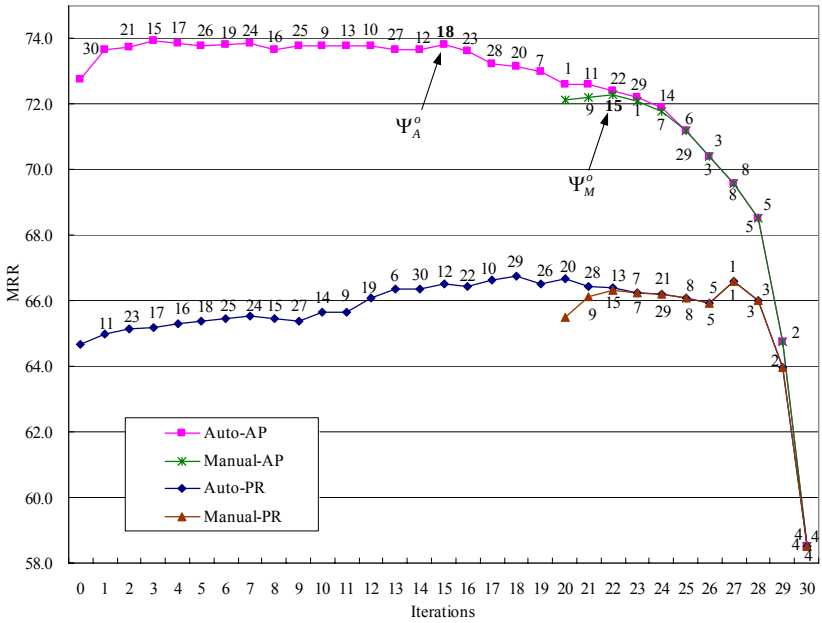

FIGURE 6 – MRR performance of ablation tests for Ψ_A and Ψ_M on the development noun lexicon

- The dependency mapping model with average perceptron significantly outperforms its counterpart with proportional weights. This suggests that weight optimization via perceptron algorithms substantially helps BLC. Therefore, the following experiments do not consider proportional weights.
- All the 4 combinations exhibit similar trends. That is, with the shrinkage of the mappings, the performance first slightly increases, then peaks at some iteration, afterwards decreases slowly, and finally drops significantly. This trend suggests that there do exist some noisy mappings, more or less in both Ψ_A and Ψ_M. However, removing them can only lead to limited performance improvement while too few mappings severely harm the performance.
- An interesting phenomenon is that the two combinations (Auto-AP and Manual-AP) converge at the last 7 iterations, so do the other two (Auto-PR and Manual-PR). This implies high consistency between manually crafted mappings and top automatically generated mappings no matter whether their weights are fine-tuned using a proper machine learning algorithm or fixed to their proportions in the corpus.

According to above observations, we select the most consistent mappings as the optimal ones in all the following experiments instead of choosing the best mappings for each combination. These sets, marked by the symbols Ψ_A^o (15 mappings for Auto_AP) and Ψ_M^o (8 mappings for Manual_AP) in the figure, include medium-sized mappings which perform the best or very

closely to the best. It is not surprising to find that 7/8 mappings in Ψ_M^o are included in Ψ_A^o because of their high consistency.

5.2 Comparison of mapping weights in Ψ_A^o and Ψ_M^o

Table 3 ranks the weights learned for each mapping in Ψ_A^o and Ψ_M^o in the descending order, where the mappings with negative weights are omitted. It shows that different mappings have very different weights, among which *conj-conj* and *poss-assmod* are ranked high while *nn-nn* and *prep_of-nn* are ranked low. This suggests that the former two are more discrimitive than the latter two in dependency mapping-based BLC, though the latter two occur more frequently as indicated in Table 2. In other words, the meaning of a noun depends more on its conjuncts and possessive/associative modifiers to a certain extent than on its prepositional phrases or noun premodifers.

Auto Ψ_A^o	Weights	Manual Ψ_M^o	Weights
conj-conj	0.2317	poss-assmod	0.3022
poss-assmod	0.2268	conj-conj	0.1866
prep_in-assmod	0.1738	amod-amod	0.1251
dobj-dobj	0.1597	prep_of-assmod	0.1141
prep_of-assmod	0.1264	*nn-nn*	0.1111
amod-nn	0.1201	dobj-dobj	0.1102
amod-amod	0.1161	amod-nn	0.1092
nn-nn	0.0982	*prep_of-nn*	0.0723
conj-dobj	0.0758	–	–
prep_of-nn	0.0501	–	–

TABLE 3 – Comparison of mapping weights in Ψ_A^o and Ψ_M^o

5.3 Performance on the test noun lexicon LN_t

Table 4 shows the performance of our dependency mapping model (DM) on the test noun lexicon LN_t. Three weighting strategies, i.e. DM (equal weights), DM_PR (proportional weights) and DM_AP (weight learning by the AP algorithm on LN_d) are used with four sets of dependency mappings (Ψ_M, Ψ_M^o, Ψ_A and Ψ_A^o). Please note that all the optimal mappings are tuned on the development lexicon as discussed in Fig. 6, though we don't present the results of ablation tests for DM there as they are similar to those of DM_PR. For comparison, the strong baseline as discussed in Section 3 is included at the top row. The table shows that:

- The AP[3] algorithm (DM_AP) achieves the best performance with the improvements of ~6 units in P and ~5 in MRR compared with DM. In most cases, DM_PR slightly underperforms DM, which means that simply using the occurrence ratio as each mapping's weight doesn't lead to performance improvement.
- In total, our method outperforms the strong baseline by ~14 units in both P and MRR across all the mapping sets. This suggests that via weight learning with a proper machine

[3] The voted perceptron algorithm achieves similar results, so here we omit them for brevity.

learning method (e.g. a simple perceptron algorithm), the dependency mapping model can dramatically improve the performance for BLC.

- A particularly important finding is that the optimal automatic mapping set Ψ_A^o performs comparably with the manual mapping set Ψ_M and slightly outperforms the complete automatic mapping set Ψ_A. This further justifies the appropriateness of automatically generating bilingual dependency mappings.

Systems	DM		DM_PR		DM_AP	
	P (%)	MRR(%)	P (%)	MRR(%)	P (%)	MRR(%)
Baseline	33.8	42.23	33.8	42.23	33.8	42.23
Manual Ψ_M	43.0	51.89	42.4	51.61	**49.2**	**57.18**
Manual Ψ_M^o	44.0	52.44	40.2	49.52	**50.0**	**57.62**
Auto Ψ_A	41.4	50.70	39.0	48.64	**46.2**	**55.50**
Auto Ψ_A^o	42.6	51.66	43.6	51.85	**48.6**	**56.43**

TABLE 4 – Performance of dependency mapping on the test noun lexicon LN_t

Above observations justifies that dependency mappings can significantly enhance the performance for BLC, and perform even better when the weight for each mapping is optimized. To explain how dependency mappings work, we take English word "profit" and its Chinese translation "利润" as an example, which is also mentioned in Section 1. Table 5 compares three kinds of similarity scores between "profit" and its two translation candidates, i.e., "利润" and "企业". It shows that due to Sim_{DM} ("profit", "利润") >Sim_{DM} ("profit","企业"), our method eventually acquires the correct translation pair of "profit" and "利润". The reason is that the dependency mapping context between "profit" and "利润", such as "实现_*dobj*" (realize_*dobj*) and "成本_*conj*" (cost_*conj*) etc., is more evidential than that between "profit" and "企业". In other words, the dependency mapping context contains more accurate bilingual corresponding words and ignores noisy ones than the dependent word context, thus leading to better performance for BLC.

Similarity	("profit", "利润")	Relationship	("profit", "企业")
Sim_{DW}	0.441	<	0.475
Sim_{DM}	0.460	>	0.393
Sim_T	0.456	>	0.409

TABLE 5 – Similarity comparison between "profit" and its two translation candidates

5.4 Performance on the general test lexicon LA_t

Table 6 compares the performance of different methods on the general test lexicon LA_t for words with different categories (i.e. nouns, verbs and adjectives) in a wide frequency range. Specifically, for the DM and DM_AP methods, the automatic mappings and their weights for nouns are the same as those in Table 2 while for verbs and adjectives, the mappings are first automatically generated and then filtered using the ablation tests with their weights learned on the development sets LV_d and LJ_d respectively. The table shows that;

- For nouns and verbs, both the DM and DM_AP methods with automatic dependency mappings outperform the baseline, though with the improvements in a less degree than those for nouns in LN_t, due to the much more data sparseness of both the dependent word context and dependency mapping context.
- For adjectives, however, the performances of three methods are quite similar. This suggests the non-effectiveness of dependency mappings on BLC for adjectives.

Parts of speech	Baseline		DM		DM_AP	
	P(%)	MRR(%)	P(%)	MRR(%)	P(%)	MRR(%)
Nouns	21.8	28.62	26.0	33.60	**28.3**	**35.02**
Verbs	19.5	27.07	23.5	31.69	**26.0**	**35.26**
Adjectives	35.5	46.22	**36.0**	**46.93**	34.5	45.63

TABLE 6 – Performance of different methods on the general test lexicon LA_t

Above observations demonstrate that our method can well adapt to nouns and verbs in a wide frequency range, but not to adjectives. Our exploration shows that, although the mappings for verbs are much different from those for nouns (cf. Table 2), both sets of mapping are diverse without a dominant single mapping. However, for adjectives dependency mapping *amod-amod* accounts for nearly 70% of total mappings. This reflects the fact that the dependency relationship between an adjective and its contextual words is much simpler than that for either a noun or a verb. The dominance of one mapping for adjectives makes the dependency mapping context highly correlated with the dependent word context, thus significantly weakens the effect of dependency mapping, while the diversity of dependency mappings for nouns and verbs ensures its efficacy.

Conclusion and perspectives

In this paper, we propose a bilingual dependency mapping model for bilingual lexicon construction from English to Chinese using a comparable corpus. When calculating the similarity between bilingual words, this model considers both dependent words and their relationships, thus providing more accurate and less noisy representation. Evaluation shows that our approach significantly outperforms a state-of-the-art baseline from English to Chinese on both nouns and verbs in a wide frequency range, though with the exception of adjectives. We also demonstrate that bilingual dependency mappings can be automatically generated and optimized without human intervention, leading to a medium-sized set of dependency mappings, and that their contributions on BLC can be fully exploited via weight learning using a simple yet effective perceptron algorithm, making our approach easily adaptable to other language pairs.

In future work, we intend to apply our method to BLC between other language pairs. Preliminary experiments show that the dependency mapping model can improve the precision for BLC by ~6 units from Chinese to English.

ABSTRACT
This paper describes the development of a web-service tool for the automatic extraction of Multi-word expressions lexicons, which has been integrated in a distributed platform for the automatic creation of linguistic resources. The main purpose of the work described is thus to provide a (computationally "light") tool that produces a full lexical resource: multi-word terms/items with relevant and useful attached information that can be used for more complex processing tasks and applications (e.g. parsing, MT, IE, query expansion, etc.). The output of our tool is a MW lexicon formatted and encoded in XML according to the Lexical Mark-up Framework. The tool is already functional and available as a service. Evaluation experiments show that the tool precision is of about 80%.

KEYWORDS: Multiword extraction, lexical resources, LMF, web services.

Proceedings of COLING 2012: Technical Papers, pages 2291–2306,
COLING 2012, Mumbai, December 2012.

1 Introduction

Multi-word expressions (MWEs) nowadays still pose problems to most language technology and applications, e.g information retrieval, text mining, semantic web. In particular, they impact greatly on the performance of Machine Translation systems and automatic dictionary compilation. In Rule-based MT, many translation mistakes can be attributed to inadequate handling of MWEs. As for Statistical MT, they constitute a problem in the word alignment of parallel corpora. Especially for such applications MWEs can be thought of as a group of words constituting a single meaning unit and often they have an unpredictable, non-literal translation. From a practical point of view, if a group of words cannot be translated using a word-by-word translation, then it is treated as a MWE. If not recognized and handled properly, MWEs will result in mis-translations (or literal translations), and because many of them have an opaque meaning, i.e., the meaning of the unit cannot be derived by the meaning of the individual constituents that make up the unit, the translation will be incorrect and not understandable, thus hampering the overall text readability (see e.g. (Monti et al.), (Bilal, 2005)).

While many experiments on methods for the automatic acquisition of MWEs have been carried out in academic research for some decades now, readily available, and possibly customizable tools for the acquisition of MWEs in languages other than English are not so popular.

In this paper we describe the implementation of a tool for the automatic creation of MWE lexicons, integrated as a web service into a distributed platform, within the context of the PANACEA project[1]. As its goal is to set up a platform for the automatic acquisition of language resources and involves handling large or massive data, the tool described here has been implemented using robust and "computationally light" methods. The purpose is not so much to devise a new or innovative method (as the state-of-the-art seems to perform sufficiently well), but to provide a free to use tool that creates a full lexical resource from web crawled data: multi words with relevant and useful attached information that can be used for further processing (parsing, MT, information extraction, query expansion and the like). Our core extraction algorithm is language independent, making use of positional information only, and does not require a list of words to be used as seeds. The tool however has been tested and evaluated on Italian only[2].

2 Related works

Given the importance of MWEs for NLP applications, much research has been conducted for their automatic acquisition, with the aim of building or expanding lexica, i.e. mainly in support of lexicographic activities both for general and specific domains.

Common statistically-based acquisition approaches usually involve the following two steps: (1) the identification of candidates (usually based on *n*-grams or pattern matching)(2) filtering and candidate ranking according to some statistical score and an experimental threshold. Along these lines, different methods have been proposed in the existing literature. The oldest and simplest approaches made use of plain text corpora and identified candidates on the basis of (positional) n-grams (sequences of n adjacent words), optionally using POS filtering to clean the candidate lists and stop word lists to reduce the search space (e.g. (Choueka, 1988), (Smadja, 1993)). Also, the extraction is generally performed for a given set of seed words.

[1] see www.panacea-lr.eu

[2] In fact, recently it has been successfully run on a test Spanish corpus and it correctly produced an output lexicon, which however has not been evaluated.

More recent methods make use of tagged or parsed corpora to first identify relevant patterns in the attempt to improve precision, although for the latter the improvement is not clearly proven due to parsing errors (cfr. (Baldwin, 2005), also see the interesting review in (Seretan and Wehrli, 2009, 73-74)). The filtering and ranking of candidates is then achieved by applying some association measure (hereafter AM) calculated on the basis of co-occurrence frequency of the content words involved in candidates. Some of the most commonly used AMs are: (Pointwise) Mutual Information, Dice, Pearson's chi-squared, Log-Likelihood Ratio, Odds Ratio, Fisher's Exact tests, and various entropy measures. Several works have also carried out detailed comparisons of the methods used in the literature, evaluating the association measures used (among others, (Pearce, 2002),(Evert, 2004), (Evert and Krenn, 2005), (Pecina, 2010)). From these, we understand that the efficacy of a given AM may depend on factors like the language being analysed, the size of the corpus and the type of MWE that has to be identified. Overall, it seems that the simplest measures (frequency, MLE and Log Likelihood) perform best[3].

Although much of the work is on English data, research on MWE extraction has been carried out also for other languages, such as German (Krenn and Evert, 2001), Dutch (Villada Moiron, 2005), Czech (Pecina, 2010), French (Laporte et al., 2008), Portuguese (Villavicencio et al., 2010), among others. For Italian, the first work on collocation extraction used a window method for identifying candidates in a plain text corpus and Mutual Information for ranking (Calzolari and Bindi, 1990). Recent efforts towards the acquisition and/or production of MWE lexica for Italian are (Zaninello and Nissim, 2010), (Bentivogli and Pianta, 2002), and (Bonin et al., 2010). The former is an effort for the creation of a database of Italian MWEs annotated according to their morpho-syntactic pattern, where MWEs were given from pre-existing dictionaries. (Bentivogli and Pianta, 2002) extract from the Collins English-Italian dictionary *hidden* MWEs, i.e. MWEs not explicitly marked as such in the dictionary. (Bonin et al., 2010) extract MW terminology for two domains, adopting a contrastive approach in order to identify domain-specific multi-word terms.

Notwithstanding the vast literature, often evaluation is either not reported or not detailed enough. Also, it is often stressed that a righteous comparison of the performance is impossible due to the differences in: methods applied, targeted MWEs types, corpus used, and evaluation methodology (cfr. (Rayson et al., 2010, 3)). Precision and recall may vary considerably: for example Smadja's reports a precision of 80% for his XTRACT system on English texts (but of 40% before the syntactic-based filtering), with evaluation carried out by manual inspection by a lexicographer. (Seretan and Wehrli, 2009, 80) performed experiments in 4 languages and reported different figures for precision (English=0.42-0.58, Spanish=0.39-0.42, French=0.46-0.35, Italian=0.32-0.37).

3 The Panacea MW acquisition tool

Because of the need to operate in a web service distributed environment, where processing time is critical, and because of possible computing and memory limitations, it was decided to avoid computationally intensive methods. Also, as often reported in the literature, simpler methods seem to perform equally well, if not even better, in little constrained set-ups. Our MWE acquisition component is thus inspired by the seminal work by (Smadja, 1993), but integrates also more recently experimented statistical methods and association measures for filtering and ranking the acquired candidates and thus for producing a cleaner output lexicon, promoting

[3]For lack of space, we will not refer here to more sophisticated approaches that aim at measuring the degrees of fixedness and/or opacity, such as e.g. (Fazly et al., 2009).

precision over recall. The input data is part-of-speech tagged corpora in CoNLL format. The tool performs a sequence of steps each implementing different methods, in such a way as to be efficient in terms of processing time and memory usage. These steps are collocation extraction, pre-filtering and ranking by association measures, pattern extraction, pattern selection and lexicon building. In the following sections a description of each step is given.

3.1 Step 1: Window based collocation extractor

The search function requires no lemmas but the POS tags of the pair of tokens representing the first and last component of a multi-word, then all instances of the POS pair in the given window are retrieved. Because all words with the given POS tag will be retrieved, differently from other approaches (e.g (Smadja, 1993)), we only consider the right window. Both the POS tag pairs and the window size are passed as user-configurable parameters to the system. The output of this step is a list of candidate collocation pairs, with their related frequencies.

3.2 Step 2: Pre-filter and collocation ranking through association measures

A pre-filtering stage is applied based on the raw frequency distribution of the collocations for reducing memory load and discarding pairs that will provide no useful statistical evidence. This filters out pairs below a given proportional threshold. Assuming a zipfian distribution for collocation frequencies, a long tail of low frequency pairs and hapaxes[4] will normally be extracted, that needs to be filtered away. So far our algorithm allows for two kinds of filtering based on two different thresholds.

With the AverageFrequency PreFilter the threshold is set to (1):

$$\theta_{AF} = \overline{X} = \frac{\sum_{i=1}^{n} f_i}{n} \tag{1}$$

where f_i is the frequency of the ith collocation/pair and n is the number of collocations extracted. Thus the AverageFrequency PreFilter filters away all collocations with f below the mean $\overline{X}$. The MaxFrequency PreFilter instead sets the threshold to (2):

$$\theta_{MF} = \frac{f_1}{10} \tag{2}$$

where f_1 is the frequency of the most frequent collocation. This latter filter is more selective, in that it discards all pairs that have frequency less than 1/10th of the most frequent pair.

Notice that both thresholds are independent of the size of the corpus. Given the zipfian distribution for each extraction, independently from the corpus, they should identify more or less the same point in the distribution curve. As pre-filter (2) was observed to be too selective for our purposes, it will not be used in the experiments described in the rest of the paper.

After applying the pre-filter, various state-of-the-art Association Measures (AMs) can be calculated, that will be used for alternative rankings of the collocations and of the subsequently acquired full MWEs. Currently Log Likelihood and Pointwise Mutual Information have been implemented.

[4] By hapaxes here we mean word pairs of frequency 1.

3.3 Step 3: Pattern extraction

For each collocation in Step 2 the algorithm retrieves the complete patterns of tokens (i.e. word sequences of minimum length 2 and maximum the window size) with their raw and relative frequencies and the attached information about lemma and POS.

The rationale behind this step is to retrieve all possible intervening patterns between word A and word B. Thus, for each word pair AB, the intervening patterns are collected in a data structure that contains lemma, token and POS for each position, including A and B. This is what we shall call the “set of patterns" for the given collocations.

A distinct pattern will thus be a sequence of elements where each element is a combination of Tokens+Lemma+PoS. Frequencies for each pattern are also retrieved.

For instance, for the pair GAS-SERRA (‘gas-greenhouse’, combined frequency: 10353) the algorithm retrieves several patterns such as[5]:

a) *gas serra* (‘greenhouse gas’): frequency 7151
b) *gas ad effetto serra* (‘greenhouse effect gas’): frequency 1547
c) *gas a effetto serra* (‘greenhouse effect gas’): frequency 1365
...

3.4 Step 4: Pattern based collocation filtering and MWE selection

Now, the collocations retained after pre-filtering go through an additional filtering step where further collocations are discarded based on the distribution of their “set of patterns". More specifically the frequencies of all patterns in the sets are treated as vectors. The goal of the algorithm is to detect whether the vector has any significantly more frequent items; if not, the collocation itself is discarded, otherwise only the significant patterns (i.e. the outliers) are retained as good MWE candidates.

For example: GAS - SERRA produces a pattern vector *v1*:
v1 = [7151,1,1,1,1,51,21,2,43,1,1,38,1547,1,1,10,1,2,4,1,5,1,1,1,1,1,1,14,1,1,6,5,71,1365]

where all elements of *v1* are the frequencies of patterns extracted for GAS-SERRA. So, *v1* contains three clearly outstanding patterns for this collocation (with frequencies 7151, 1547, and 1365, corresponding to the above listed patterns A, B, C).

On the other hand, the collocation MARE-COSTA (‘sea - coast’) produces a long vector as in v2:
v2 = [1,1,1,1,8,1,1,1, ...]

with less clearly recognizable outstanding patterns. Given our approach, this can be seen as evidence for the lower fixedness of the second collocation with respect to the first, and thus as a criterion for rejecting the collcation altogether (i.e. the collocation and its set of patterns).

In order to quantify this intuition, mean ($\overline{X}$) and standard deviation (σ) are calculated for each set of patterns.

$$\sigma = \sqrt{\frac{\sum_{i=1}^{k}(f_i - \overline{X})^2}{k}} \tag{3}$$

[5]Here only the sequence of tokens is given

where f_i is the frequency of the ith pattern k is the number of patterns extracted.

We empirically assessed that only collocations whose vectors show $\sigma > 1$ have some chance of producing at least one significant pattern. This excludes those collocations that are normally made up by long series of very low frequency items, differing from each other very little in frequency. The only exception is when $\sigma = 0$ because the collocation extracts just one pattern of identical frequency. In this case the algorithm selects the pattern as a good MWE without further analysis[6].

Now that we have filtered out a lot noise and irrelevant collocations, the algorithm has to select the good patterns to be encoded in the output lexicon. This is done by using the same variance analysis of the distribution in the sets of patterns described above with the aim of selecting more than one relevant pattern. In particular, the presence of outliers is evaluated in terms of standard deviation above the mean. Empirical evidence showed that one σ above the mean is a good enough threshold in our case. This threshold normally extracts 1-3 significant MWEs per collocation.

Thus for each collocation A+B the algorithm (which we call henceforth SigmaPatternExtraction) runs as follows (figure 1):

```
f(A+B), the frequency of a collocation (A+B)
v(A+B), the vector of pattern frequencies for each collocation
p_i(A+B), a given pattern i of A+B
f(p_i(A+B)), the frequency of p_i(A+B)
θ = 1, c = 1

if f(A+B)== f(p(A+B))
      then return p_i(A+B)
elseif σ of v(A+B) > θ
      for each p_i(A+B)
        if the f(p_i(A+B)) > c * σ(v(A+B)) + X̄(v(A+B))
          then return p_i(A+B)
```

Figure 1: Outline of the SigmaPatternExtraction Algorithm.

Higher values for both θ and c result in more filtering and, possibly higher precision / lower recall.

Notice how this approach differs from the one used in (Smadja, 1993)). There the task was searching for collocates on the basis of a given list of words. Thus the vector was built in order to determine the position of any word W with respect to a word from the list. Thus, in Smadja's approach a high standard deviation indicates randomness, and therefore low association strength between the two words.

In our case the pair, not a single word, is considered. Consequently, the only case when a low sigma is indicative of a good candidate pair is when σ equals zero because its set of patterns actually contains only one element. Randomness however is null in this case. In all other cases, good pattern vectors will contain a strongly uneven distribution, with ideally one or few very frequent patterns and a long tail of very low frequency elements.

In order to evaluate the SigmaPatternExtraction Algorithm a simpler method was also devised (henceforth FirstPatternExtraction, figure 2), which consists in extracting only the most frequent

[6]This is the case for very fixed MWEs such as *stati membri*, "member states"

pattern for each collocation.

```
f(p1(A+B)), the highest value in v(A+B)

if f(A+B)== f(p(A+B)), then return p(A+B)
else return p1(A+B)
```

Figure 2: Outline of the FirstPatternExtraction Algorithm.

Notice that, so far, the system is language independent, as only distributional information is used[7]. Additional steps may be added as post-filters for further pruning the results. Such post-processors might be built ad-hoc for the language/domain in use: e.g. by using lists of stop words, or special heuristics to deal with language or tagger specific issues.

3.5 Step 5: The lexicon builder

The final step of the tool is lexicon building, that compiles the MWEs that were selected according to the steps/filters described above into a full XML-encoded lexicon, that conforms to the LMF standard (Gil Francopoulo, 2006)[8]. Figure 3 below exemplifies the representation of an entry[9].

```
<LexicalEntry id="0">
  <feat att="entryType" val="Multiword"/>

    </Component>
  </ListOfComponents>
</LexicalEntry>
```

Figure 3: Example of the encoding of an extracted MWE entry following LMF-XML.

At the entry level we record information on its type (MWE or NE[10]), on the POS pattern it instantiates, on the frequency and the Log Likelihood measure calculated during the acquisition process. Each entry is then characterized by a specification of the components forming the

[7] The tool is still inevitably format and tag set dependent. Still, we believe it is fairly general: the input data format is in fact CoNLL, a widely used de-facto standard, and the initial search input is a pair of POS tags which is passed as an external parameter set by the user.

[8] In fact, it is valid according to the LMF DTD-rev16.

[9] Notice that, for the sake of readability of the example, the single word LexicalEntries corresponding to each component have been omitted.

[10] NEs can be identified on the basis of simple heuristics exploiting the tagging of proper names, if available in the POS tagged corpus.

MWEs with related information: information about the rank or position of the components, their POS, orthographic form and lemma.

3.6 Requirements and deployment as a Web service

The tool was developed as a java application and it runs in less than 30 minutes any recent server, but it requires a maximum heap memory of 4GB for a corpus of 37 million words (250.3 MB) with window = 5. This is due to the remarkable size of the data structure containing the pairs and their intervening patterns before pre-filtering. Pre-filtering is therefore highly necessary in order to reduce the data-structure to a tractable size for further processing. The tool is then deployed as a web service using Soaplab on Apache Tomcat[11]. Services can be chained together and run as work-flows using a work-flow manager such as Taverna. A typical work-flow for our extractor will include a POS-tagger and a converter to CoNLL[12], as well as the extractor [13]. Post-filters might be developed as stand-alone services and chained to the MW_Extractor to obtain higher quality results.

4 Evaluation

In order to tune the extraction steps and to evaluate the tool, experiments have been performed on a domain specific corpus of Italian: the domain is ENVIRONMENT, one of the domains targeted in the PANACEA project. The tool is evaluated according the standard intrinsic evaluation procedure, against a reference resource that we will refer to as the gold standard.

Evaluation is split into three phases: 1) evaluation of the pre-filtering phase, where the removal of the long tail of low frequency co-occurrences is justified, followed by 2) the evaluation of the pattern extraction algorithm: automatic evaluation of the extracted patterns against the gold standard with the standard precision, recall and F-measures; 3) manual inspection of false positives.

This last step is necessary since, unsurprisingly, the gold standard is incomplete in terms of coverage at different levels: not only are good (domain) multi-word expressions missing, but in some cases, as an analysis of the false negatives has shown, the multi-word acquired from the corpus occurs in a different form than in the gold standard (usually the citation/lemmatised form). A manual exploration of the false positive results is thus necessary. As we are acquiring by POS patterns and not by a list of words, we are likely, and hopefully, extracting multi-word terms that are not present in existing resources, or were not considered interesting domain terms for the given glossary, but which may well be interesting and useful for NLP applications, and especially MT.

In the following sections we describe the data, the experiments and the results obtained.

4.1 The corpus and targeted MWEs

The (Environment) corpus used in the experiments was automatically produced with focussed monolingual crawling and cleaning services within the project[14]; its size is of about 37 million word tokens.

[11] `http://langtech3.ilc.cnr.it:8080/soaplab2-axis/services/panacea.estrattore_mw`

[12] See also (Rubino et al., 2012)

[13] The work-flows can be found on the PANACEA work-flow registry `http://myexperiment.elda.org/workflows/`

[14] http://registry.elda.org:3001/services/160, http://registry.elda.org/services/158

The evaluated extraction, henceforth called SIGMA extraction, was carried out by using the following parameters:
target = extraction of nominal Multiwords, i.e. multiwords whose first and last word is a noun (N-N henceforth)
window = 5 tokens including the first and last element (i.e. the extracted MWEs have a maximum length of 5 words)
prefilter = AverageFrequency PreFilter as in equation (1)
pattern extraction = using the SigmaPatternExtraction as in figure (1)

This extraction will be evaluated against a simpler one, henceforth FIRST extraction, where:
pattern extraction = uses the FirstPatternExtraction as in figure (2)

4.2 The gold standard

A gold standard, or reference resource, for the Environment domain has been created by semi-manually by collecting from several authoritative web glossaries and thesauri relevant nominal Italian MWEs (i.e. N-N MWEs). For each MWEs collected, its frequency in the corpus was computed using simple regular expressions to search for potential morphological variants, and never occurring MWEs are "discarded".

In the gold standard the citation forms were kept as they were found in the given resources. If the same multi-word was present in two sources with two different citation forms - e.g. singular and plural - they were not merged into one single entry in the gold standard nor was their relatedness marked.

4.3 Evaluation of the pre-filtering phase

Before we evaluate the core of the pattern extraction algorithm, it is important to analyze how much is lost in the pre-filtering phase. A MWE can never be extracted with our method if the corresponding collocation (that is the pair of lemmas corresponding to the first and last words of the MWE) is thrown away by the pre-filter. The extraction of the relevant collocation is thus a necessary pre-condition, although not a sufficient one, in that the pattern selection algorithm may then fail to extract the correct pattern, that is the one corresponding to the MWE.

For our evaluation we chose the Average Frequency pre-filter (1). Without this pre-filter our corpus of 37 million words produces 2,046,532 collocations, containing a long tail of hapaxes. With the Average Frequency pre-filter the collocations reduce to 259,848[15].

When evaluated against the gold standard, the non pre-filtered extraction contains 2710 eligible pairs, that is collocations whose first and last word are the same as a gold standard entry[16]. With pre-filtering eligible pairs are reduced to 1746. This may seem a heavy loss, but the 964 lost eligible pairs are to be found among 1,786,684 others. This means that the portion of the extraction that is filtered away (1,786,684 pairs) has a precision in terms of collocations of less than 0.0005 with respect to our gold standard, whereas the density in terms of eligible pairs of the remaining portion (259,848) is, 0.007 that is ten times higher[17]. Since our goal is to

[15]The lowest collocation has frequency 5, the highest has frequency 10,353

[16]The recall in terms of eligible pairs is maximum, which is not surprising, considering that the gold standard contains only MWEs that are present in the corpus.

[17]Although the gold standard is far from complete, these figures can help us getting a general picture of the distribution of our data.

achieve high precision in an acceptable processing time, this loss in recall can be considered acceptable. Notice that an eligible collocation may still not produce a genuine MWE, and that very low frequency collocations defy analysis with any association measure and are discarded in several approaches (Evert, 2004).

Evaluation of ranking is also important, since users may want to take into account only the top portion of the returned MWEs. We shall take ranking into account here, considering that association measures are a property of the collocation rather the MWE, since they are a measure of the association strength between the first and the last element of the MWE.

Two association measures - Pointwise Mutual Information and Log Likelihood - are calculated for each collocation. Collocations can be thus re-ranked by AM as well as by frequency. It is interesting to check which one is the best ranking by calculating the interpolated precision over a complete extraction. No matter what pre-filter is used to extract MWEs from collocations, raw frequency and Log Likelihood produce similar interpolated precision curves (see figure 4); both manage to rank eligible collocations at the top (frequency working slightly better), and both perform significantly better than Pointwise Mutual Information. In the figure the PMI line is almost invisible, being constantly below the baseline and close to zero in the portion taken into account. It is known in the literature (Pecina, 2010) that different kinds of AMs give different results depending on the kind of MWE extraction task. Frequency is also known to perform well (Justeson and Katz, 1995) when filtering on PoS is used.

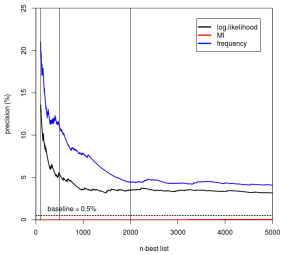

Figure 4: Interpolated precision graph for the different rankings (AverageFrequency pre-filter and SigmaPatternExtraction method). Baseline represents the average precision. The graph shows how precision progresses in the different rankings (only the first 5000 positions are shown).

4.4 Evaluation of MWE extraction

In this section the SigmaPatternExtraction Algorithm is evaluated. Thus two extractions are compared, the SIGMA extraction and the FIRST extraction as described above in 3.4, with FIRST acting as our baseline. Two kinds of evaluations are carried out:

SIMPLE: Simply check the extracted patterns against the gold standard. This evaluation is interesting for the recall; given that the gold standard is incomplete precision is not really significant

REDUCED: Only collocations that could produce patterns in the gold standard are selected

from the full extractions, and all MWEs related to those collocations used for evaluation. This is useful in order to evaluate precision more realistically and to allow an approximate comparison with other approaches described in the literature (see section 2 above on comparability). The "reduction" algorithm is a fairly simple one and implies some stemming, due to the fact that the gold standard is not lemmatised (and that, although UTF-8 is used, some issues related to accented chars still remain) and runs as follows 5:

```
for each mwe of length l in gold-standard
      select w_0 and the w_{l-1}
      remove the last two characters from w_0 and w_{l-1}
      add w_0 + w_{l-1} to eligible-pairs
for each mwe of length l in extraction
      select w_0 and the w_{l-1}
      remove the last two characters from w_0 and w_{l-1}
      if w_0 + w_{l-1} is in eligible-pairs
        add mwe to the reduced-set
evaluate reduced-set against the gold-standard
```

Figure 5: Outline of the reduction algorithm.

For example: if *fondo del mare* is in the gold standard, we search for pairs of the form *fon** - ma***, and return all MWEs that the algorithm has extracted for such pairs in order to evaluate them against the gold standard[18].

The results for both kinds of evaluation and for both methods are given below. Table 1 shows the results for the SIMPLE evaluation.

SIMPLE	**FIRST**	**SIGMA**
test	259848	209471
gold	2191	2191
precision	0.0038	0.0050
recall	0.4505	0.4770
F1	0.0075	0.01

Table 1: Precision and recall for the FIRST and the SIGMA extraction, with a SIMPLE evaluation method. 'Test' and 'gold' show the number of MWEs in, respectively, the evaluated extraction and the gold. While the number of MWEs in the gold remains the same, the number of MWEs in the test changes depending on the kind of algorithm used.

Notice how the test set (the number of MWEs in the extraction that are being evaluated) is smaller with SIGMA, since a number of "low sigma" pairs have been filtered out by the SigmaPatternExtraction Algorithm. Still both precision and recall are increased, that is more good patterns are extracted by not just stopping at the most frequent ones (see Figure 4 for the precision graph). Table 2 shows the results for the REDUCED evaluation.

While in the non-reduced evaluation the SIGMA method was increasing the precision due to the reduction of the test set, in the reduced evaluation FIRST seems to perform better in terms

[18] Notice how this stemming method is quite unsophisticated, and produces more pairs than it should. In this case it would also extract expressions such as *fonti nel mare*, if extracted. This means that the precision figures given for the REDUCED evaluation are probably slightly underestimated.

REDUCED	**FIRST**	**SIGMA**	**SIGMA** +edit	**SIGMA** manual
test	1746	2105	-	-
gold	2191	2191	-	-
precision	0.56	0.50	0.60	0.81
recall	0.45	0.48	0.58	0.60
F1	0.50	0.49	0.59	0.67

Table 2: Precision and recall for the FIRST and the SIGMA extractions, with a REDUCED evaluation method

of precision although SIGMA retrieves a higher absolute number of true positives (1043 vs 984) and thus improves in terms of recall. The reason for this is to be found in a higher test set for SIGMA. This is not surprising if we consider how the REDUCED evaluation is carried out. In this case many of the low sigma pairs that the SIGMA algorithm removes are filtered away by the reduction algorithm also for FIRST; at the same time SIGMA extracts more than one pattern per pair, thus ending up with a higher (reduced) test set. Given that it is infrequent for MWEs from the same collocation (same first and last word) to be present in the gold standard, extracting more than one pattern per collocation, as SIGMA does, is penalizing for the precision with respect to our gold standard. Still, a quick manual check of the false positives reveals that most of the extracted patterns are actually correct, in that they are variants of the first pattern, such as:

```
fonte di inquinamento > fonti di inquinamento
```

Thus, if a more flexible comparison is applied, such as allowing for edit distance (Damerau, 1964) up to 3 between the strings, these variants are recognized as true positives and for SIGMA improves by 10 points, as is shown in the fourth column of table 2.

As shown by the interpolated precision graph for this last evaluation (figure 6), when reducing the set of collocations, association measures actually perform better than simple frequency.

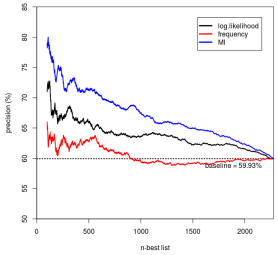

Figure 6: Interpolated precision graph for Pointwise Mutual Information, Log Likelihood and frequency for an extraction with AverageFrequency pre-filter and SigmaPatternExtraction. REDUCED evaluation method; match with edit distance = 3

4.4.1 Manual evaluation of MWE extraction

Further manual inspection of the false positives shows that precision is much higher in fact.

For instance the gold standard contains *zona di pressione* ('pressure zone'), which selects ZONA-PRESSIONE as an eligible pair. This collocation is thus retained in the REDUCED evaluation set, extracting from the corpus *zona di pressione* and *zona di bassa pressione* ('low pressure zone'). The latter is not contained in the gold standard, but is in fact a genuine MWE. By analysing false positives for the REDUCED evaluation and adding the good MWEs found to our gold standard, we obtain a precision of 81% (see table 2).

As the REDUCED evaluation method roughly simulates an extraction from a fixed, predefined set of targeted lemmas, as is usually the case with experiments reported in the papers, it allows for some comparison with other approaches.

Our result is thus in line with the precision performance of Smajda's XTRACT (Smadja, 1993)[19].

However, we observed that with the REDUCED evaluation, much of the noise present in the data (mainly due to the automatically crawled nature of the corpus) was filtered out through the reduction of eligible pairs (and therefore did not impact on the evaluation scores). To arrive at a more realistic assessment of the tool then a manual evaluation of the complete extraction (that is without evaluation filter) was also attempted. Considering the large amount of results obtained by our SIMPLE method, our priority was to verify the precision of the top portion of our extraction. This is meant to ensure that a user who blindly extracts MWEs from a (domain) corpus will get a significant amount of genuine results in the higher ranks. As we have seen when evaluating the pre-filter, our best ranking is raw frequency, followed by LogLikelihood. We thus evaluated the first 1000 highest frequency results against the gold standard, then we checked the false negatives and added such as turned out to be genuine to the gold standard for a second run.

$$\text{first run precision} = 0.40, \text{second run precision} = 0.78$$

The results of the first run tell us that 40% of the MWEs from the original gold are to be found in the top 1000 results. The second run, most significantly, tells us that 78% of the first 1000 returned results are correct, and that it is thus possible to extract MWEs without seed words and still get a precision that approaches the state of the art. Notice also how the "real" precision of the top 1000 portion of the extraction is just 2% lower than the one obtained with the REDUCED evaluation method, the latter thus providing a fairly good approximation for the first.

Conclusion and Future Work

We have presented a tool for the acquisition of multi-word expressions of various lengths and types that generates an LMF MWEs lexicon as output. The tools is already functional and has been deployed as a web service within a distributed platform that deals with large/massive data. First evaluation results (with a reduced extraction that is rendered comparable to the gold standard) are encouraging. If possible, we plan to extend the manual evaluation in order to have a more accurate estimate of the real precision.

Regarding the service, future improvements are possible especially based on users' feedback in particular regarding the properties to be left as configurable parameters and output formats. Regarding the tool, we intend to continue improving the method by:

[19] In fact, our system is likely even to outperform it given that the evaluation carried out is slightly penalizing for the system both because of the naive stemming and because the gold-standard also contains MWEs with frequency 1 and 2, which are most likely not retrieved by the system.

1. Adding further filtering/cleaning of the extracted MWEs. In particular we might experiment with merging patterns that are sub strings of others when they have the same frequency, as they create noise and lower precision. For instance: *sicurezza sul posto* (lit. 'safety on the place') and *sicurezza sul posto di lavoro* (lit. 'safety on the place of work') all have the same frequency (630); clearly, the genuine MWE is *sicurezza sul posto di lavoro* and the others are substrings thereof.

2. Extracting MWEs with PoS patterns by progressive test and reduction of patterns for learning the "free slots" in the multiwords. For instance we may want to derive a pattern of the form *articolo NUM della legge* ("article NUM of the law") from a series of patterns of the form: *articolo 6 della legge, articolo 12 della legge, articolo 23 della legge, ...*

3. Language specific fine tuning will also be implemented, in the form of post-filtering (e.g. via optional stop words list and legitimate patterns check), as well as of post-editing (e.g. with head detection heuristics).

4. Automatic conversion to, or direct output in-, an RDF format (e.g. according to the Lemon model), as to make the resource publishable as L(O)D potentially exploited for reasoning or by other web services[20].

Regarding the evaluation, the next step will be a task based evaluation. Interesting tasks could be: rule-based machine translation, syntactic parsing, or subcategorisation frame acquisition (which would be interesting to assess the impact of automatically acquired multi-word prepositions).

Acknowledgments

This work has been realized at CNR-ILC within the EU FP7 funded project PANACEA (Platform for Automatic. Normalized Annotation and Cost-Effective Acquisition of Language Resources for Human Language Technologies) under grant agreement n. 248064. We thank PANACEA reviewers and the COLING anonymous reviewers for their comments and incentives to improve. In particular, we want to thank Fabio Affé who helped us with the final modifications to the java code and with the deployment in Soaplab.

[20]We thank an anonymous reviewer for his/her suggestions concerning LOD and NIF. Although the NLP Interchange Format (`http://nlp2rdf.org/nif-1-0`) seems to be a format for corpus data, while our tool outputs a lexicon, in our future work within the LOD framework we will attempt to ensure compatibility with NIF in terms of basic vocabulary and data categories used.

ABSTRACT
We address the problem of unsupervised tagging of phrase structure trees with phrase categories (parse tree nonterminals). Motivated by the inability of a range of direct clustering approaches to improve over the current leading algorithm, we propose a mixture of experts approach. In particular, we tackle the difficult challenge of producing a *diverse* collection of useful tagging experts, which can then be aggregated into a final high-quality tagging. To do so, we use the particular properties of the Dirichlet Process mixture model. We evaluate on English, German and Chinese corpora and demonstrate both a substantial and consistent improvement in overall performance over previous work, as well as empirical justification of our algorithmic choices.

1 Introduction

Grammar induction is the task of learning grammatical structure from plain text without human supervision. The task is valuable for the understanding of human language acquisition and its output can potentially be used by NLP applications, avoiding the costly and error prone creation of manually annotated corpora. The task has been widely explored (Klein, 2005) and its importance has increased due to the recent availability of huge corpora.

The induced grammar can be represented in various ways. Most work (e.g., (Klein and Manning, 2004; Smith and Eisner, 2006; Seginer, 2007; Headden et al., 2009)) annotate text sentences using an unlabeled hierarchical phrase or a dependency structure, and thus represent the induced grammar through its behaviour in a parsing task.

An important task in theory and practice that we consider in this work is how to enrich phrase structures with syntactic categories. The two grammars that have been widely explored by the NLP community in the last two decades, phrase structure grammars and dependency grammars, allow the induced structure to be either labeled or not and use the labeling to describe substantially different syntactic functions. In this paper we focus on the former formalism and induce parse tree nonterminals (e.g., 'NP', 'VP', 'PP') in an unsupervised manner. We keep the discussion of dependency parsing for future research.

Many linguistic theories posit a hierarchical labeled constituent (or constructional) structure, arguing that it has a measurable psychological reality (e.g., (Goldberg, 2006)). Practically, most of the syntactic annotation of corpora used by the NLP community comes in the form of labeled structures. Indeed, modern *supervised* syntactic parsers aim at learning labeled structures. Moreover, phrase categories are often used in a variety of NLP tasks, such as SRL (Gildea and Jurafsky, 2002; punyakanok et al., 2008), alignment in syntax-based machine translation (Zhang and Gildea, 2004), information extraction (Miyao et al., 2008), etc.

Phrase categories can be induced either jointly with the phrase structure (Haghighi and Klein, 2006) or given a previously induced structure (Borensztajn and Zuidema, 2007; Reichart and Rappoport, 2008). Reichart and Rappoport (RR08), which has the leading results, uses a two stage approach where the second stage clusters the phrases of the parse trees induced by an unsupervised parser (Seginer, 2007). This is done by inducing an over-expressive large number of categories using the BMM model of Borensztajn and Zuidema (2007), and then clustering these categories into a final set.

In this work we focus on improving the critical last stage of narrowing down the large number of induced BMM labels into a smaller set of informative categories[1]. Naively, one might think that simply replacing the simple clustering algorithm used by RR08 with a more elaborate approach would result in improved final categories. However, as we show in Section 3, a variety of clustering approaches did not lead to a noticeable improvement.

To overcome this difficulty, we adopt a qualitatively different solution and tackle this task using a multiple experts approach (Dietterich, 2000). Intuitively, averaging over multiple predictions (experts) is useful when the output of the various experts obeys two requirements: (1) the output of *each* expert is of useful quality; (2) the experts are sufficiently different from each other.

[1] It is also possible to directly cluster phrases without first inducting BMM categories. This, however, leads to inferior overall results which we do not report for clarity.

The central challenge in building such ensembles is in ensuring that different experts capture different characteristics of the problem. To do so, we build on the Dirichlet Process Mixture Model (DPMM) (Ferguson, 1973; Antoniak, 1974) which relies on the Bayesian framework to induce an a posteriori clustering. Each DPMM expert is characterized by a concentration parameter, and we vary this parameter to induce different experts (clusterings). As our experiments show, it is the particular properties of the DPMM that lead to a diverse ensemble.

Finally, with a diverse ensemble at hand, we aggregate the experts into a single coherent phrase structure tagging. Qualitatively, the tendency of two phrases to share a category should increase with the number of DPMM experts that independently cluster them together. We formalize this idea as a global optimization problem and use the k-way normalized cut algorithm (Yu and Shi, 2003) to solve it.

We evaluate our algorithm on English, German and Chinese, using various tag set sizes and evaluation measures. Our results justify our reliance on DPMM and normalized-cut, and demonstrate consistent improvement over previous work.

2 Previous Work

Unsupervised parsing attracts researchers for many years (see reviews in (Clark, 2001; Klein, 2005)). In recent years efforts have been made to evaluate the algorithms on manually annotated corpora such as the WSJ PennTreebank (Klein and Manning, 2002, 2004; Dennis, 2005; Bod, 2006; Smith and Eisner, 2006; Seginer, 2007; Cohen and Smith, 2009; Headden et al., 2009; Berg-Kirkpatrick and Klein, 2010; Blunsom and Cohn, 2010; Gillenwater et al., 2010; Spitkovsky et al., 2010a,b, 2011b,a). All these works induce unlabeled phrase or dependency structures.

In this paper we focus on the induction of syntactic categories for unlabeled phrase structures (parse tree nonterminals) and its evaluation on corpora annotated with a similar representation. There are three previous papers we are aware of that address this problem. Haghighi and Klein (2006) presented two models: $PCFG \times NONE$ and $PCFG \times CCM$. These models use the inside-outside and EM algorithms to induce bracketing and labeling simultaneously [2].

Borensztajn and Zuidema (2007) presented the Bayesian Model Merging (BMM), a framework for inducing a PCFG containing both a bracketing and a labeling. They use Stolcke's algorithm (Stolcke, 1994; Stolcke and Omohundro, 1994) with features from Petasis et al. (2004). The BMM model uses an iterative greedy search for an optimal PCFG according to the Bayesian criterion of maximum posterior probability. The data likelihood is proportional to the data description length according to the grammar and the prior distribution on the grammar is proportional to the grammar description length.

The number of categories induced by the BMM model is very large. For example, for the 7422 sentences of the WSJ10 corpus it induces 4944 categories. To enable generalization over the unlabeled bracketing, a much smaller number of final categories should be induced.

RR08 proposed a clustering algorithm for the BMM categories. They map each of the BMM categories to one of the R most frequent categories produced by the algorithm. Frequency was determined according to the number of phrases each BMM category tags. To perform the mapping, they construct a feature vector representation for each BMM category. The vector consists of $3|M| + |S|$ features, where M is the set of BMM categories and S is the set of POS

[2] Their other models, which were the core of their paper, are semi-supervised.

tags in the corpus. For each category l, they compute the cosine metric between its vector and that of every category among the R most frequent BMM categories. l is mapped to the category with which it obtains the highest cosine score.

RR08 applied their clustering scheme to the bracketing produced by the unsupervised parser of Seginer (2007). The labeled phrase structure trees induced by RR08 are better than those induced by (Haghighi and Klein, 2006) and (Borensztajn and Zuidema, 2007) which motivates separate learning of the phrase structures and their categories. In this work we provide an alternative algorithm for BMM categories clustering. We provide a detailed comparison to the work of RR08 and show superior results.

Sangati and Zuidema (2009) proposed head assignment algorithms. The concept of a head is related to syntactic categories. Their algorithms are trained on data without head annotations, but, unlike our unsupervised approach, requires manually created labeled phrase-structure trees as input.

The concept of head naturally connects to dependency parsing (Kubler et al., 2009) which has been extensively studied in the last decade. While the categories assigned to dependency structures are different in nature from the phrase categories explored in this paper, our algorithm may be applicable to this case as well. We keep this question for future research.

DP has been used for unsupervised syntactic acquisition tasks. Finkel and Manning (2007) Used DP for unsupervised POS induction from dependency structures. Liang et al. (2009) proposed a nonparametric Bayesian generalization of PCFG, based on the hierarchical Dirichlet Process, and applied it to supervised parsing. DP has been used for many other NLP tasks as well (e.g. (Goldwater et al., 2006; Johnson et al., 2007; Haghighi and Klein, 2007; Johnson and Goldwater, 2009)). However, we are not aware of works that explored DP as a model for creating a diverse ensemble of experts for clustering tasks.

3 Building a Diverse Clustering Ensemble

As discussed, to induce phrase categories we adopt a two stage approach where we first induce a large number of categories and then narrow this into a final set. The first stage, leading to a collection of BMM categories is similar to RR08. Our novelty is in taking a qualitatively different approach to the critical stage of narrowing down the large number of categories into a small informative set.

Motivation For the Ensemble Approach. To motivate our ensemble approach we must first consider more straightforward alternatives. Probably the simplest one is to use a one stage approach where we cluster phrases directly using several clustering algorithms (K-means, complete link, single link and average link) and distance metrics (Euclidean and cosine). Another alternative, is to keep running the BMM until the desired number of categories is obtained (that is, by selecting the least harmful update of its objective when no further improvement is possible) . In preliminary experiments, these approaches resulted in inferior results to RR08. For example, for WSJ10 with 26 clusters, the best of these algorithms (K-means with cosine distance), achieves F-score with many-to-one mapping of 38.7 compared to 58.9 of RR08 (see Table 2).

Building on the good performance of RR08, we next tried to simply replace its final clustering algorithm (of BMM labels). We tried the K-mean algorithm both with a random starting point and an informed starting point with the cluster centers initialized as the K most frequent BMM

	V	NVI	Many–to–1
DP	0.26	1.53	34.1
	0.23	1.59	37
	0.2	1.68	44.1
KM	0.65	0.74	69.4
	0.6	0.83	65.2
	0.65	0.75	66.8
RR08	0.67	0.71	73.1
	0.64	0.74	71.6
	0.61	0.84	68

Table 1: Average pairwise similarity between the clustering experts induced by the different clustering algorithms we use in this paper. KM is K–means. RR08 is the algorithm of Reichart and Rappoport (2008) run each time with a different number of induced clusters. For each clustering algorithm, the first line is for WSJ10 (English), the second line is for NEGRA10 (German) and the third line is for CTB10 (Chinese). Higher V and Many–to–1 and lower NVI scores imply that the clusterings are more similar. DP produces the least similar clusterings.

categories. We tried both variants with several different cluster set sizes. In both cases, the resulting final clustering was not superior to that of RR08.

Our next step was to adopt a Bayesian approach where multiple clusterings are considered. Concretely, the Dirichlet process mixture model (DPMM) defines a distribution over clusterings that is governed by a concentration parameter α. Given α, to get a specific clustering, the *maximum a-posteriori* clustering is a natural choice. One can also consider defining a prior over α to lessen the arbitrariness of the choice of parameters. We tried DPMM with a uniform prior over α which did not lead to an improvement in the results. Furthermore, individual clusterings for a range of α values, were all of similar quality. Thus, we cannot expect a more informed prior over α to lead to better performance[3].

Ensemble Construction: First Approach. With the above evidence as to the need of an ensemble approach, we are still left with the challenge of constructing diverse clustering experts. Intuitively, if we allow a different number of clusters for each experts we would often get qualitatively different solutions as, for example, the best three cluster solution is typically not a simple refinement of the best two cluster solution. The simplest approach to carry this out is to run different K-means, each with a different number of target clusters. Another possibility is to use the method of RR08, again with a different number of target clusters. Unfortunately, as Table 1 shows, in both cases the similarity of the different experts (clusterings) is quite high. Indeed, as we report in Section 7, this did only result in small improvement of the performance.

Part of the difficulty with this approach for constructing a clusterings ensemble is that both clustering methods used highly depend on the initial (informed) starting point. Unfortunately, as discussed above, starting with random initializations leads the K-means algorithm to low-quality clusterings.

Ensemble Construction: Improved Approach. To overcome the sensitivity to the initial clustering, we consider the Bayesian DPMM framework. Using standard MCMC techniques

[3]The effective range of α values in our experiments is $[10^{-4}, 10]$. We run the DP algorithm 1000 times with α values changed from 10^{-4} to 10 in steps of 10^{-3}.

(e.g., Gibbs sampling), the resulting clustering converges to the mode of the posterior solution, which is *independent* of the initialization of the procedure[4]. We start by describing the DPMM framework and then explain how it can be used to construct multiple diverse clusterings.

The DPMM defines a prior over the number of clusters that can be described via the so-called Chinese restaurant process (CRP). In this metaphor we have a Chinese restaurant with an infinite number of tables (clusters), each of which can seat an infinite number of customers (BMM categories). The first customer enters the restaurant and seats at the first table. When a new customer (BMM category) arrives at the restaurant, s/he either sits at an existing table with probability proportional to the number of customers already seated at the table (cluster size), or at a new table with probability proportional to α. This process defines a coherent probabilistic prior over the number of clusters (Ferguson, 1973).

Formally, let G be a collection of likelihood parameters, sampled for each cluster. Parameters $\theta_{1:M}$, one for each sample, are drawn from G and, finally, observations, $x_{1:M}$ (the BMM categories) are drawn from a distribution associated with the parameters. Each observation x_i is represented by a vector in N^d, and the values in its corresponding parameter vector, $\theta_i \in R^d$, sum to 1 (d is fixed for all observations). The probability of the i-th observation x_i is associated with the i-th parameter θ_i by a likelihood function $F(\theta_i)$. Now, since the number of clusters is unknown a-priori, the DP defines a distribution over G, governed by a base measure G_0 (parameter factory) and the concentration parameter α. The entire generative process is defined by the equations:

$$G|\alpha, G_0 \sim DP(\alpha, G_0)$$

$$\theta_m|G \sim G$$

$$x_m|\theta_m \sim F(\theta_m)$$

Our likelihood function $F(\theta_i)$ is a multinomial (see below) with parameters $\theta_{1:M}$. G_0 is chosen to be the Dirichlet distribution, the conjugate of the multinomial. The DP concentration parameter, α is kept fixed during the clustering process.

Given a DPMM, a concrete clustering is defined by the mode of the posterior distribution. Each cluster is assigned a different parameter from the collection defined by G, and observations (x_i, BMM labels) belonging to the same cluster (final phrase category), share this parameter.

Constructing multiple experts using the DPMM framework is simply done by varying the concentration parameter α. That is, each expert is associated with a different α value, resulting in a different clustering. While the quality of each such expert is not substantially different than RR08, as Table 1 shows, the resulting experts (clusterings) are substantially more varied than the alternatives considered above.

4 Model Averaging

We now face the task of aggregating the individual clusterings induced by the different DP experts. Intuitively, if several experts independently cluster together two BMM categories, our belief that these categories belong in the same cluster should increase.

[4]In practice, there are deterministic effective alternatives to the stochastic Gibbs procedure which are highly effective. In this work we use the one proposed in Daume (2007).

We now formalize this idea using the k-way normalized cut clustering algorithm (Yu and Shi, 2003). Its input is a undirected graph $G = (V, E, W)$ where V is the set of vertices, E is the set of edges and W is an edge weight matrix assumed to be non-negative and symmetric. For $A, B \subseteq V$ define:

$$links(A, B) = \sum_{i \in A, j \in B} W(i, j).$$

Using this definition, the normalized link ratio of A and B is defined to be:

$$NormLinkRatio(A, B) = \frac{links(A, B)}{links(A, V)}.$$

The k-way normalized cut problem is to minimize the links that leave a cluster relative to the total weight of the cluster. Denote the set of clusterings of V that consist of k clusters by $C = \{c_1, \ldots c_t\}$ and the j-th cluster of the i-th clustering by c_{ij}. Then

$$c^* = \underset{c_i \in C}{\operatorname{argmin}} \sum_{j=1}^{k} NormLinkRatio(c_{ij}, V - c_{ij})$$

To apply an algorithm that solves this clustering problem to our task, we construct the input graph G from the clusterings contained in the ensemble. The graph vertices V correspond to the BMM categories and the (i, j)-th entry of the matrix W is the number of ensemble members that cluster the ith and jth BMM categories together.

A low edge weight implies that a small number of ensemble members cluster together the BMM categories represented by the vertices connected by the edge. To reduce noise, we exclude edges whose weight is less than 3 from the graph.

5 Feature Representation

To complete the picture, we now describe the feature representation of the BMM categories. We create for each BMM category a vector $x \in N^{6 \cdot |S|}$ where S is the set of POS tags in the corpus. The first $2S$ features correspond to the appearance of a POS tag in the leftmost/rightmost position of a constituent labeled by the represented BMM category. Specifically, the i-th feature ($i \in \{1, \ldots, |S|\}$) is the number of times the i-th POS tag appears in the leftmost position of a constituent labeled by the represented BMM category, and the $(|S| + i + 1)$-th feature is the number of times that tag appears in the rightmost position of a constituent labeled by the BMM category.

Similarly, the next $2|S|$ features correspond to the appearance of a POS tag in the leftmost/rightmost position of a leftmost sibling of a constituent annotated by the BMM category, and the last $2|S|$ features correspond to the appearance of a POS tag in the leftmost/rightmost position of a rightmost sibling. A constituent $C1$ is defined to be the leftmost sibling of a constituent $C2$ iff $C1$ is an immediate left neighbour of $C2$, and $C1$ and $C2$ have the same parent. A rightmost sibling is defined accordingly.

Note that DP does not force a specific parametric family for the likelihood. Our decision to use a multinomial likelihood function is due to the fact that our features are counts of events.

6 Experimental Setup

Overall Setup. We evaluated our algorithm on English, German and Chinese corpora: the WSJ Penn Treebank, the Negra corpus (Brants, 1997), and version 5.0 of the Chinese Penn Treebank (Nianwen et al., 2002). In each corpus, we used the sentences of length at most 10[5], numbering 7422 (WSJ10), 7542 (NEGRA10) and 4626 (CTB10). We used the gold standard POS tag annotation of these corpora.

To initialize the clustering algorithms, we sort the BMM categories according to the number of constituents they label, and use the most frequent ones. For K-means, this provides an informed starting point, which proved crucial to the performance of the algorithm. For DPMM, although in theory the algorithm does not depend on its starting point, such initialization is helpful in practice[6].

We induce $D = 10$ different experts. For the K-means and RR08 baselines we do so by changing the number of induced clusters from 5 to 50, in steps of 5. For DPMM we use different values of α sampled log-uniformly in the range $[10^{-4}, 10]$ (5 orders of magnitude). The DP search procedure we use is that of (Daume-III, 2007)[7], whose good convergence properties have been demonstrated. The k-way normalized cut code was written by Jianbo Shi[8]. The code of RR08 was provided to us by the authors[9].

Number of Final Categories. As discussed, the quality of the different experts (clusterings) induced by the DPMM was not substantially different than RR08. Thus, despite the fact that the number of clusters for each expert is inferred automatically, we are still faced with the problem of choosing the final number of categories that will be inferred using the expert ensemble. We face the same problem when considering the baseline ensembles.

Reichart and Rappoport (2008) induced for each corpus two sets of clusters. A first set consists of T clusters, where T is the number of gold categories in the experimental corpus. For the second set size they observed that in all three corpora about 95% of the constituents are covered by 23% – 37% of the categories, and the curve rises very sharply until that 95% value. Therefore, the number of clusters in the second set is the number of categories that cover at least 95% of the constituents in the corpus (denoted by P, for *prominent* categories). Following their work, we induce for each corpus T and P categories according to the values they defined.

The specification of syntax annotation schemes, including the number of categories, usually involves arbitrary decisions (see (Klein and Manning, 2003) for an example and its effects on parsing). We thus induce for each corpus 5 different sets of clusters. Two of these are the set consisting of T clusters and the set consisting of P clusters. The other set sizes are the 3 values in $\{5, 10, \ldots 25\}$ that are not the two closest values to T and P (see Table 2).

Evaluation Measures. The induced labels have arbitrary names. To evaluate them against a manually annotated corpus, a proper correspondence with the gold standard labels should be established. We explore two types of evaluation measures, one is based on mapping between the induced and gold labels and one is based on information theory (IT) concepts. All measures

[5] Excluding punctuation and null elements, as in (Klein, 2005) and other previous work.

[6] Note that this is true even when stochastic algorithms are used to infer the clusterings since convergence time *strongly* depends on the starting point.

[7] http://www.cs.utah.edu/∼hal/DPsearch

[8] http://www.cis.upenn.edu/∼jshi/

[9] We thank the authors for letting us use their code.

are based on the co-occurrence matrix between the induced and gold labels defined as follows: given a corpus tagged once with the n_1 gold standard labels and once with the n_2 induced labels, the co-occurrence matrix has $n_1 \times n_2$ and the number in the (i, j)-th entry is the number of times the i-th gold cluster and the j-th induced cluster annotate the same constituent.

We evaluate with two mapping schemes: greedy *many–to–1* and greedy *1–to–1* mappings. In both cases we find the mapping between the induced and gold clusters which maximizes the co–occurrence between the clusterings. In the first mapping two induced clusters can be mapped to the same gold standard cluster, while in the latter each and every induced cluster is assigned a unique gold cluster. Under both mapping schemes, if the number of induced clusters is lower than the number of gold clusters, there will be gold clusters to which no induced cluster is mapped. Computing the greedy 1–to–1 mapping is equivalent to finding the maximal weighted matching in a bipartite graph, whose weights are given by the co-occurrence matrix. We use the Kuhn–Munkres (Kuhn, 1955; Munkres, 1957) algorithm to solve this problem.

For these measures, we follow the previous works and apply labeled parse trees evaluation by first mapping the induced labels to the gold labels and then computing the standard labeled parsing F–score [10]. While the labeling accuracy after mapping is not explicitly given, it can computed by dividing the unlabeled F–score with the labeled F–score.

The IT based measures provides a way to evaluate the induced clustering without performing a direct mapping to the gold standard. They are based on the observation that a good clustering reduces the uncertainty of the gold standard cluster given the induced cluster and vice-versa. Several such measures exist, we use two widely–accepted ones, the **V** (Rosenberg and Hirschberg, 2007) measure and the **VI** (Meila, 2007) measure.

The V measure is defined as follows:

$$V = \frac{2hc}{h+c}$$

$$h = 1 - \frac{H(G|T)}{H(G)}, c = 1 - \frac{H(T|G)}{H(T)}$$

For the VI measure, we report its normalized version, **NVI**. NVI and VI induce the same order over clusterings but NVI values for good clusterings ranges in $[0, 1]$ (Reichart and Rappoport, 2009). The NVI measure is defined to be:

$$NVI = \frac{H(G|T) + H(T|G)}{H(G)}$$

Note that V scores are in [0, 1] and the higher the score, the better the clustering. For NVI, the scores are non-negative and lower scores imply improved clustering quality. We use e as the base of the logarithm. Many other clustering evaluation measures exist. The ones we use here are well accepted in the literature. For a recent review see (Reichart and Rappoport, 2009).

7 Results

In this section we demonstrate the effectiveness of our DPMM ensemble for the task of unsupervised induction of syntactic categories (parse tree non-terminals) for three different languages. We start by demonstrating an overall and consistent improvement over RR08 and then provide evidence that justify the specific algorithmic choices.

Table 2: Comparison between our main clustering ensemble model and the model of Reichart and Rappoport (2008) (RR08). DP: Dirichlet process. NC: normalized cut. The top three tables are for information theoretic based measures. The bottom three tables are for mapping-based measures. The columns of each table represent the specified number of induced clusters. F(m:1) and F(1:1) are labeled F-score values computed after the induced categories were mapped to the gold categories with many-to-one and 1-to-1 mappings respectively. Higher V, F(m:1) and F(1:1) and lower NVI scores imply the induced clustering to be more similar to the gold standard. The clustering ensemble model (DP+NC) provides considerable improvement over RR08.

Our Expert Ensemble Approach. We start by comparing our DPMM with normalized-cute approach (DP+NC) to RR08. Table 2 shows that DP+NC clearly outperforms the RR08 model. For IT measures it is better in 28 out of 30 experimental conditions and for F(1:1) it is better in 14 of 15 conditions. For F(m:1), DP+NC is better for English while for German and Chinese it is better when the number of induced clusters is small.

RR08 showed that their algorithm is superior to an algorithm that performs random labeling or replaces their final BMM mapping with a random mapping. Since our algorithm is shown to be superior over theirs, it is also better than these random baselines.

Note that RR08 proposed a representation vector of $3|M| + |S|$ features where M is the number of BMM categories. Our DPMM algorithm with this feature representation is very slow due to the high values of $|M|$ (between 2299 and 5559 for our experimental corpora). Consequently, we used a different representation (Section 5). To make sure that our results are not due to this change of features, we also ran their algorithm using our feature set. The superiority of our approach relative to RR08 using this setting was essentially similar to that reported above.

DPMM Clustering. To justify our selection of a DPMM for clustering we compare our results to a variant where DPMM is replaced by K-means (KM) with a cosine similarity measure. KM is known to be very sensitive to its initialization. We ran it once where the cluster centers are randomly initialized and once where, like our DPMM models, cluster centers are initialized to be the k most frequent BMM categories. Since the former model has a substantially inferior performance, we only compare to the latter. We also compare to an ensemble of experts, where each expert is a run of the BMM mapping scheme of RR08 with a different number of target clusters. For both K-means and RR08, we averaged the resulting experts using the same normalized cut algorithm used by our method.

Due to the large number of experimental conditions (3 models and 60 setups: 3 corpora, 4 measures and 5 label set sizes), for clarity of exposition, we only provide a summary of the results. For V, NVI and F(1:1), DP+NC achieves the best score in 39 out of 45 cases. For F(m:1), DP+NC is the best performing model for WSJ10. For NEGRA10 and CTB10, RR08+NC and KM+NC often provide the best performance, but DP+NC is superior to RR08 when the number of induced clusters is small.

Normalized Cut Model Averaging. To justify our selection of the normalized cut algorithm for model averaging, we experimented with various variants of our algorithm (DP+NC) and of the baseline ensemble of experts algorithm where the experts are induced by the informed KM algorithm (KM+NC). In these variants only the model averaging component (NC) is changed. We experimented with several linkage clustering algorithms (complete, single and average) and distance functions (cosine, sample correlation between observations, sample Spearman's correlation between observations and Euclidean). In these experiments each BMM category j is represented by a vector in which the value of the ith coordinate is the number of ensemble members that cluster the ith and jth categories together. We report only the results of the complete link (CL) with cosine distance that provides the best results[11].

In 52 out of the 56 cases where a clustering ensemble model outperforms RR08 NC is the algorithm that is used by the best performing model. Over all cases, DP+NC produces better clustering than DP+CL in 53 of the 60 cases.

[11] In summary, we now discuss five ensemble models. The three that were defined above: DP+NC, KM+NC, and RR08+NC, and the DP+CL and KM+CL defined here.

	No. of Constituents	1	2	3	4	5	6
NP	7898	40.4	59.76	70.4	80.3	88	90.1
VP	6758	60.18	74.77	85.35	90.2	94.24	95.96
PP	3234	44.77	45.92	63.73	71.8	79.22	85.93
S	1076	25.84	43.22	58.74	70.07	81.13	89.22
SBAR	492	34.15	47.56	60.57	72.97	80.78	87.2
ADJP	331	47.13	67.98	74.02	79.76	85.2	90.7

SQ	119	45.38	85.7	96.6	98.3	100	100

Table 3: Performance of the DP+NC model on the 8 most frequent WSJ10 syntactic categories. For each gold category (lines) we show the fraction of the constituents it annotates that are labeled in the induced annotation by the *k* induced categories that label the most of these constituents (column headed with '*k*').

Measure	V	NVI	F(m:1)	F(1:1)
English	0.034	0.12	0.013	0.117
German	0.048	0.049	0.017	0.040
Chiense	0.031	0.119	0.032	0.123

Table 4: The standard deviation to mean performance ratio of the DP+NC model when the number of induced clusters is varied. The effect of the change in the number of clusters on the F(1:1) and NVI measures is an order of magnitude larger, for English and Chinese.

The Mixture of Experts Approach. Finally, we want to demonstrate the importance of adopting an ensemble approach regardless of the specifics of the experts or the aggregation algorithm. Looking at a total of 60 experiments for corpora (3), evaluation measures (4) and number of induced clusters (5), we see a clear advantage of the ensemble approach: in 56 of the 60 cases the ensemble models substantially outperform the RR08 model, and are competitive in the other 4 experiments.

For F(m:1) the difference is up to 11.4% (WSJ10), up to 4.3% (NEGRA10) and up to 1.9% (CTB10). For V it is up to 12%, up to 9% and up to 6% for these corpora respectively. Results are even more impressive for F(1:1) and NVI. For F(1:1), improvement is up to 8.1% (WSJ10), 6.9% (NEGRA10) and 6.5% (CTB10). For NVI, the error reduction[12] is up to 18.3%, 20.2% and 20.6% respectively.

8 Qualitative Analysis

To get a better understanding of the quality of the syntactic categories induced by our model, we provide in this section a qualitative analysis of the performance of our model. We first provide a detailed error analysis of the performance of one of our models, the DP+NC model on the WSJ10 corpus when 15 categories are induced [13]. We then analyze the cross-lingual effect of an important aspect of our model – the number of induced clusters.

English Error Analysis The WSJ10 gold annotation obeys the Zipf law according to which most of the constituents (phrases) of the corpus are annotated with a small number of categories

[12] NVI values are not limited to [0,1], we thus report error reduction, computed as: $\frac{NVI_{model} - NVI_{baseline}}{NVI_{baseline}}$

[13] In order to better analyze the ability of our algorithm to detect the 'S' category, in the analysis of this section we do not count the sentence level constituent which is annotated with this category in 84.7% of the cases.

and the rest of the constituents are annotated by a larger number of much smaller categories. Concretely, while this gold annotation consists of 26 categories, 97.6% (91.8%) of the corpus constituents are labeled with the 8 (4) categories that annotate the highest number of constituents (referred to as 'the most frequent 8(4) categories').

A similar pattern is observed in the categories induced by the DP+NC model: the 8(4) most frequent categories annotate 88.5% (62.2%) of the constituents. The stronger magnitude of the Zipfian effect in the gold annotation suggests that biasing our model towards a stronger Zipfian pattern (e.g. by adding a normalization term to the NC optimization problem) may improve its performance.

Table 3 presents the distribution of each of the 8 most frequent gold categories between the 6 most frequent induced categories that annotate most of its constituents. The table shows that for 6 of these categories (all categories except from 'S' and 'SBAR') at least 40% of the constituents are annotated by the same induced category and 63.7%-96.6% of the constituents are annotated by 3 induced categories. The algorithm is shown to performs especially well in detecting the 'VP' and 'SQ' categories (60.18%-85.35% and 45.38%-96.6% of the constituents in 1-3 induced categories respectively). Performance on the 'SBAR' and 'S' categories are somewhat lower (at least in terms of overlapping with their 3 most overlapping categories).

Cross-Lingual Analysis Here we provide cross-lingual error analyse for one of the choices made by our model, the number of induced clusters. Table 4 shows the standard deviation to mean performance ratio for the DP+NC model in all three languages. While for German, all measures are relatively indifferent to the number of clusters, for Chinese and English the ratio for the F(1:1) and NVI measures is an order of magnitude larger than for F(m:1) and V.

This pattern leads us to two interesting observations that may guide future research in the field. First, a large number of clustering evaluation measures have been proposed in the literature (Reichart and Rappoport, 2009). Our experiments suggest that F(1:1) and NVI are more sensitive to a change in the number of induced clusters. Second, the performance of our model on German is mostly indifferent to the number of clusters, according to all measures. This calls for a deeper investigation of the properties of our algorithm especially with respect to languages that are typologically similar to German.

Conclusion and perspectives

We presented a novel clustering ensemble model for unsupervised induction of syntactic categories. Our model uses the Dirichlet process mixture model for expert induction and normalized-cut model averaging, providing a substantial improvement over previous works in English, German and Chinese.

Our contribution is two-fold. First, we bring the idea of ensemble learning into the task of unsupervised induction of syntactic categories, leading to substantial performance improvement. Second, and more importantly, we show how to construct a diverse ensemble of experts using the Dirichlet Process mixture model.

In future work we intend to experiment with more languages. The hierarchical generalization of the Dirichlet Process offers an opportunity for future joint learning of the syntactic structures and its annotation. On an orthogonal axis, the output of our algorithm can be used to train supervised parsers.

ABSTRACT
We report a wide range of comparative experiments establishing for the first time contrastive foundations for a completely unsupervised approach to bilingual grammar induction that is cognitively oriented toward early category formation and phrasal chunking in the bootstrapping process up the expressiveness hierarchy from finite-state to linear to inversion transduction grammars. We show a consistent improvement in terms of cross-entropy throughout the bootstrapping process, as well as promising decoding experiments using the learned grammars. Rather than relying on external resources such as parses, POS tags or dictionaries, our method is fully unsupervised (in the way this term is typically understood in the machine translation community). This means that the bootstrapping can only rely on information gathered during the previous step, which necessitates some strategy for expanding the expressiveness of the grammars. We present principled approaches for moving from finite-state to linear transduction grammars as well as from linear to inversion transduction grammars. It is our belief that early, integrated category formation and phrasal chunking in this unsupervised bootstrapping process is better aligned to child language acquisition. Finally, we also report exploratory decoding results using some of the learned grammars. This is the first step towards an end-to-end grammar-based statistical machine translation system.

1 Introduction

We report a wide range of comparative experiments establishing for the first time contrastive foundations for a completely unsupervised approach to bilingual grammar induction that is cognitively oriented toward early category formation and phrasal chunking in the bootstrapping process up the expressiveness hierarchy from finite-state to linear to inversion transduction grammars.

In the context of bilingual grammar induction, "unsupervised" means that a transduction grammar (or synchronous grammar) is learned without using any external resources such as parses, POS tags, or dictionaries. In contrast, many, if not most, tree-based statistical MT approaches rely on monolingually parsed, chunked, and/or tagged parallel corpora (e.g., Galley et al. (2006)), from which a transduction grammar is extracted. Such approaches must compensate for monolingual analyses that often are not designed optimally for expressing the relationship between, say, English and Chinese. Exceptions include the hierarchical phrase-based SMT method of learning ITGs (Chiang, 2005), which does not rely on external resources.

However, unlike Chiang (2005) where huge numbers of (linguistically questionable) phrase translations are essentially memorized, our present work aims at inducing syntactic categories at an early stage in the learning, as occurs in child language acquisition. While only time will tell whether our more cognitively motivated approach to the induction of structural and lexical relationships between two languages will lead to better machine translation models, it is our belief that ultimately, learning the correct categories as early as humans do will provide a more accurate generalization bias for subsequent learning of more complex transduction rules.

In this paper, we report a large body of foundational experiments that, for the first time, illuminate how EM-based bilingual grammar induction behaves as we move up the complexity hierarchy of transduction grammars. We investigate various bootstrapping approaches to induction of finite-state transduction grammars (FSTGs), linear transduction grammars (LTGs), and inversion transduction grammars (ITGs). We then turn to various combinations of phrasal chunking to induce segmental transduction grammars, which can represent various classes of phrase-based translations. We then integrate category induction methods in various combinations.

This research thread represents a long term effort to investigate how a more principled, generalization-oriented model of bilingual grammar induction could gradually replace various parts of the long chain of heuristics used in the more memorization-oriented approaches. Although we do also look at preliminary BLEU and NIST scores from MT decoding using the induced transduction grammars, we believe it is premature to place excessive emphasis on such scores because too many other factors (such as the language model, to name one) are entangled. At this early stage of establishing the foundations for understanding category formation in bottom-up bilingual grammar induction, it is more important to compare more *directly* how well the relationships between the two languages are learned by the very many possible various combinations of bootstrapping between transduction expressivity levels, phrasal chunking, and category formation. Therefore, we focus more on the cross entropy of the induced bilingual grammars—which is exactly the bilingual form of the standard way to evaluate how well monolingual grammar induction captures monolingual data.

Note that, as observed in Wu (1997), this way of analyzing bilingual grammar induction can also be viewed as the problem of *bilingual language modeling*—modeling two languages simultaneously. We attack this problem of bilingual language modeling by extending a surprisingly effective finite-state baseline in two different ways: adding reordering capabilities and adding context information in the form of categories. The ultimate aim of this research direction is to have a grammar-based end-to-end statistical machine translation system, which would enable the usage of the same model in training and decoding instead of relying on a pipeline of different mismatched models trained independently. The bilingual language models we learn in this paper are grammar-based, and they thus represent a step towards this goal. Our new model is still extremely simple, even with the two proposed extensions. Reordering is added by first promoting the finite-state model to a linear model, which allows reading from the beginning or end of the two sentences independently and then by promoting the linear model to a fully nesting model. Contextual information is added in the form of a handful of categories, which are learned exclusively from the raw data.

We start by allowing any input token to translate into any output token, we also allow the input or output token to be empty. The lexical rules can contain input and output strings of length zero or one, but at least one of them must be nonempty. This initial search space is reigned in by training, which eliminates some of the (very unlikely) rules, but it is mainly expanded by allowing observed sequences to be taken up as lexicalized sequences (chunking), and by allowing category diversification (splitting). This initial stage of search space expansion is carried out in a very weak grammar formalism, which forces it to focus on learning lexical rules, since the weak structure of the grammar makes it rely heavily on surface form. Once the lexical chunks have been found and tentatively categorized, we will move the grammar into a more expressive formalism, and further train it. The idea is that we will have found enough good rules in the expansion phase that training with the more expressive formalism is mainly about establishing the structure and getting rid of useless rules. This approach also has the benefit that a lot of the "heavy lifting" can be done in the weaker grammar formalism, which is also less expensive to compute.

We will consistently use *preterminalized finite-state transduction grammars* (PFSTGs) as the weak grammar formalism, and *preterminalized linear inversion transduction grammars* (PLITGs) and *inversion transduction grammars* (ITGs) as the more expressive grammar formalisms.

The PFSTG's weakness comes from the fact that they have no structural way to reorder the input into the output. Instead they have to rely on singletons – lexical rules that delete from the input or insert into the output. These rules allow the PFSTG to disregard parts of a sentence pair, but still account for the parts that it can account for. It also means that PFSTGs need to keep a lot of singleton rules around that a more expressive grammar could do without.

ITGs are capable of considerable structural reordering, they are in fact the most expressive transduction grammar that can be used to parse a parallel corpus in polynomial time. They are, in other words, the most expressive grammar that can possibly be afforded.

PLITGs are wedged between PFSTGs and ITGs in terms of expressiveness. They do allow for some structured reordering. Like PFSTGs, the parse trees are chains rather than trees, but unlike PFSTGs, the links in these chains do not have to be physically adjacent. Allowing the first input token to be lexically associated with the last output token is an example of the kind of reordering that PLITGs allow, which make them more expressive than PFSTGs. The fact that these reorderings are limited to lexical units only is what makes them less expressive than ITGs (Saers et al., 2011) .

The rest of the paper is structured so that we begin by describing the initial finite-state transduction grammar that we will start our bootstrapping sequence (Section 2). We then describe how the lexical chunking (Section 3) and category splitting (Section 4) is carried out before moving on to expressivity expansion: first from finite-state to linear transduction grammars (Section 5), and then from linear to inversion transduction grammar (Section 6). We then move on to an illustrative example of what the bootstrapping process actually entails (Section 7), along with some tentative decoding results, before offering some concluding remarks (Section 8).

2 Initial grammar

As a grammar-based translation model baseline, we will use the simplest possible transduction grammar: the finite-state transduction grammar. A finite-state transduction grammar is the grammar form of a finite-state transducer. The transformation into a grammar is trivial and gives us FSTGs.

2.1 Definition 1

A FSTG over languages L_0 and L_1 is a tuple $G = \langle N, \Sigma, \Delta, S, R \rangle$, where N is a finite nonempty set of nonterminal symbols, Σ is a finite nonempty set of L_0 tokens, Δ is a finite nonempty set of L_1 tokens, $S \in N$ is the designated start symbol and R is a finite nonempty set of finite-state transduction rules on the forms:

$$A \rightarrow e/f\,B, \quad A \rightarrow \epsilon/\epsilon$$

where $A, B \in N$ *and* $e/f \in (\Sigma^* \times \Delta^*) - \{\epsilon/\epsilon\}$.

To harmonize this kind of grammar with future extensions to it, we will preterminalized it. A *preterminalized* FSTG has a special class of nonterminals called *preterminals*, which have a monopoly on rewriting to biterminals. This does not change the expressivity of the grammar, nor its asymptotic time complexity. To see why, simply imagine the degenerate case where every biterminal has exactly one unique preterminal symbol associated with it. In this paper, the only FSTGs we will use are *preterminalized finite-state transduction grammars*, or PFSTGs.

2.2 Definition 2

A PFSTG over languages L_0 and L_1 is a tuple $G = \langle N, P, \Sigma, \Delta, S, R \rangle$, where N is a finite nonempty set of nonterminal symbols, P is a finite nonempty set of preterminal symbols, disjoint from N, Σ is a finite nonempty set of L_0 tokens, Δ is a finite nonempty set of L_1 tokens, $S \in N$ is the designated start symbol and R is a finite nonempty set of preterminalized finite-state transduction rules on the forms:

$$A \to QB, \quad A \to \epsilon/\epsilon, \quad Q \to e/f$$

where $A, B \in N$, $Q \in P$ and $e/f \in (\Sigma^* \times \Delta^*) - \{\epsilon/\epsilon\}$.

As a baseline, we will choose the simplest possible PFSTG: a *bracketing* PFSTG. The bracketing PFSTG has only one nonterminal symbol and one preterminal symbol. As such it relies solely on lexical information to find translation correspondences. The lexical information is surprisingly powerful when both sentences are given.

To assign scores to the sentence pairs, we need a weighting function for the rules, making it a *weighted* PFSTG. We will go one step further, and require the weighting function to define proper probability distributions such that:

$$p(\psi \to \varphi) \equiv Pr(\varphi \mid \psi)$$

which makes the grammar *stochastic*. These kind of conditional probabilities over rules can be tuned towards a corpus of examples (a training corpus) through expectation maximization, or EM. Expectation maximization can only be used to tune existing parameters, so to have something to tune, we initialize the grammar using the training corpus. The structural rules will have uniform probability, and the lexical rules will have a portion of the probability mass relative to their cooccurrence in the training corpus. Specifically, we will initialize a stochastic bracketing FSTG such that:

$$\begin{aligned} p(S \to A) &= 1, \\ p(A \to QA) &= 0.5, \\ p(A \to \epsilon/\epsilon) &= 0.5, \\ p\left(Q \to e/f\right) &= \frac{c\left(e/f\right)}{\sum_{e' \in \Sigma, f' \in \Delta} c\left(e'/f'\right)} \end{aligned}$$

where $c\left(e/f\right)$ is the cooccurrence count for the biterminal $e/f \in ((\Sigma \cup \{\epsilon\}) \times (\Delta \cup \{\epsilon\})) - \{\epsilon/\epsilon\}$.

To calculate the expectations for the expectation maximization, we will parse the training corpus with the grammar we have, using an adaptation of the parsing algorithm described in Saers et al. (2010). The adaptation consists of allowing multiple categories (not simply bracketing grammars), and to handle preterminals. Although this algorithm was designed for the linear family of transduction grammars, the PFSTGs are merely a restricted form of PLITGs, which means that the algorithm applies to them as well.

Training this grammar on IWSLT07 ChineseEnglish data (Fordyce, 2007) gave us a sentence-level cross-entropy of 110.2. The results of all training runs can be found in Table 1, where the baseline model is designated `fstg`.

3 Chunking helps

We can induce new lexical rules by allowing lexical entities to combine in order to form larger lexical entities. The end results are similar to phrase-based machine translation, but the method of arriving at the segments (chunks or "phrases") is very different.

To apply chunking to our PFSTG, we use the method described in Saers and Wu (2011). The method was originally developed for PLITGs, which is a superset of PFSTGs, so it can be applied as is. The gist of the method is to allow two bitokens that are observed next to each other to combine into a new, larger bitoken. The process is thus limited to produce bitokens of twice the length of existing bitokens. There is, however, nothing stopping us from applying the method several times, getting larger and larger chunks. The maximum bitoken length of the baseline grammar is 2 (one input token and one output token), which we can double by chunking.

By applying chunking to the baseline PFSTG, and training with the chunks (model `fstg_c` in Table 1), we get a cross-entropy of 73.0, which is significantly better than the 110.2 that the baseline grammar (model `fstg`) scored. If we repeat the chunking (model `fstg_c_c`), we go all the way down to 45.0. A third round of chunking and training (model `fstg_c_c_c`) gets us a small improvement down to 43.9. This is interesting, since going from segments of length 1 to segments of length 2 helps tremendously, and proceeding to segments of length 4 goes a long way indeed. Pushing it up to segments of length 8 (which is close to the default "maximum phrase length" of Moses: 7), does surprisingly little. Either way, chunking was responsible for cutting the cross-entropy in more than half.

4 Splitting helps

We can introduce new nonterminal or preterminal symbols by splitting off some of the probability mass of an existing symbol to one or more new symbols. This gives us the possibility of diversifying the categories used by the grammar, which is necessary in order to move away from bracketing grammars to more interesting types of grammars.

Splitting into new symbols is a problem that can be formulated as splitting the probability mass of one symbol to several existing symbols. This requires the new symbols to be inserted into the grammar before the splitting takes place, which is a reasonable prerequisite. The assumption that the probability mass of the symbol being split could end up in any of the existing symbols makes it necessary to have some mechanism to control the destination of the probability mass. Furthermore, it is desirable to have some mechanism to introduce perturbations into the splitting of the probability mass, since exactly splitting it uniformly will inhibit learning. In addition to this wish list, we also wanted to differentiate between the case when the nonterminal was on the left-hand side of a rule, and when it was on the right-hand side. Remember that we are dealing with preterminalized grammars, and being able to have different splitting policies depending on where in the rule the symbol occurs is important. We want preterminals to be heavily perturbed on the left-hand side, but lightly perturbed on the right-hand side. When the preterminal is on the left-hand side, it is assigning a category to the terminal pair it rewrites to; by having larger differences in probability mass, we are essentially assigning a category at random, but keeping some of the mass in the other category, just in case the decision was wrong. When the preterminal is on the right-hand side, it determines the contexts in which a particular category can occur, which we do not want to randomize too much; relying on training is better. It turns out that all these desiderata can be addressed in a

very simple way.

To split a nonterminal x, we give a set of target nonterminals $y_0, y_1, ..., y_k$ paired up with a kind of pseudo counts $a_0, a_1, ..., a_k$ that represent "how often x was split into y_i". The as are used as parameters to a Dirichlet distribution, from which a categorical distribution is randomly drawn every time x has to be split.

If any of the ys do not exist in the grammar, they are added to it. If no pseudo count is given for a nonterminal, it is assumed to be zero. This means that the Dirichlet distribution will be well-defined over the set of nonterminal symbols in the grammar. The expected categorical distribution drawn from the Dirichlet distribution will be "relative frequency" over the pseudo counts, but since we are drawing the categorical distribution at random, there will be some perturbation to it. The magnitude of the perturbation will be inversely proportional to the total number of pseudo counts in the Dirichlet distribution. Intuitively, the more pseudo counts we have, the more certain we can be that they are correct. Conversely, with few pseudo counts, there is a lot of uncertainty, and therefore a lot of variation in the categorical distributions we draw.

Once we have a categorical distribution over the set of nonterminals, we can distribute the probability mass of a rule containing x, into the expected portion according to the categorical distribution. To keep x as a symbol, it needs to retain some of the probability mass, and the simplest way to do this is to have non-zero pseudo counts for it; this is the approach we took.

To allow for different behavior depending on where in the rule x occurs, we simply supply two Dirichlet distributions: one to be used when x is on the left-hand side of a rule, and one to be used when it is on the right-hand side.

The pseudo code for the algorithm is give below.

4.1 General nonterminal (and preterminal) splitting algorithm

To refresh memory, a rule consists of a single nonterminal (or preterminal) symbol (i) on the left-hand side, and a sequence of nonterminal (or preterminal) and biterminal symbols on the right-hand side (ϕ). Furthermore, there is a permutation over the right-hand side (π). The rule form is thus $i \rightarrow \phi ; \pi$. There is also a probability function that assigns a probability to each rule (p).

Input: a set of rules R, a nonterminal to split x, a probability function p over R, a left-hand side Dirichlet distribution over nonterminals D_l, a right-hand side Dirichlet distribution over nonterminals D_r.

Output: a new set of rules R' and a new probability function p' over R'.

$R' \leftarrow ()$
for all $i \rightarrow \phi ; \pi \in R$ **do**
  $R'' \leftarrow ()$
  if $i = x$ **then**
    Draw the parameters to a categorical distribution over nonterminals $\alpha \sim D_l$
    for all nonterminal y **do**
      $R'' \leftarrow (R'', [y \rightarrow ; \pi, \alpha_y p(i \rightarrow \phi ; \pi)])$
    end for

else
$R'' \leftarrow ([i \rightarrow; \pi, p(i \rightarrow \phi; \pi)])$
end if
for all $0 \leq k < \left|\phi\right|$ **do**
$R''' \leftarrow ()$
for all $[z \rightarrow \psi_{0..k}; \pi, p''] \in R''$ **do**
if $\phi_k = x$ **then**
Draw the parameters to a categorical distribution over nonterminals $\alpha \sim D_r$
for all nonterminals y **do**
$R''' \leftarrow (R''', [z \rightarrow \psi_{0..k} y; \pi, \alpha_y p''])$
end for
else
$R''' \leftarrow (R''', [z \rightarrow \psi_{0..k} \phi_k; \pi, p''])$
end if
$R'' \leftarrow (R'', R''')$
end for
end for
for all $[r, p''] \in R''$ **do**
$R' \leftarrow (R', r)$
$p'(r) += p''$
end for
end for

We consistently used pseudo counts of 1000 (both for left- and right-hand side) when splitting nonterminals, and 0.5 (for left-hand side) and 1000 (for right-hand side) when splitting preterminals.

So far, we only have four PFSTGs, with different segment lengths. We did not carry out all possible experiments, but the ones we did carry out all show that splitting helps (all models in Table 1 with an `s` followed by some number have had all their symbols split into the given number of symbols). Sometimes it helps as little as when moving from 73.0 for a bracketing PFSTG with segment length 2, to 72.5 for the same grammar with its pre- and nonterminal split in two (model `fstg_c` to `fstg_c_s2`). The same modest improvement was observed when splitting the grammar with segment length 4, where we moved from 45.0 cross-entropy to 44.5 (model `fstg_c_c` to `fstg_c_c_s2`). However, splitting again gave 42.9 (moving to `fstg_c_c_s2_s2`), and a third time gave 39.5 (moving to `fstg_c_c_s2_s2_s2`). Beyond the first split, we see a better improvement than chunking an extra time.

5 Moving to linear transductions helps

The *preterminalized finite-state transduction grammar* is very closely related to the *preterminalized linear inversion transduction grammar*. The only difference is that the latter has more structural rules. As a reminder, the PFSTG has rules on the following forms:

$$A \rightarrow QB, \quad A \rightarrow \epsilon/\epsilon, \quad Q \rightarrow e/f$$

Whereas the PLITG has rule on the following forms:

$$A \rightarrow [QB], \quad A \rightarrow [BQ], \quad A \rightarrow \langle QB \rangle, \quad A \rightarrow \langle BQ \rangle, \quad A \rightarrow \epsilon/\epsilon, \quad Q \rightarrow e/f$$

Where the square and angled brackets have their customary interpretation as straight and inverted permutations respectively. The difference is in the structural rules, and each of the structural rules in a PFSTG corresponds to four structural rules in a PLITG. To move from a PFSTG to a PLITG, we merely have to add these rules, and distribute the probability mass. We distribute the probability mass uniformly.

Another possibility that PLITGs have that PFSTGs do not is to canonize the singletons. In the PLITGs we have used so far, there is always some ambiguity due to the fact that singletons are empty in one of the languages, and there is no way to tell whether the empty string should attach to the front or the back of the string in that language. This ambiguity can be eliminated by insisting that it attach to the same end that the known string attaches to in its language. This enforces a canonical form for singletons, and reduces complexity.

To canonize a PLITG, start by creating two new preterminal symbols, one for input singletons and one for output singletons for every existing preterminal. Then move all the singleton realizations of that preterminal to the newly created symbols. Consider the preterminal P. We will split it into $P^{e/f}$ (non-singletons), P^{f} (input singletons) and P^{e} (output singletons), and divide the set of rules so that the singletons must be produced by the singleton symbols, and the non-singletons must be produced by the non-singleton symbol.

To produce the new preterminal symbols, we also need to account for the case when P is on the right-hand side of a structural rule, and withholding some of the possible new rules will make the grammar singleton canonical. In a PLITG in normal form there may be at most one preterminal symbol on the right-hand side. Consider the four kinds of rules where P could occur in a PLITG:

$$A \rightarrow [PB], A \rightarrow [BP], A \rightarrow \langle PB \rangle, A \rightarrow \langle BP \rangle$$

To keep the PLITG canonical, we would like to have the following rules:

$$A \rightarrow \left[P^{e/f} B \right], A \rightarrow \left[B P^{e/f} \right], A \rightarrow \langle P^{e/f} B \rangle, A \rightarrow \langle B P^{e/f} \rangle,$$
$$A \rightarrow [P^{e} B], A \rightarrow \langle P^{e} B \rangle, A \rightarrow \left[P^{f} B \right], A \rightarrow \langle B P^{f} \rangle$$

The probability mass is divided to reflect the probability of P rewriting to non-singletons and the singletons respectively.

Whether we use a canonical PLITG or not, it allows us to move from any of the grammar we have trained so far to a PLITG and resume training with this more expressive grammar formalism. This gives a consistent improvement in cross-entropy (this can be seen in Table 1, where the PLITG models end in `_ltg`, and are meaningful to compare to the models preceding them).

6 Moving to inversion transductions helps

Moving from a PFSTG or PLITG into an ITG is a much more complicated process than moving from a PFSTG to a PLITG. Since we have that first step covered, we will focus on moving from a PLITG to an ITG. Once this step is in place, we can move from a PFSTG to an ITG *via* a PLITG (with or without training at the PLITG stage).

Model	cross-entropy
fstg	110.2
fstg_ltg	108.9
fstg_ltg_itg	95.5
fstg_itg	93.2

6.1 Definition 3

A syntax-directed transduction grammar (SDTG) in normal form is a tuple $\langle N, \Sigma, \Delta, S, R\rangle$ where N is a finite nonempty set of nonterminal symbols, Σ is a finite nonempty set of input language symbols, Δ is a finite nonempty set of output language symbols, $S \in N$ is the designated start symbol, and R is a finite nonempty set of syntax-directed transduction rules on the forms:

$$S \to A, \quad A \to \varphi; \pi, \quad A \to e/f$$

where $A \in N$, $\varphi \in NNN^*$, π is a permutation vector over φ, and $e/f \in (\Sigma^* \times \Delta^*) - (\epsilon/\epsilon)$.

6.2 Definition 4

An inversion transduction grammar (ITG) in normal form is an SDTG in normal form, where the number of nonterminals allowed on the right-hand side is exactly two for all nonterminals

except the start symbol (which may only have one). The rules are thus on the forms:

$$S \rightarrow A, \quad A \rightarrow BC; \pi, \quad A \rightarrow e/f$$

Since there are only two possible permutation vectors (straight and inverted), the rules are typically expressed as:

$$S \rightarrow A, \quad A \rightarrow [BC], \quad A \rightarrow \langle BC \rangle, \quad A \rightarrow e/f$$

where the square brackets represent straight order, and the angled brackets represent inverted order.

To make a PLITG in normal form into an ITG in normal form, all that has to be done is to eliminate the rules where a nonterminal is allowed to go to nothing (empty rules). This does, however, leave us with an ITG that generates the exact same transduction that the PLITG generated, which is not necessarily what we want. It is more likely that we want a grammar that is more expressive than the grammar we had. To this end, we will promote the preterminals to full nonterminals. Since the removal of the empty rules entails having the nonterminals behave as preterminals, and promoting the preterminals to full nonterminals entails having the preterminals behave as nonterminals, there is no longer any point in making the distinction between the two classes of symbols. Indeed, an ITG only has nonterminal symbols.

The theory of promoting preterminals to nonterminals is to insert unary rules, where the preterminal rewrites into exactly one nonterminal symbol. For every preterminal that is to be promoted, one such rule is generated for each nonterminal. To control how much of its "preterminal-ness" the preterminal retain, we employ a hyperparameter α. The probability mass of the preterminal is redistributed so that α of it is retained in its original rules, whereas $1 - \alpha$ is redistributed to the new unary rules. The last thing that needs to be determined is the preterminals affinity to specific nonterminals. We use the function $\beta\left(y\right)$ for this, which gives the probability of the nonterminal y given the preterminal that is being promoted. In this round of experiments, β was uniform over all nonterminals. Naturally, we want to keep the new ITG in normal form, so we will actually not insert the unary rules, but rather anything the nonterminal can expand into. This gives us the following new probability function (p') over the new and old rules:

$$p'(x \rightarrow \phi; \pi) = \alpha p(x \rightarrow \phi; \pi) + (1 - \alpha) \sum_{y \in N} \beta\left(y\right) p(y \rightarrow \phi; \pi)$$

Where x is the preterminal being promoted, N is the set of nonterminals, ϕ is a sequence of nonterminals and biterminals, and π is a permutation over ϕ.

To train at the ITG stage, we use the algorithm presented in Saers et al. (2009), which we generalize to handle multiple nonterminals rather than being restricted to bracketing ITGs.

It is clear from Table 1 that the ITG models explain the data better than any other kind of model, and that more induction steps are better (the best model is the most heavily processed one, with two chunking steps and three splitting steps before moving on to ITGs). In the cases where we move to ITGs via PLITGs, we also see some improvements, which is encouraging.

7 Qualitative analysis and translation assessments

In this section, we present a qualitative analysis of an example to illustrate the nature of alignments learned during various stages in the training. As a step forward towards our goal of purely inducing ITGs in an unsupervised manner for the purpose of translation, we report our initial findings on using these bootstrapped models in translation tasks.

7.1 Bootstrapping improves the alignments

Although the cross-entropy scores indicate an improvement in the quality of the grammars learned after LTGs and ITGs with FSTGs, we were interested in understanding the qualitative nature of generalizations the model was learning. Such an analysis would reveal how new generalizations might emerge as expressivity of models increases. They would also help identify overfitting of the model and how errors propagate from one stage to another.

An important consideration in bootstrapping would be to identify whether or not alignments that could not be learned in less expressive models could be learned by more expressive models after bootstrapping. In order words, whether bootstrapping enables learning of those alignments that would otherwise be impossible to learn with less expressive models. One should also consider the possibility that incorrect alignments in the initial stages might prevent the correct alignments from ever being learned.

With the above question in mind, we decided to investigate one of the simplest and most common manifestations of this scenario in Chinese-English parallel data. Typically, locatives in chinese appear before the verb whereas in English they appear after the verb. Hence, the alignments of bisentences which contain these locative markers require the model to permit a certain degree of reordering. We present below, a qualitative analysis of the translation rules learned for one such locative marker at various stages in our bootstrapping pipeline.

We choose the Chinese locative marker which occurs 67 times in our data set. typically translates to *inside* in English. The following are two sentences that occur in our training data.

Source:
Gloss: inside is what ?
Translation: what is inside ?

Source:
Gloss: inside is what thing ?
Translation: what does it contain ?

In the first example, the correct alignment would require an alignment permutation of $[2, 1, 0, 3]$ which is beyond the expressive power of the FSTG models. As the translation that is present in the training data for the second example is inexact, the locative marker is forced to align to . These examples are representative of the way in which appears in the training corpus.

Table 2 shows some of the best translations (in the decreasing order of probability) of the token learned after the FSTG, FSTG_LTG, FSTG_ITG and FSTG_LTG_ITG stages in our training pipeline, in contrast to directly inducing ITGs. It is not surprising that FSTGs fail to learn the correct translations of the locative as most alignments of sentences containing the

FSTG		FSTG_LTG		FSTG_LTG_ITG		ITG	
$P \rightarrow$	/	$P \rightarrow$	/inside	$P \rightarrow$	/inside	$A \rightarrow$	/inside
$P \rightarrow$	/there	$P \rightarrow$	/it	$P \rightarrow$	/	$A \rightarrow$	/in
$P \rightarrow$	/it	$P \rightarrow$	/there	$P \rightarrow$	/it	$A \rightarrow$	/
$P \rightarrow$	/what	$P \rightarrow$	/	$P \rightarrow$	/in	$A \rightarrow$	/it
$P \rightarrow$	/I	$P \rightarrow$	/what	$P \rightarrow$	/I	$A \rightarrow$	/I

Table2: The best translation rules for the Chinese locative marker at various stages in the training pipeline.

Model	Cross-Entropy	BLEU	NIST
FSTG	110.2	7.95	0.4752
FSTG_LTG	108.9	8.34	0.7466
FSTG_LTG_ITG	95.5	8.83	0.8554

Table3: The correlation between the cross-entropy and the BLEU and NIST scores for token based models.

token are non-monotonic. From the second column of the table we can observe that the correct translation is learned to be the best translation after bootstrapping with LTGs alone. However, singleton translation and other synonyms of do not appear in the top five translations. Upon bootstrapping ITG with the FSTG_LTG, we identify that the translation *in* makes it into the top translations. The translations learned at FSTG_LTG_ITG stage are almost comparable to directly inducing an ITG as shown in the rightmost column.

Although locatives represent an extreme case of the nature of generalizations that could be learned from bootstrapping, we find that this kind of learning applies to all alignments at the FSTG stage. The correct alignments tend to get rewarded through successive stages of bootstrapping while the noisy alignments are drowned out. The end result is comparable to that of inducing LTGs and ITGs directly without the overhead of such an induction.

7.2 Successive bootstrapping promises improvements in translation quality

The final goal of our approach is to build a theoretically principled SMT system with well-defined representations. Although cross-entropy is a good measure of gauging how our models explain the data, it is not sufficient to guarantee an SMT system with a good performance. It is important to observe an improvement in the performance on a translation task that correlates with the improvement in cross-entropy of the model.

We approach this promise with caution as our models in their current state, are not optimized to compete with the state of the art SMT systems. We report the results of our preliminary experiments on using our trained models for the task of SMT.

Table 3 shows the BLEU scores obtained using only token based models (without any sort of chunking) on the IWSLT07_CE test set. These scores gives a gist of how translation quality changes with the grammar formalism, but a token-based model will naturally perform poorly compared to the state of the art. We used an in-house decoder for the purpose of decoding using our models. We used a trigram LM trained using SRILM (Stolcke, 2002) on the IWSLT dataset and a part of the gigaword data set.

We can observe significant gains in the BLEU (Papineni et al., 2002) and NIST (Doddington, 2002) scores after training on LTGs and a further improvement after training on ITGs. Further, these scores seem to be reflecting our estimates about the goodness of our models using cross-entropy.

Due to time constraints, we could not perform extensive experiments on the quality of translations produced with other models discussed in the rest of the paper. We also want to emphasize that an exhaustive evaluation of the performance of these models on translation tasks would result in a combinatoric explosion of models where chunking and splitting could be applied at various stages in the training pipeline with different chunking and splitting strategies. Therefore, in order to realize a competitive SMT system using our bootstrapping technique, we would first need to understand the qualitative and quantitative effects of using different models and the respective chunking and splitting strategies. We intend to pursue this task more confidently given our encouraging results on cross-entropy and the BLEU score correlation.

8 Conclusions

We reported a wide range of comparative experiments for a completely unsupervised approach to bilingual grammar induction with early category formation and phrasal chunking in the bootstrapping process up the expressiveness hierarchy from finite-state to linear to inversion transduction grammars. We reported a consistent improvement in the cross-entropy as we move through FSTGs to LTGs and ITGs. We also saw a substantial improvement in cross-entropy scores upon chunking and inducing categories. We reported an illustrative example that indicates generalizations learned from bootstrapping are equivalent to inducing models with higher expressivity directly but at a much lower cost. Finally, we discussed some of the encouraging results of our translation assessment experiments using bootstrapped models.

ABSTRACT
Underspecified queries are common in vertical search engines, leading to large result sets that are difficult for users to navigate. In this paper, we show that we can automatically guide users to their target results by engaging them in a dialog consisting of well-formed binary questions mined from unstructured data. We propose a system that extracts candidate attribute-value question terms from unstructured descriptions of records in a database. These terms are then filtered using a Maximum Entropy classifier to identify those that are suitable for question formation given a user query. We then select question terms via a novel ranking function that aims to minimize the number of question turns necessary for a user to find her target result. We evaluate the quality of system-generated questions for grammaticality and refinement effectiveness. Our final system shows best results in effectiveness, percentage of well-formed questions, and percentage of answerable questions over three baseline systems.

KEYWORDS: Query refinement, question generation, search as a dialog.

1 Introduction

Vertical search engines, i.e., domain-specific search engines, retrieve ranked entities from an underlying database, often via unstructured keyword queries. Popular engines, such as Yelp, Bing Travel, IMDB, and Amazon share a common aspect with niche engines, such as BlueWine and OpticsPlanet: user queries are often underspecified. Whether because of the seemingly infinite inventory in the larger engines, or because of the esoteric collections in niche engines, or simply because users seek to browse a collection of results, underspecification is pervasive. When the set of specified entities exceeds the common limit of ten blue links, finding the desired entity can be a long and frustrating process.

For example, consider the query “blue polo with purple stripes" issued to the Bing Shopping engine. Pages of results are returned with correctly matching products. Browsing through these, especially in a mobile or handsfree scenario, can be prohibitively difficult. In most result sets, however, entities can form natural clusters based on important attributes. In our example, clusters can be formed based on price, designer, shirt patterns, etc. Some vertical search engines leverage such editorially defined clusters by forming a faceted search experience, where users can refine search results by selecting attribute values. Such experiences are expensive to build, require a heavily curated ontology to define the important attributes, and consequently are only feasible for large sites with significant revenue streams.

In this paper, we explore methods to automatically discover important attributes from unstructured data associated with entities in a database. Further, in a runtime scenario, we propose algorithms for selecting the best candidate attribute to ask about, based on various criteria, and we construct a binary natural language question for the user to answer. The main idea is to let the data guide the user in her search such that she can more quickly and effectively find her targeted entity.

Our first challenge is to select attribute terms from unstructured text that are in general important for a particular class of entities. We employ a Maximum Entropy technique for recognizing strings that appear to be good attribute terms. Our second challenge is to select the most appropriate attribute term given a user query and result set. Here we propose a set of ranking functions that optimize against the number of necessary questions to find the desired entity. On average, our ranking functions ensure finding the target entity using $\log_2(m)$ questions where m is the number of entities in the original result set. Finally, we transform the selected attribute term into a well-formed natural language question by matching against a set of lexico-syntactic question templates. We evaluate our systems' ability to quickly and effectively find target entities in an Xbox Avatar Editor scenario. Question well-formedness (as a function of factors such as grammaticality and spelling) is also evaluated.

The rest of the paper is organized as follows. Previous work on interactive question generation is summarized in Section 2 and in Section 2 we formally define our problem and the Xbox Avatar experimental dataset. We present our algorithms for finding question candidates in Section 3. Finally, we present our experimental results in Section 4 and conclude with a discussion of future work in Section 5.

2 Related Work

With the recent evolution in online search systems, question generation systems that improve the retrieval results in response to a user query have become an important area of research.

A major step in this process is *what to ask in the conversation?*. This involves clustering either the entire web (pre-retrieval method) (Voorhees, 1985) or only the retrieved results in response to a user query (post-retrieval method) (Cutting et al., 1993; Hearst et al., 1996; Allen et al., 1993; Leouski and Croft, 1996). In this paper, we follow the post-retrieval method to cluster the retrieved results. The description of the cluster is then used in the form of a question to the user.

Scatter/Gather (Cutting et al., 1993; Hearst et al., 1996) is a cluster-based approach which divides the documents in the collection into K clusters. Based on a query, a subset of clusters are selected which are dynamically reclustered (Carpineto et al., 2009). The scatter/gather method assigns attribute terms (descriptions) to the clusters from the feature vector or centroid. These attribute terms are difficult to use and understand especially in our scenario where we want to use them as questions to the user.

Suffix Tree Clustering ensures that the attribute terms of the clusters are meaningful and usable (Zamir and Etzioni, 1999). The idea is to extract terms from the text which are complete, self contained and meaningful. Zamir and Etzioni (1999) achieved this by taking frequent terms which are not crossing sentence boundaries. The problem with Suffix Tree Clustering is that only terms are used in the similarity metric for documents. This results in a decrease in the quality of clusters – especially for languages with free constituent order where parts of speech may come in various orders in a sentence (Carpineto et al., 2009; Masłowska, 2003).

Another class of algorithms focuses both on the quality of the cluster and the quality of its attribute terms. Vivísimo and Lingo (Osinski, 2006) are algorithms of this type. Lingo follows similar steps as that of Suffix Tree Cluster. It differs at query level where it finds abstract concepts from the query and matches them with frequent terms.

Kotov and Zhai (2010) add a question/answering feature to a search engine in order to improve search results and to guide the user to the output they are looking for. They generate a question for every candidate attribute and rank the questions using various heuristics, such as the number of query words that a question candidate matches. A set of top ranked questions are shown to the user who then selects the most relevant question according to their requirement. This user action leads to a modification of the original query and to an update of the search results. They require user input to select the best question. In this paper, we propose a ranking function to automatically rank the questions in a way that minimizes the number of questions needed to find the target entity.

Ontology-based term selection methods use dictionaries, thesauri and WordNet to learn the association between query terms and candidate terms (Bhogal et al., 2007; Hersh et al., 1992; Basili et al., 2007). Each term is mapped to a concept in an ontology. A term is a good candidate for selection if it belongs to the same concept as the query term. The drawback of using ontologies is that they are not available for all languages and for all domains, and their construction is expensive and time consuming. A detailed analysis of ontology-based query expansion can be found in Bhogal et al. (2007).

In contrast to most of the previous work on methods to browse web results, our domain is a web of entities. We learn good attribute terms from the unstructured data associated with the entities using a Maximum Entropy technique. We propose a set of ranking functions that optimize against the number of necessary questions to find the desired entity. Our

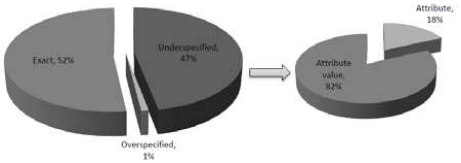

Figure 1: *Left*: Percentage of query types found in a random sample of the Avatar Dataset. *Right*: Percentage of relevant question types for underspecified queries.

method does not require any knowledge-based resource or user feedback, and uses only unstructured text.

In this section, we formally define the problem of helping a user quickly and effectively find her target result in a vertical search scenario.

2.1 Query Scope

Queries to vertical search engines can be categorized by the type of result set they generate: 1) an **exact query** is one that leads to a single result; 2) an **underspecified query** is one that leads to multiple results; and 3) an **overspecified query** is one that leads to zero results. For underspecified and overspecified queries, a follow-up user action is necessary in order to satisfy the information need.

The left pie chart in Figure 1 illustrates the percentage of query types in one dataset, introduced in Section 2.3. Although numbers vary by source and domain, the underspecified queries generally greatly outnumber overspecified queries.

Underspecified queries, which form the focus of this paper, result in multiple valid matches called a **confusion set**. When this set is large, it is difficult for a user to navigate through the matches to find her target result. There is an opportunity to help the user by building a system capable of interactively narrowing-down the confusion set.

2.2 Task Definition

We refer to the underlying data store being queried as a **Database**. We assume no structure within the database other than: 1) the set of records constituting the full search space; and 2) records belong to one or more semantic categories. For example, in a clothing database, each item of clothing is a record belonging to categories such as *pants, t-shirts, sweaters,* and *socks*. Some databases will contain other structured information such as attributes (e.g., t-shirts have a *color*, *price* and a *designer*) and relations (e.g., a particular t-shirt coordinates well with a set of pants). Although this information can be (and has been) leveraged for guiding users through a faceted search experience, we focus in this paper on the extraction of salient questions from **unstructured data**. Specifically, we aim to leverage user-generated comments and descriptions of database records as the source of information from which we will guide search users.

Problem Statement: Consider a database $\mathscr{D}$ where each record r is associated with a set of semantic categories C_r and a set of unstructured textual descriptions $S_r = \{s_{r1}, s_{r2}, ..., s_{rk}\}$.

Given a user query and a matching confusion set $R = \{r_1, r_2, ..., r_m\}$, our task is to ask a natural language question to the user that, based on the user's answer, best reduces the size of the confusion set.

For example, consider our query "*blue polo with purple stripes*" from our Bing Shopping scenario in Section 1. Suppose that there are 30 resulting matches in R consisting of 14 long-sleeved shirts and 16 short-sleeved shirts, as well as 10 shirts each from three fashion designers Ralph Lauren, Calvin Klein and Marc Jacobs. Suppose also that the user is seeking a short-sleeved polo from Ralph Lauren. Candidate questions to ask the user include: Q_1 "Are you looking for a long-sleeved shirt?"; Q_2 "Do you want a shirt by Marc Jacobs?"; and Q_3 "What fashion designer would you like?" The answer to Q_1 would result in cutting the confusion set nearly in half, whereas the answers to Q_2 and Q_3 would remove a third and two thirds of the confusion set, respectively. In this case then, Q_3 is the question that best reduces the size of the confusion set. Formulations of how to best reduce a confusion set are discussed in detail in Section 3.

Questions can be categorized as attribute questions or attribute value questions. An **attribute question** is one that seeks the value of an attribute of a semantic category. For our t-shirt category above, Q_3 is an example attribute question. It is seeking the value of the *fashion designer* attribute. An **attribute value question** is a binary question that asks if the target result has a particular attribute value. Q_1 and Q_2 are example attribute value questions, where Q_1 is asking if the desired sleeve length is *long* and Q_2 is asking if the desired fashion designer is *Marc Jacobs*. Attribute questions generally result in finer reductions in the confusion set, however they are cognitively harder to answer than their binary counterparts. Not considered in this paper are other more complex question types such as set questions (e.g., "*Is the shirt blue, red, or green?*") and compound questions (e.g., "*Is the shirt blue and short-sleeved?*").

We manually inspected the underspecified queries illustrated in Figure 1 along with their resulting confusion sets. We annotated each according to the question type (attribute or attribute value) of the question that would lead to the largest reduction in size of the confusion set. When both question types resulted in the same reduction of the confusion set, we preferred the binary attribute value type since it is easier for users to answer. The rightmost chart in Figure 1 illustrates the result of the study. In 82% of the cases, an attribute value question was deemed more appropriate than a value question. Based on this insight, we limit the scope of this paper to the automatic generation of attribute value questions.

Textual Grounding: We learn attribute value questions without access to any ontological structure in the database. In the textual descriptions S_r associated with a record r, we leverage the fact that many users will refer to the salient attributes and values of r. All unigrams, bigrams, and trigrams will be considered as candidate attributes and values, and we build statistical models to identify them.

2.3 Avatar Dataset

Very few people in the research community have access to the underlying databases powering vertical search engines such as Yelp, Bing Shopping, and Amazon. For the experiments in this paper we use a dataset that we believe is sufficiently similar to datasets used in vertical search engines on the Web, building upon publicly available data.

Category	Count	Category	Count
Trousers	54	Shoes	36
Wrist wear	16	Shirt	131
Ring	16	Nose	18
Mouth	27	Hat	34
Facial other	26	Gloves	16
Glasses	34	Hair	90
Facial hair	17	Eyes	45
Eyebrows	27	Ears	9
Earrings	34	Chin	9
Costume	27		

Table 1: Semantic categories in the Avatar Dataset.

We consider the domain of Xbox Avatars. Users of the Xbox gaming console associate themselves with an avatar that they can personalize with clothing, body features, and accessories. We refer to each item that can be personalized, such as clothing, as an **asset**. We utilize a dataset that was developed for a separate research project and will be publicly released in early 2013 as part of that project (Volkova et al., forthcoming). Below we briefly describe that project's process for creating the data.

There are a total of 666 assets in the dataset and each asset can belong to one of 19 categories. Each category contains 35 assets on average. Table 1 shows the categories and the number of assets in each category. We define $\mathcal{D}$ as this collection of assets.

The textual descriptions S are collected using Mechanical Turk. To ensure the quality of the annotation, a two-tier process (similar to Chen and Dolan (2011)) was followed. First, the annotations were manually inspected in order to select a group of trusted workers based on the quality of their annotations and their commitment to work with the project for a longer period of time. Only these trusted workers were then allowed to annotate.

For each asset, 50 descriptions were obtained from 50 different workers, where descriptions were produced in a task-independent manner (i.e., the annotators were not aware of the final use of these descriptions). Workers were asked to produce a description of the asset and its distinctive features. Sample descriptions of an asset from the category *Hat* are shown in Table 2.

Category attributes, such as the color of eyes, are grounded in the crowdsourced descriptions. Consider the category *Shirt* which has *sleeves*, *color* and *design* as general attributes. An instance (asset) of the category *shirt* contains the values of these attributes such as *long*, *brown* and *flag on chest* for the attributes *sleeves*, *color* and *design* respectively. These attributes and their values are not explicitly stored for assets. Instead, this information is grounded in the free text description of the assets.

We refer to this data set as the **Avatar Dataset**.

2.4 Summary

Our goal is to generate meaningful and well-formed attribute value questions for underspecified queries in the Avatar Dataset. In the next section, we describe our system architecture for question generation.

Descriptions of a hat asset
Green color flower design hat
Drab and yellow beanie with flowers
Green, flower print elastic clothing hat
Green toboggan with flowers and stripes
Green and yellow winter hat, daisy design on them and pompom on top

Table 2: Example descriptions for an Avatar asset from the category *Hat*.

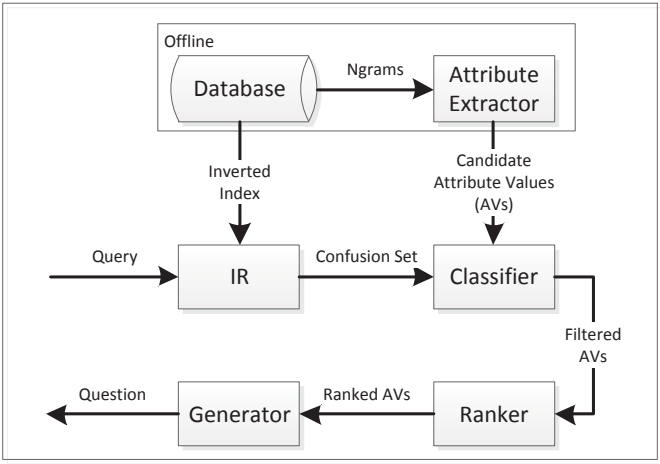

Figure 2: Question generation architecture.

3 Question Generation

Figure 2 outlines our question generation architecture. The input is an unstructured and underspecfied user query and the output is a well-formed attribute value question to the user. Offline processes are first applied to build an inverted index mapping each word in S (the textual descriptions defined in Section 2.2) to its corresponding assets, and to extract candidate attribute values from S. Given a user query, an IR system retrieves a confusion set consisting of matching assets in the database. A classifier is applied to select the appropriate candidate attribute values, which are then ranked according to how they are expected to reduce the size of the confusion set. The top ranked attribute value is formulated into a question by the generator. Below we describe each component in turn.

3.1 Attribute Extractor

As described in Section 2.2, category attributes are not explicitly modeled in the database and must instead be inferred from the textual descriptions associated with each asset. Each unigram, bigram, and trigram is considered as a potential attribute value. The Attribute

Extractor associates with each category the ngrams that appear to be most likely attribute value candidates.

If an attribute value, such as the sleeve length of a shirt, is salient to a category, then we hypothesize that strings referring to the attribute value, such as "short-sleeved" and "short sleeves", will occur more often in descriptions for assets of the category then for other assets. We therefore seek ngrams that are highly associated with each category, where association can be measured using statistics such as pointwise mutual information (PMI) and log-likelihood. In this paper, we use PMI. Given an ngram $n \in S$, we measure its association with a category c as:

$$\text{PMI}(n; c) = \log \frac{P(n, c)}{P(n)P(c)} \tag{1}$$

where $P(n, c)$ is the probability that an ngram in a description of an asset in c is n, $P(n)$ is the probability that an ngram in any description is n and $P(c)$ is the probability of any ngram occurring in a description in class c.

Ngrams with a PMI score higher than a predetermined threshold with a category are selected as candidate attribute values for that category. The resulting candidates are noisy and will be further filtered online by the Classifier component.[1] Table 3 lists examples of good and bad candidate attribute values for an asset from the *Shirt* category.

Entity	Blue half sleeved polo with stripes
Attribute values	
Answerable	Blue, half sleeved, polo, stripes
Unanswerable	polo with, with, with stripes

Table 3: Sample ngrams extracted as candidate attribute values by the Attribute Extractor for an asset from the *Shirt* category.

3.2 IR

Following (Salton, 1971), we build an inverted index mapping each ngram n in S to its corresponding asset r along with its tf-idf, defined as:

$$\text{tf-idf}(n, r) = tf(n, r) \times \log idf(n) \tag{2}$$

where $tf(n, r)$ is the frequency of n in S_r, and $idf(n)$ is the fraction of textual descriptions $s \in S$ containing n.

Let $\mathbf{r}$ be a vector of all ngrams in S_r where the value of each ngram is its tf-idf with r. Then, given a query q, we form a query vector $\mathbf{q}$ consisting of all ngrams in q, where the value of each feature is 1. Our IR component first retrieves from the inverted index all assets matching an ngram with q. For each matching asset r, we then compute a simple IR rank score as the cosine of the angle between $\mathbf{q}$ and $\mathbf{r}$:

$$\text{cosine}(\mathbf{q}, \mathbf{r}) = \frac{\sum_i q_i \cdot r_i}{\sqrt{\sum_i q_i^2 \cdot \sum_i r_i^2}} \tag{3}$$

[1] In this paper, we experimentally set the threshold to 1.

Binary features unigram, bigram, trigram, POS tag sequence of candidate, separate POS tag of every word in the candidate, candidate is a substring of the query, candidate contains the queried category
Real-valued features PMI score, log-likelihood score

Table 4: Features used in our Maximum Entropy classifier.

3.3 Classifier

The Attribute Extractor provides a shortlist of salient attribute value candidates, but we still need to further filter this list to arrive at our final list of candidates. For example, we still find spurious and rare candidates as well as non-constituent terms ("long and") in the candidates. In addition, we know that the ultimate usefulness of a salient attribute is dependent on the query: An attribute value candidate may be salient for a category, but given a specific query, it can still be useless as a refinement candidate. For example, a salient attribute value may not lead to any reduction in the confusion set or it could overlap with what is already asked for in the query, making it redundant for a refinement question.

To address these issues, we use a machine learned model that utilizes features derived from both the user's query and the Attribute Extractor provided list, and filters out attribute value candidates that are unanswerable or not relevant given the query.

The model we use is a Maximum Entropy classifier. The selection of the training data for this supervised classification approach is described in detail in Section 4. For every query in the training set, we retrieve a confusion set using the IR component (Section 3.2) and select candidates from the list provided by the Attribute Extractor that also match at least one description of the entities in the confusion set: an attribute value candidate that does not fulfil that criterion is by definition not able to serve as a disambiguator on the set. We use the Ranker module (Section 3.4) to select two attribute-value candidates for every query in the training set and annotate them with nine automatically extracted features as summarized in Table 4. The *unigram* feature indicates that the candidate term is a unigram, similarly for *bigram* and *trigram*. The feature *POS tag sequence of candidate* represents the part-of- speech tags of the words in a candidate. *POS tag of every word in the candidate* indicates all individual POS tags. Information about the relation of the candidate to the query and the category of the queried record is captured using the features *candidate is a substring of the query* and *candidate contains the queried category* respectively. We also utilize real-valued features for the PMI score and log-likelihood score of the candidates wrt the category. Finally, we manually annotate each example as a positive example (good candidate) or a negative example (bad candidate). The Maximum Entropy classifier is trained on the annotated examples. Given a list of candidate attribute values, the Classifier predicts whether the attribute values are good candidates or bad. The values which are good candidates according to the Classifier are then input to the Ranker module.

3.4 Ranker

Recall our problem definition from Section 2.2, which states that we aim to ask a question that best reduces the size of the confusion set, thus allowing a user to find her target result

with the minimum number of refinement questions. Our goal of finding the target result in an end to end system is difficult to evaluate without deployment. We instead introduce a ranking component that we reasonbaly expect to correlate with that goal of finding the right result. Our Ranker component orders the filtered attribute values from the Classifier according to how well each is expected to reduce the size of the confusion set. The top ranking attribute value will be used in formulating the final question asked to the user.

Since attribute value questions are binary, the most effective questions will be those that result in dividing the confusion set in half. This would result in an optimal interaction strategy where $\log_2 m$ questions are needed to guide a user through a confusion set of size m. We define our ranking score for an attribute value n and confusion set R, $\text{score}_R(n)$, as a real-valued function ranging from zero to one where *zero* indicates that n will cut the confusion set in half and *one* indicates that n will leave the confusion set unchanged. We seek questions that minimize this score. Formally:

$$\text{score}_R(n) = 2\left|\frac{\sum_{r\in R}\phi_R(n)f(r)}{\sum_{r\in R}f(r)} - 0.5\right|$$

where $\text{score}_R(n)\colon \mathbb{R} \to [0,1]$, $f(r)$ represents a weight function associated with each asset r in the confusion set, and $\phi_R(n)$ is the number of assets in the confusion set that hold the attribute value n (estimated by whether or not at least one textual description mentions n).

If $f(r) = 1$, $\text{score}_R(n)$ is minimized when n cuts the confusion set in half. Recall however that each asset in the confusion set has a relevance score assigned by the IR module (see Section 3.2). It is therefore reasonable to assume that items at the head of R will be more likely the target asset than items at the tail of R. We derive various definitions of the weight function $f(r)$ to capture this intuition:

$$f(r) = \begin{cases} M_1: & 1 \\ M_{rank}: & \frac{1}{\text{rank}(r)} \\ M_{ir}: & IR(r) \\ M_{dcg}: & \begin{cases} 1 \text{ for } \text{rank}(r) = 1 \\ \frac{\text{rank}(r)}{\log_2 \text{rank}(r)} \text{ otherwise} \end{cases} \end{cases}$$

M_1 considers all assets in the confusion set equally probable to be the target asset. M_{rank} weighs assets according to their rank in R and M_{ir} weighs them according to their cosine with the user query. Similarly, M_{dcg} weighs assets according to their gain discounted by rank position (similarly to that done in the Discounted Cumulative Gain (DCG) metric used primarily in IR).

The attribute value candidate with the lowest score is selected to form the final question. We use the Attribute Extractor score as tie-breaker (see Section 3.1).

In our experiments, we build our system using M_{rank}. M_1, M_{ir}, and M_{dcg} are used as evaluation metrics (see Section 4).

Template	POS
Should it be	JJ (Cat: NN)
Should they be	JJ (Cat: NNS)
Do you want	DT JJ NN
Do you want (a/an)	JJ NN NN
Are these	JJ VB NNS
Is it	RB VBN
Is it (a/an)	JJ VB NN
Does it have	NN NNS

Table 5: Question templates used to form a question

3.5 Generator

The final component in our system takes an attribute value as an input and produces a grammatical binary question from it. We use eight manually created question templates for this purpose. These question templates contain part-of-speech placeholders for the attribute value. Table 5 shows our question templates and a few examples of the part of speech sequences that can be used to complete each question template into a well-formed question. For question templates that only differ by an article (*a*, *an*), we check the first character of the question term to select the appropriate question template.

4 Experiments

4.1 Data Sets and Systems

From the Avatar Data Set described in Section 2.3, we sub-sampled a set of 160 assets for manual analysis. We refer to this set as the *Sampled Avatar Data Set*. For each asset we randomly chose one of the 50 available descriptions to serve as a set of random queries for the Sampled Avatar Data Set. Of the 160 queries, 75 were underspecified, which forms our *Underspecified Query Set*. Each query in that set is also associated with a confusion set as retrieved by the IR system from all assets in the Sampled Avatar Data Set.[2] We split the Underspecified Query Set into 50 query/asset pairs for training the maximum entropy classifier, called the *Classifier Training Set*, and 25 pairs for testing of the end-to-end system, called the *Test Set*.

We compare our system from Section 3, labeled *SYS*, against three baseline systems. For every query in the Test Set, we generate one question from each of the three baseline systems and our final system.

All three baseline systems extract attribute value candidates from the Attribute Extractor and that are relevant to the assets in the confusion set. As opposed to *SYS*, they do not use Classifier to filter the good candidate attribute values and use the output of the Attribute Extractor directly in Ranker. The systems select a question candidate based on the Ranking Function using M_{rank} as a weight function. PMI is used as a tie-breaker. The baseline systems differ with respect to the ngram size that they consider. System *B1* considers unigram attribute value candidates, *B2* considers bigram candidates and *B3* trigram candidates.

[2]The IR system was built using 49 textual descriptions per asset since one was reserved for the Underspecified Query Set.

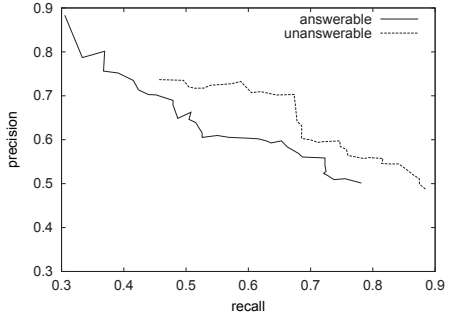

Figure 3: Precision-recall curve of the answerable and unanswerable classes.

4.2 Training of the Classifier

From the Classifier Training Set we need to derive a set of positive and negative examples for training. Positive examples are attribute values that are meaningful with respect to the given query and answerable if used in a question, whereas negative examples are either not meaningful or unanswerable. For simplicity, we refer to these examples as *answerable* and *unanswerable*, respectively.

Ideally, we would annotate all attribute value candidates for each query in the Classifier Training Set as answerable or unanswerable. In order to make the annotation task feasible, however, consider that the classifier needs to be optimized for its runtime task of filtering out attribute value pairs from the list provided by the Attribute Extractor. It is reasonable, therefore, to pick examples for annotation that are likely to be relevant in that scenario. For this purpose we first form the intersection of (i) the terms in the descriptions of the assets in the confusion set; and (ii) the list of attribute values produced by the Attribute Extractor. This produces a set of attribute value candidates just like the ones that the classifier will be exposed to at runtime. We also need to focus on finding answerable training cases, since the negative (unanswerable) cases are in the majority and hence much easier to come by. Of particular importance are cases that are selected by the Attribute Extractor and highly ranked by the Ranker, i.e. "borderline" candidates. We collect the top-10 attribute values (selected by the Attribute Extractor) for a given query and confusion set as measured by the Ranker (using M_{rank} as a weight function). From this top-10 set, we pick the top candidate and a random candidate to annotate as answerable or unanswerable. The resulting training set consists of 100 data points, 47 answerable and 53 unanswerable. We represent each training case as a feature vector as described in Section 3.3.

We evaluate the classifier based on 10-fold cross validation on the training set. The precision-recall curve of answerable (solid line) and unanswerable (dotted line) for different probability thresholds is shown in Figure 3. For our final system, we select a probability threshold greater than 0.7 for the answerable question terms.

4.3 Output Judgments

There are two properties of a system-generated question that we want to evaluate. First and most importantly, we want to know how good a final question is with respect to best dividing

	ANS	M_1	M_{rank}	M_{ir}	M_{dcg}
B1	0.6	0.6	0.63	0.62	0.74
B2	0.76	0.38	0.44	0.39	0.57
B3	0.68	0.41	0.48	0.46	0.61
SYS	**0.88**	**0.26**	**0.36**	**0.32**	**0.49**

Table 6: System effectiveness at reducing the size of the confusion set. Better systems will have a high ANS score (i.e., more questions are answerable) and low values for M_1, M_{rank}, M_{ir}, and M_{dcg}.

the confusion set. Second, we evaluate the grammaticality of the question to address the quality of our question generation component. During the latter task, we found some cases where the POS sequence of a question term does not match with any of the POS sequences allowed for question templates in our generation component. In these cases no question can be generated and we distinguish these cases from the "formulated" questions.

We designed an evaluation form which shows a query from the test set with its corresponding gold asset and four questions generated by the four systems. For every question, the judge has to select whether (i) the correct answer to the question is "yes" or "no"; or (ii) whether the question is answerable. The confusion set is then reduced based on the answer to the question by matching the attribute value ngram against the descriptions for each asset in the confusion set. We keep separate statistics for the unanswerable questions as determined by the judge's input to (ii). One of the authors served as the judge.

4.4 Results

Table 6 shows the results of all systems on our four metrics (recall that our final system uses M_{rank} in its Ranking Function, so the M_{rank} column is not a bona fide evaluation result and is only included for completeness). The "ANS" column refers to the percentage of questions that are answerable and relevant in context of the gold asset. Better systems maximize ANS and minimize M_1, M_{rank}, M_{ir}, and M_{dcg}.

Our final system shows a significant increase in the percentage of answerable question terms in comparison with the baseline systems. It also has the lowest scores for every evaluation metric, which shows that the question terms generated by our system divide the confusion set better than the baseline systems.

One author also rated every question for well-formedness. Each question was judged for grammaticality and for non-grammar errors (e.g., spelling errors), which are accounted for in a separate category "Other". Table 7 summarizes the results. Our system resulted in the most well-formed queries, with fewer mismatches with the POS templates described in Table 5 and fewer grammatical errors.

The lower percentage of well-formed questions for B2 and B3 reflects the fact that bigrams and trigrams tended to contain more rare POS sequences (such as non-constituents) that could not be accommodated by any question template.

4.5 Error Analysis

For a few test queries, our system produces meaningless questions like "shaped mustache" in response to a query "long and broad mustache with terror face look". This can happen

	Well-Formed	Errors		
		Template	Grammatical	Other
B1	0.52	**0.16**	0.24	0.16
B2	0.48	0.36	0.16	**0**
B3	0.28	0.52	0.20	**0**
SYS	**0.68**	**0.16**	**0.16**	0.04

Table 7: Question well-formedness. Error types include no matching POS template (i.e., the Generator component did not fire), grammatical errors, and other errors such as misspelling.

when the classifier rejects all question candidates as unanswerable and the system selects a question term from the list provided by the Attribute Extractor with the lowest M_{rank} score.

The answer to 30% of the questions resulted in the removal of the target asset from the confusion set. We found that there are two reasons for this, neither of which is a shortcoming of the system: either the user has made a mistake in answering the question or the description of the gold asset is not correct. We examined the latter cases and found that some textual descriptions associated with a few assets were inaccurate. For example, a pair of red pants was described as "red shorts" by a microtask worker. Similarly, some t-shirts are described as jackets. Suppose a user is searching for a pair of red pants and based on the description of the target asset and the confusion set, the system asks, "Are these shorts?" The correct response "no" will lead to the elimination of the target asset from the confusion set. Answering questions pertaining to the value of scalar facial attributes depends on a user's perception. The answer to questions "are these long lips?" or "are these bushy eyebrows?" depends on the user's notion of long and bushy. Here, again, the target asset may be wrongly excluded from the reduced confusion set. Similarly, the annotators sometimes confuse the position (left/right) of the attribute of an asset (e.g., "mole under the left/right eye").

Examining the ungrammatical questions, we found that the most common source of error is the use of a singular article with a mass noun, due to the fact that we neglected to distinguish between mass and count nouns in our question templates.

5 Conclusion

We have proposed a question generation system that produces refinement questions for underspecified queries from unstructured text in a vertical search scenario. We applied our system to an Xbox Avatar personalization dataset and found that compared to three baselines, our system offers the best reductions in confusion set size and the highest percentage of well-formed natural language questions.

There are many opportunities for future research in this area and on the Avatar Dataset. Some examples include automatic detection of inconsistent asset descriptions, refinements in attribute value extraction, and improved question generation including the generation of more complex questions.

Acknowledgments

The authors thank Bill Dolan, Chris Brockett, Yun-Cheng Ju, and Svitlana Volkova for sharing their Avatar Dataset and providing vision and valuable guidance.

Abstract

We propose an approach to correcting spelling errors and assigning part-of-speech (POS) tags simultaneously for sentences written by learners of English as a second language (ESL). In ESL writing, there are several types of errors such as preposition, determiner, verb, noun, and spelling errors. Spelling errors often interfere with POS tagging and syntactic parsing, which makes other error detection and correction tasks very difficult. In studies of grammatical error detection and correction in ESL writing, spelling correction has been regarded as a preprocessing step in a pipeline. However, several types of spelling errors in ESL are difficult to correct in the preprocessing, for example, homophones (e.g. **hear/here*), confusion (**quiet/quite*), split (**now a day/nowadays*), merge (**swimingpool/swimming pool*), inflection (**please/pleased*) and derivation (**badly/bad*), where the incorrect word is actually in the vocabulary and grammatical information is needed to disambiguate.

In order to correct these spelling errors, and also typical typographical errors (**begginning/beginning*), we propose a joint analysis of POS tagging and spelling error correction with a CRF (Conditional Random Field)-based model. We present an approach that achieves significantly better accuracies for both POS tagging and spelling correction, compared to existing approaches using either individual or pipeline analysis. We also show that the joint model can deal with novel types of misspelling in ESL writing.

Keywords: Part-of-Speech Tagging, Spelling Error Correction.

Proceedings of COLING 2012: Technical Papers, pages 2357–2374,
COLING 2012, Mumbai, December 2012.

1 Introduction

Automated grammatical error detection and correction have been focused on natural language processing (NLP) over the past dozen years or so. Researchers have mainly studied English grammatical error detection and correction of areas such as determiners, prepositions and verbs (Izumi et al., 2003; Han et al., 2006; Felice and Pulman, 2008; Lee and Seneff, 2008; Gamon, 2010; Dahlmeier and Ng, 2011; Rozovskaya and Roth, 2011; Tajiri et al., 2012). In previous work on grammatical error detection and correction, spelling errors are usually corrected in a preprocessing step in a pipeline. These studies generally deal with **typographical** errors (e.g. **begginning/beginning*). In ESL writing, however, there exist many other types of spelling errors, which often occur in combination with, for example, **homophone** (**there/their*), **confusion** (**form/from*), **split** (**Now a day/Nowadays*), **merge** (**swimingpool/swimming pool*), **inflection** (**please/pleased*), and **derivation** (**badly/bad*) errors. Unlike typographical errors, these spelling errors are difficult to detect because the words to be corrected are possible words in English.

Previous studies in spelling correction for ESL writing depend mainly on edit distance between the words before and after correction. Some previous works for correcting misspelled words in native speaker misspellings focus on homophone, confusion, split, and merge errors (Golding and Roth, 1999; Bao et al., 2011), but no research has been done on inflection and derivation errors.

One of the biggest problems in grammatical error detection and correction studies is that ESL writing contains spelling errors, and they are often obstacles to POS tagging and syntactic parsing. For example, POS tagging fails for the following sentence[1]:

Input:
... it is **verey/very *convent/convenient* for the group.
without spelling error correction:
... it/PRP, is/VBZ, verey/PRP, convent/NN ...
with spelling error correction:
... it/PRP, is/VBZ, very/RB, convenient/JJ ...

Conversely, spelling correction requires POS information in some cases. For instance, the sentence below shows that the misspelled word **analysys/analyses* is corrected according to its POS (NNS), while it is difficult to select the best candidate based only on edit distance (analysis/NN or analyses/NNS).

Input:
... research and some **analysys/analyses*.
when assigning POS tags:
... and/CC, some/DT, analysys/NNS ...
candidates and their POS:
['analysis/NN', 'analyses/NNS']

In order to detect and correct errors in ESL writing, spelling correction is essential, because sentences with misspelled words cannot be parsed properly. However, the conventional pipeline for grammatical error detection and correction has a limitation due to the different types of spelling errors and the unavailability of contextual information, which results in failures in the subsequent POS tagging and syntactic parsing (Figure 1(1)).

In this work, we propose a joint model for spelling correction and POS tagging (Figure 1(2)). The model is based on morphological analysis, where each node in a lattice has both POS and

[1] We use Penn treebank-style part-of-speech tags.

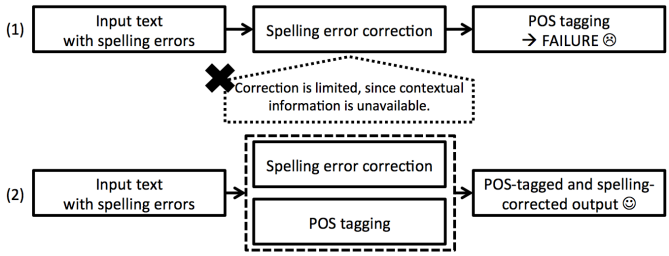

Figure 1: A limitation of pipeline analysis (1), and our proposed joint model (2).

spelling information as features. Because of these features, our method can deal with not only typographical errors but also homophones, confusion, split, merge, inflection and derivation errors. Also, higher accuracy with spelling correction improves POS tagging. We evaluated the joint model with two different ESL learners' error-annotated corpora, with the results showing 2.1% and 3.8% improvement in F-values of POS tagging for the corpora, and 5.0% in F-value of spelling errors. The results significantly outperform baseline and pipeline.

There are three main contributions described in this paper:

1. This is the first joint model for assigning POS tags and correcting misspelled words simultaneously.

2. Our work shows that the joint model improves the accuracy of both POS tagging and spelling correction for ESL writing compared to conventional pipeline methods.

3. This is the first model which is able to correct a wide range of misspelled words, including misspellings due to inflection and derivation errors.

In the following, we first present previous research done on grammatical error correction, spelling correction, and joint analysis (Section 2), and then describe our proposed method in detail (Section 3). The experimental setting and the results are presented in Section 4, and error analysis is given in Section 5. Finally, we conclude in Section 6.

2 Related works

In spelling error correction, the main concern is how to extract confusion pairs that consist of words before and after correction. A number of studies depend on such edit distance between written and corrected words as *Levenshtein Distance* (LD), *Longest Common Subsequence* (LCS) string matching, and pronunciation similarities (Kukich, 1992; Brill and Moore, 2000; Islam and Inkpen, 2009; Bao et al., 2011; Toutanova and Moore, 2002). In order to cover more misspelled words, many spelling errors were collected from web search queries and their results (Chen et al., 2007; Gao et al., 2010), click through logs (Sun et al., 2010), and users' keystroke logs (Baba and Suzuki, 2012). Note that previous studies for spelling correction described above focus on errors made by native speakers rather than second language learners, who show a wider range of misspellings with, for example, split, merge, inflection and derivation errors.

In most grammatical error detection and correction research, spelling error correction is performed before such linguistic analysis as POS tagging and syntactic parsing. Spelling correction as preprocessing generally uses existing spelling checkers such as GNU Aspell[2] and Jazzy[3], which depend on edit distance between words before and after correction. Then, candidate words are often re-ranked or filtered using a language model. In fact, in the Helping Our Own (HOO) 2012 (Dale et al., 2012), which is a shared task on preposition and determiner error correction, highly-ranked teams employ the strategy of spelling correction as preprocessing based on edit distance.

Some recent studies deal with spelling correction at the same time as whole grammatical error correction. For example, (Brockett et al., 2006) presents a method to correct whole sentences containing various errors, applying a statistical machine translation (SMT) technique where input sentences are translated into correct English. Although this approach can deal with any type of spelling errors, it suffers from a poverty of error-annotated resources and cannot correct misspelled words that have never appeared in a corpus. Similarly, (Park and Levy, 2011) propose a noisy channel model to correct errors, although they depend on a bigram language model and do not use syntactic information. A discriminative approach for whole grammatical error correction is also proposed in a recent study (Dahlmeier and Ng, 2012) where spelling errors are corrected simultaneously. In terms of spelling error types, however, typographical errors using GNU Aspell are dealt with, but not other misspelling types such as split and merge errors. Our proposed model uses POS features in order to correct spelling. As result, a wider range of spelling errors such as inflection and derivation errors can be corrected. Inflection and derivation errors are usually regarded as grammatical errors, not spelling errors. However, we include inflection and derivation error correction in our task, given the difficulty of determining whether they are grammatical or spelling errors, as will be explained in Section 4.1.

Joint learning and joint analysis have received much attention in recent studies for linguistic analysis. For example, the CoNLL-2008 Shared Task (Surdeanu et al., 2008) shows promising results in joint syntactic and semantic dependency parsing. There are also models that deal with joint morphological segmentation and syntactic parsing in Hebrew (Goldberg and Tsarfaty, 2008), joint word segmentation and POS tagging in Chinese (Zhang and Clark, 2010), and joint word segmentation, POS tagging and dependency parsing in Chinese (Hatori et al., 2012). These studies demonstrate that joint models outperform conventional pipelined systems. Our work applies for the first time a joint analysis to spelling correction and POS tagging for ESL writing in which input sentences contains multiple errors, whereas previous joint models deal only with canonical texts.

3 Joint analysis of POS tagging and spelling correction

In this section, we describe our proposed joint analysis of spelling error correction and POS tagging for ESL writing. Our method is based on Japanese morphological analysis (Kudo et al., 2004), which disambiguates word boundaries and assigns POS tags using re-defined Conditional Random Fields (CRFs) (Lafferty et al., 1999), while the original CRFs deal with sequential labeling for sentences with word boundaries fixed. We use the re-defined CRFs rather than the original CRFs because disambiguating word boundaries is necessary for split and merge error correction. In terms of decoding, our model has a similar approach to the decoder proposed by (Dahlmeier and Ng, 2012), though the decoder by Dahlmeier and Ng uses beam search. In (Kudo et al., 2004), they define CRFs as the conditional probability of an output path $\mathbf{y} = \left(\langle w_1, t_1 \rangle, ..., \langle w_{\#\mathbf{y}}, t_{\#\mathbf{y}} \rangle \right)$, given

[2] http://aspell.net/
[3] http://jazzy.sourceforge.net/

an input sentence $\mathbf{x}$ with words w and labels t:

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_{\mathbf{x}}} \exp\left(\sum_{i=1}^{\#\mathbf{y}} \sum_{k} \lambda_k f_k\big(\langle w_{i-1}, t_{i-1} \rangle, \langle w_i, t_i \rangle \big) \right)$$

where $\#\mathbf{y}$ is the number of tokens according to the output sequence, and $Z_{\mathbf{x}}$ is a normalization factor for all candidate paths $\mathcal{Y}(\mathbf{x})$,

$$Z_{\mathbf{x}} = \sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{x})} \exp\left(\sum_{i=1}^{\#\mathbf{y}'} \sum_{k} \lambda_k f_k\big(\langle w'_{i-1}, t'_{i-1} \rangle, \langle w'_i, t'_i \rangle \big) \right)$$

Here, $f_k\big(\langle w_{i-1}, t_{i-1} \rangle, \langle w_i, t_i \rangle \big)$ is a feature function of the i-th token $\langle w_i, t_i \rangle$ and its previous token $\langle w_{i-1}, t_{i-1} \rangle$. λ_k is the weight for the feature function f_k. When decoding, the most probable path $\hat{\mathbf{y}}$ for an input sentence $\mathbf{x}$ is

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} P(\mathbf{y}|\mathbf{x})$$

which can be found with the Viterbi algorithm.

The lexicon consists of basic information: surface form, its base form, and its POS tag. In order to deal with misspelled words, we extend the format of the lexicon appending correctness of spelling and correct form in conjunction with the basic information. With the extended format, we prepare a misspelling dictionary in addition to the existing English dictionary. Here are examples of lexical entries in both dictionaries:

Examples of correct lexicon:
writing,-40,VB,write,VBG,CORR,*
English,152,NN,English,NNP,CORR,*
Examples of lexicon of spelling errors:
absoletuly,-18,RB,absolutely,RB,INCO,absolutely
difficultly,36,JJ,difficult,JJ,INCO,difficult

where each entry consists of a surface form, followed by cost of the word, POS group[4], base form, POS, CORR (correct) / INCO (incorrect) spelling error flag, and correct spelling form. If the flag is CORR, the correct spelling form is written as '*'. In the above examples for the lexicon of spelling errors, **absoletuly/absolutely* is a typographical error and **difficultly/difficult* is a derivation error. The unigram costs in the correct lexicon and POS bigram costs are calculated as a result of learnt weights in the CRFs, and the detail of weights learning of the CRFs is found in Kudo et al.(2004). The cost in the lexicon of spelling errors is obtained based on the corresponding correct form. In other words, the model is able to decode unseen spelling errors, if correct candidates for the misspelled word exist in the correct lexicon. The way to construct a lexicon of spelling errors is described in detail in Section 4. With the additional lexicon, where the cost for each entry is determined, we can decode sentences including spelling errors, with simultaneous spelling correction and POS tagging. Algorithm 1 shows a brief overview of our proposed model for decoding. Figure 2 shows examples of the decoding process, where **beggining/beginning*, **Auguest/August*, and **swimingpool/swimming pool* are misspelled. Without a misspelling dictionary, we fail to decode spelling error words and to assign POS tags (as shown in dotted lines in Figure 2). Because we prepare a misspelling dictionary as explained above, we can decode **begginning* as *beginning*,

[4]POS groups are a coarse version of Penn Treebank POS tags. For example, JJ, JJR and JJS are merged into JJ.

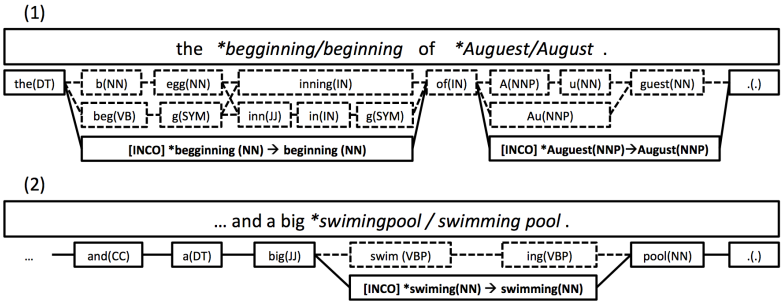

Figure 2: Samples of decoding process with proposed method. "[INCO]" is a misspelling flag.

Algorithm 1 Proposed joint POS tagging and spelling correction algorithm

Input: *Lexicon, Sentence* // *Sentence* ignores blanks between words.
Output: *Best path for the input sentence*
  Lattice $= \phi$
  $i = 0$ // i is letter index of a *Sentence*.
  repeat
    for each node ending with Sentence[i] **do**
      right_nodes = Lexicon.commonPrefixSearch(Sentence[i+1:])
      for for each right_node in right_nodes **do**
        Append right_node with unigram cost into *Lattice*
        Append the edge between node and right_node with POS bigram cost into *Lattice*
      end for
    end for
    i++
  until The end of the input sentence
  Best_Path = **Decode_Viterbi**(*Lattice*)
  return Best_Path

**Auguest* as *August* in Figure 2(1) (shown in solid lines). Furthermore, since the re-defined CRFs deal with word boundary ambiguity, this model is suitable for split and merge spelling error detection and correction as shown in Figure 2(2). In Figure 2(2), where **swimingpool* is a merge error, the misspelled word is split into **swiming/swimming* and *pool*, and corrected from **swiming* to *swimming*.

4 Experiment

4.1 Data

For our experiments, we use two different ESL learners' corpora: the Cambridge Learners Corpus First Certificate in English (CLC FCE) dataset (Yannakoudakis et al., 2011) and the Konan-JIEM learner corpus (KJ corpus) (Nagata et al., 2011). Table 1 shows the statistics of the two corpora. The CLC FCE dataset, which is one of the largest and most commonly used ESL learners' corpora, consists of 1,244 files, and each file consists of two essays with gold-standard error annotation.

	CLC FCE dataset	KJ corpus
# Essays	2,488	233
# Sentences	28,033	3,199
# Tokens	423,850	25,537
1st language	16 languages	Japanese
Error Tagged	Yes	Yes* (Spelling errors are not tagged.)
POS Tagged	No	Yes

Table 1: Statistical overview of the datasets: CLC FCE dataset and KJ corpus.

CLC FCE dataset		KJ corpus	
Error Types	%	Error Types	%
Verb	20.8	Noun	27.6
Punctuation	14.2	Verb	23.9
Spelling	10.7	Article	18.4
Preposition	10.5	Preposition	13.0
Determiner	9.5	Adjective	4.1
Noun	9.3	Adverb	3.4

Table 2: The top 6 error types in CLC FCE dataset and KJ corpus.

The KJ corpus consists of more than 200 essays written by Japanese ESL learners. This is the only dataset where POS tags are assigned for ESL writing. Table 2 shows the proportion of error types for the two datasets. Note that the KJ corpus does not contain error tags for spelling errors and other ungrammatical errors such as punctuation errors.

In terms of spelling errors in the CLC FCE dataset, there are 'S'(spelling) and 'SX'(spelling confusion) error tags. The number of 'S' and 'SX' are 4,922 and 789 respectively. Under the definition of spelling error types in our work, *homophone*, *confusion*, *split*, and *merge* errors are included in 'S' and 'SX' error annotations. There are also 760 'I' (inflection) and 1,913 'D' (derivation) error tags that contain spelling errors such as **usefull/useful* and **suppost/supposed*, in addition to clear examples of inflection/derivation errors (e.g. **badly/bad*). In total, there are 8,349 spelling errors in the CLC FCE dataset, which accounts for 1.9% of the spelling errors in the whole corpus. The distribution of spelling error types is shown in Table 3. A confusion pair is excluded when the original word length is less than 3 letters or when the word is a pronoun, in order to avoid highly frequent words being corrected. We also exclude a confusion pair when the pair derives from semantic confusion (e.g. **dead/killed* and **although/however*).

4.2 Methodology

For training and decoding, we use the MeCab[5] toolkit, a CRF-based POS and morphological analyzer. Table 4 shows the feature template for MeCab (i.e. CRF) training. As mentioned in Section 3, we also use the POS bigrams as the cost of a sequential edge.

The CLC FCE dataset is used for training, development and test sets, where files are randomly divided into 1,000 for training, 100 for development and 100 for test sets. For statistical analysis,

[5]MeCab 0.98 `http://mecab.googlecode.com/svn/trunk/mecab/doc/index.html`

Spelling Error Types	Numbers	%
Typographical	4,859	58.2
Homophone or Confusion	789	9.5
Split	17	0.2
Merge	11	0.1
Inflection	760	9.1
Derivation	1,913	22.9
Total	8,349	

Table 3: A distribution of spelling error types in the CLC FCE dataset.

we take five different samples from the CLC FCE dataset. We use the development set for deciding a hyper-parameter c during MeCab training. We use the KJ corpus only as a test set for POS tagging, because it does not have a gold standard for spelling errors. For evaluating the KJ corpus, we use the same training and development sets of the CLC FCE dataset explained above.

Since the CLC FCE dataset does not contain POS tags, we need to assign POS tags for the corrected sentences in the CLC FCE corpus. We use a MeCab trained on Penn Treebank[6] with the NAIST English dictionary (NAIST edic)[7] (hereafter referred to as MeCab-PTB). The accuracy of MeCab-PTB is 0.974 of precision, 0.980 of recall, and 0.977 of F-value as a result of a preliminary experiment[8]. We assign POS tags by MeCab-PTB for the CLC FCE training set in which all sentences are corrected, and the output is used as the POS-tagged CLC FCE training set (CLC-POS-Train). Then, we train again MeCab-PTB on both Penn Treebank and CLC-POS-Train (referred to as MeCab-CLC).

In order to analyse spelling errors, we extract the pairs of misspelled and corrected words in the CLC FCE training set, so as to develop a lexicon of spelling errors (hereafter LexTrain) as shown in Section 3. The cost for each misspelled entry is extracted from cost-learnt NAIST edic in MeCab-CLC. For example, when the misspelled and corrected word is **bok/book*, the word '*book*' is found in learnt NAIST edic as *book/NN* and *book/VB*. Since the costs for these two candidates are determined, we can construct a lexicon of spelling errors with the flag "INCO". For each of the five training sets, 4,656 entries on average are extracted for the lexicon of spelling errors, including all spelling error types.

For the CLC FCE test set, since we cannot add the gold-standard pairs of misspelled word and its correction directly into the lexicon, we obtain candidates for misspelled words in a test set using GNU Aspell[9]. If the pair of misspelled word and its candidate does not exist in LexTrain, we add the pair into a new lexical dictionary (LexTest), where the cost of learning, POS group, and POS are extracted from learnt NAIST edic in MeCab-CLC. As is the case with LexTrain, all possible entries are added into LexTest for the words that have several POS tags (e.g. NN and VB for *book*). If a candidate word does not exist in learnt NAIST edic, we do not add its pair because no

[6]The Penn Treebank Project Release 2 `http://www.cis.upenn.edu/treebank/`

[7]NAIST-edic-0.2.0 `http://sites.google.com/site/masayua/p/naist-edic`

[8]We use the sections 0-18 of the Penn Treebank for training and sections 22-24 for evaluation. However, it is difficult to make a fair comparison of the result with other PTB POS taggers, since we use *.pos files for training and test sets instead of the *.mrg files that are generally used. We use *.pos files because they have more data.

[9]Because the CLC FCE contains some words, such as proper nouns, that GNU Aspell does not recognize, we add all words in correct sentences of the CLC FCE training set into the GNU Aspell dictionary.

Feature description (Unigram)	Feature description (Bigram)
WORD[i]	WORD[i-1] + WORD[i]
WORD[i] + POS[i]	WORD[i-1] + WORD[i] + POS[i-1]
WORD[i] + POS_group[i]	WORD[i-1] + WORD[i] + POS[i]

Table 4: Feature template of *i*-th token used for training CRF.

information about the cost for the candidate is available. We develop MeCab-CLC+Lex by adding the indices of LexTrain and LexTest into MeCab-CLC.

In our experiment, we analyse test set sentences, where all but spelling errors are corrected beforehand. We compare three conditions for POS tagging: POS-BASELINE, POS-PIPELINE, and POS-JOINT. For POS-BASELINE and POS-PIPELINE, we use MeCab-CLC to analyse test set sentences. In the case of POS-PIPELINE, unknown words in the test set are replaced by the best candidate suggested by GNU Aspell and re-ranked by a 5-gram language model built on the Google 1T Web corpus (Brants and Franz, 2006) with IRSTLM toolkit[10]. In POS-JOINT, we use MeCab-CLC+Lex to analyse the test set.

For spelling correction, we compare two conditions: SP-BASELINE and SP-JOINT. We use GNU Aspell as SP-BASELINE, and the output from POS-JOINT is used for SP-JOINT. With respect to gold standard POS and spelling correction, we analyse the error-free test set with MeCab-PTB.

4.3 Evaluation

We evaluated the performance of POS tagging and spelling correction by computing precision, recall, and F-value. In POS tagging, for each sentence, we count the number of words in the gold standard (*REF-POS*) as N_{REF} and the number of words in system output (*SYS-POS*) as N_{SYS}. In addition, we count the the number of words when the word tokenization and POS tagging match exactly between gold standard and system output (*CORR-POS*) as N_{CORR}. For example, when an input sentence is "*Are you *studing a lot?*" and its reference and output are as follows,

REF-POS: {Are/VBP, you/PRP, studying/VBG, a/DT, lot/NN, ?/? }
SYS-POS: {Are/VBP, you/PRP, stud/JJ, ing/NN, a/DT, lot/NN, ?/?}
CORR-POS: {Are/VBP, you/PRP, a/DT, lot/NN, ?/?}

then N_{REF} is 6, N_{SYS} is 7, and N_{CORR} is 5.

With respect to spelling correction, along with the POS tagging, we count N_{REF}, N_{SYS}, and N_{CORR}, looking at the spelling of tokenized words. N_{REF} is the number of gold-standard spelling correction pairs in (*REF-SP*), N_{SYS} is the number of corrected pairs in the system output (*SYS-SP*), and N_{CORR} is the number of pairs in the system output that correctly identifies the gold standard (*CORR-SP*). For instance, when an input is "*There aren't *convinent *appliaces in their houses yet.*" and the output is "*There aren't **convenient places** in **there** houses yet.*", the result is as follows:

REF-SP: {*appliaces/appliances, *convinent/convenient}
SYS-SP: {*appliaces/places, *convinent/convenient, *their/there}
CORR-SP: {*convinent/convenient}

[10] irstlm 5.70 `http://sourceforge.net/projects/irstlm/files/irstlm/`

		Precision	Recall	F-value
CLC FCE	POS-BASELINE	0.950	0.971	0.960
	POS-PIPELINE	0.961 (+1.1%)	0.976 (+0.5%)	0.968 (+0.8%)
	POS-JOINT	**0.982 (+3.2%)***†	**0.979 (+0.8%)**	**0.981 (+2.1%)***†
KJ corpus	POS-BASELINE	0.794	0.857	0.824
	POS-PIPELINE	0.827 (+3.3%)*	0.857 (± 0.0%)	0.842 (+1.7%)*
	POS-JOINT	**0.853 (+5.9%)***†	**0.871 (+1.4%)***†	**0.862 (+3.8%)***†

Table 5: Experimental result on POS tagging. Statistically significant improvements over the baseline are marked with an asterisk (*), and those over the pipeline are marked with a dagger (†), where $p < 0.05$.

		Precision	Recall	F-value
CLC FCE	SP-BASELINE	**0.519**	0.427	0.468
	SP-JOINT	0.445 (-7.3%)*	**0.622 (+19.5%)***	**0.519 (+5.0%)***

Table 6: Experimental result on spelling error correction. Statistically significant improvements over the baseline are marked with an asterisk (*), where $p < 0.05$.

and therefore, in this case, N_{REF} is 2, N_{SYS} is 3, and N_{CORR} is 1.

Precision, Recall, and F-value are computed by N_{REF}, N_{SYS}, and N_{CORR} as the following equations.

$$Precision = \frac{N_{CORR}}{N_{SYS}}, \quad Recall = \frac{N_{CORR}}{N_{REF}}, \quad F\text{-}value = \frac{2 \times Precision \times Recall}{Precision + Recall}$$

4.4 Result and Analysis

The experimental results of POS tagging is shown in Table 5. From the table, we make the following observations.

First, the joint model and the pipeline perform better than the baseline both in the CLC FCE dataset and the KJ corpus. For the two corpora, the joint model achieves 2.1% and 3.8% improvements and the pipeline achieves 0.8% and 1.7% in F-value, although only POS-JOINT shows statistical significance. Second, the result of the KJ corpus is lower than that of the CLC FCE dataset. This may be because there is a slight difference in segmentation and POS format in the KJ corpus. For example, some words are assigned multiple POS tags such as *everyday/DT-NN* and *logout/VBN-RP*. Furthermore, in the KJ corpus, there are a lot of Japanese words written in Roman letters (e.g. *Onigiri* (*rice ball* in English), *himawari* (*sunflower*)), which make it difficult to segment words and assign POS tags in this corpus. Third, the result shows that our joint analysis performs better in POS tagging than the pipeline in all three metrics for the two ESL learners' corpora. This is because our proposed model assigns POS tags and corrects spelling errors simultaneously, and the joint model can correct not only typographical spelling errors but also homophone, split, merge, inflection, derivation, and confusion errors. Finally, the overall results in the CLC FCE dataset show relatively high values for POS tagging. This may be because the topics in the CLC FCE dataset are limited and there are categorical overlaps between training and test sets.

In terms of spelling error correction, Table 6 presents our experimental results. Overall, the joint model performs better in recall (+19.5%) and F-value (+5.0%), whereas the precision decreases

from 0.519 to 0.445. The result of higher recall and less precision is not surprising, since the joint model can deal with all types of spelling errors whereas only typographical errors are corrected in the baseline.

5 Discussion

In this section, we look at our experimental results in detail and discuss the contribution of our work.

First, looking at the cases when POS tagging and spelling error correction are successfully analysed, we find that the joint model (POS-JOINT) works well for all 7 types of spelling errors we defined. Figure 3 shows successful examples of the 7 error types. For instance, (1) in Figure 3 shows that the word **surprice* is misspelled and split into two words *sur* and *price* in the baseline (POS-BASELINE), whereas the joint model corrects the spelling error and assigns a POS tag successfully. Of course, these typographical errors can be corrected using conventional ways such as edit distance, and in fact these errors are also corrected in the pipeline (POS-PIPELINE), where misspelled words are corrected using edit distance before POS tagging.

The rest of the examples, (2) to (7), in Figure 3 are harder to correct if we depend only on edit distance. However, as pointed out above, the joint model can correct these different kinds of spelling errors. In (2) in Figure 3, the homophone error **hear/here* is corrected in the joint analysis, since the model compares the path costs between the POS sequences of "**... am(VBP)-hear(VB)-to(TO) ...**" and "**... am(VBP)-here(RB)-to(TO) ...**", while the baseline and pipeline cannot figure out the homophone spelling error. The confusion and split errors such as the examples in Figures 3(3) and 3(4) are corrected successfully with the joint model, as is the case of homophone errors. When it comes to merge errors as shown in Figure 3(5), a misspelled word **swimingpool* should be rewritten from **swiming* to *swimming* and also split into *swimming pool*. The joint analysis corrects the error successfully, while the baseline fails to split and the pipeline fails to correct the spelling error. Previous studies, as mentioned in Section 2, deal with the spelling error types shown in examples (1) to (5) in Figure 3, but our work widens the scope of spelling error types to *inflection* and *derivation* errors as shown in the examples in (6) and (7) in Figure 3, since ESL writing contains a number of inflection and derivation errors, as shown in Table 3. In addition, hyphenated words (e.g. **fourty-five/forty-five*) are also corrected by the joint model.

Second, we find several errors, where POS tagging and spelling correction fail. In many error cases, incorrect POS tagging is due to a failure in spelling error correction. In other words, when misspelled words are corrected successfully, the result of POS tagging is also correct. Therefore, we analyse errors in cases of failed spelling correction.

With regard to false positives, when our model could not correct spelling errors in the experiment, we found two main patterns. First, the joint model (SP-JOINT) suggests different words for typographical errors, while the baseline (SP-BASELINE) also tends to fail to correct spelling errors. For example, Figures 4(1) and 4(2) show the failures in typographical error correction. In (1), the misspelled word **beginers* is corrected to *beginner* instead of *beginners*. In the same manner, **concer* in 4(2) is changed to *cancer*. For this pattern, both the baseline and the joint model are able to detect typographical spelling errors, although they fail to suggest correct words. These errors are difficult to correct, because we need information about the broader context or semantics information that sometimes goes beyond the sentence level. Second, our joint model changed correct words into different words. The examples seen in Figures 4(3) and 4(4) show that the proposed model rewrites correct words into different words. In Figure 4(3), the correct word *fell* is rewritten

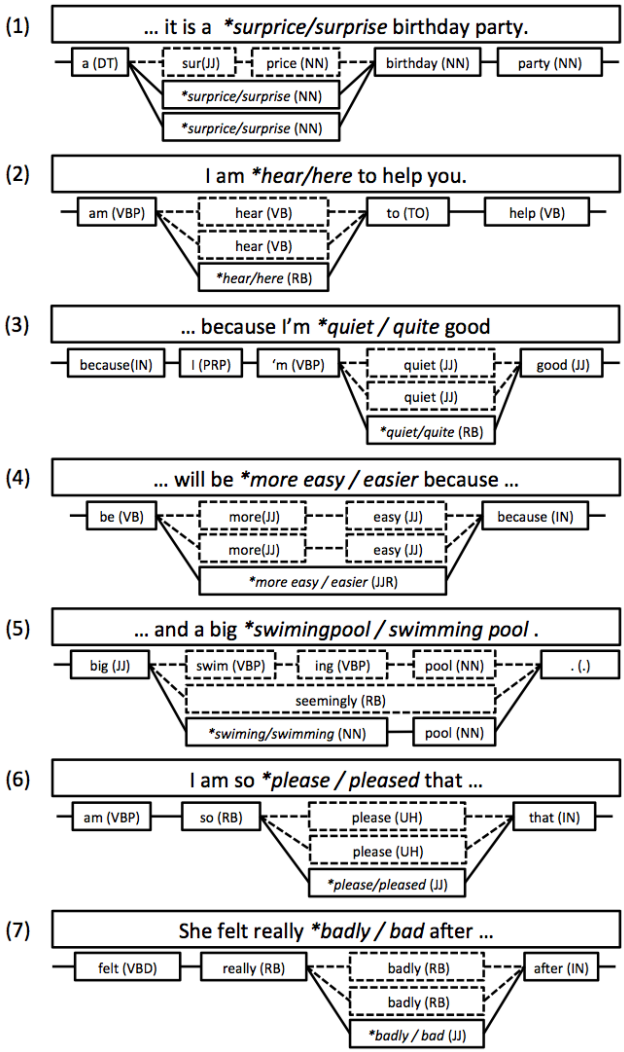

Figure 3: Examples of true positives for POS tagging and spelling correction. Branched nodes represent the output of POS-BASELINE, POS-PIPELINE and POS-JOINT models respectively. Paths and nodes are dotted when they are incorrect. (1) is an example of *typographical error*, (2) is *homophone error*, (3) is *confusion error*, (4) is *split error*, (5) is *merge error*, (6) is *inflection error*, and (7) is *derivation error*.

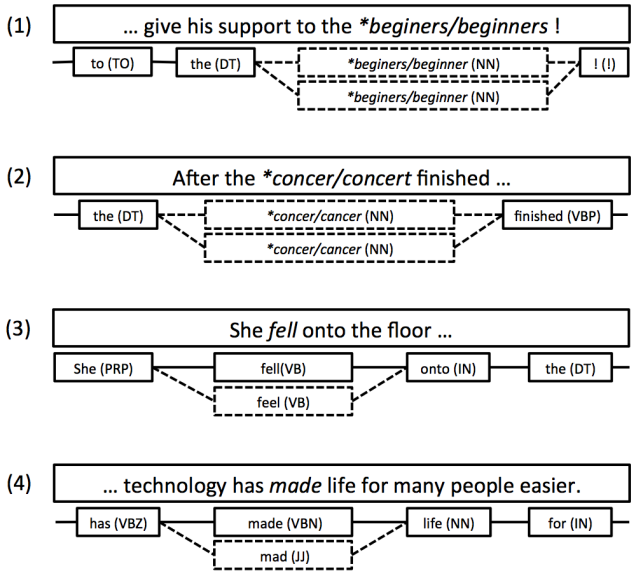

Figure 4: Examples of false positives for spelling correction. Branched nodes represent the output of SP-BASELINE and SP-JOINT models respectively. Edges and nodes are dotted when they are incorrect.

as *feel* and *made* is changed to *mad*. These false positives may be caused by insufficient feature templates and/or data sparseness (overfitting), and we need to deal with them in further research. Of course, both in (3) and (4), this type of wrong corrections does not occur in the baseline, because baseline concerns only typographical errors and does nothing for other types of spelling errors. Since the joint model can detect and correct a wider range of spelling errors, as shown in Figure 3, it causes more false positives, resulting in a lower precision than the baseline. We also find some false positives where the corrected words are also acceptable but regarded as false positives due to the gold standard. Examples of these are British spellings such as *color/colour*, and some adverbs (e.g. *first/firstly*). If we can deal with these cases, the precision will increase.

As shown in Figure 5, we find several examples of false negatives where the system cannot detect spelling errors. In the false negatives, most errors belong to confusion or derivation types, whereas some errors are also found in split and inflection types, indicating that when words before correction are existing words they are hard to detect. For example, Figure 5(1) shows that a misspelled *main* is not detected as an error by the joint model. The error in Figure 5(2) "**After words/Afterwards*" is not corrected, since this error contains a combination of split and typographical errors. With regard to inflection and derivation errors, as Figures 5(3) and 5(4) show, some errors are hard to detect, because the POS sequence before correction is also acceptable to some extent. In order to reduce false negatives, and also false positives, more contextual information will be needed.

Finally, we find that there are some annotation errors in the CLC FCE dataset. For instance, **ab-*

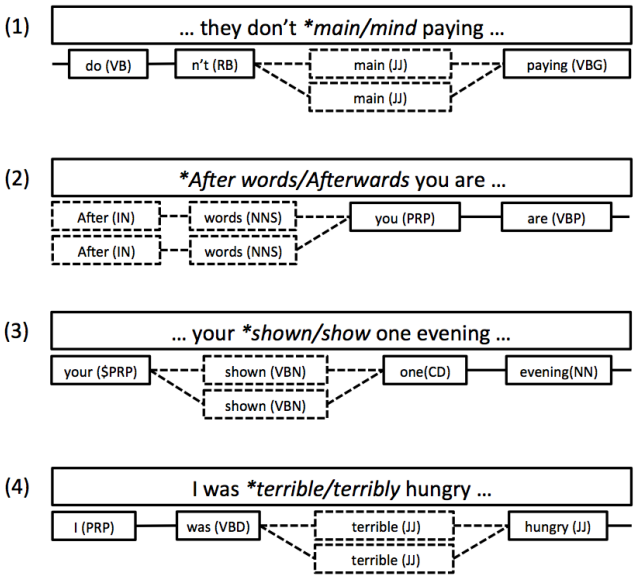

Figure 5: Examples of false negatives for spelling correction. Branched nodes represent the output of SP-BASELINE and SP-JOINT models respectively. Paths and nodes are dotted when they are incorrect.

solutly is corrected to **abolutely* instead of *absolutely*, and **dissapointing* is corrected to **diappointing* instead of *disappointing*. This may force precision downward, though perhaps not to such a great extent.

6 Conclusion

We have presented a joint model of POS tagging and spelling error correction for ESL writing. The model is a CRF-based morphological analysis with word boundary disambiguation. Because the model deals with word boundary ambiguities, it can detect and correctly split and merge errors. In addition, we add misspelled words and their correct/candidate forms into the lexicon, so that the model can deal with not only typographical errors but also a wider range of spelling errors such as homophone, confusion, split, merge, inflection, and derivation errors that often appear in ESL learners' corpora. Our model shows statistically significant improvements in POS tagging and spelling correction, achieving 2.1% and 3.8% of F-value improvements for POS tagging and 5.0% of F-value improvement for spelling error correction compared to the baseline. We have also showed that the joint model improves F-values more than the pipeline model, which is statistically significant.

Acknowledgments

We would like to thank anonymous reviewers for their valuable and very helpful comments.

ABSTRACT

Psychological disorders are frequently under-diagnosed and consequently have an irreversible impact on individuals and society. The stigma associated with such disorders makes face-to-face discussions with family members and clinicians difficult for many individuals. In contrast, people openly relate experiences on Internet forums. This paper describes a novel system that analyses forum posts to: (1) detect distress indicators that directly map to the Diagnostic and Statistical Manual of Mental Disorders (DSM) IV constructs, and (2) assess the severity of distress for prioritizing individuals who should seek clinical help (i.e. triage). For distress indicator detection, we use support vector machines (SVMs) trained on a suite of innovative intra- and inter-message features. We show significant improvements in multi-label classification accuracy using human-generated rationales in support of annotated distress labels. For triage assessment, we demonstrate the effectiveness of Markov Logic Networks (MLNs) in dealing with noisy distress label detections and encoding expert rules.

1 Introduction

Psychological health disorders pose a growing threat to individuals, their family members and to society. Disorders such as Depression, Post-Traumatic Stress Disorder (PTSD), and mild Traumatic Brain Injury (mTBI), are often under-diagnosed and under-treated (Kessler et. al, 1999). Failure to intervene early and effectively impacts individuals and their family members adversely and results in profound long-term costs to society.

The standard approach to diagnosing psychological health disorders is through a series of clinically administered diagnostic interviews and tests (Weathers et. al, 2001). However, assessment of patients using these tests is expensive and time-consuming. Furthermore, the stigma associated with mental illnesses motivates inaccurate self-reporting by affected individuals and their family members, thus making the tests unreliable.

In recent years, there has been a tremendous growth in social interactions on the Internet via social networking sites and online discussion forums. In contrast to clinical tests, the Internet is an ideal, anonymous medium for distressed individuals to relate their experiences, seek knowledge, and reach out for help. Web-forum discussions of symptoms, thoughts and experiences are open, descriptive, and honest, making them an ideal source for observing communications of individuals for assessing psychological status.

In this paper, we present a multi-stage text classification system for assessing psychological status of individuals based on their text postings on online web forums. Specifically, our system combines state-of-the-art NLP and machine learning techniques to: (1) extract fine-grained psychological distress indicators/labels derived from Diagnostic and Statistical Manual of Mental Disorders (DSM) IV (American Psychiatric Association, 2000), and (2) assesses the severity of distress that can be used to triage individuals who should seek clinical help.

The same factors that make web-forum data interesting for observing psychological distress also make automated analysis extremely challenging. For instance, the language used in such forums is highly informal, with ill-formed, grammatically incorrect sentences, misspellings, and special character sequences such as emoticons. Vague references to emotional states, description of present vs. past traumatic experiences, and relating one's own versus other's experience all pose novel challenges to natural language processing (NLP). Additionally, any approach for psychological health analysis of text interactions must incorporate domain knowledge from expert psychologists and clinicians. Together these challenges make this domain a fascinating research area with the potential for research advances to revolutionize psychological healthcare.

1.1 Previous Work

Existing applications for automatic detection of psychological disorders have been limited to structured questionnaires and formal clinical records (Brown, et. al. 2006). In contrast, our work is focused on noisy, informal text messages from Web-forums. Text classification research on such data has primarily focused on identifying social roles in scientific forums (Wang, et. al, 2011) and sentiment analysis (Abbasi et. al, 2008). To the best of our knowledge, the work presented in this paper for assessing psychological status from web-forum text is first of its kind.

Several rule-based approaches have been explored for detecting PTSD and mTBI from clinical narratives (Elkin et. al, 2010) (Trusko et. al, 2010). However, these approaches rely on annotating individual words as positive, negative, or neutral indicators of the condition. Such annotation is

laborious, lacks consistency, and requires deep subject matter expertise. Instead, our approach uses statistical models that do not require such laborious annotation and encode domain knowledge by learning weights for the domain rules from data.

1.2 Novel Contributions

We present several novel techniques within a multi-stage text classification framework for assessing psychological status from informal text posted on Web-forums. First, we describe a suite of features and classifiers trained on expert-annotated text to detect distress indicators. The training data itself is a first of its kind, where each message has been annotated by psychologists using a codebook of 136 distress labels that directly map to DSM-IV constructs. Since messages are often tagged with multiple distress indicators, the detection task is a multi-label classification problem with a large set of labels. Additionally, a fraction of our data is annotated with rationales that support distress labels. We show that these rationales can be effectively used to improve multi-label classification accuracy. Specifically, we observe a relative improvement of 14.6% over using plain text features. Another key contribution of this work is the use of probabilistic logic, namely Markov Logic Networks (MLNs) (Richardson and Domingos, 2006) to incorporate domain-specific rules, and handle the inherent noise in the data. We show that MLNs improve the triage classification accuracy, and provide a robust approach for inferring triage codes from noisy distress label detections as well as potentially contradictory domain rules.

2 Corpus for Experimentation

Our corpus consists of threads downloaded from an online forum for veterans with post-combat psychological issues. The forum fosters anonymous discussions between returning military personnel with PTSD or suspected of PTSD, and their caregivers. Note that we do not identify any individuals from their posted text nor do we trace any distress signals to a specific poster.

In consultation with psychologists, a codebook of 136 psychological distress labels spanning PTSD, mTBI, and depression symptoms was developed. Codes/labels were mostly derived from the DSM-IV guidelines (American Psychiatric Association, 2000). The labels were organized into five broad categories: Stress Exposure (e.g., Combat Exposure, Traumatic Loss, Captivity), Affect (e.g., Anger/Rage/Frustration/Contempt, Fear, Worthlessness), Behaviour (e.g., Social Isolation, Sleep problems, Excessive Drug Use), Cognition (e.g., Intrusive Thoughts and Memories, Homicide Ideation, Posttraumatic Amnesia), and Domains of Impairment (e.g., Legal Problems, Financial Problems, Occupational Impairment). In the annotation process, each message is first tagged to indicate if a message is relevant to assessing the author's psychological state. Each relevant message is then annotated with one or more labels from the codebook characterizing the psychological state of the author in accordance with the message content. Additionally, for a subset of messages, we highlighted contextual rationales to support the distress labels annotations. Figure 1 shows a snapshot of the distress labels and their hierarchy.

Expert psychologists next annotated each author in a thread with a triage code that indicates treatment acuity or the priority assigned to a referral for additional treatment. We used three triage codes in our annotation – TR1 indicating current or imminent danger to self or others; TR2 indicating behavioural disturbances, distress, functional impairment and/or suicidal/homicidal ideation without any imminent danger to self or others; and TR3 where there is no evidence of current behavioural disturbance, distress or functional impairment. For each of these triage codes,

the treatment acuity varies from emergency intervention or urgent care evaluation for TR1 to non-urgent treatment referral for TR2 to no recommendation for treatment for TR3. Since online forums are moderated and expunged of sensitive content, we rarely observed any occurrences of TR1 in the forum posts. Our focus in this paper is hence restricted to distinguishing between codes TR2 and TR3. However, our approach is extensible to the detection of TR1 if appropriate training data were available.

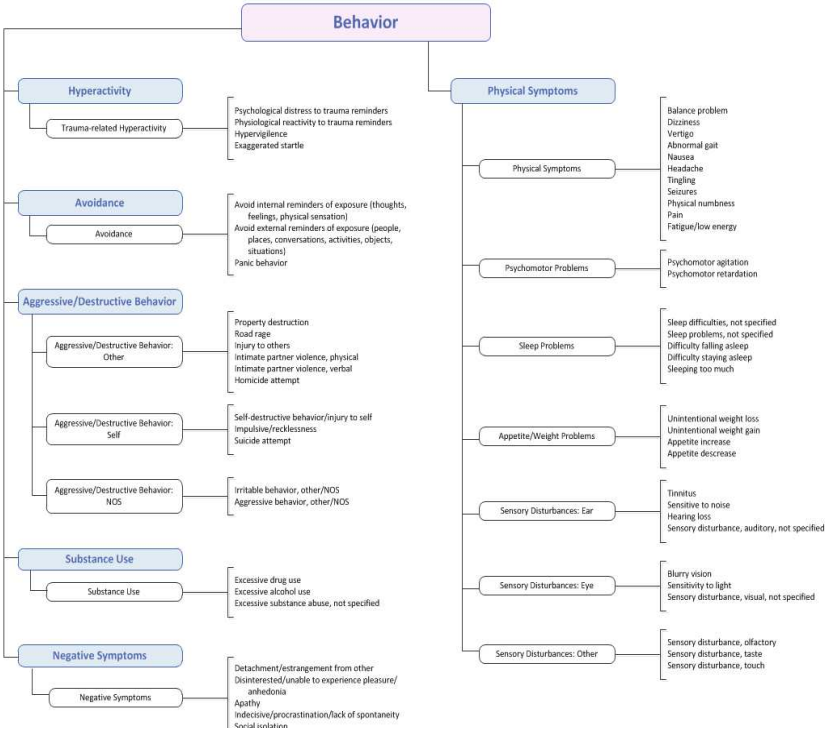

Figure 1: Snapshot of codebook of distress labels and their hierarchy.

3 Approach Overview

Figure 2 gives an overview schematic of our approach. We use a trainable multi-stage text-classification system to detect distress indicators from text interactions on Web forums and severity of distress of an author for prioritizing need for clinical care. Our system analyses the text posted by an author to first determine if it is relevant for psychological distress. If relevant, the text is further processed using multi-label classification to estimate fine-grained

psychological distress indicators. Next, information from the text and the detected distress labels is combined using domain-specific rules to estimate priority for intervention. In what follows, we describe the details for fine-grained distress detection and severity assessment.

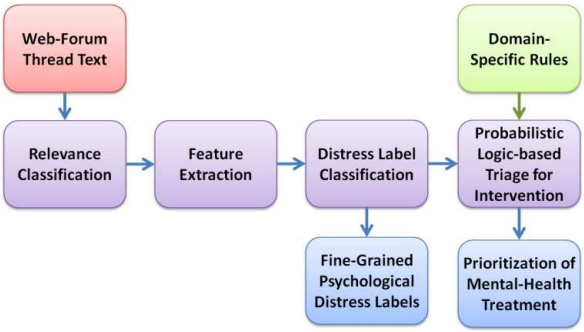

Figure 2: Schematic of Approach to Estimate Psychological Distress Labels and Prioritization of Mental-Health Intervention from Web-Forum Text.

4 Multi-label Distress Classification

4.1 Classifier

Algorithms for multi-label classification, the task of assigning one or more labels to an instance, can be grouped into two main categories: (1) problem transformation methods, and (2) algorithm adaptation methods (Tsoumakas et al. 2011). Problem transformation methods transform the multi-label classification problem into many single-label classification problems. Algorithm adaptation methods extend specific learning algorithms in order to handle multi-label data directly. Given the large size of our label set (118 observed labels out of 136 total), we could not find a memory-efficient way to use many of the algorithm adaptation methods. Instead, we focused on problem transformation methods using binary one-versus-all Support Vector Machines (SVMs) that detect the presence or absence of each of the fine-grained distress labels.

4.2 Features

Most systems for text classification represent documents as a bag-of-words. While this approach works well for most tasks with adequate training data, it does not capture any semantic correlations or higher order information between words. In our experiments, we explored a variety of features that look beyond the identity of the words in the message. These include message-level features computed based on the content of individual messages as well as thread-level features that exploit the structure of the discussion thread and look at other messages in the thread. In all cases, the features are binary, integer, or real valued and contain no Personally Identifiably Information (PII).

A1: Unigrams – We extracted unigrams from the forum messages by first removing stop words. Next, we apply Porter stemming to remove the common morphological and inflectional endings in English. Emoticons such as smileys were retained and used as features.

A2: Pronoun Count – Pronouns are typically discarded in most text classification applications in the pre-processing stage under the assumption that they occur too frequently to bear any information. However, in (Campbell and Pennebaker, 2003) it was shown that changes in the way people use pronouns when writing about traumatic experiences is a powerful predictor of changes in physician visits or an indicator of their general health. We hence included the normalized pronoun count as a feature.

A3: Punctuation Count – Normalized count of punctuations in the message calculated as the percentage of tokens/words in the message that are punctuations.

A4: Average Sentence Length - Average number of words in the message sentences, where sentence segmentation was determined based on punctuations and line breaks.

A5: Sentiment Words - Sentiment bearing words are correlated with specific distress labels (especially in the Affect category of distress labels). Identifying and grouping such words in a message could positively influence the classification performance of these labels. We extracted 125 binary features indicating the presence or absence of sentiment bearing words in the message. These words were selected from two sources: 68 lexicons form the Linguistic Inquiry and Word Count (LIWC) (Pennebaker et. al, 2007), and 57 lexicons from the General Inquirer (GI) system (Stone, 1966). The LIWC includes categories corresponding to affective and emotional processes (e.g.: positive/negative emotions), Cognitive Processes (e.g.: causation) and Social Processes (e.g.: friends) among others. The GI System includes valence categories (positive, negative) and motivation related words.

A6: Lead Author Post -Binary feature indicating whether the message was posted by the author who started the thread.

A7: First Responder Post -Binary feature indicating whether the message was posted by the author who first responded to the lead message of the thread.

A8: Thread Similarity - Real-valued feature that measures the average cosine similarity of the words in the message to the other messages in the thread.

A9: First Message Similarity - Real-valued feature that measures the cosine similarity of the words in the message to the words in the first message posted in the thread.

A10: Domain Phrases Derived from Rationales – (Zaidan et. al, 2008) showed improved performance in a sentiment classification task using annotator rationales within a contrastive learning framework of an SVM. Here, we use the rationales by extracting label-specific textual features from them. For every label, we first find the most frequent n-grams (n <= 5) in the highlighted rationales. We then filtered n-grams that had a high overlap ratio with other labels and also those that consisted solely of words in a pre-defined stop word list. The resulting n-grams were then used as binary features for classification. Examples of such phrases for the label Suicidal Ideation include: “thought about jumping”, “me suicidal”, “end their life”, “feel like killing myself”.

5 Psychological Triage Models for Severity Assessment

Our goal is to find authors who might require treatment or medical evaluation based on any behavioural disturbances, distress, functional impairments and/or suicidal or homicidal ideation. We explored two approaches to address this problem. The first approach uses an SVM trained on the words and predicted distress labels for the messages posted by the author. Our second approach uses Markov Logic Networks (MLNs) (Richardson and Domingos, 2006) to encode domain knowledge using probabilistic first order rules with associated weights.

In our system, the MLN computes the probability of a triage code using: (1) the distribution of words in the messages posted by an author, (2) the predicted distress labels, and (3) domain-specific rules that encode dependencies between the text, distress labels and the triage. The domain-specific rules were derived from existing diagnostic criteria as follows:

1. Rules derived from Primary Care-PTSD (PC-PTSD) screening test (Prins et al. 2003) used routinely in the VA to screen for PTSD. It comprises of 4 questions which map to 10 distress labels from the codebook.
2. Rules derived from DSM-IV guidelines for PTSD. These comprise of 4 criteria consisting of questions that map to distress labels in the codebook. For example, a criterion encoded as a rule in the MLN is the presence of one or more of the trauma exposure labels and one or more of the fear/helpless labels.

hasSymptom(Helplessness, p) OR hasSymptom(Fear, p) OR hasSymptom(Horror,p) => triageCode(+t, p)
hasSymptom(Intimate family impairment, p) OR hasSymptom(Extended family impairment, p) OR hasSymptom(Friendship impairment, p) OR hasSymptom(Social impairment, p) OR hasSymptom(Occupational impairment, p) OR hasSymptom(Educational impairment, p) OR hasSymptom(Self-care impairment, p) OR hasSymptom(Financial problems, p) OR hasSymptom(Legal problems, p) => triageCode(+t, p)
hasSymptom(Sleep problems, p) OR hasSymptom(Difficulty falling asleep, p) OR hasSymptom(Anger, p) OR hasSymptom(Road rage, p) OR hasSymptom(Property destruction, p) OR hasSymptom(Concentration problem, p) OR hasSymptom(Hypervigilence, p) OR hasSymptom(Exaggerated startle, p) => triageCode(+t, p)
hasSymptom(Intrusive thoughts, p) OR hasSymptom(Nightmares, p) OR hasSymptom(Reliving event, p) OR hasSymptom(Psychological distress to trauma reminders, p) OR hasSymptom(Physiological reactivity to trauma reminders, p) => triageCode(+t, p)
hasSymptom(Nightmares, p) OR hasSymptom(Reliving event, p) OR hasSymptom(Intrusive thoughts and memories of events, p) => criterion1(True, p)

Table 1: Examples of domain-specific rules derived from DSM-IV guidelines and PC-PTSD screening tests. Here, p is variable ranging over authors of messages; and t ranges over triage codes.

MLNs have two key advantages for our application. First, the use of statistical inference provides robustness to noise in the text and label predictions, and potential contradictions in the domain-specific rules. Second, the relative weights for the domain-specific rules can be automatically learned from the training data.

We employed Alchemy, an implementation of learning and inference algorithms for MLNs, (Richardson and Domingos, 2006) for our experiments. To learn the weights of the domain-specific rules, we used discriminative training, which maximizes the conditional likelihood of target labels (in our case the triage codes) given the observed variables (in our case the message words and distress labels). Alchemy uses an approach referred to as pre-conditioner scaled conjugate gradient for discriminative weight learning (Lowd and Domingos, 2007). The inference is performed using MaxWalkSAT; see (Richardson and Domingos, 2006) for details. Table 1 shows examples of domain-specific rules incorporated in the MLN based on DSM-IV guidelines and PC-PTSD screening test.

6 Experimental Results

6.1 Inter-annotator Agreement

We performed an inter-annotator agreement study for both distress label classification and triage annotation. Annotation for distress labels was performed by four Subject Matter Experts (SMEs). We measured inter-annotator agreement among multiple annotators using the Fleiss Kappa statistic (Fleiss, 1971). In order to compute the overall Kappa for the distress labels, we first computed the Fleiss Kappa for each label, and then performed a weighted combination of these scores. We observed a Kappa of 0.68 for the "Relevant" tag and 0.59 for the "Distress Labels" on a set of 9 threads comprising 126 messages that were annotated by all four SMEs. In general, a Kappa of 0.41-0.60 suggests moderate agreement, and 0.61 to 0.80 suggests good agreement (Landis and Koch, 1977). We found that the inter-annotator agreement, i.e. the Kappa values, for the individual distress labels spanned a wide range. Some of the distress labels had very good agreement, e.g., Sleep problems, and Alcohol abuse, possibly because the messages contained extensive descriptions of the distress conditions. The labels that were in poor agreement were typically those that required inference and world knowledge, e.g., Despair and Worthlessness. We will further investigate this inter-annotator agreement disparity as part of future work. Annotation for the triage classification was performed by six SMEs. We again measure the Fleiss Kappa statistic for triage codes assigned to 43 authors across 10 threads. We found this value to be 0.71, indicating good agreement.

6.2 Multi-label Distress Classification

We chose a set of 512 threads, comprising of 5000 relevant and irrelevant messages, for our multi-label distress classification experiments. We held out 90 threads for testing, and used the remaining for the training set. We collected rationales for 650 messages in training. The SVM parameters were tuned based on 10-fold cross validation on the training set where threads were randomly distributed across 10 different subsets. Performance is reported on the held-out test set. Table 2 shows the data statistics of the experimental corpus.

Category		Train	Test
Threads		422	90
Authors		1166	260
Relevant	Messages	1868	440
	Total Words	397K	92K
	Unique Labels	118	97
	Average Number of Labels per message	2.8	2.9

Table 2: Corpus setup for Multi-Label Distress Classification

As described in Figure 2, we approached the problem of automatically detecting psychological distress indicators in forum posts in two stages. We first applied a classifier to filter out messages that have no bearing on the detection of psychological distress. Irrelevant messages include cases such as when authors choose to post very short messages that do not have any information bearing content, like a simple "Thank you", and when the topic of discussion digresses to sub-topics or tangential topics. In order to identify relevant versus irrelevant messages, we trained an SVM on the annotated forum messages, and used it to automatically recognize relevant messages in the test set. We then applied multi-label classifiers to predict one or more distress labels described by the author on the relevant messages. In this paper, we focus on this second stage of text classification, and report closed-set results on messages that we know are relevant.

Classification performance is measured by computing the mean of the Area Under the Curve (AUC) for all labels. The AUC for each label is computed on a Receiver Operating Characteristic (ROC) curve with the false acceptance rate (FAR) bounded at 10%, and normalized such that the maximum possible AUC is 1.We also report the overall AUC number for the entire ROC curve, i.e. FAR of 100%. The labels detected for all messages posted by the same author within a thread were pooled for evaluation. For our experiments with SVMs, we used the Weka machine learning software (Hall et. al, 2009) with the Radial Basis Function (RBF) kernel. We performed grid-search to find the best regularization (C) and gamma (g) parameters on the cross-validation set. For the baseline experiment with SVMs, each message was treated as a bag of words with normalized (TF-IDF) frequencies. Next, the remaining features described in section 4.1 were incrementally added to the baseline feature set of the SVM classifier. Table 3 shows the performance of the SVM with the unigram TF-IDF features as well as the improvements from adding the other features. For a random classifier, the mean-AUC bounded up to False Acceptance Rate of 10% is 0.05, and the overall AUC is 0.5. No significant change in performance is seen with the incremental addition of the message level features A2-A5 and thread level features A6-A9. We retained these features since their addition did not explicitly hurt performance. Overall, the mean-AUC improves by 14.6% relative using the full set of features in section 4.1 over just the unigram words (Table 3). We see a large gain from the addition of the domain phrase features derived from rationales (A10).

We found that our approach of using the rationales by extracting label specific domain phrase features out-performed the contrastive approach in (Zaiden et. al, 2008). The latter gave a

bounded mean-AUC of 22.3, whereas our feature-based approach yielded 23.5 when added to the unigram feature set.

Feature Set	Mean AUC Bounded for 0-10% False Accept Rate	AUC (Overall)
A1	0.213	0.6757
A1, A2, A3, A4, A5	0.211	0.6699
A1, A2, A3, A4, A5, A6, A7, A8, A9	0.212	0.6699
A1, A2, A3, A4, A5, A6, A7, A8, A9, A10	0.244	0.6874

Table 3: Multi-label distress classification results with different feature sets

It is to be noted that the dataset has a high class imbalance. The most frequently occurring label – Anger/Rage/Frustration/Contempt has 698 training examples whereas half of the labels have less than 20 examples in training. Hence, a large number of labels perform poorly merely due to the lack of sufficient training data. In Figure 3 we also show the AUCs for all the labels. Approximately half the labels have an AUC < 0.2. The maximum value of individual AUC was found to be 0.884 for Excessive Substance Use. The top 5 labels with maximum AUC are Excessive Substance Use, Panic behavior, Nightmares or Unpleasant Dreams, Concentration Problems and Child Maltreatment. In all of these labels, there is extensive description of the distress condition in the messages. In contrast, there are many labels that are implied in the text, and are inconsistently inferred even amongst human annotators. We demonstrated this in the inter-annotator agreement study where we found only moderate agreement between annotators in the coding of these distress labels.

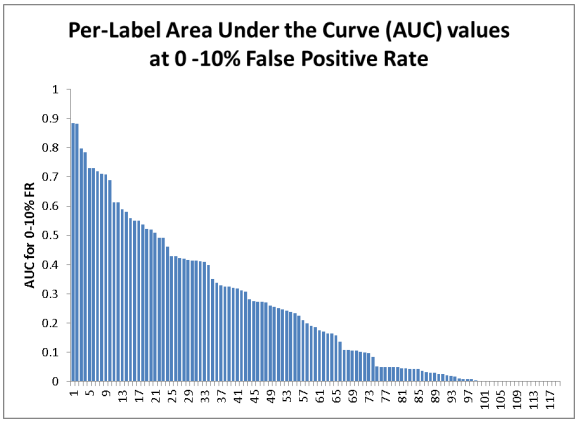

Figure 3: Per-label AUC values for false positive rate capped at 10%. The AUC is normalized such that the maximum possible value is 1.0.

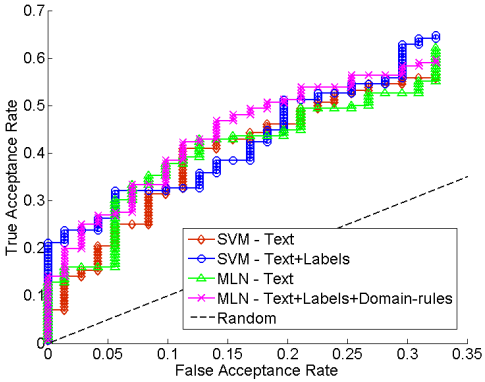

Figure 4: ROC curves for triage classification for SVM and MLN for Text and Text + Distress Labels. MLN with Text and Distress Labels combined using domain specific rules gives best results.

6.3 Triage Assessment

A subset of authors in the downloaded forum threads were tagged with triage codes, specifically 907 authors out of 1426. We used 680 of these for training the triage models, and 227 for evaluation. We compare the triage classification performance for SVM and MLN using ROC curves, i.e. rate of correct acceptance of TR2 versus false acceptance of TR3. The performance was measured using area under the curve (AUC). We capped the ROC curves to false acceptance rates less than 33% based on the fact that high false acceptance rates make the triage impractical for our application. The AUC is normalized such that the maximum possible AUC is 1. The AUC of a random/chance classifier is 0.165. Table 4 presents the AUC values for SVM and MLN for different types of inputs. As can be observed, MLNs provide statistically significant gains over SVMs by using domain-specific rules for combining information from text as well as the distress label detections. Figure 4 shows the ROC curves for the triage classification.

Method	**Area Under the Curve (AUC) with Bounded False Accept Rate of 33%**
SVM - Text	0.4090
SVM – Text + Distress Labels	0.4354
MLN – Text	0.4148
MLN – Text + Distress Labels + DSM-IV and PC-PTSD Rules	**0.4515**

Table 4: Triage classification performance AUC for ROC curves capped at false acceptance rate less than 33%. The AUC is normalized such that maximum possible value is 1.0

7. Conclusions and Future Work

In this paper, we introduced a powerful system that automatically detects psychological distress indicators from text in online forum posts, and demonstrated it in a novel domain of unconstrained web-forums. We presented multi-label classification for 136 labels of fine-grained psychological distress conditions on extremely challenging unstructured text data, and a novel approach based on probabilistic logic to employ domain-specific rules for combining information from text features and the distress label detections. We also showed that incorporating rationales from domain experts for the label annotations helps improve the multi-labeling performance, and presented a novel feature to exploit the rationale annotations.

In the future, we intend to investigate methods that exploit label dependencies. We will also investigate contextual features for classification that exploit information from previous messages within a thread. Finally, we plan to validate the system on text data from subjects diagnosed with PTSD and compare the outcomes on a control group that does not suffer from PTSD.

ABSTRACT
Brute-force word sense disambiguation (WSD) algorithms based on semantic relatedness are really time consuming. We study how to perform WSD faster and better on the span of a text. Several stochastic algorithms can be used to perform Global WSD. We focus here on an Ant Colony Algorithm and compare it to two other methods (Genetic and Simulated Annealing Algorithms) in order to evaluate them on the Semeval 2007 Task 7. A comparison of the algorithms shows that the Ant Colony Algorithm is faster than the two others, and yields better results. Furthermore, the Ant Colony Algorithm coupled with a majority vote strategy reaches the level of the first sense baseline and among other systems evaluated on the same task rivals the lower performing supervised algorithms.

TITLE AND ABSTRACT IN FRENCH

Algorithme à colonie de fourmis pour la désambiguïsation lexicale non supervisée de textes : comparaison et évaluation

Les algorithmes exhaustifs de désambiguïsation lexicale ont une complexité exponentielle et le contexte qu'il est calculatoirement possible d'utiliser s'en trouve réduit. Il ne s'agit donc pas d'une solution viable. Nous étudions comment réaliser de la désambiguïsation lexicale plus rapidement et plus efficacement à l'échelle du texte. Nous nous intéressons ainsi à l'adaptation d'un algorithme à colonies de fourmis et nous le confrontons à d'autres méthodes issues de l'état de l'art, un algorithme génétique et un recuit simulé en les évaluant sur la tâche 7 de Semeval 2007. Une comparaison des algorithmes montre que l'algorithme à colonies de fourmis est plus rapide que les deux autres et obtiens de meilleurs résultats. De plus, cet algorithme, couplé avec un vote majoritaire atteint le niveau de la référence premier sens et rivalise avec les moins bons algorithmes supervisés sur cette tâche.

1 Introduction

Word Sense Disambiguation (WSD) is a core problem in Natural Language Processing (NLP), as it may improve many of its applications, such as multilingual information extraction, automatic summarization, or machine translation. More specifically, the aim of WSD is to find the appropriate sense(s) of each word of a text among a pre-definied sense inventory. For example, in "*The mouse is eating cheese.*", for the word ‹*mouse*›, the WSD algorithm should choose the sense that corresponds to the animal rather than the computer device. There exist many methods to perform WSD, among which, one can distinguish between supervised methods and unsupervised methods. The former are based on machine learning techniques that use a set of (manually) labelled training data, whereas the latter do not.

This article focusses on an unsupervised knowledge-based approach for WSD, derived from the method proposed by (Lesk, 1986). This approach uses a similarity measure that corresponds to the number of overlapping words between the definitions of two word senses. With this metric, one can select, for a given word of a text, the sense that yields the highest relatedness to a certain number of its neighbouring words (with a fixed window size). Works such as (Pedersen et al., 2005) use a brute-force (BF) global algorithm that evaluates the relatedness between each word sense and all the senses of the other words within the considered context window. The execution time is exponential in the size of the input, thus reducing the maximum possible width of the window. The problem can become intractable even on the span of short sentences: a linguistically motivated context, such as a paragraph for instance, can not be handled. Thus, such approaches can not be used for applications where real time is a necessary constraint (image retrieval, machine translation, augmented reality).

In order to overcome this problem and to perform WSD faster, we are interested in other methods. In this paper, we focus on three methods that globally propagate a local algorithm based on semantic relatedness to the span of a whole text. We consider two unsupervised algorithms from the state of the art, a Genetic Algorithm (GA) (Gelbukh et al., 2003) and a Simulated Annealing (SA) algorithm (Cowie et al., 1992), as well as an adaptation of an Ant Colony Algorithm (ACA) (Schwab et al., 2011). Our aim is to provide an empirical comparison of the ACA with the two other unsupervised algorithms, using the Semeval-2007, Task-7, Coarse grained corpus (Navigli et al., 2007) (both in terms of quality and execution time). Furthermore, we also evaluate the results after applying a majority vote strategy.

After a brief review of the state-of-the-art of WSD, the algorithms are described. Subsequently, their implementations are discussed, as well as the estimation of the *best* parameters and the evaluation of the tested algorithms. Finally, an analysis of the results is presented as well as a comparison to other systems on Semeval 2007 Task 7. Then, we conclude and propose some perspectives for future work.

2 Brief State of the art of Word Sense Disambiguation

In simple terms, WSD consists in choosing the best sense among all possible senses for all words in a text. There exist many methods to perform WSD. The reader can refer to (Ide and Véronis, 1998) for works before 1998 and (Agirre and Edmonds, 2006) or (Navigli, 2009) for a complete state of the art.

Supervised WSD algorithms are based on the use of a large set of hand-labelled training data to build a classifier which can determine what are the right sense(s) for a given word in a given context. Most classical supervised learning algorithms have been applied to WSD, and

even though they tend to yield better results (on English) over unsupervised approaches, their main disadvantage is that hand-labelled examples are rare and expensive resources (knowledge acquisition bottleneck) that must be created for each sense inventory, each language and even each specialized domain. We share the opinion of (Navigli and Lapata, 2010) that unsupervised methods would be better in order to overcome these obstacles in the short term.

Among unsupervised WSD methods some use raw corpora to build word vectors or co-occurrence graphs while others use external knowledge sources (dictionaries, thesauri, lexical databases, ...). The latter are based on the use of semantic similarity metrics that assign a score representing how *related* or *close* two word senses are. Many such measures exist and can be classified in three main categories: taxonomic distance in a lexical graph; taxonomic distance weighted by information content; feature-based similarity. More recent efforts go towards hybrid measures that combine two or more of the above. Readers may consult (Pedersen et al., 2005), (Cramer et al., 2010), (Tchechmedjiev, 2012) or (Navigli, 2009) for a more complete overview.

Commonly, similarity measures use WordNet (Fellbaum, 1998), a lexical database for English widely used in the context of WSD. WordNet is organised around the notion of "synonym sets" (*synsets*), which represent a word, its class (noun, verb, ...) and its connections to all semantically related words (synonyms, antonyms, hyponyms,...), as well as a textual definition for each corresponding synset. The current version, WordNet 3.0, contains over 155000 words for 117000 synsets.

3 Local and global WSD Algorithms

3.1 Our local algorithm : A variant of the Lesk Algorithm

Our local algorithm is a variant of the Lesk Algorithm (Lesk, 1986). Proposed more than 25 years ago, it is simple, only requires a dictionary and no training. The score given to a sense pair is the number of common words (space separated strings) in the definition of the senses, without taking into account neither the word order in the definitions (bag-of-words approach), nor any syntactic or morphological information. Variants of this algorithm are still today among the best on English-language texts (Ponzetto and Navigli, 2010).

Our local algorithm exploits the links provided by WordNet: it considers not only the definition of a sense but also the definitions of the linked senses (using all the semantic relations from WordNet) following (Banerjee and Pedersen, 2002), henceforth referred as $ExtLesk$[1]. Contrarily to Banerjee, however, we do not consider the sum of squared sub-string overlaps, but merely a bag-of-words overlap that allows us to generate a dictionary from WordNet, where each word contained in any of the word sense definitions is indexed by a unique integer and where each resulting definition is sorted. Thus we are able to lower the computational complexity from $O(mn)$ to $O(m), m > n$, where m and n are the respective length of two definitions. For example for the definition: "Some kind of evergreen tree", if we say that *Some* is indexed by 123, *kind* by 14, *evergreen* by 34, and tree by 90, then the indexed representation is $\{14, 34, 90, 123\}$.

3.2 Global algorithms

A global algorithm is a method that allows to propagate a local measure to a whole text in order to assign a sense label to each word. The simplest approach is the exhaustive evaluation of

[1] All dictionaries and Java implementations of all algorithms of this article can be found on our WSD page `http://getalp.imag.fr/xwiki/bin/view/WSD/`

sense combinations (BF), used for example in (Banerjee and Pedersen, 2002), that assigns a score to each word sense combination in a given context (window or whole text) and selects the one with the highest score. The main issue with this approach is that it leads to a combinatorial explosion in the length of the context window or text: $\prod_{i=1}^{|T|}(|s(w_i)|)$, where $s(w_i)$ is the set of possible senses of word i of a text T. For this reason it is very difficult to use the BF approach in real-life scenarios as well as on analysis windows of more than a few words.

Several approximation methods can be used in order to overcome the combinatorial explosion problem. On the one hand, *complete approaches*, try to reduce dimensionality using pruning techniques and sense selection heuristics. Some examples include: (Hirst and St-Onge, 1998), based on lexical chains that restrict the possible sense combinations by imposing constraints on the succession of relations in a taxonomy (e.g. WordNet); or (Gelbukh et al., 2005) that review general pruning techniques for Lesk-based algorithms; or yet (Brody and Lapata, 2008).

On the other hand, *incomplete approaches* generally use stochastic sampling techniques to reach a local maximum by exploring as little as necessary of the search space. Our present work focuses on such approaches. Furthermore, we can distinguish two possible variants:

- local neighbourhood-based approaches (new configurations are created from existing configurations) among which are some approaches from artificial intelligence such as genetic algorithms or optimization methods such as simulated annealing ;
- constructive approaches (new configurations are generated by iteratively adding new elements of solutions to the configuration under construction), among which are for example ant colony algorithms.

3.3 Context of our work

The aim of this paper is to compare our Ant Colony Algorithm (incomplete and constructive approach) to other incomplete approaches. We choose to first confront our algorithm to two classical neighbourhood-based approaches that have been used in the context of unsupervised WSD: genetic algorithms (Gelbukh et al., 2003) and simulated annealing (Cowie et al., 1992).

The underlying assumption to our work is that the span of the analysis context should be the whole text (similarly to (Cowie et al., 1992), (Gelbukh et al., 2003) and more recently (Navigli and Lapata, 2010)), rather than a smaller context window (like many other methods do for computational reasons). Indeed, in our opinion, using a context window smaller than that of the whole text raises two main issues: no guarantee on the consistency between two selected senses; contradictory sense assignments outside of the window range.

For example in the following sentence, considering a window of 6 words: "*The two planes were parallel to each other. The pilot had parked them meticulously.*", *plane* may be disambiguated wrongly due to *pilot* being outside the window of *plane*. Furthermore it can be detrimental to the semantic unity in the disambiguation, given that as (Gale et al., 1992) or (Hirst and St-Onge, 1998) pointed out, two words used several times in the same context tend to have the same sense. Therefore, some algorithms that are similar to our Ant Colony Algorithm but that use a context window have not been studied here (notably the adaptation (Mihalcea et al., 2004) of *PageRank* (Brin and Page, 1998) to WSD).

Moreover, we are not interested in comparing these incomplete algorithm, which cannot pragmatically be used in a real-life context, to the optimal disambiguation (Brute Force). Even with a reduced windows of the context and weeks of execution time we were only able to

achieve a 77% coverage of the corpus with BF, as detailed in (Schwab et al., 2011).

4 Global stochastic algorithms for Word Sense Disambiguation

The aim of these algorithms is to assign to each ambiguous word w_i in a text of m words the most appropriate of its senses $w_{i,j}$ given the context. The definition of a sense j of word i is noted $d(w_{i,j})$. The search-space corresponds to all the possible sense combinations for the text being processed. Therefore, a configuration C of the problem can be represented as an array of integers such that $j = C[i]$ is the selected sense j of w_i.

4.1 Problem configuration and global score

The algorithms require some *fitness* measure to evaluate how good a configuration is. With this in mind, the score of the selected sense of a word can be expressed as the sum of the local scores between that sense and the selected senses of all the other words of the text. Hence, in order to obtain a *fitness* value (*global score*) for the whole configuration, it is possible to simply sum the scores for all selected senses of the words of the text: $Score(C) = \sum_{i=1}^{m} \sum_{j=i}^{m} ExtLesk(w_{i,C[i]}, w_{j,C[j]})$. The complexity of this algorithm is hence $O(m^2)$, where m is the number of words in the text.

4.2 Genetic algorithm for Word Sense Disambiguation

The Genetic Algorithm (GA) based on (Gelbukh et al., 2003) can be divided into five phases: initialisation, selection, crossover, mutation and evaluation. During each iteration, the algorithm goes through each phase but the initialisation.

The initialisation phase consists in the generation of a random initial population of λ individuals (λ configurations of the problem).

During the selection phase, the score of each individual of the current population is computed. A crossover ratio (*CR*) is used to determine which individuals of the current population are to be selected for crossover. The probability of an individual being selected is *CR* weighted by the ratio of the score of the current individual over that of the best individual. Individuals who are not selected for crossover are merely cloned (copied) into the new population. Additionally the best individual is systematically kept. After each iteration, the size of each subsequent population is a constant λ.

During the crossover phase individuals are sorted according to their global score. If the number of individuals is odd, the individual with the lowest score is unselected and cloned into the new population as it cannot serve for crossover. The crossover operator is then applied on the individuals two by two in decreasing order of their score: the resulting configurations are swapped around two random pivots (everything but what is between the pivots is swapped).

During the mutation phase, each individual has a probability of mutating (parameter *MR*, for Mutation Rate). A mutation corresponds to *MN* random changes in the configuration. Thus, after the mutation phase, we obtain a modified configuration $C_{c'}$.

The evaluation phase corresponds to the test of the termination criteria: convergence of the score of the best individual. In other words if the score of the best individual remains the same for a number of generations (*STH*), the algorithm terminates.

4.3 Simulated annealing for Word Sense Disambiguation

The simulated annealing approach as described in (Cowie et al., 1992) is based on the physical phenomenon of metal cooling.

Simulated annealing works with the same configuration representation as the genetic algorithm, however it uses a single randomly initialised configuration. The algorithm is organised in cycles and in iterations, each cycle being composed of *IN* iterations. The other parameters are the initial temperature T_0 and the cooling rate $ClR \in [0;1]$. At each iteration a random change is made to the current configuration C_c, which results in a new configuration $C_c^{'}$. Given that $\Delta E = Score(C_c) - Score(C_c^{'})$, $C_c^{'}$, the probability $P(A)$ of acceptance (the probability of replacing $C_{c'}$) of configuration $C_c^{'}$ is :

$$P(A) = \begin{cases} 1 & \text{if } \Delta E < 0 \\ e^{\frac{-\Delta E}{T}} & \text{otherwise} \end{cases}$$

The reason why configurations with lower scores have a chance to be accepted, is to prevent the algorithm from converging on a local maximum. Lower score configurations allow to explore other parts of the search-space which may contain the global maximum.

At the end of each cycle, if the current configuration is the same as the configuration at the end of the previous cycle, the algorithm terminates. Otherwise, the temperature is lowered to $T \cdot ClR$. In other words, the more cycles it takes for the algorithm to converge, the lower the probability to accept lower score configurations: this guarantees an eventual convergence. The configuration with the highest score is saved after each iteration and will be taken as a result regardless of the convergence configuration.

5 Global Ant Colony Algorithm

5.1 Ant Colony Algorithm

Ant colony algorithms (ACA) come from biology and from observations of ant social behavior. Indeed, these insects have the ability to collectively find the shortest path between their nest and a source of food (energy). It has been demonstrated that cooperation inside an ant colony is self-organised and emerges from interactions between individuals. These interactions are often very simple and allow the colony to solve complex problems. This phenomenon is called swarm intelligence (Bonabeau and Théraulaz, 2000) and is increasingly popular in computer science where centralised control systems are often successfully replaced by other types of control based on interactions between simple elements.

Artificial ants have first been used for solving the Traveling Salesman Problem (Dorigo and Gambardella, 1997). In these algorithms, the environment is usually represented by a graph, in which virtual ants exploit pheromone trails deposited by others, or pseudo-randomly explore the graph.

These algorithms are a good alternative for the resolution of problems modeled with graphs. They allow a fast and efficient exploration close to other search methods. Their main advantage is their high adaptivity to changing environments. Readers can refer to (Dorigo and Stützle, 2004), (Monmarche et al., 2009) or (Guinand and Lafourcade, 2010) for a state of the art.

5.2 Ant colony Algorithm for Word Sense Disambiguation

5.2.1 Principle

The environment of the ant colony algorithm is a graph that can be linguistic, a morphological lattice (Rouquet et al., 2010), morpho-syntactic (Schwab and Lafourcade, 2007), or simply organised following the structure of the text (Guinand and Lafourcade, 2010).

Depending on the environment chosen, the results of the algorithm differ. We are currently investigating this aspect, but as the focus of our article is to make a comparison between ACA and the two other methods presented earlier, we will use a simple graph following the structure of the text (see Fig. 1) that uses no external linguistic information (no morpho-syntactic links within a sentence for example).

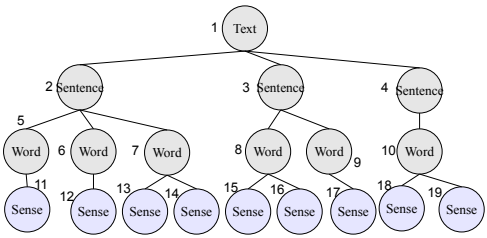

Figure 1: The environment for our experiment: text, sentences and words correspond to common nodes (1-10) and word senses to nests (11-19).

In this graph, we distinguish two types of nodes: nests and plain nodes. Following (Schwab, 2005) or (Guinand and Lafourcade, 2010), each possible word sense is associated to a nest. Nests produce ants that move in the graph in order to find energy and to bring it back to their mother nest: the more energy is deposited by ants, the more ants can be produced by the nest in turn. Ants carry an odour (array) that contains the words of the definition of the sense of its mother nest. From the point of view of an ant, a node can be: (1) *its mother nest*, where it was born; (2) *an enemy nest* that corresponds to another sense of the same word; (3) *a potential friend nest*: any other nest; (4) a *plain node*: any node that is not a nest. Furthermore, to each plain node is also associated an odour vector of a fixed length that is initially empty. For example, in Fig. 1, for an ant born in nest 19: nest 18 is an enemy (as their are linked to the same word node, 10), its potential friend nodes are from 11 to 17 and common nodes are from 1 to 10.

Ant movements depends on the scores given by the local algorithm (cf. Section 3.1), of the presence of energy, of the passage of other ants (when passing on an edge ants leave a pheromone trail that evaporates over time) and of the nodes' odour vectors (ants deposit a part of their odour on the nodes they go through). When an ant arrives on a nest of another term (that corresponds to a sense thereof), it can either continue its exploration or depending on the score between this nest and its mother nest, decide to build a bridge between them and to follow it home. Bridges behave like normal edges except that if at any given time the concentration of pheromone reaches 0, the bridge collapses.

Depending on the lexical information present and the structure of the graph, ants will favour

following bridges between more closely related senses. Thus, the more closely related the senses of the nests are, the more a bridge between them will contribute to their mutual reinforcement and to the sharing of resources between them (thus forming *meta-nests*); while the bridges between more distant senses will tend to fade away. We are thus able to build (constructive approach) interpretative paths[2] through emergent behaviour and to suppress the need to use a complete graph that includes all the links between the senses from the start (as is usually the case with classical graph-based optimisation approaches).

5.2.2 Implementation details

In this section we first present the notations used (Table 1) as well as the parameters of the Ant Colony Algorithm and their typical value ranges (Table 2), followed by a detailed description of the different steps of the algorithm.

Notation	Description
F_A	Nest that corresponds to sense A
f_A	Ant born in nest F_A
$V(X)$	Odour vector associated with X (ant or node)
$E(X)$	Energy on/carried by X (ant or node)
$Eval_f(N)$	Evaluation of a node N by an ant f
$Eval_f(A)$	Evaluation of an edge A (quantity of pheromone) by an ant f
$\varphi_{(t/c)}(A)$	Quantity of pheromone on edge A at given moment t or cycle c

Table 1: Main notations for the Ant Colony Algorithm

Notation	Description	Value
E_a	Energy taken by an ant when it arrives on a node	1-30
E_{max}	Maximum quantity of energy an ant can carry	1-60
δ	Evaporation rate of the pheromone between two cycles	0.0-1.0
E_0	Initial quantity of energy on each node	5-60
ω	Ant life-span	1-30 (cycles)
L_V	Odour vector length	20-200
δ_V	Percentage of the odour vector components (words) deposited by an ant when it arrives on a node	0-100%
c_{ac}	Number of cycles of the simulation	1-500

Table 2: Parameters of the Ant Colony Algorithm and their typical value-ranges

5.2.3 Simulation

The execution of the algorithm is a potentially infinite succession of cycles. After each cycle, the state of the environment can be observed and used to generate a solution. A cycle is composed of the following actions: (1) eliminate dead ants and bridges with no pheromone; (2) for each nest, potentially produce an ant; (3) for each ant: determine its mode (energy search or return); make it move; potentially create an interpretative bridge; (4) update the environment (energy levels of nodes, pheromone and odour vectors).

Ant production, death and energy model Initially, we assign a fixed quantity of energy E_0 to each node of the environment. At the beginning of each cycle, each nest node N has an

[2]Possible interpretation of the text.

opportunity to produce an ant A using 1 unit of energy, with a probability $P(N_A)$. In accordance with (Schwab and Lafourcade, 2007) or (Guinand and Lafourcade, 2010), we define it as the following sigmoid function (often used with artificial neural networks (Lafourcade, 2011)): $P(N_A) = \frac{arctan(E(N))}{\pi} + 0.5$.

When created, an ant has a lifespan of ω cycles (see Table 2). When the life of an ant reaches zero, the ant is deleted at the beginning of the next cycle and the energy it carried is deposited on the node where it died. By thus doing, we ensure that the global energy equilibrium of the system is preserved, which plays a fundamental role in the convergence (monopolization of resources by certain nests) to a solution.

Ant movements The ants' movements are random, but influenced by the environment. When an ant is on a node, it assigns a transition probability to the edges leading to all neighbouring nodes. The probability to cross through an edge A_j in order to reach a node N_i is $P(N_i,A_j) = \frac{Eval_f(N_i,A_j)}{\sum_{k=1,l=1}^{k=n,l=m} Eval_f(N_k,A_l)}$, where $Eval_f(N,A) = Eval_f(N) + Eval_f(A)$ is the evaluation function of a node N when coming from an edge A.

A newborn ant seeks food. It is attracted by the nodes which carry the most energy ($Eval_f(N) = \frac{E(N)}{\sum_0^m E(N_i)}$), but avoids to go through edges with a lot of pheromone, $Eval_f(A) = 1 - \varphi_t(A)$ in order to favour a greater exploration of the search space. The ant collects as much energy as possible until it decides to bring it back home (return mode) with the probability $P(return) = \frac{E(f)}{E_{\max}}$ [3]. Then, it moves while following (statistically) the edges that contain the most pheromone, $Eval_f(A) = \varphi_t(A)$ and leading to nodes with an odour close to their own, $Eval_f(N) = \frac{ExtLesk(V(N),V(f_A))}{\sum_{i=1}^{i=k} ExtLesk(V(N_i),V(f_A))}$.

Creation, deletion and types of bridges When an ant arrives on a node adjacent to a potential friend nest (i.e. that corresponds to a sense of a word), it has to decide between taking any of the possible paths or to go on that nest node. As such, we are dealing with a particular case of the ant path selection algorithm presented above in Section 5.2.3, with $Eval_f(A) = 0$ (The pheromone on the edge is ignored). The only difference is that if the ant chooses to go on the potential friend nest, a bridge between that nest and the ant's home nest is built and the ant follows it to go home. Bridges behave like regular edges, except that if the concentration of pheromone on them reaches 0, they collapse and are removed.

Pheromone Model Ants have two types of behaviours: they are either looking to gather energy or to return to their mother nest. When they move in the graph, they leave pheromone trails on the edges they pass through. The pheromone density on an edge influences the movements of the ants: they prefer to avoid edges with a lot of pheromone when they are seeking energy and to follow them when they want to bring the energy back to their mother nest.

When passing on an edge A, ants leave a trail by depositing a quantity of pheromone $\theta \in \mathbb{R}^+$ such that $\varphi_{t+1}(A) = \varphi_t(A) + \theta$.

Furthermore, at each cycle, there is a slight (linear) evaporation of pheromones (penalizing little frequented paths). Thus, $\varphi_{t+1}(A) = \varphi_t(A) \times (1-\delta)$, where δ is the pheromone evaporation rate.

[3] Consequently, when the ant reaches its carrying capacity, the probability to switch to return mode is 1.

Odour The odour of a nest is the numerical sense vector (as introduced in Section 3.1) and corresponds to the definition of the sense associated to the nest. All ants born in the same nest have the same odour vector. When an ant arrives on a common node N, it deposits some of the components of its odour vector (following a uniform distribution), which will be added to or will replace existing component of the node's vector $V(N)$. The odour of nest nodes on the other hand is never modified.

This mechanism allows ants to find their way back to their mother nest. Indeed, the closer a node is to a given nest, the more ants from that nest will have passed through and deposited odour components. Thus, the odour of that node will reflect its nest neighbourhood and allow ants to find their way by computing the score between their odour (that of their mother nest) and the surrounding nodes and by choosing to go on the node yielding the highest score. This process leaves some room for error (such as an ant arriving on a nest other than its own), which is beneficial as it leads ants to build more bridges (see Section 5.2.3).

5.3 Global Evaluation

At the end of each cycle, we build the current problem configuration from the graph: for each word, we take the sense corresponding to the nest with the highest quantity of energy. Subsequently, we compute the global score of the configuration (see Section 4.1). Over the execution of the algorithm we keep the configuration with the highest absolute score, which will be used at the end to generate the solution.

5.4 Main parameters

Here we present a short characterisation of the influence of the parameters on the emergent phenomena in the system:

- The maximum amount of energy an ant can carry, E_{max}, influences how much an ant explores the environment. Ants cannot go back through an edge they just crossed and have to make circuits to come back to their nest (if the ant does not die before that). The size of the circuits depend on the moment the ants switch to return mode, hence on E_{max}.
- The evaporation rate of the pheromone between cycles (δ) is one of the memories of the system. The higher the rate is, the least the trails from previous ants are given importance and the faster interpretative paths have to be confirmed (passed on) by new ants in order not to be forgotten by the system.
- The initial amount of energy per node (E_0) and the ant life-span (ω) influence the number of ants that can be produced and therefore the probability of reinforcing less likely paths.
- The odour vector length (L_v) and the proportion of odour components deposited by an ant on a plain node (δ_V) are two dependent parameters that influence the global system memory. The higher the length of the vector, the longer the memory of the passage of an ant is kept. On the other hand, the proportion of odour components deposited has the inverse effect.

Given the lack of an analytical way of determining the optimal parameters of both the Ant Colony Algorithm and the other algorithms presented, they have to be estimated experimentally, which is detailed in Section 6.

6 Empirical Evaluation

In this section we first describe the evaluation task we used to evaluate the three systems, followed by the methodology we used for the estimation of the parameters, and then the experimental protocol for the empirical quantitative comparison of the algorithms and subsequently, the interpretation of the results. Finally, we briefly compare the number of evaluations of the semantic similarity score function ($ExtLesk$) and discuss the positioning of our system relatively to the other systems that are evaluated with Semeval 2007 Task 7 (participating systems and more recent advances).

6.1 Evaluation Campaign Task

We evaluated the algorithms with the SemEval 2007 coarse-grained English all-words task 7 corpus (Navigli et al., 2007). Composed of 5 texts from various domains (journalism, book review, travel, computer science, biography), the task consists in annotating 2269 words with one of their possible senses from WordNet, with an average degree of polysemy of 6.19. The evaluation of the output of the algorithm is done considering coarse grained senses distinction i.e. close senses are counted as equivalent (e.g. snow/precipitation and snow/cover).

A Perl script that evaluates the quality of the solutions is provided with the task files and allows us to compute the **P**recision, **R**ecall, and F_1 score[4], which are the standard measures for evaluating WSD algorithms (Navigli, 2009).

6.2 Parameter estimation

The algorithms we are interested in have a certain number of parameters that need tuning in order to obtain the best possible score on the evaluation corpus. There are three approaches:

- Make an educated guess about the value ranges based on *a priori* knowledge about the dynamics of the algorithm;
- Test manually (or semi-manually) several combinations of parameters that *appear* promising and determine the influence of making small adjustments to the values ;
- Use a learning algorithm on a subset of the evaluation corpus, for example with SA or GA to find the parameters that lead to the best score.

Both GA and SA, as presented in (Gelbukh et al., 2003) and (Cowie et al., 1992) respectively, use the Lesk semantic similarity measure as a score metric. We reimplemented them with the $ExtLesk$ measure and used the *optimal* parameters provided. However, the similarity values are higher than with the standard Lesk algorithm and we had to adapt the parameters to reflect that difference. We made one parameter vary at a time over 10 executions, in order to maximise the F_1 measure.

For our ACA, given that an execution of the algorithm is very fast[5], it was possible to use a simplified simulated annealing approach for the automated estimation of the parameters. For each parameter combination we ran the algorithm 50 times and considered the means coupled with the p-values from a one-way ANOVA. We still needed to use our *a priori* knowledge to set likely parameter intervals and discreet steps for each of them[6].

The best parameters we found are:

[4] F_1 is the harmonic mean of P and R. When 100% of the corpus is annotated, $P = R = F_1$.

[5] Depending on the parameters the execution takes between 15s to 40s for the first text of the corpus.

[6] Supervised approach to parameter tuning which does not affect the unsupervised nature of the algorithm itself.

- For GA: $\lambda = 500$, $CR = 0.9$, $MR = 0.15$, $MN = 80$, $CR = 0.9$;
- For SA: $T_0 = 1000$, $ClR = 0.9$, $IN = 1000$;
- For ACA: $\omega = 25$, $E_a = 16$, $E_{max} = 56$, $E_0 = 30$, $\delta_v = 0.9$, $\delta = 0.9$, $L_V = 100$

6.3 Experimental Protocol

The objective of the experiments is to compare the three algorithms according to different criteria. First, the F_1 score obtained on the Task 7 of Semeval 2007 and then the execution time. Furthermore, given that they use the same similarity measure and that it is the computational bottleneck, we also measure the average number of similarity computations between word senses.

Since the algorithms are stochastic, we need to have a representation of the distribution of solutions as accurate as possible in order to make statistically significant comparisons and thus we ran the algorithms 100 times each.

The first step in the evaluation of the significance of the results is the choice of an appropriate statistical tool. In this case we are using a one-way ANOVA analysis (Miller, 1997), coupled with a Tuckey' HSD post-hoc pairwise analysis (Hsu, 1996). These two techniques rely on three principal assumption: independence of the groups, normal distribution of the samples, within group homegeneity of variances.

After the direct comparison of the results we apply a majority voting strategy for each word among ten consecutive executions so as to obtains 100 overlapping vote results. The same evaluation methodology is applied. In both cases, the baseline for our comparison is the first-sense(FS) baseline. Let us now check for the ANOVA assumptions and analyse the results.

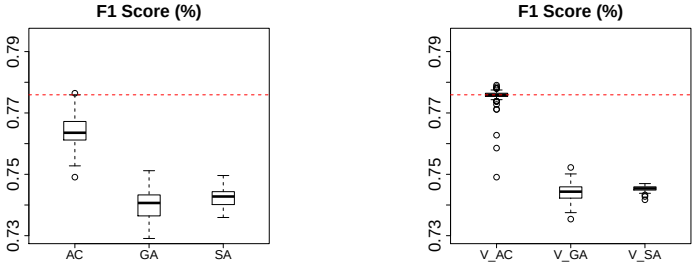
6.4 Quantitative results

In order to check the normality assumption for ANOVA, we computed the correlation between the theoretical (normal distribution) and the empirical quantiles. For all metrics and algorithms there was always a correlation above 0.99. Furthermore we used Levene's variance homogeneity test and found a minimum significance level of 10^{-6} between all algorithms and metrics.

Algorithm	F_1 (%)	σ_{F_1}	$Time(s)$	σ_{Time}	Sim. Eval.	$\sigma(S.Ev.)$
F.S. Baseline	77.59	N/A	N/A	N/A	N/A	N/A
G.A.	73.98(74.53)†	0.0052	4,537.6†	963.2	137,158,739†	13,784.43
S.A.	74.23(75.18)†	0.0028	1,436.6†	167.3	4,405,304†	50,805.27
A.C.A.	76.41(77.50)†	0.0048	65.46†	0.199	1,559,049†	17,482.45

Table 3: Comparison of the F_1 scores (after vote between brackets), execution times and similarity measure evaluations of the algorithms ($\dagger \longleftrightarrow p < 0.01$) over texts 2 through 5.

Table 3 presents the results, for the three algorithms with the F_1 scores, execution time and number of evaluations of the similarity measure along with their respective standard deviations. For all three metrics and between all three algorithms, the difference in the means was systematically significant with p<0.01. Since the first text was used to train the ACA parameters, in this sections the F_1 scores presented are calculated for the 4 next texts in order to remove any bias.



(a) Normal Execution (b) Majority Vote

Figure 2: Boxplots of the F_1 compared to the first sense baseline (dashed line)

Figures 2a and 2b respectively present boxplots of the distributions of F_1 scores for all three algorithms with and without vote compared to the first sense baseline.

In terms of F_1 score, SA and GA obtain similar results, even though SA is slightly better and shows a lower variability in the score distribution. As for ACA, the scores are on average +1.61% better than SA and +1.76% better than GA, with a variability similar to that of GA. All three algorithms are below the FS baseline, even though the maximum of the ACA distribution is close. After applying a majority vote on the answer files 10 by 10, for SA and GA there is a slight improvement of the scores ($p<0.01$), respectively +0.17% and +0.46% and for ACA, there is a larger improvement ($p<0.01$) of +1.17% (despite a certain number of lower-bound outliers). ACA tends to converge on solutions close to the FS baseline. After the vote, the distribution is practically centred around the latter as far as the score is concerned.

In terms of execution times there are huge differences between the algorithms, the slowest being GA, which on average runs over 1.5h (±16 min). SA is much faster and takes on average about 24m (± 2.8m), but still remains much slower that ACA, which converges on average in 65s(± 190ms). As one would expect, the number of evaluations of the similarity measure is directly correlated with execution times of the algorithms (cor_p=0.9969).

6.5 Comparison to other Task 7 systems

For the comparison to other systems, we restricted ourselves to those that disambiguate the whole text and not only a subset, in order to make a fair comparison. Furthermore, given that the results are over the 5 texts, we will consider the ACA results for the 5 texts as well contrarily to the previous section. Vis-a-vis the original participants, our algorithms is ahead of all other unsupervised systems, and beats the weakest supervised system by getting very close to the first sense baseline. However, most supervised systems are still ahead. If we add more recent results from the experiments of (Navigli and Pozetto, 2012) using Babelnet, a multilingual database which adds multilingual and monolingual links to WordNet, the Degree algorithm reaches a score almost as good as ACA (only WordNet) -0.63%, followed by Pagerank (Mihalcea et al., 2004) (adapted to Babelnet) -5.43%. When a voting strategy is used, ACA is ahead with 1.75% compared to Degree. However, it is important to note that when looking a the scores per part of speech, Degree exhibits notably higher results for nouns (85% versus 76.35%), while ACA performs much better for adverbs adjectives and verbs (83.98%, 82.44%, 74.16%).

Conclusions and perspectives

In this paper we have presented three stochastic algorithms for knowledge-based unsupervised Word Sense Disambiguation: a genetic algorithm, a simulated annealing algorithm, and an ant colony algorithm; two from the state of the art, and our own ant colony algorithm. All three algorithms belong to the family of incomplete approaches, which allows us to consider the whole text as the disambiguation context and thus to go further towards ensuring the global coherence of the disambiguation of the text. We have estimated the *best* parameter values and then evaluated and compared the three algorithms empirically in terms of the F_1 score on Semeval 2007 Task 7, the execution time as well as the number of evaluation of the similarity measure. We found that the ACA is notably better both in terms of score and execution time. Furthermore, the number of evaluations of the similarity measure are directly correlated with the computation time. Then, we applied a majority vote strategy, which led to only small improvements for SA and GA and more substantial improvements for ACA. The vote strategy allowed ACA to reach the level of the first sense baseline, to beat the state-of-the-art unsupervised systems and the lowest performing supervised systems.

However, some open-ended questions remain. The three methods rely on parameters that are not (*a priori*) linguistically grounded and that have an influence both on the results and the computation time. The estimation of the parameters, whether manual or through an automated learning algorithm prevent these algorithms from being entirely unsupervised. However, the degree of supervision remains far below supervised approaches that use training corpora approximately 1000 times larger. Our work is currently focussed on the study of these parameters for ACA. Their values seem to depend mostly on the structure of the text and on its consequences on the environment graph of ACA, as we have outlined in the paper. Moreover, we are also interested in determining the degree to which the similarity measure and the lexical resources it uses influences the parameters. We are currently adapting our $ExtLesk$ to use Babelnet in order to investigate the matter further as well as to enable us to perform Multilingual Word Sense Disambiguation.

Learnability-based Syntactic Annotation Design

Roy Schwartz *Omri Abend* *Ari Rappoport*

Abstract

There is often more than one way to represent syntactic structures, even within a given formalism. Selecting one representation over another may affect parsing performance. Therefore, selecting between alternative syntactic representations (henceforth, *syntactic selection*) is an essential step in designing an annotation scheme. We present a methodology for syntactic selection and apply it to six central dependency structures. Our methodology compares pairs of annotation schemes that differ in the annotation of a single structure. It selects the more *learnable* scheme, namely the one that can be better learned using statistical parsers. We find that in three of the structures, one annotation is unequivocally better than the alternatives. Our results are consistent over various settings involving five parsers and two definitions of learnability. Furthermore, we show that the learnability gains incurred by our selections are both considerable (error reductions of up to 19.8%) and additive. The contribution of this work is in demonstrating that syntactic selection has a substantial and predictable effect on parsing performance, and showing that this effect can be effectively used in designing syntactic annotation schemes.

1 Introduction

The formal manner in which syntactic relations are represented is at the core of the study of grammar. Numerous representations have been proposed over the years for expressing similar syntactic relations. This diversity of representations is expressed in a variety of syntactic annotation schemes currently in use in NLP. Examples include, for constituency annotation, schemes by (Marcus et al. 1993; Sampson 1995; Nelson et al. 2002, *inter alia)* and for dependency annotation, schemes by (Collins 1999; Rambow et al. 2002; Yamada and Matsumoto 2003; Johansson and Nugues 2007, *inter alia)*. Variation within the same formalism is expressed in structures that have several alternative annotations (henceforth *Varying Syntactic Structure* or *VSS*).

In this work we focus on dependency structures, where some of the most basic structures are VSS's. One example is prepositional phrases, which consist of a preposition followed by a noun phrase (e.g., "about everyone"). While some schemes select the preposition to head the NP (Collins 1999), others select the NP as the head of the preposition (Johansson and Nugues 2007) (see Figure 1). Other prominent VSS's include coordination structures and verb group constructions (see Section 3). In fact, more than 40% of the tokens in the Penn Treebank (Marcus et al. 1993) participate in at least one VSS (Schwartz et al. 2011).

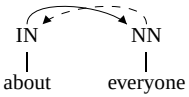

Figure 1: An example of a prepositional phrase – a Varying Syntactic Structure (VSS). Both annotation alternatives for this structure are plausible: either setting the preposition ("about" – solid line) as head, or the noun phrase ("everyone" – dashed line).

Despite the similar content represented by the alternative annotations to VSS's, selecting one over the other (*syntactic selection*) may have significant empirical implications. Previous work showed that syntactic selection can affect the parsing performance of a specific parser (see Section 7). In this work, we are the first to show that in some VSS's, syntactic selections improves parsing performance consistently across different parsers. As our findings are not parser-specific, they can be used to guide future syntactic annotation design.

The empirical implications of syntactic selection stem from the inter-relations between the VSS's and their surrounding structures. Figure 2 presents two alternative annotations for the sentence "he is sure about everyone". The alternatives differ in whether the preposition ("about") or the NP ("everyone") is selected to head the PP ("about everyone"). The two annotations can be deterministically derived from one another and express a similar syntactic relation, namely in both cases the PP is the complement of the adjective "sure". However, selecting one of the alternatives (the preposition) and not the other (the NP) results in a more learnable scheme.

Concretely, in dependency grammar, an adjective's complement is encoded by setting the head of the complement (either "about" or "everyone") as a dependent of the adjective ("sure"). It is plausible that a parser which is strongly guided by POS tags would not select an adjective ("sure") as the head of a noun ("everyone") as it is unlikely for adjectives to head nouns. This would result in a parsing error as in Figure 2(b). On the other hand, a similar parser would more likely select an adjective ("sure") to head a preposition ("about"), resulting in a correct parse as in Figure 2(a). Indeed, the MST parser (McDonald et al. 2005) exhibits such behavior.

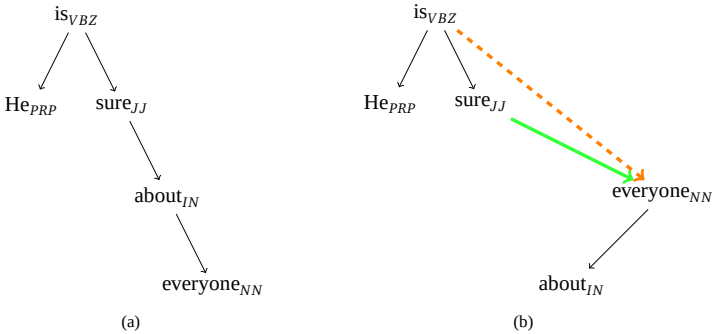

Figure 2: Exploring the effect of VSS annotation on neighboring structures. The sentence "He is sure about everyone", annotated when prepositions head PPs (Figure 2(a)) and when NPs head PPs (Figure 2(b)). Thin solid black lines mark gold+parser edges, thick green solid edges mark **gold edges**, and thick orange dashed lines mark **parser edges**.

The implications of syntactic selection underscore the importance of taking empirical considerations into account when designing an annotation scheme. In this work, we propose *learnability* as an empirical criterion for syntactic selection. The notion that more learnable schemes are preferable is motivated both practically and theoretically. Practically, more learnable schemes result in more accurate parsers. Theoretically, learnability has been a major consideration in the design of phrase structure grammar (Chomsky 2006), and can also be seen as a measure of simplicity, a fundamental principle in many other scientific fields (see Section 7).

We present a learnability-based methodology for syntactic selection and apply it to six central VSS's. We compare alternative annotations for each VSS, by examining pairs of schemes that differ only in their annotation of this VSS. For each pair, we pick the scheme that can be more easily learned using statistical parsers. We select an annotation for this VSS if we find that the schemes that use this annotation are consistently picked.

We experiment with five parsers of various types and using two different learnability measures. We obtain highly consistent results. Our experiments show that for three of the VSS's there is one alternative that is more learnable over all settings. That is, training any of the five parsers on an annotation scheme that uses the more learnable alternative results in higher parsing performance. The differences are substantial in magnitude, yielding error reductions that range between 2.4%-19.8%. Moreover, this gain is additive – using all three of the more learnable alternatives results in an even more accurate parser.

To further establish learnability as a coherent empirical criterion for syntactic selection, we show that our results are consistent with a parser-independent measure based on information theoretic notions.

The contribution of this paper is twofold. First, we present the first study focusing on syntactic selection and showing that it has a substantial and predictable effect on parsing performance. Second, we show that this effect can be used for designing syntactic annotation schemes. Specifically, our findings indicate that future dependency schemes should use (a) prepositions as heads of PPs (b) conjuncts as heads of coordination structures and (c) nouns (and not their determiners) as heads of NPs.

Section 2 describes our methodology. Section 3 discusses Varying Syntactic Structures (VSS). Experimental setup and results are described in Sections 4, 5. Section 6 discusses our methodology and presents further experiments that provide a wider context for understanding our findings. Section 7 surveys related work.

2 Methodology

We present a learnability-based methodology for selecting between alternative annotations for VSS's.

2.1 Notation

In the following we give a formal definition of an annotation scheme. We then turn to describe the different settings in which our methodology conducts experiments.

Our methodology experiments with a set S of VSS's. For each $s \in S$, we examine a set of alternative annotations. For clarity of presentation we assume each VSS has exactly two alternatives and denote them α_s, β_s. Let k denote the size of S ($k = 6$ in our experiments).

An annotation scheme is defined as a selection of an annotation for each of the structures in the language. It therefore includes a (fixed) annotation for non-VSS's, as well as a selected annotation for each of the VSS's. We can thus represent a scheme $\mathscr{A}$ as a k-tuple that selects one of the alternative annotations for each of the VSS's in S (all in all, 2^k schemes). Table 1 shows an example of two annotation schemes that differ in the annotation of exactly one structure (s_4).

Structure	s_1	s_2	s_3	s_4	s_5	s_6
$\mathscr{A}_1$	α	β	α	$\boldsymbol{\alpha}$	α	β
$\mathscr{A}_2$	α	β	α	$\boldsymbol{\beta}$	α	β

Table 1: Applying our methodology to VSS's ($s_1, \ldots, s_6$): $\mathscr{A}_1, \mathscr{A}_2$ are annotation schemes that are identical in their annotation of all the VSS's but s_4 (bold red **column**). α, β are short for $\alpha_{s_i}, \beta_{s_i}$ respectively.

To obtain robust results, our methodology repeats each experiment in different settings, each determined by a parser and a learnability measure. We use P (L) to refer to the set of parsers (learnability measures). We use $|P| = 5, |L| = 2$, all in all $5 \times 2 = 10$ settings.

2.2 Learnability Measures

We propose two straightforward definitions of learnability. They are both defined with respect to a parser p and an annotation scheme $\mathscr{A}$ (as defined above). Both measures assume a fixed corpus partitioned into a training set and a test set.

The first measure is "Accuracy-Learnability". To compute it, we train p on the training set annotated according to $\mathscr{A}$, parse the test set, and evaluate it against the annotation determined by $\mathscr{A}$. We use attachment score for evaluation, which is the standard measure for dependency parsing evaluation. An annotation for which p receives a higher attachment score is considered more learnable.

The second measure is "Rate-Learnability" that measures the rate in which the different annotation schemes can be learned to a given accuracy. We define a target attachment score β. We train p on a corpus annotated with $\mathscr{A}$ several times, using an increasingly larger number of samples. We then

evaluate the trained parser on our test data (annotated with $\mathscr{A}$) and create a learning curve of p and $\mathscr{A}$. An annotation for which p reaches β using less training samples is considered more learnable.

2.3 Learnability-based Methodology

We turn to describing a methodology for selecting learnable annotations for VSS's. The methodology runs a set of experiments, each using a parser p, a learnability measure l and a scheme $\mathscr{A}$. In each experiment, we compute the learnability of $\mathscr{A}$ with respect to p and l.

For every $s \in S$ and alternative annotations α_s, β_s, there are $2^k/2$ pairs of schemes that differ only in their annotation of s, one using α_s, and the other using β_s (see Table 1 for an example). Given a parser p and a learnability measure l, we compute the learnability of each pair of schemes and pick the more learnable scheme (see Table 2). We count the number of pairs in which the scheme using α_s is picked and the number of pairs in which the scheme using β_s is picked. We thus receive two figures that sum up to $2^k/2$ (32 in our experiments).

Annotation	s_1	s_2	s_3	s_4	s_5	s_6	score
$\mathscr{A}_1$	α	α	α	α	α	α	0.91
$\mathscr{A}_2$	α	α	α	α	α	β	**0.92**
$\mathscr{A}_3$	α	α	α	α	β	α	**0.94**
$\mathscr{A}_4$	α	α	α	α	β	β	0.935
⋮							
$\mathscr{A}_{2^k-1}$	β	β	β	β	β	α	0.892
$\mathscr{A}_{2^k}$	β	β	β	β	β	β	**0.896**

Table 2: Applying our methodology for selecting a syntactic annotation for VSS s_6, under parser p and learnability measure l: each row in the table is an experiment with annotation scheme $\mathscr{A}_i$. The experiment compares the learnability (last column) of pairs of annotation schemes that differ only in their annotation of s_6 (where the annotations for $s_1, \ldots, s_5$ are fixed). For each pair of annotation schemes, the more learnable annotation for s_6 is in boldface (blue for $\boldsymbol{\alpha}$, red for $\boldsymbol{\beta}$).

We then define a significance value $1 \geq r \gg 0.5$. If one annotation (say α_s) is more learnable than the other (with respect to p, l) in a relative portion r of these pairs, we say that p is r-*biased* towards α_s with respect to l.

If for some $s \in S$, it holds that for every $p \in P, l \in L$, p is r-biased ($r \gg 0.5$) with respect to l towards the same annotation (say, α_s), we say there is a *unanimous* r-*bias* towards α_s. Consequently, α_s is the *empirically preferred annotation* of s.

3 Varying Dependency Structures

Varying syntactic structures are prevalent in many syntactic formalisms (see Section 7). In this section we focus on dependency structures.

Dependency structures receive varying annotation when the identity of the structure's head is debatable. This stems from the multiple, occasionally conflicting, criteria for defining a head. A few of the more generally acknowledged criteria for defining H to be the head of D in constituent C are (Kübler et al. 2009):

1. H determines the syntactic category of C and can often replace C.
2. H determines the semantic category of C; D gives semantic specification.
3. The form of D depends on H.

These definitions can often be applied to determine the identity of the head. For example, according to (1,2) a noun is the head of its modifying adjective (e.g., "cat" in "big cat") and a verb is the head of its adverb (e.g., "eat" in "eat quickly").

In VSS's, these criteria are either inapplicable or conflicting. For example, in a sequence of proper nouns (e.g., "John Smith"), neither criterion is applicable. In a verb group construction (e.g., "can eat"), the main verb should be the head according to (2). On the other hand, the preceding modal restricts the main verb to be in infinitive form, and thus should be the head according to (3) (e.g., "he can eat" vs. "he eat**s**").

Such structures have led to the creation of several dependency schemes, each taking a different approach to annotating them (Collins 1999; Rambow et al. 2002; Yamada and Matsumoto 2003; Johansson and Nugues 2007, *inter alia)*. We turn to describing the VSS's that we experiment with and the alternatives annotations we consider for them. All of these annotations are in use in NLP. They are also plausible from a theoretical standpoint. Figure 3 shows a diagram for each of the structures, along with their possible annotations.

Coordination Structures are composed of two words, separated by a conjunction (e.g., "John and Mary"). It is not clear which token should be the head of this structure, if any (Nilsson et al. 2006). We consider two alternative annotations: (a) setting the conjunction as head, and both conjuncts as its dependents and (b) setting either of the conjuncts as head, selected according to the specific structure type (e.g., noun phrase, verb phrase).

Infinitive Verbs are verb phrases that contain the sequence "to" + infinitive verb (e.g., "to eat"). In (Yamada and Matsumoto 2003) the verb is the head, while in (Collins 1999) the "to" token is the head. We consider both annotations.

Noun Phrases that contain a determiner and a noun (e.g., "the apple" or "a dog"). Either the determiner (Bosco and Lombardo 2004) or the noun (Collins 1999) may serve as the head. We consider both annotations.

Noun Sequences are noun phrases that contain sequences of more than one noun (e.g., "John Doe"). Various alternative annotations for this structure include (Collins 1999), which takes the last noun as head, and BIO's scheme which is somewhat more complex (Dredze et al. 2007). We consider either the rightmost or the leftmost noun as head, and mark all other nouns as its dependents.

Prepositional Phrases consist of a preposition and a noun phrase (e.g., "in a bag" or "of Rome"). Complement clauses that contain a subordinating conjunction (e.g., "after you go") are also included[1]. Either the preposition/subordinating conjunction (Collins 1999) or the NP/clause (Johansson and Nugues 2007) can be the head. We consider both alternatives.

Verb Groups are composed of a verb and a modal verb (e.g., "can come"). Some schemes select the modal as head (Collins 1999), others select the verb (Rambow et al. 2002). We consider both

[1]For brevity, we use the term Prepositional Phrases to refer to both structures.

alternatives[2].

4 Experimental Setup

4.1 The Parsers

In this work we experiment with five parsers of different types. We briefly describe them.

Dependency Model with Valence (DMV) (Klein and Manning 2004) is a generative parser that defines a probabilistic grammar for unlabeled dependency structures. This parser is widely used in the field of *unsupervised* dependency parsing, where the great majority of recent works are in fact elaborations of this model (e.g., (Cohen and Smith 2009; Headden III et al. 2009)). In our experiments we use a *supervised* version of this parser, by training it using maximum likelihood estimation (MLE). This approach was used in various previous works as an upper bound for the unsupervised model (Blunsom and Cohn 2010; Spitkovsky et al. 2011). Decoding is performed using the Viterbi algorithm[3].

MST Parser (McDonald et al. 2005)[4] formulates dependency parsing as a search for a maximum spanning tree (MST). It uses online training and extends the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer 2003) to learning with structured outputs.

Clear Parser (Choi and Nicolov 2009)[5] is a fast transition-based parser that uses the robust risk minimization technique (Zhang et al. 2002). *k*-best ranking is used to prune the next state in decoding.

S_u Parser (Nivre 2009)[6] is a transition-based parser and an extension of the MALT parser (Nivre et al. 2006). The parser starts by constructing arcs between adjacent words and then swaps the order of input words in order to learn more complex structures. It uses the *stackeager* algorithm, and is trained using various linear classifiers (including SVM).

NonDir Parser (Goldberg and Elhadad 2010)[7] is a non-directional, easy-first parser, which is greedy and deterministic. It first attempts to induce a non-directional version of the easiest arcs in

[2]Some definitions of verb groups also include auxiliaries. We choose to exclude them from our definition since we use the PTB POS set, which distinguishes modals, but not auxiliaries, from other verbs.

[3]http://www.cs.columbia.edu/~scohen/parser.html

[7]http://www.cs.bgu.ac.il/~yoavg/software/easyfirst/

a dependency structure, and continues by iteratively selecting the best pair of neighbors to connect, until a complete dependency tree is created.

These parsers span the major approaches to statistical dependency parsing. The two main approaches are (Kübler et al. 2009) (a) *transition-based* methods that use state machines to map sentences to dependency graphs, attempting to reach the optimal state; and (b) *graph-based* methods, which try to find the best scoring dependency graph in some graph space. *Clear Parser* and S_u *Parser* are examples of (a), while *MST Parser* and *DMV* are examples of (b). NonDir takes a somewhat different parsing approach.

4.2 Technical Details

Following standard practice in English, used in the great majority of recent works, all the corpora are generated by converting constituency annotation to dependency using a set of head percolation rules[8]. Using these rules is also suitable here since they can easily be manipulated to create the different corpora required for applying our methodology.

Parsers are trained on sections 2–21 of the Penn TreeBank (PTB) WSJ corpus (Marcus et al. 1993), and are tested on section 23. We use the default feature set for each of the parsers. Evaluation is done using unlabeled attachment score, a common evaluation measure for dependency parsing.

For the Rate-Learnability measure, we select a different β value for each parser, due to their different performance levels; β is set to be the attachment score of the least learnable annotation for that parser, as determined by our experiments with the Accuracy-Learnability measure. This is the highest value of β that all schemes would reach at some point along their learning curve.

5 Results

Table 3 shows our results. In three out of the six structures, a strong unanimous bias is found. A unanimous 0.9-bias is found towards (a) selecting the preposition as head of prepositional phrases, and (b) selecting either of the conjuncts as head of coordination structures. A unanimous 0.7-bias is found towards the noun in noun phrases. For these structures, one annotation is clearly more learnable than the other, independently of the selected annotations for the other structures. This gives an empirical motivation for using these annotations.

In two of the remaining structures (verb groups and noun sequences), we find a trend towards one of the annotations; in five of the settings a 0.7-bias is found towards one alternative (modal and leftmost noun, respectively). In the other five settings no strong bias is found towards either alternative. In these structures, it might be the case that certain modeling assumptions incorporated into the parsers affect whether one alternative is preferred or not. This calls for a more detailed investigation, which we defer to future work.

Finally, no considerable bias is found in the infinitive verb structures, as a 0.7-bias towards any alternative is found in only one setting. Thus, our experiments suggest no preference towards either alternative in this case.

[8] We use a slightly modified version of the *pennconvertor*, tailored for our experimental setup (`http://nlp.cs.lth.se/software/treebank_converter/`) (Johansson and Nugues 2007).

Table 3: Exploring the learnability of the different annotation schemes. Each row pair corresponds to a pair of annotations for a given VSS, and each column pair corresponds to a parser, under Accuracy-Learnability (*A.L.*) and Rate-Learnability (*R.L.*) (see Section 2). For a given VSS, learnability measure and parser, we show the number of times one annotation is more learnable than the alternative. There are 32 experiments with each such combination, each has a single winner, resulting in a pair of numbers that sums up to 32. Gray cells mark settings in which the annotation is substantially more learnable than the alternative (dark/light gray correspond to $r = 0.9/0.7$ respectively). Rows marked with an arrow (◄) mark annotations that are *unanimously* biased. The annotations (see Section 3): Coordinations – headed by one of the conjuncts (CONJ) or by the conjunction (CC) ; Infinitive Verbs – headed by "to" (TO) or by the Verb (VB) ; Noun Phrases – headed by the noun (Noun) or by the determiner (DT) ; Noun Sequences – headed by the left/rightmost noun (LEFT/RIGHT); Prepositional Phrases – headed by the preposition (IN) or by the noun phrase (NP) ; Verb Groups – headed by the modal (MD) or by the Verb (VB). The Parsers (see Section 4.1): *DMV* (Klein and Manning 2004) ; *MST* (McDonald et al. 2005) ; *Clear* (Choi and Nicolov 2009) ; S_u (Nivre 2009) ; *N.D.* – NonDir (Goldberg and Elhadad 2010).

5.1 Analysis

The empirically preferred annotations cannot be reduced to any simple, intuitive rule. For example, they do not match simple distinctions such as the one between closed and open classes: some of the more learnable annotations select closed class tags as heads (e.g., the preposition in prepositional phrases), while others select open class tags (e.g., the noun in noun phrases). Similarly, it is also not necessarily the rightmost or the leftmost word in the structure that is preferred.

Our results indicate that the biases are substantial. Table 4 shows that the difference between the accuracies of the most learnable annotation and the least learnable annotation for each parser under the Accuracy-Learnability measure. The accuracies range between 2.5-8.3%, which correspond to 22.2-35.3% error reduction. Table 4 also shows the the average performance gain from selecting each of the three empirically preferred annotations. These gains are substantial and yield error reductions that range between 3.7-19.8%, 2.4-4.8% and 7.4-15.3% for Coordinations, NPs and PPs respectively. Moreover, the gains are additive. That is, selecting all three of the empirically preferred annotations results in a gain similar to the sum of the average gains in the individual structures.

	Struct.	*DMV*	*MST*	*Clear*	S_u	*N.D.*	Err. Red.
Avg. Per. Diff.	Coord.	1.3%	1.2%	2.1%	1.6%	0.9%	**3.7-19.8%**
	NP	1.6%	0.2%	0.3%	0.5%	0.2%	**2.4-4.8%**
	PP	2.6%	1.6%	1.1%	1.0%	0.9%	**7.4-15.3%**
Best – Worst		8.3%	3.4%	4.2%	3.4%	2.5%	**22.2-35.3%**
Avg. Per.		66.2%	90.1%	90.2%	89.2%	90.4%	—

Table 4: The average performance gain incurred by selecting the empirically preferred annotations for the VSS's for which a unanimous bias is found. The last column is the error reduction range. The last row shows the mean attachment score of each parser when averaging over all schemes. The row before shows the difference between the lowest scoring and the highest scoring scheme for each parser. Annotation abbreviations (see Section 3): Coord. – Coordinations, NP – Noun Phrases, PP – Prepositional Phrases. Parser names are taken from Table 3.

Another natural question to ask is whether there is a single scheme that receives the highest score in all settings. We find that in fact this is the case. Figure 4 shows this scheme. The obtained scheme does not exactly match any of the commonly used annotation schemes, although it closely resembles that of (Collins 1999), differing only in the annotation of noun sequences. We note that since we addressed a particular set of VSS's, the winning scheme presented here is optimal only with respect to this selection.

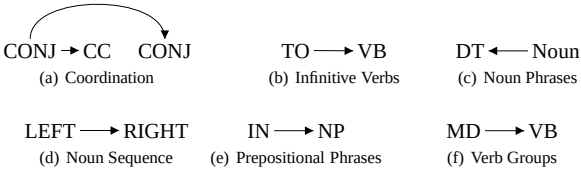

Figure 4: The scheme that receives the highest score under all settings. Annotation abbreviations are taken from Table 3.

Correlation between Settings. We aim to show that our results are independent of the setting, and can therefore be seen as reflecting underlying phenomena. The parsers and the specific learnability measures can thus be seen as proxies by which these phenomena are observed.

In each setting (i.e., parser + learnability measure), we sort the different schemes according to their learnability (a total of 2^k values per ordering). The ten different settings (5 parsers $\times$ 2 learnability measures) yield ten relative orderings. To assess their similarity we compute the Kendall rank correlation coefficient (Kendall 1938)[9] between each pair of relative orderings ($\binom{10}{2} = 45$ pairs). The coefficient receives values in $[-1, 1]$, where 1 indicates equality, 0 indicates no correlation, and -1 indicates anticorrelation. We also compute a significance p-value, which is the probability for obtaining a given correlation at random (Abdi 2007).

Results show that the relative orderings obtained in the different settings are very much in concordance. The obtained Kendall τ correlation coefficients range between $(0.46, 0.88)$. Interestingly, when excluding DMV, results are even more significant (correlation in $(0.64, 0.88)$). This corresponds to p-values smaller than 10^{-7} and smaller than 10^{-13} if we exclude DMV.

[9]This is a commonly used measure in NLP (Lapata 2006; Brody and Kantor 2011).

Relation between Learnability Measures. In order to explore the relations between the two learnability measures, we focused on pairs of orderings that use the same parser, but different learnability measures ($|P| = 5$ pairs). The Kendall τ values in this case range between (0.75, 0.82), which corresponds to p-values $< 10^{-18}$.

Despite the high correlation between the measures, the biases discovered under the Accuracy-Learnability measure are stronger than the ones discovered under the Rate-Learnability measure. This demonstrates the somewhat different perspectives obtained by using different definitions of learnability.

6 Discussion

6.1 Syntactic Selection in a Wider Context

This paper presents a methodology for syntactic selection using learnability. The use of learnability is justified both for theoretical (see Section 7) and practical reasons, as it has direct implications on parsing technology. Namely, it is advantageous to train parsers on schemes that are inherently more learnable.

In the following we define a different, simplified empirical measure for syntactic selection and show that it correlates with learnability. The proposed measure is conceptually simpler than learnability and can therefore be used to partially explain the learnability results. However, it will be argued that learnability has several advantages over it as an empirical measure for syntactic selection.

We define the *predictability* of a scheme as minus the entropy of a parent given its child (unlike learnability, *predictability* is not defined with respect to a parser). We represent a word (x) as its POS tag, and a parent ($Pa(x)$) as the conjunction of its POS tag and the direction of the parent relative to the child (left or right). Concretely (P denotes the set of POS tags):

$$predictability = -H(Pa(x)|x) =$$

$$\sum_{x \in P} \sum_{\substack{Pa(x) \in \\ P \times \{L,R\}}} Pr(Pa(x)|x) \cdot \log Pr(Pa(x)|x)$$

Intuitively, *predictability* measures how easy it is to predict a word's head. On the face of it, higher *predictability* is likely to imply higher learnability. For example, if predictability is very high (i.e., the entropy is very low), words generally determine their parents, which facilitates learning. The opposite case, when predictability is very low, occurs when given a word, any other word is equally probable to serve as its parent. It is likely that such a scheme would be hard to learn.

We repeated the experiments described in Section 4, this time using predictability instead of learnability[10]. Results show that in the three structures where a unanimous learnability bias is found, a strong predictability bias is also found. Predictability yields similar results to learnability in the infinitive verb structure as well, both showing no strong bias. However, in the two other structures results diverge. In noun sequences, predictability shows a strong bias towards the left noun, while learnability showed a weaker trend (with no unanimous bias). In verb groups, a strong predictability bias is found in the opposite direction to the non-unanimous one found with learnability.

In addition, we derive a relative ordering of the different schemes (see Section 5.1). We compare this ordering to each of the orderings obtained in the learnability experiments. The obtained Kendall τ values range between (0.38, 0.66), which corresponds to p-values $< 10^{-4}$.

[10] Note that this time there is only one setting.

Predictability is a simple measure to understand and compute. The fact that it correlates with learnability can provide a partial explanation to the learnability results. However, it has several disadvantages compared to learnability. First, learnability relates directly to parsing technology, as parsers trained on more learnable schemes are likely to obtain higher results. Second, learnability is better motivated theoretically – it has been used extensively as a deciding factor in both linguistics and cognitive science (see Section 7). Third, predictability only quantifies a specific aspect of an annotation scheme (namely the POS tag and direction of the parent relative to its child), while parsers tend to take into account many other factors. These factors are captured by learnability.

Looking at our results, we observe that while correlations between predictability and learnability orderings are relatively high (mean Kendall τ value 0.51), they are generally lower than the correlations between the different settings of our learnability experiments (mean Kendall τ value 0.67). We conclude that predictability does give partial explanation to our results, but that further research is required in order to fully comprehend why exactly are some schemes more learnable than others.

6.2 The Methodology

Our methodology is designed for deciding between several alternatives, each having equal a-priori plausibility. It is therefore applicable for deciding between alternative annotations in VSS's.

Although we compare performance against different test sets, we find the comparison meaningful. Presumably, had there been no preference to either of the annotations, the performance on all these data sets should have been equivalent. Our experiments show that this is usually not the case, and by this reveal a non-trivial property of both the parser and, in those cases where the bias is unanimous, of the structures in question.

The consistent results obtained across five parsers using two learnability measures, which are in turn consistent with the results of a parser-independent predictability experiment, demonstrate the robustness of our results. However, it is still possible that a future parser will exhibit different patterns. Such a parser would very likely be fundamentally different, in some way, from the set of parsers used in this work. Our methodology can thus be used to discover an interplay between parser families and their empirically preferred annotations, an interesting topic in its own right.

Finally, we remark that learnability cannot by itself be used as a criterion for the quality of a scheme. For example, consider the simple right-branching scheme, where each word receives the word to its right as its head. It is trivial to learn despite its inferiority as a dependency scheme. We address this issue by applying our methodology only to compare between annotations that aim to represent the same structure and that were proposed as valid dependency annotation schemes. All considered schemes are derived by combining annotations to VSS's that were proposed in the literature (see Section 3). It is exactly because of the lack of consensus with regard to these structures that applying a complementary criterion, such as learnability, is required.

7 Related Work

7.1 Varying Syntactic Structures

The exact formal manner in which syntax should be represented has been the subject of endless debates. The diversity of approaches yielded a variety of annotation schemes for encoding similar structures.

Representational variation can be seen in virtually any formalism for syntactic annotation. In the field of POS tagging, the Brown Corpus (Francis 1964), the Penn Treebank (PTB) (Marcus et al.

1993), the British National Corpus (BNC) (Aston and Burnard 1998) and the SUSANNE corpus (Sampson 1995) all proposed different schemes for representing grammatical categories. Another example is the different annotation schemes used for noun compounds (Nastase and Szpakowicz 2003; Moldovan et al. 2004). In the field of constituency annotation, (Marcus et al. 1993; Sampson 1995; Kim et al. 2003) vary in the details of their representation of English syntax. Variation in dependency annotation, the focus of this paper, was discussed in (Ivanova et al. 2012) and is described in detail in Section 3. While these examples are all taken from English, variation is found in any language for which sufficient resources are available (Zeman et al. 2012).

Many previous works addressed the difficulties imposed by the lack of established standards for syntactic representation. Jiang and Liu (2009) adapted statistical tools trained with one annotation standard to another. Other works proposed to normalize the different representations into a standard scheme (Ide and Bunt 2010; Zeman et al. 2012). Parsing evaluation is also highly affected by VSS's. Schwartz et al. (2011) suggested Neutral Edge Direction (NED), an evaluation measure for unsupervised dependency parsing that accepts more than one plausible annotation for dependency VSS's. Tsarfaty et al. (2011) suggested a new evaluation measure for supervised dependency parsing to address representational variation. The measure is based on tree edit distance. Tsarfaty et al. (2012) extended this measure for comparing between annotations from different formalisms.

The emphasis of all the above works was mainly to overcome the problems incurred by the lack of standard, and not to select the most advantageous annotation according to some empirical criterion. In contrast, other works addressed the advantages some schemes have over their alternatives, and selected a scheme which best suited their needs.

One of the motivations behind the LTH dependency scheme (Johansson and Nugues 2007) was to facilitate semantic-role-labeling (SRL). They showed that an SRL tool that used their scheme performed better than a tool that used an alternative dependency scheme. While their method provides empirical reasons for using the LTH scheme, our work has a few advantages: first, our methodology examines each VSS individually, while they only compared an annotation scheme as a whole; second, while they performed the comparison on a single (basic) SRL tool, we compared the schemes on five different parsers (four of them state-of-the-art) using two definitions of learnability. Stanford dependencies (de Marneffe et al. 2006) were also designed using empirical considerations, namely to facilitate information extraction. However, they did not attempt to propose a methodology for syntactic selection.

Nilsson et al. (2006) modified the gold standard dependency annotations of two VSS's in order to improve parsing accuracy. They were able to improve performance by training a parser on a transformed corpus, parsing, and re-transforming the induced parse. While their work evaluated against a fixed gold standard, our work provides a methodology for designing an optimal gold standard with respect to learnability considerations. Furthermore, while they experimented with a single parser[11], our experiments use five parsers of different types and two learnability measures. As a result, their findings may be parser-specific, while our consistent results reveal a property of the scheme itself. Therefore, our results are directly applicable to annotation design. Last, our work is more extensive in terms of the number of examined structures (six vs. two). Kübler (2005) and Maier (2006) conducted similar experiments in constituency parsing.

[11] They experimented with two variants of the same parser.

7.2 Learnability

The notion that simpler or more *learnable* structures should be preferred is a recurring theme, both in theoretical linguistics (Chomsky 2006; Clark 2010) and more generally in the discussion of representations in cognitive science (Chater and Vitányi 2003). In the context of language learning, learnability refers to the question of what biases are required in order to learn a language, and in particular its grammar (Pinker 1989). In formal linguistics, learnability using distributional methods has been used as an important consideration in designing the phrase structure formalism (Chomsky 2006).

In Machine Learning, the term learnability refers to the question of whether, under certain assumptions, an underlying hypothesis may be learned given sufficient training samples (prominently, PAC-learnability (Valiant 1984)).

An empirical study by Perfors et al. (2011) used learnability considerations to decide between different syntactic formalisms. This line of research bears resemblance to model selection techniques in statistics, which aim to find which *model* best explains a fixed data set. Our work takes a similar direction. However, our methodology assumes the parsers are acceptable models for the given formalism, and tries to find the most suitable *annotation* from a set of a-priori equally likely alternatives. To the best of our knowledge, no previous work has tackled a similar task.

Predictability. Previous works used information theoretic measures to quantify sentence complexity, taking into account its syntactic representation. Hale (2006) explored a similar measure to predictability in the context of context-free-grammar. Hale (2001) and Levy (2008) explored a different measure ("surprisal"). These works demonstrated that their complexity measures correlate with human judgments on sentence comprehension difficulty.

Conclusion and Perspectives

In this paper we showed that selecting between alternative syntactic representations (syntactic selection) has a substantial and predictable effect on parsing performance. We presented a novel learnability-based methodology for syntactic selection and applied it to six central dependency structures that have several alternative annotations. Our methodology produced highly consistent results, and revealed a unanimity among all parsers in three of the structures. We showed that the gain from selecting the empirically preferred annotations is both substantial (error reduction of up to 19.8%) and additive. That is, selecting all three results in an even more accurate parser.

The higher learnability of the preferred annotations can be seen as an indication for their consistency with the rest of the scheme and has direct implications for parsing performance. We therefore suggest using the preferred annotations when designing future dependency schemes.

Future work will include applying our methodology to languages other than English, in order to assess whether the biases discovered in this work generalize cross-linguistically. We also plan to apply it to deciding between alternative annotations in other syntactic formalisms (such as constituency parsing) and in other NLP tasks such as POS tagging and noun-compound annotation.

ABSTRACT
This paper introduces a method to improve supervised word sense disambiguation performance by including a new class of features which leverage contextual information from large unannotated corpora. This new feature class, *selectors*, contains words that appear in other corpora with the same local context as a given lexical instance. We show that support vector sense classifiers trained with selectors achieve higher accuracy than those trained only with standard features, producing error reductions of 15.4% and 6.9% on standard coarse-grained and fine-grained disambiguation tasks respectively. Furthermore, we find an error reduction of 9.3% when including selectors for the classification step of named-entity recognition over a representative sample of OntoNotes. These significant improvements come free of any human annotation cost, only requiring unlabeled Web-Scale corpora.

KEYWORDS: word sense disambiguation, lexical semantics, semi-supervised learning.

Proceedings of COLING 2012: Technical Papers, pages 2423–2440,
COLING 2012, Mumbai, December 2012.

1 Introduction

Supervised word sense disambiguation (*WSD*) systems often rely directly on the local contexts in which target words appear. For example, the state-of-the-art system of Zhong et al. (2008) uses features based on collocations centered on the target word. Models relying on such features do well with copious amounts of training data, but they are prone to errors when the local context of a test instance differs from local context observed during training. Consider the sentences below.

1. *The workers loaded the **port** onto the ship this morning.*
2. *She purchased a couple of bottles of **port** from the store.*
3. *The couple enjoyed their richly-flavored **port**.*

Though referring to the same sense of 'port', "a sweet dark-red dessert wine" (Miller et al., 1993), it is difficult to connect any two instances based on local context; the parts-of-speech even differ substantially. Models for disambiguation can benefit from the addition of a feature that does not rely directly on the local context.

We present a new class of features which encodes an abstraction of a word's context, rather than encoding contents of the local context itself. We refer to this new feature class as *selectors*, borrowing the term from an approach to knowledge-based (unsupervised) word sense disambiguation which uses the idea of searching for words that share the same context (Lin, 1997; Schwartz and Gomez, 2008). More precisely, selectors are words that show up in the same local context as a given instance of another word. For example, selectors for 'port' in sentence 1 might be 'bottles', 'crates', 'passengers', 'wine', 'luggage', etc. Considering that the other sentences may share some of the same selectors such as 'bottles' or 'wine', one can see how this abstraction of context to selectors can be beneficial. Figure 1 demonstrates mapping the context from one instance to selectors, which match the selectors of another instance. In this sense, it is the contexts (or word instances) that have selectors rather than the words themselves.

The contribution of this paper is the introduction of a novel and effective type of feature that improves *WSD* accuracy at no cost in human annotation. Rather than requiring more examples of labeled context to match a given test instance, we need only to match against an orders-of-magnitude-larger unlabeled set of data. Because *selectors* leverage unlabeled data, their inclusion in a supervised system constitutes semi-supervised learning.

The paper proceeds with a discussion of related work in semi-supervised *WSD* and the use of web-scale data in language processing (Section 2). Then, we present our approach to acquiring selectors as features from n-grams, and show how we translate selectors into features (Section 3). The effectiveness of selectors is evaluated within supervised word sense disambiguation classifiers over the SemEval-2007 Task 17 (Pradhan et al., 2007), Senseval 3 English Lexical Sample (Mihalcea et al., 2004), and OntoNotes 4 (Weischedel et al., 2011) (Section 4). We also test selectors as features for the classification step of named-entity recognition over a representative sample of OntoNotes. Lastly, we discuss the robustness of selectors as features by inspecting actual instances from our experimental corpus (Section 5).

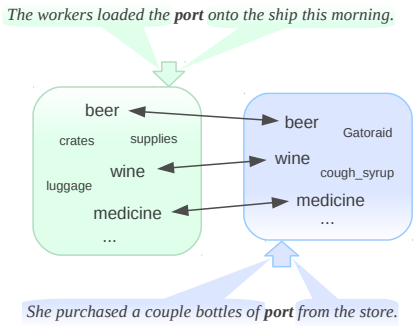

Figure 1: Word instances which do not share context can share selectors.

2 Related Work

The idea of improving a supervised classifier by utilizing unlabeled data has been investigated at different levels. For example, other approaches to disambiguation have used bootstrapped samples (Yarowsky, 1995; Mihalcea and Moldovan, 1999; Mihalcea, 2004; Pham et al., 2005), Wikipedia concepts (Mihalcea, 2007), or parallel corpora (Chan et al., 2007). Most of these approaches, which are considered semi-supervised learning (Zhu, 2008), exploit some facet of unannotated text to collect more training instances. Rather than produce more training instances, we introduce a method to leverage massive unlabeled corpora to create a richer and robust set of features.

One can contrast *selectors* with clusters of words formed via context or distributional similarity (for seminal examples see (Brown et al., 1992; Pereira et al., 1993; Lin, 1998; Schütze, 1998; Pantel and Lin, 2002)). Distributional clusters are made up of words that appear in similar contexts to each other, whereas selectors are words which show up in the specific context of a single instance. In other words, selectors are instance-specific while distributional clusters are created based on observing many instances of context. This key difference should become more clear when we present our method of acquiring selectors.

The traditional use of selectors is in knowledge-based word sense disambiguation systems, not utilizing training data. In Lin (1997), dependency relationships over a small corpus were used to find noun selectors. We previously extended this to the Web, treating context as surrounding text and introduced the ideas of acquiring selectors for additional parts-of-speech as well as for words in context in addition to the target word (Schwartz and Gomez, 2008, 2009). Similar to selectional preferences (Resnik, 1997), *selectors* essentially indicate the types of concepts expected in a given syntactic or grammatical position. In these knowledge-based approaches, disambiguation is performed by computing the semantic distance between *selectors* and senses of the target word. These approaches rely on both a knowledge source such as WordNet (Miller et al., 1993) and a semantic distance metric. In contrast, in the current approach we do not need such a knowledge source or similarity judgments, and since our approach is data-driven, selectors function as an abstraction of word instance context rather than as a list of semantically similar words. Our current goal is to get the most out of supervised training data by leveraging unannotated data via selectors (no use of a knowledge-base or similarity metrics). Consequently,

our system achieves state-of-the-art results in line with top supervised systems while our earlier knowledge-based approaches produce results in line with systems not utilizing training data.

A couple previous works have integrated unannotated data as features into supervised disambiguation systems. Dligach and Palmer (2008) used *dynamic dependency neighbors*, a feature encoding verbs with the same object, according to a dependency parsed corpus, as a given target verb in a verb WSD task. Besides our method not being limited to verbs, selectors are much more specific than dependency neighbors; They are found by matching a larger context and from a much larger, web-scale, dataset. Cárcamo et al. (2008) adapt the predominant sense method of McCarthy et al. (2004) to find the best sense choice for a word instance rather than it's most common sense over a corpus. Yuret (2007) leveraged web-scale data to acquire probability distributions of *substitutes* being within the same context as target instances. Unlike selectors which are open-ended, substitutes were chosen from an *a priori* word list derived from thesauri, and contextual part-of-speech was not considered. Additionally, the substitutes' probability distribution itself was the entire feature set, rather than used to supplement an existing feature set, and the resulting accuracies were lower than those we find with selectors.

Our approach utilizes web-scale N-grams, a source of unlabeled data which has previously been used for many other supervised lexico-semantic tasks including delimiting named entities, preposition selection, spelling correction, search query processing, adjective ordering, verb POS disambiguation, and noun compound bracketing (Downey et al., 2007; Bergsma et al., 2009; Huang et al., 2010; Bergsma et al., 2010). All of these systems utilized n-grams to find frequency information for specific n-grams. In contrast, we use the n-grams as a source for acquiring sets of lexical data (selectors), where we search with context and ask for the missing piece rather than search for a complete n-grams. We believe this is the first work to use web-scale N-grams as a source for selectors; motivation for using this source is discussed in the next section.

3 Acquiring Selectors

A selector is a word which appears in the same local context as a given instance of a *focus word*. For example, in the sentence below, with 'port' as the *focus word*, one might find selectors such as 'bottles', 'cargo', 'crates', 'wine', 'passengers', or 'supplies'.

> *The workers loaded the* ***port*** *onto the ship last night.*

More formally, for a given word instance, w_i, selectors are found based on the particular context of w_i. What defines the context may vary from syntactic or dependency relations (i.e., other nouns which are objects of the verb 'loaded') to simple sequences of tokens (e.g.,finding words that fill in the blank in "The workers loaded the ___ onto the ship last night.").

3.1 Approach

We find selectors by searching for sequences of tokens in the Google N-grams version 2, which contains 4.1 billion n-grams that were automatically part-of-speech tagged (Lin et al., 2010). The primary reason we chose web-scale N-grams as a source is because it has become difficult to get selectors via search engines.[1] Still, using web-scale n-grams for context searches has advantages: there is a decent likelihood of finding selectors for a given instance, the search

[1]The Web search engines which support wildcard queries no longer run public APIs or allow scripted access.

*Workers loaded the **port** onto the ship last night.*
workers loaded $\langle det \rangle$? ($\langle noun \rangle$+) onto
loaded $\langle det \rangle$? ($\langle noun \rangle$+) onto
($\langle noun \rangle$+) onto $\langle det \rangle$ ship last

---

*My objective was to **fight** as a mother for what I hold dearest.*
was to ($\langle verb \rangle$+) as $\langle det \rangle$
to ($\langle verb \rangle$+) as $\langle det \rangle$? mother
objective was to ($\langle verb \rangle$+)

---

*The new economy in the US depends heavily, for one thing, on a deep foundation of basic scientific research, which comes up with revolutionary **products** like genetically modified foods.*
with revolutionary ($\langle noun \rangle$+) like genetically
revolutionary ($\langle noun \rangle$+) like
($\langle noun \rangle$+) like genetically modified

---

*...which comes up with **revolutionary** products like...*
up with ($\langle adj \rangle$+) products like
up with ($\langle adj \rangle$+) products
with ($\langle adj \rangle$+) products

Table 1: Example search sequences produced for the given focus word focus word (***in bold***) and context (*in italic*).'()' surrounds the *focus word*, '?' implies optional match and '+' allows multiple matches. The bottom three examples are from our experimental corpus.

process is offline, this version of the Google N-grams provides part-of-speech information, and they have been shown helpful for other lexico-semantic tasks (Bergsma et al., 2009; Huang et al., 2010; Bergsma et al., 2010). On the downside, because the Google N-grams are at most 5-grams, the selectors can only be found using a relatively small context. – up to 4 tokens. For this first investigation of selectors as features we think this trade-off is worthwhile.

We search the n-grams by constructing 3 to 5 token sequences consisting of words or part-of-speech (*POS*) tags. Determiners, conjunctions, possessives, and symbols in the sequence are replaced with their *POS* tag, and determiners are also marked as optional if they do not begin or end the phrase. The slot of the *focus word*, the word for which selectors are being acquired, is restricted by *POS* and permitted to match multi-word phrases (taking the head-word as the selector in such cases). Examples of search sequences are given in Table 1.

Searching based on all sequences can be expensive in terms of disk IO, so the sequences are sorted such that the process can be halted once enough selectors have been found. In particular, we define four *criteria* of informative value for a given sequence seq:

1. the number of tokens in seq:
$length(seq) = \frac{|tokens(seq)|}{max\_tokens}$
2. the number of content words (noun, verbs, adjective, or adverbs):
$nvar(seq) = \frac{|nouns(seq)|+|verbs(seq)|+|adjectives(seq)|+|adverbs(seq)|}{max\_tokens}$

3. the distance from the focus word to the center: $center(seq) = 1 - \frac{|before(seq) - after(seq)|}{|tokens(seq)|}$

4. if the *focus word* is an edge of seq:
$$\neg edge(seq) = \begin{cases} 0, & \text{if focus word is at front or back} \\ 1, & \text{otherwise} \end{cases}$$

where $max\_tokens = 5$, the maximum number of tokens in a sequence, and $before$ / $after$ are the number of token before and after the focus word. The overall informative value is defined as the sum of weighted (α_i) *criteria* ($c_{1..4} = [length(seq), nvar(seq), center(seq), \neg edge(seq)]$):

$$info(seq) = \sum_{i=1}^{4} \alpha_i c_i$$

Next, we iterate through the list of sorted search sequences in order to aggregate selector(s) frequencies. During aggregation, the selector frequencies are normalized and weighted by $info(seq)$:

$$score(s) = \sum_{seq \in seqs} info(seq) * \frac{freq(s)}{\max_{s' \in sels(seq)} freq(s')}$$

where $sels(seq)$ is the set of selectors found when searching with sequence seq. This favors both selectors occurring with multiple sequences as well as those found based on a more informative context. In practice we break the aggregation loop one iteration after acquiring a soft minimum (k) of selectors to improve runtime. [2]

3.2 Selectors as Features.

We have described acquisition of selectors for an arbitrary *focus word* instance. In order to use selectors as features, we acquire selectors for all target words (words being disambiguated) and encode the top k, according to $score(s)$, as binary features. We selected $k = 50$ as well as weightings $\alpha_{1..4} = [0.2, 0.2, 0.1, 0.5]$ after cross-validating over the *training set* (defined in Section 4).

4 Experiments

We evaluate whether the *selector* class of features can benefit *WSD* classifiers above and beyond a standard set of features in a variety of datasets and situations. Supervised classifiers are trained with and without utilization of *selectors* and we record a simple accuracy of $\frac{|correct\_instances|}{|all\_instances|} * 100$ of the testing data.[3] In particular, we use support vector classifiers implemented with Scikit-learn (Pedregosa et al., 2011) with a radial basis kernel and other parameters set via 5-fold cross-validation over the training set. As a standard point of comparison, *most frequent sense* (MFS) accuracy is also reported, indicating the testing accuracy if the system always predicted the most common sense according to the training data. As often noted, state-of-the-art supervised systems often perform just above the MFS (Navigli et al., 2007; Pradhan et al., 2007).

[2] An implementation of this method is included in supplementary data.

[3] $accuracy = precision = recall$ under the standard (SemEval) definition of precision and recall for WSD, and because we attempt all instances of our samples.

4.1 Data Sets

We test *selectors* over three sense-annotated corpora. For our primary corpus, we use the SemEval-2007 Task 17: Lexical Sample (Pradhan et al., 2007) (results in sections 4.3.1 and 4.3.3). This corpus is an early selection from the Wall Street Journal portion of OntoNotes (Weischedel et al., 2011), and contains coarse-grained noun and verb senses. We also experiment over the Senseval-3 English Lexical Sample data(Mihalcea et al., 2004), containing fined-grained noun, verb, and adjective sense annotations over selections of the British National Corpus (Clear, 1993) (section 4.3.2). The inclusion of adjectives, fine-grained senses, and difference in corpus gives us a more robust evaluation of selectors. Lastly, we experiment with random samples over portions of the full Ontonotes 4.0 in order to test on out-of-domain data and to examine if selectors help for another lexico-semantic task: named-entity classification. Details about the OntoNotes test sets are included when discussing those results (sections 4.3.4 and 4.3.5).

4.2 Baseline Features

As a consistent baseline throughout our experiments, we use the same features as Zhong et al. (2008)'s state-of-the-art system, first explored by Lee and Ng (2002). These features give the best published results that we are aware of over the Wall Street Journal portion of OntoNotes, plus they are the common denominator in many high-performance supervised WSD systems (Cai et al., 2007; Chan et al., 2007; Zhong et al., 2008).

- **collocations** (*coll*). Tokens relative to the target, denoted $c_{i,j}$, starting at i; ending at j.
  1-grams: $c_{-1,-1}$, $c_{+1,+1}$, $c_{-2,-2}$, $c_{+2,+2}$,
  2-grams: $c_{-2,-1}$, $c_{+1,+2}$,
  3-grams: $c_{-3,-1}$, $c_{+1,+3}$, $c_{-1,+1}$,
  4-grams: $c_{-2,+1}$, $c_{-1,+2}$
- **parts-of-speech** (*pos*). The part-of-speech for the following words relative to the target word: $p_{-3}, p_{-2}, p_{-1}, p_0, p_{+1}, p_{+2}, p_{+3}$ (0 is the target word).
- **surrounding words** (*surr*). The bag-of-words from the current, previous, and next sentence.

4.3 Results

4.3.1 SemEval-2007

Table 2 shows the results with and without selectors over the SemEval-2007 corpus. We see that including selectors improves performance over a state-of-the-art set of features with a significant ($p < 0.01$) error reduction of 15.4%.[4] This puts our system just behind the top system participating in SemEval-2007, NUS-ML (Cai et al., 2007), which achieved an accuracy of 88.7. Moreover, we see improvements from selectors for both nouns and verbs.

Tables 3 and 4 break the results down for each word. Though it is possible for selectors to introduce noise leading to occasional errors, we see that both words with many training instances as well as those with fewer ones can benefit from selectors. We will inspect a couple instances where selectors helped prediction in Section 5.

[4] **error reduction**= $\frac{(1-acc1)-(1-acc2)}{1-acc1}$, where $acc1$ and $acc2$ represent the two accuracies.

Table 4: Classifier accuracies for each verb of the SemEval-2007 Task 17 test set.

	base	**w/ sels**	***mfs***	***tests***
noun	68.5	**72.1**	54.1	*1766*
verb	72.0	72.4	57.9	*1927*
adjective	49.4	**53.4**	54.7	*148*
all	69.4	**71.5**	56.1	*3841*

Table 5: Sense classifier accuracies without (**base**) and with the selector class of features (**w/ sels**) over Seneval-3: English Lexical Sample. (*mfs*: accuracy of classifying with the most frequent sense of the training data, *tests*: number of instances in the test set.)

4.3.2 Senseval-3

We also tested selectors as features over the Senseval-3 data(Mihalcea et al., 2004) to get a more robust idea of their impact. The instances in this sample come from a difference corpus, the British National Corpus, include fine-grained sense annotations, and a limited number of adjectives.

Examining the results in Table 5, we see an improvement from using selectors over the baseline for all three parts-of-speech. Overall error reductions is 6.9%. Selectors seem to help the most for both nouns and adjectives, but in the case of adjectives we actually see the *mfs* just outperforms the supervised systems. We suspect this is partly due to the average adjective having many more possible senses (10.2, versus 5.8 for nouns and 6.3 for verbs), and one should also keep in mind the small number of adjective examples.

4.3.3 Feature Impact Analysis

Results discussed thus far imply *selectors* are contributing information beyond that of the standard set of features. However, since selectors represent an abstraction of context and the baseline features encode various contextual information, it is possible that all information from certain baseline features is subsumed by selectors. In this experiment, we try to understand the type of information being contributed by selectors by observing accuracies when features are removed.

Table 6 shows accuracy results when building classifiers with all combinations of feature types. For these tests, we used the SemEval-2007 data set, the larger and more recent of the two previously mentioned evaluation data sets. We see a clear benefit from the inclusion of selectors across the board. Interestingly, we see that although *surr* class of features gets the system beyond the *mfs* baseline, it seems to provide more distractions than help once other features are included as well. In fact, our best results come from the combination of collocations, part-of-speech information, and selectors with an accuracy of 88.1.

4.3.4 Out-of-Domain Test Data

It is often noted that *WSD* systems perform poorly on test data from a different domain than that of the training data (Zhong et al., 2008; Agirre et al., 2010). We examine whether selectors keep their benefit when tested on out-of-domain data over a portion of OntoNotes 4.0 (Weischedel et al., 2011). We put together all occurrences of a random selection of 100 nouns and verbs over three portions of OntoNotes: The Wall Street Journal ***(WSJ)***, Xinhua New Agency ***(Xh)***, and Sinorama Magazine ***(Sr)***. The Xinhua and Sinorama corpora correspond to a different *source* of newswire data and a different *genre* (magazine) respectively. As is standard, we used

feature types	accuracy w/o sels	w/ sels	err reduc
coll	86.3	**87.9**	11.7 %
pos	83.8	**86.3**	15.3 %
surr	82.5	**86.8**	24.6 %
coll, pos	86.9	**88.2**	9.9 %
pos, surr	86.0	**87.7**	12.1 %
surr, coll	85.5	**87.4**	13.1 %
coll, pos, surr	85.7	**87.9**	15.4 %
sels alone	-	84.7	-
(***mfs***)	78.8	-	-
mean err reduc	-	-	14.5 %

Table 6: Accuracy of classifier utilizing all combinations of feature types on the SemEval-2007 Task 17 test set. **err reduc** is the error reduction when using selectors. Refer to section 4.2 for feature type identifiers.

	base	**w/ sels**	***mfs***	***tests***
WSJ	82.5	**84.3**	80.7	*166*
Xh	77.1	**78.2**	75.4	*564*
Sr	58.1	58.8	46.8	*816*

Table 7: Accuracy of the classifiers when training on the WSJ, and applying to another source of news (Xh) or another genre of text (Sr) within OntoNotes 4.

samples from sections 02-21 of *WSJ* as training, while samples from section 22 of *WSJ* plus all sections of *Xh* and *Sr* were used for testing. We decided to use OntoNotes because our main testing corpus, SemEval-2007 Task 17, is itself derived from OntoNotes, though it lacked multiple genres of text.

We see from Table 7 that *selectors* still give an improvement in the case of another *source* of newswire. When moving to a more distant domain, such as another *genre*, the improvement still exists though it is no longer significant. The difficulty of the out-of-domain task is exemplified by lower MFS values, which are still based on the most frequent sense in the training data (always WSJ in this case). The results demonstrate relative robustness across minor shifts in domain, and potential for greater success if one combined them with a domain-adaptation technique.

4.3.5 Named Entity Classification

We believe *selectors* can benefit other supervised lexical disambiguation tasks. In this experiment, we seek preliminary evidence for such a belief based on improving the classification step of named entity recognition.

In *named entity classification*, one is given a noun phrase representing an entity with its context, and one attempts to classify the named entity into a variety of classes. We build a classifier which labels entities with one of the 18 classes provided by OntoNotes. We sample 1000 randomly selected sentences from The Wall Street Journal, Xinhua, and Sinorama portions of OntoNotes. The data is divided into training and testing samples:

base	w/ sels	*mfc*	*tests*
85.0	**86.4**	20.2	259

Table 8: Named-entity classifier accuracies without (**base**) and with the selector class of features (**w/ sels**) across a random sample of the WSJ, Xh and Sr portions of OnotNotes. (*mfc*: accuracy of predicting the most frequent named entity class in training data, *tests*: number of instances in the test set.)

- The Wall Street Journal ***(WSJ)***: *sections 02 - 21(train); section 22(test)*
- Xinhua New Agency ***(Xh)***: *sections 0000 - 0209(train); sections 0210 - 0325(test)*
- Sinorama Magazine ***(Sr)***: *sections 1001 - 1059(train); sections 1060 - 1078(test)*

For the WSJ we stick with standard training and test sets, while we divide Xh and Sr corpora similarly. Out of the 1,000 randomly selected sentences across these corpora there are 2,106 total named entity instances: 1,847 training examples and 259 test examples. We find this to be a representative sample of the WSJ, Xh, and Sr portions of OntoNotes [5].

We choose our features by looking at the most common types of features used during the CoNLL-2003 Shared Task in Named Entity Recognition(Tjong Kim Sang and De Meulder, 2003), and more recent developments(Ratinov and Roth, 2009; Finkel and Manning, 2009). To the best of our knowledge state-of-the-art features have not been established for labeling all classes of Named Entities in OntoNotes, though Finkel and Manning use the three most common classes and group the others into a *misc* category.

- **character n-grams.** Character sequences of length 1 to 6.
- **case information.** Case of the first, second, and last letter, as well as an indicator for punctuation.
- **lexical information.** The target word, its base form, as well as the same collocations used in WSD: $c_{-1,-1}$, $c_{+1,+1}$, $c_{-2,-2}$, $c_{+2,+2}$, $c_{-2,-1}$, $c_{+1,+2}$, $c_{-3,-1}$, $c_{+1,+3}$, $c_{-1,+1}$, $c_{-2,+1}$, $col_{-1,+2}$
- **parts-of-speech.** The part-of-speech for the following words relative to the target word: $p_{-3}, p_{-2}, p_{-1}, p_0, p_{+1}, p_{+2}, p_{+3}$ (0 is the target word).
- **gazetteers.** Mapping of target tokens (or n-grams initiated at the target) to 31 categories based on lists downloaded from Ratinov & Roth (2009).
- **cluster membership.** Mapping of words to Brown (1992) clusters (also downloaded from Ratinov & Roth) based on these positions relative to the target word: $bc_{-2}, bc_{-1}, bc_0, bc_{+1}, bc_{+2}$.
- **selectors.** Selectors were included for the target word as in WSD.

Table 8 shows the results for named entity classification. Here, we used one classifier and many potential labels, and thus the most frequent class accuracy is very low, corresponding to the prediction of *organization* for each instance. The inclusion of selectors as features increased the accuracy of our named entity classification system, with a significant 9.3% error reduction. These results, combined with the extensive WSD tests lead us to believe that selectors can also be used successfully as features for many tasks requiring contextual information, such as *prepositional phrase attachment* or *semantic role labeling*, could also benefit from the inclusion of selectors as features.

[5]The Pearson correlation between frequencies of each entity type in our sample versus all instances are 0.982 and 0.945 for the *training* and *test* sets respectively.

bill-n.1	*bill-n.2*	*bill-n.3*	*occur-v.1*	*occur-v.2*	*occur-v.3*
bill	bill	**market**	be	go	go
it	**staff**	system	**happen**	get	**look**
legislation	system	**paper**	occur	come	**break**
system	**money**	**note**	go	have	**remove**
program	**time**	bill	**take**	**try**	**find**
law	it	**bond**	work	**lead**	get
plan	**tax**	**stock**	come	**listen**	**place**
you	**work**	**debt**	**see**	work	**keep**
measure	**rent**	**rate**	have	be	**stick**
project	**tuition**	**report**	**change**	**belong**	**stop**

Table 9: The ten most common selectors for each sense of the noun 'bill' and the verb 'occur'. Top selectors which are unique to each sense are emboldened.

5 Discussion: On the Robustness of Selectors

In the previous section we saw that adding selectors to a standard feature space increases classifier accuracy. In this section, we discuss this improvement by examining the values of features extracted for instances in the SemEval-2007 experimental corpus. Particularly, we endeavor to show that selectors contribute robustness to the *WSD* feature space through an abstraction of context that distinguishes senses of words.

The idea of abstracting context is based on the notion that contexts which realize words of similar meaning have similar selectors. Consider the selectors for senses of both words in Table 9: 'bill' and 'occur'. We see that each of the sets of selectors varies depending on the sense of each word. Furthermore, though coarse-grained, one may even infer the sense of each word by considering its most common selectors; they should be similar to the sense.

For the the supervised classifier, selectors are an encoding or abstraction of context to help identify each sense with no need for concept similarity judgments. For example, both sentences below were annotated incorrectly without selectors, but correctly with selectors.

1. *Polls show wide, generalized support for some vague concept of service, but the **bill** now under discussion lacks any passionate public backing.*
2. *Emerson, in his lecture, refers to the "startling experience which almost every person confesses in daylight, that particular passages of conversation and action have **occurred** to him in the same order before, whether dreaming or waking, a suspicion that they have been with precisely these persons in precisely this room, and heard precisely this dialogue, at some former hour, they know not when".*

For sentence 1, selectors of *bill-n.1* seem to best match the instance's local context (i.e. one can imagine inserting selectors from *bill-n.1* in place of 'bill' more easily than selectors from other senses of bill). Though the training set never contained the exact context "...but the ___ now under..", it did produce selectors which match this context. In sentence 2 the immediate context before and after the target word seem contradictory: "... action have **occurred**..." implies *occur-v.1* (to "happen or take place"), while "... **occurred** to him ..." implies *occur-v.1* (to "come to mind"). However, when considering the whole context *occur-v.2* fits best, and in fact, the selectors for this instance match with many of the most frequent selectors for *occur-v.2* such as 'belong', 'lead', 'listen', and 'try'.

5.1 Extensions

We presented evidence that selectors may benefit other lexico-semantic classification tasks in section 4.3.5. Here, we discuss a few extensions to our selector acquisition approach that we believe could bring about further improvements in accuracy. The primary reason we chose to use n-grams as a source for selectors is because the Web search engines that support wildcard search (Yahoo and Google), which is necessary for efficient selector acquisition, no longer support APIs which return all matches. However, because our n-grams were restricted to the order of 5 tokens, the size of local context is limited.

To allow one to search with larger local context, a couple more advanced approaches might be employed. One solution is to use non-wildcard Web search queries (The still-supported Microsoft API could handle this) where candidate selectors are inserted in place of the wildcard. Because this would result in an expensive number of Web queries, one could limit candidates to selectors found through the web-scale 5-grams corpora. Another idea might be to use a smaller corpus than the Web where it is practical to base selectors on grammatical or dependency relationships. A similar approach was done by Lin (1997) without supervision. One can now produce dependency parses over much larger corpora. This would allow one to focus on the important constituents in context as well as capture long distance relationships. Still, part of the attractiveness of web-scale n-grams for selectors is the simplicity. Should our n-gram selectors not contain sufficient local context, one would expect selectors to be ineffective as a type of feature. We found that is not the case.

6 Conclusion

We introduced a novel method for increasing the informative value of a supervised disambiguation set of features by leveraging large unannotated corpora to encode an abstraction of local context via *selectors*. When tested over SemEval-2007 Task 17 and Senseval-3 English Lexical Sample, we found that word sense disambiguation classifiers utilizing selectors performed significantly better than those without. The improvements from selectors come free of any annotation cost, requiring only a web-scale n-gram collection. We believe other tasks, such as *prepositional phrase attachment* or *semantic role labeling*, could also benefit from the inclusion of selectors as features.

ABSTRACT
In recent years, statistical parsers have reached high performance levels on well-edited texts. Domain adaptation techniques have improved parsing results on text genres differing from the journalistic data most parsers are trained on. However, such corpora usually comply with standard linguistic, spelling and typographic conventions. In the meantime, the emergence of Web 2.0 communication media has caused the apparition of new types of online textual data. Although valuable, e.g., in terms of data mining and sentiment analysis, such user-generated content rarely complies with standard conventions: they are *noisy*. This prevents most NLP tools, especially treebank based parsers, from performing well on such data. For this reason, we have developed the French Social Media Bank, the first user-generated content treebank for French, a morphologically rich language (MRL). The first release of this resource contains 1,700 sentences from various Web 2.0 sources, including data specifically chosen for their high noisiness. We describe here how we created this treebank and expose the methodology we used for fully annotating it. We also provide baseline POS tagging and statistical constituency parsing results, which are lower by far than usual results on edited texts. This highlights the high difficulty of automatically processing such noisy data in a MRL.

KEYWORDS: Treebanking, User Generated Content, Parsing, Social Media.

Proceedings of COLING 2012: Technical Papers, pages 2441–2458,
COLING 2012, Mumbai, December 2012.

1 Introduction

Complaining about the lack of robustness of statistical parsers whenever they are applied on out-of-domain text has almost became an overused *cliché* over the last few years. It remains true that such parsers only perform well on texts that are comparable to their training corpus, especially in terms of genre. As noted by Foster (2010) and Foster et al. (2011b), most studies on out-of-domain statistical parsing have been focusing mainly on slightly different newspaper texts (Gildea, 2001; McClosky et al., 2006a,b), biomedical data (Lease and Charniak, 2005; McClosky and Charniak, 2008) or balanced corpora mixing different genres (Foster et al., 2007). The common point between these corpora is that they are edited texts. This means that their underlying syntax, spelling, tokenization and typography remain standard, even if they slightly depart from the newspaper genre. Therefore, standard NLP tools can be used on such corpora. Now, new forms of electronic communication have emerged in the last few years,namely social media and Web 2.0 communication media, either synchronous (micro-blogging) or asynchronous (forums), and the need for comprehensive ways of coping with the new languages types carried by those media is becoming of crucial importance.

In fact, the main consequence of the *Web 2.0 revolution* is that what was formerly restricted to one's inner circle of relations has now became widely available and is furthermore seen as containing potentially the same informativeness as written broadcast productions, that have undergone a full editorial chain, and that serve, most of the time, as the basis of our treebanks. Anyway, if those unlimited stream of texts were all written with the same level of proficiency as our canonical data source, the problem would be *simply*[1] a matter of domain adaptation. Yet, this is far from being the case as shown by Foster (2010). Indeed, in her seminal work on parsing web data, different issues preventing reasonably good parsing performance were highlighted; most of them were tied to lexical differences (coming from either genuine unknown words, typographical divergences, bad segmentation, etc.) or syntactic structures absent from training data (imperative usage, direct discourse, slang, etc.). This suboptimal parsing behavior on web data was in turn confirmed in follow-up works on Twitter and IRC chat (Foster et al., 2011a; Gimpel et al., 2010; Elsner and Charniak, 2011). They were again confirmed during the SANCL shared task, organized by Google, aimed at assessing the performances of parsers on various genres of Web texts (Petrov and McDonald, 2012).

Needless to say, such observations are likely to be even more true on web data written in morphologically rich languages (MRLs). These languages are already known to be arguably harder to parse than English for a variety of reasons (e.g., small treebank size, rich inflexion, free word order, etc.) exposed in details in (Tsarfaty et al., 2010). However, a lot of progress has been made in parsing MRLs using, for examples, techniques built on richer syntactic models, lexical data sparseness reduction or rich feature set. See (Tsarfaty and Sima'an, 2008; Versley and Rehbein, 2009; Candito and Crabbé, 2009; Green and Manning, 2010) to name but a few. The questions are thus to know: (1) to what extend MRL user generated content is *parsable*? and (2) more importantly, what is needed to fill that performance gap?

To answer question 1, we introduce the first release of the French Social Media Treebank, a representative gold standard treebank for French user-generated data. This treebank consists in around 1,700 sentences extracted from various types of French Web 2.0 user generated content (Facebook, Twitter, video games and medical board). This treebank was developed independently from the Google Web Treebank (Bies et al., 2012), the treebank used as development and test data for the above-mentioned SANCL shared task. In order to get first insights

[1] Cf. (McClosky et al., 2010) for numerous evidences of the non-triviality of that task.

into question 2, we provide a first set of POS tagging and parsing results using state-of-the-art systems trained on the French Treebank (FTB, Abeillé et al. (2003)), using our treebank as an evaluation corpus. These results show how difficult it is to process French user-generated data: for example, parsing results range from an astoundingly low 39.11% of labeled brackets F-score for the noisiest type of texts to 71-72% for better edited web parts — to be compared with the 86-89% regularly obtained on the FTB.

In the remaining of this paper, we first describe how we built the French Social Media Bank and the underlying motivations; we then introduce our annotation scheme which is based on the French Treebank (Abeillé et al., 2003) guidelines but extends it in many ways, due to the specificities of user-generated content. Next, we describe our annotation methodology, including the pre-processing tools that we developed and used, which were specifically adapted to deal with noisy texts. Finally, we discuss the results of baseline evaluation experiments on POS tagging, including results when using a dedicated wrapper for dealing with noisy texts, and constituency parsing. Since our tools were only trained on the FTB, which means that our results are baselines for future work based on our new French Social Media Bank.

2 Motivation and Corpus

As its English counterpart, the French web 2.0 generates a virtually unlimited stream of textual data. This term covers a wide range of practices, among which we decided to focus on microblogging (FACEBOOK and TWITTER) and on two types of web forums: one dedicated to general health issues for a wide public audience, DOCTISSIMO and one centered around video games issues (platform, help centers), JEUXVIDEOS.COM.[2] As we said in the introduction, we want to use these corpora to evaluate how difficult it is to parse raw user generated content in French and establish a realistic baseline using techniques we have successfully applied on well-written French texts.

To this end, we selected our corpora by direct examination through various search queries and ranked the texts according to our perception of how far they were from the French Treebank style (see below for details). We further added some very noisy texts to serve as a stress test for French statistical parsing. Table 1 presents some properties of our main corpora.

	# sent.	# tokens	avg. Length	std dev.
DOCTISSIMO	771	10834	14.05	10.28
high noisiness subcorpora	36	640	17.78	17.63
other subcorpora	735	10194	13.87	9.74
JEUXVIDEOS.COM	199	3058	15.37	14.44
TWITTER	216	2465	11.41	7.81
high noisiness subcorpora	93	1126	12.11	8.51
other subcorpora	123	1339	10.89	7.20
FACEBOOK	452	4200	9.29	8.17
high noisiness subcorpora	120	1012	8.43	7.12
other subcorpora	332	3188	9.60	8.49

Table 1: Corpus properties

Measuring noisiness In order to quantitatively corroborate our intuitions concerning the level of noise in our corpora, and for measuring their various levels of divergence compared to

[2] `http://facebook.fr`, `https://twitter.com` (automatically configured to provide French tweets first based on IP address geo-localization), `http://forum.doctissimo.fr/` and `http://www.jeuxvideo.com/`

the French Treebank (Abeillé et al., 2003), we defined an ad-hoc *noisiness* metrics. It is simply defined as a variant of the Kullback–Leibler divergence[3] between the distribution of trigrams of characters in a given corpus and the distribution of trigrams of characters in a reference corpus.[4] As can be seen from Table 2, to which we added scores for the FTB dev and test sets for comparison purposes, our intuitions are confirmed by this metric. It shows that we cover various levels of noisiness, and that our reference corpus actually diverges more from the subcorpora that we have tagged as particularly *noisy*. As we shall see below, we have used this information for deciding for each subcorpus whether to pre-annotate it in a standard way or using a dedicated noise-tolerant architecture described in section in Section 5.1.

	noisiness score
DOCTISSIMO	0.37
high noisiness subcorpora	1.29
other subcorpora	0.31
JEUXVIDEOS.COM	0.81
FTB DEV	0.03
FTB TEST	0.003

	noisiness score
TWITTER	1.24
high noisiness subcorpora	1.46
other subcorpora	1.08
FACEBOOK	1.67
high noisiness subcorpora	2.44
other subcorpora	1.30

Table 2: Noisiness scores computed on tokenized version of the various sub-corpora. The (tokenized) FTB training set is used as a reference.

2.1 Corpus Overview

In this section we briefly introduce our corpora. All but the JEUXVIDEOS.COM corpus were collected in two phases: A first one dedicated to a light study of their contents (lexical differences, required level of preprocessing, etc.). At first glance, they seemed almost too edited and almost *too easy* for our parser. So in a second phase, we decided to look explicitly for texts harder to read and understand for average French speakers. We used French slang words in our search queries, including *verlan*[5] words, as well as urban youth idiomatic constructions such as *grave*[6] or *sa race*[7]. This lead to subcorpora that we found noisier, as was confirmed by the above-described metrics (see Table 2). In the case of the DOCTISSIMO part, we gathered texts from a forum dedicated to sexual intercourse problems between young adults. This choice was not without causing ethical concerns but given the fact that all private mentions were of course anonymized and all explicit references were filtered out, we ended up with 50 extremely noisy sentences, but greatly diverging from the newswire genre, and thus extremely

[3]It differs from a standard Kullback–Leibler distance because we apply a preliminary pre-processing to the corpora involved: (i) URLs, e-mail addresses, Twitter hashtags and mentions are removed, (ii) all characters that do not belong to an extensive list of characters that might be used in French sentences are replaced by a unique "non-standard character," (iii) non-content sentences are ignored (e.g., tweet headers such as *Firstname Lastname @firstnamelastname*).

[4]Preliminary experiments on character bigrams and 4-grams have shown that the former are not informative enough and the latter lead to similar results than with trigrams. We also tried comparing distributions of tokens. Correlation with both intuition and parsing accuracy prove similar to that obtained with character 3-grams. However, token-based distribution divergences are less adequate for several reasons, among which: (i) correctly spelled unknown words affect more heavily token distributions than character-based distributions, whereas they should not affect the noisiness measure (e.g., they have a limited impact on tagging and parsing accuracy); (ii) character trigram distributions are less sparse than token distributions; (iii) there are more character trigrams than tokens in a sentence. Put together, the two last reasons show that a sound noisiness score on small corpora, or even at the sentence level, is more likely to be sound when working on character trigrams than on tokens.

[5]Very common French slang words where syllables are inverted to form new words which can in turn be *verlanized*. For instance, *arabe* 'arabic' is turned into *beur* which has been inverted again into *rebeu*.

[6]Post or pre-verbal intensifier adverb. *J'ai adoré grave!*, similar in meaning and style to *I totally enjoyed it!*.

[7]Post-verbal intensifier adverbial phrase, with the same usage as "one's a.. off."

interesting to evaluate our parsing chain.
Let us now describe and give examples for the various extracted subcorpora.

JEUXVIDEOS.COM [8] We collected data from 4 threads: *Call of Duty: Modern Warfare 3©*, *PC*, *Xbox 360©*, *Wii©* and *Linux*. Apart from spelling errors often involving phonetic spelling, which is found in all our corpora, this corpus is interesting because of the frequent use of English words, if not phrases, and a highly specialized lexicon.
In the examples below, the first line reproduces the original text, the second line is a standardized French version and the third line, an English translation attempt.

(1) a. Ces pas possible déjà que battelfield a un passe online
Ce n'est pas possible, Battlefield a déjà un pass en ligne
It's not possible, Battlefield already has an online pass

b. Si y'a que Juliet &Zayn qui sont co' sur le RPG,et qui font leur vie tranquilles
Si, il n'y a que Juliet et Zayn qui sont connectés sur le jeux de rôle et qui font leur vie tranquilles
Only Juliet and Zayn are connected on the RPG and are quiet doing their own business

DOCTISSIMO This corpus is made of two parts, each focusing on a different subtopic concerning birth control: patch birth control and pregnancy test related questions. These topics are populated by women of different ages and with different writing styles. The latter one being filled by younger women, the writing style is somewhat more sloppy. Moreover, as mentioned above, we added 50 extremely noisy sentences from the sexual intercourse section.

(2) a. pt que les choses ont changé depuis ?
Peut-être que les choses ont changé depuis ?
Maybe things have changed since then?

b. lol vu que 2-3 smaine apres qd jai su que j'etai enceinte jetai de 3 semaine.....
lol, vu que 2-3 semaines après, quand j'ai su que j'étais enceinte, je l'étais de 3 semaines....
Lol, given that 2-3 weeks later, when I learned I was pregnant, I was for 3 weeks...

c. car je ne me senté pa desiré, pa aimé, pa bel du cou, g t pa grd chose en fet.
Car je ne me sentais pas désirée, pas aimée, pas belle du coup, je n'étais pas grand chose en fait.
Because I didn't feel desired, nor loved, thus not beautiful, I wasn't much actually.

TWITTER This corpus is made of two parts: the first one focuses on news events of late November 2011.[9] Because all these tweets seemed to originate from semi-professional writers (mostly bloggers, journalists, politically engaged people), we built a second part with genuine non edited text. We used a list of keywords to gather such tweets and selected a balanced subset of those, as far as the style of writing is concerned.

(3) a. Je soupçonnes que "l'enfarineuse" était en faite une cocaineuse vu la pêche de #Hollande ce soir à #Rouen.
Je soupçonne que l'enfarineuse était en faite une cocaïneuse vu la pêche de #Hollande ce soir à #Rouen.
I suspect that the "flouring-lady" was actually a cocaïn-lady given the energy of #Hollande this night at #Rouen.

[8] Collected on November 9, 2011.

[9] An incident involving the left-wing candidate to the French presidency election, a so-called French hidden son of Adolf Hitler, and the then new right-wing election motto.

b. @IziiBabe C mm pa élégant wsh tpx mm pa marshé a coté dsa d meufs ki fnt les thugs c mm pa leur rôle wsh
Ce n'est même pas élégant voyons, tu ne peux même pas marcher à coté de sa petite amie qu'ils font les voyous, ce n'est même pas leur rôle voyons.
It is not even elegant. One cannot even walk besides his girl friend, they already start bullying people. It is not even their role.[10]

FACEBOOK This corpus was built using publicly available comment threads on public profiles, with a focus on relatively known reality TV pseudo-artists known for their personal usage of French mixed with English. More texts were added using queries based on common first names (Sophie, Romain) and some French public personalities . One of the difficulties of FACEBOOK lies in the varying usage of the displayed login name in comments: it can either be part of the sentence (e.g., "[Spiderman] is tired") or not (e.g., "[Spiderman] I'm tired"). We decided to systematically keep these logins. We leave it to a post-processing step to remove them if appropriate. Note that the noisiest part of this corpus was not taken into account while adapting our POS tagger as described below.

(4) a. L' Ange Michael vraiment super conten pour toi mé tora plus grace a moi tkt love you !
L'Ange Michael: (Je suis) Vraiment super content pour mais tu auras plus grace à moi. Ne t'inquiètes pas. Je t'aime !
The Angel Michael: (I am) Really very happy for him but you'll get more because of me. Don't worry. I love you!

b. Afida: Viens on se check dans la vibes du moove pour voir comment on peut faire la hype à Hollywood avec Jane et Bryan
Afida: n/a
Afida: Come on, we'll check in into the moove's vibe to see how we can be hip in Hollywood with Jane and Bryan

3 Linguistics of user generated content

It is important to note that the aim of our work is to provide a sample of user-generated texts that are particularly difficult to parse for any parser based on an edited text treebank. It does not correspond to an single homogenous domain, although some specificities of user-generated content are found across various types of web data. Moreover, in some cases, and most notably TWITTER, such data include both linguistic content and media-specific meta-language. This meta-language (such as TWITTER's "RT" ("Retweet"), at-mentions and hashtags) is to be extracted before parsing *per se* or other types of linguistic processing. In this work, we focused on the linguistic content. Therefore, we deal with meta-language tokens only when they are embedded within or adjacent to purely linguistic content (e.g., the tweet itself, provided it consists of one or several sentences).

Prevalent idiosyncrasies in user generated content can be characterized on two axes: one which can be roughly describe as "the encoding simplification axis" which covers ergographic (1) and transverse phenomena (2) and the other "sentiment expression axis" which cover phenomena, qualified below as marks of expressiveness (3), emulating the same goal as sentiment expressed through prosody and gesture in direct interaction.

1. **Ergographic phenomena**, that is phenomenon aiming at reducing the writing effort, perceived as first glance as genuine misspell errors, cover in fact such a various set

[10]The translation is most certainly not accurate as even the original text is barely understandable for us.

of strategies it can be seen as a simplification of the encoding. Besides obvious typos, such as letter inversion[11], errors in letter doubling[12], wrong present participle[13] and so on, misspellings can be hard to categorize as such if they result in simpler word forms. This is why we include this category in the following list of phenomenon even if its intentionality is not always attested.

Phenomenon	Attested example	Standard counterpart	Gloss
a. Diacritic removal	*demain c'est l'***ete**	*demain c'est l'été*	'tomorrow this is summer'
b. Phonetization	*je suis* **oqp**	*je suis occupé*	'I'm busy'
c. Simplification	*je* **sé**	*je sais*	'I know'
d. Spelling errors	*tous mes* **examen** **son** *normaux*	*tous mes examens sont normaux*	'All my examinations are normal'

To this list we can also note the somewhat frequent omission of copula verbs and more generally different forms of elision (the subject pronoun, the negative adverb "ne"). Although not strictly lexical, this omission results also in less writing efforts. This is also noted in the Google Web Treebank where they compare this tendency in user generated content English to pro-drop languages' clitic elision.

2. **Transverse phenomenon: Contractions and typographic diaeresis.** Some phenomena can affect the number of tokens, compared to standard French, either by replacing several standard language tokens by only one, which we shall call a *contraction*, or conversely by splitting one standard language token into several tokens, called *typographic diaeresis*. Such phenomena are frequent in our corpora, and they need a specific annotation scheme (cf. Section 4). Note that the resulting non-standard tokens might be homographs of existing words, bringing more ambiguities if not properly analyzed.

   Contractions are way more diverse than in standard French (as instanced in the FTB). The only contractions that exist in standard French involve the prepositions *à* and *de* when followed by the definite article *le(s)* or the (rare) relative pronoun *le(s)quel(s)*. For instance, *à les* 'to the$_{\text{PLUR}}$' mandatorily becomes *au*.
   Within the FRENCH SOCIAL MEDIA BANK, we found sequences such as: (i) contraction between a subject clitic, a verbal form and a negation particle (e.g., *lapa* for *elle n'a pas*, 'she has not') ; (ii) contraction of interrogative verbal forms (e.g., *atu* for *as-tu*, 'have you') ; (iii) contraction and apocope of word compounds (e.g., *nimp* for *n'importe quoi*, 'rubbish'); (iv) contraction of determiners and nouns (e.g., *lesprit* for *l'esprit*, 'the spirit') and (v) contraction of object relative pronouns (or subordinate conjunction) and subject clitic (e.g., *qil* for *qu'il*, literally 'that he').

   Typographic diaeresis can be illustrated by *c a dire*, where these three tokens stand for the standard one-token conjunction *c'est-à-dire* (standing for "that is" or "namely"). It can also happen on top of a presumably already contracted token (e.g., *c t* for *ct/c'était*,'it was'). Note that many contractions and typographic diaeresis are built around a verb which is prefixed by a clitic. Therefore such contractions can project function labels and most of the time are the head of the sentence. Their mishandling can therefore propagate errors way beyond their immediate morpho-syntactic context and thus impacts parser performance very strongly.

[11] As in *J'ia* instead of *J'ai*/'I have'.
[12] e.g., *Dévelloppement* instead of *développement*/development
[13] e.g., "-ent" instead of "-ant"/ing, which are pronounced the same.

3. **Marks of expressiveness**
   Our treebank focuses in providing a sample of French Social Media web data, therefore most of its content describe dialogs and various forms of interaction between users through social media interface. Lacking ways of expressing sentiments, irony or anger through prosody and gesture, users deploy a wide range of strategy to add another dimension to their text stream. Most of them are evident, like graphical stretching, overuse of strong punctuation marks (as in "BEST. MOVIE. EVER." or "!!!!Greaaat!!!), abuse of emoticons, sometimes used as a verb (e.g., *Je t'<3* for *Je t'aime*,'I love you') or inside usernames, mixing between lowercase and uppercase and so on. Some are more anecdotal and tied to the particular type of software used to support a web forum, which allows the inclusion of url pointing to an animated picture, itself used to replace an emoticon. Needless to say that such urls add a considerable amount of noise in web forum texts. We list the main cases of such phenomenon in the table below.

Phenomenon	*Attested example*	*Standard counterpart*	Gloss
e. Punctuation transgression	*Joli !!!!!!*	*Joli !*	'nice!'
f. Graphemic stretching	*superrrrrrrrr*	*super*	'great'
g. Typographic transgression	*N* *U* *L*	*nul*	'bad'
h.Emoticons/smileys	*:-),<3*	–	–

Obviously the main effect of those different writing artifacts is to considerably increase the level of unknown words (compared to a treebank). More importantly, the new morphology brought by the those phenomenon complicates any processing based on regular unknown word identification through suffix analysis.
However, our general annotation strategy consists in staying as close as possible from the French Treebank guidelines (Abeillé et al., 2003) in order to have a data set as compatible, as much as possible, with existing resources.

4 Annotation scheme

In order to obtain evaluation treebanks compatible with parsers trained on the FTB, we have used as basis the FTB annotation scheme and followed as much as possible the corresponding annotation guidelines for morphology, syntagmatic structure and functional annotation (Abeillé et al., 2003). More precisely, we started from a slight modification of this annotation scheme, referred to as the FTB-UC and added specific guidelines for handling idiosyncrasies user-generated content corpora.

4.1 FTB-UC vs. FTB

We targeted the annotation scheme of the FTB-UC (Candito and Crabbé, 2009), that was obtained by automatic modification of the FTB. The modifications with respect to the orignal FTB concern the tagset, the standardization of preposition and complementizer projections, and multi-word units:

- Multi-word units are very frequent in the FTB: 17% of the tokens belong to a compound. Compounds range from very frozen multi-word expressions like *y compris* 'including' (literally 'there included') to named entities. They include syntactically regular compounds with compositional semantics, such as *loi agraire* 'land law', that are encoded

as compounds because of a non-free lexical selection. These syntactically regular compounds tend to be inconsistently encoded in the FTB.[14] Further, the FTB includes "verbal compounds" that are potentially discontinuous, which provoke variable annotations. In the FTB-UC, these syntactically regular compounds are automatically mapped to a regular syntagmatic representation. We followed this rule for the annotation of the French Social Media Treebank. This has the virtue of uniformity, but clearly requires further treatment to spot clear cases of compounds (with non compositional semantics).

- Tagset: the tagset includes 28 POS tags —originally tuned by Crabbé and Candito (2008) to optimize parsing—, which are a combination of one of the 13 coarse-grained categories and other information that is encoded in the FTB as features, such as verbal mood information, proper versus common noun distinction, wh-feature, etc.
- Complementizers and prepositions: we annotate so that prepositions project a PP independently of the category of their object, contrary to the FTB's guidelines, in which prepositions with nominal objects project a PP, but those with infinitival objects don't. Further, we systematically use a sentential phrase as sister node to complementizers, contrary to the flat structure of the FTB.

Other notable additions to the annotation scheme concern the non-terminal tagset to which we added the FRAG label. It concerns phrases that cannot be syntactically attached to the main clause of a syntactic unit, e.g., mostly salutations, time stamp, meta sentential marks of emotion (emoticons, strong interjections). It also covers the case of usernames, at-mentions, and URL appended to a post/sentence (cf. FACEBOOK sentence 4a).

4.2 Additional extensions

A first extension needed for dealing with our data was to add two new POS tags, namely *HT* for TWITTER hashtags and *META* for meta-textual tokens, such as TWITTER's "RT". Note that TWITTER at-mentions as well as URLs and e-mail addresses have been tagged *NPP*. The rationale for this is to remain consistent with our tagging and parsing models trained on the FTB, which do not contain such tokens. This constitutes the main difference with other works on user-generated data.

However, the main extensions we added to the FTB annotation scheme are related to contraction and typographic diaeresis phenomena described in Section 3. The way we annotate (and automatically preannotate) such sequences is illustrated in Table 4. Let us now provide a few more details on each of these two cases.

Contracted tokens are associated with a combined POS tag which lists the sequence of each underlying words' tag. Let us illustrate this on *qil*, a non-standard contraction for *qu' il*. At least in some contexts, the tokens in the standard version *qu' il* would have been tagged respectively *CS* and *CLS*. In such contexts, the non-standard contracted token *qil* is tagged *CS+CLS*. Table 3 lists all such compound tags occurring more than twice in the treebank (37 more remaining).In some cases, such contractions involve two underlying forms, one being a verb and the other an argument of the verb (e.g., *jai* for *j' ai* 'I have'). In such cases, function labels are associated directly with the contracted token.

On the other hand, in cases of typographic diaeresis, the category of the multi-token standard counterpart is given to the last token, all others receive the special tag *Y*. Taking *c a dire* as an

[14] For instance *pays industrialisés* (*industrialized countries*) appears twice as a compound and 41 times as two words; *taux d'intérêt* (*interest rate*) appears 80 times as a compound and 25 times as two words.

Compound tag	Tag occ.	Attested example	Standard counterpart	Gloss
CLS+V	54	*c*	*c' est*	'it is'
ADV+CLO	12	*ni*	*n' y*	'(neg. adv.) (loc. clitic)'
CS+CLS	12	*qil*	*qu' il*	'that it/he'
CLS+CLO	11	*jen*	*j' en*	'I (gen. clitic)'
CLO+V	9	*ma*	*m' a*	'me$_{\text{dative}}$ has'
DET+NC	9	*lamour*	*l' amour*	'the love'
ADV+V	7	*non*	*n' ont*	'(neg. adv.) have$_{\text{3rd plur}}$'

Table 3: Non-standard compound tags occurring at least 3 times.

example, which stands for the coordination conjunct *c'est-à-dire*, the first two tokens is tagged *Y* and *dire* is tagged *CC*. Note that this is consistent with the way such cases are annotated in the Google Web Treebank.[15]

Note that both phenomena can appear together. This is the case for example with *c t* instead of *c' était* 'it was' (tag sequence: *CLS V*): both letters *c* and *t* are used phonetically — as in using *U* for *you* in English — and sound like the two syllables of *c'é* and *tait*. Therefore, mapping *c* to *c'* and *t* to *était* is not adequate. In this case, we consider that a contraction followed by an typographic diaeresis has occurred, and associate *c* with the tag *Y* and *t* with *CLS+V*.

5 Annotation Methodology

We built manually validated treebank following a now well established methodology: we first defined a sequence of annotation layers, namely (i) sentence splitting, tokenization and POS tagging, (ii) syntagmatic parsing, (iii) functional annotation. Each layer is annotated by an automatic preprocessing that relies on previously annotated layers, followed by validation and correction by human annotators. At each step, annotators were able modify the choices made at previous stages. Our methodology is summarized as follows and detailed section 5.1:

- Segmentation, tokenization and POS tagging followed by manual validation and correction by one expert annotator.
- Constituency parsing followed by manual validation and correction by two annotators followed by an adjudication step.
- Functional annotation followed by manual validation and correction by two annotators followed by and adjudication step.

5.1 Pre-annotation strategies for the tokenization and POS layers

As mentioned above, we used two different strategies for tokenization and POS pre-annotation, depending on the noisiness score.

For less *noisy* corpora (those with a noisiness score below 1), we used a slightly extended version of the tokenization and sentence splitting tools from our standard FTB-based parsing architecture, Bonsai (Candito et al., 2010). This is because we want to have a tokenization that is as close as possible from the principles underlying the FTB's tokenization. Next, we used the POS-tagger MORFETTE (Chrupała et al., 2008) as a pre-annotator.

For corpora with a high noisiness score, we used a specifically developed pre-annotation process. This is because in such corpora, spelling errors are even more frequent, but also because

[15] In the Google Web Treebank, the counterpart of our tag *Y* is the tag *GW*.

the original tokens rarely match sound linguistic units, as can be seen on the example in Table 4 taken from the DOCTISSIMO file with the highest noisiness score. The idea underlying this pre-processing is to wrap the POS tagger (in this case, MElt) in such a way that it actually has to tag a sequence of tokens that is as close as possible to standard French, or, rather, to its training corpus (in this case, the FTB). Hence the following process, illustrated on a real example in Table 4:

1. We first apply several regular-expression-based grammars taken from the SxPipe pre-processing chain (Sagot and Boullier, 2008) for detecting smileys, URLs, e-mail addresses, Twitter hashtags and similar entities, in order to consider them as one token even if they contain whitespaces.
2. Next, we use the same tokenizer as for less *noisy* corpora.
3. We apply a set of 327 rewriting rules that were forged as follows: first, we extracted from our development corpus (all subcorpora but for the *noisy* Facebook subcorpus) *n*-gram sequences involving unknown tokens or occurring at an unexpectedly high frequency; then we manually selected the relevant ones and provided them manually with a corresponding "correction". The number of "corrected tokens" obtained by applying these rules might be different from the number of original tokens. In such cases, we use 1-to-*n* or *n*-to-1 mappings. For example, the rule *ni a pa* → *n'␣y a pas* explicitely states that *ni* is an amalgam for *n'* and *y*, whereas *pas* is the correction of *pa*.
4. We use the MElt tagger (Denis and Sagot, 2009), trained on the FTB-UC and the Le*fff* lexicon (Sagot, 2010), for POS-tagging the sequence of corrected "tokens".
5. We apply a set of 15 generic and almost language-independent manually crafted rewriting rules, originally developed for English data (see below), that aim at assigning the correct POS to tokens that belong to categories not found in MElt's training corpus, i.e., the FTB; for example, all URLs and e-mail addresses are post-tagged as proper nouns whatever the tag provided by MElt; likewise, all smileys get the POS for interjections.
6. We assign POS tags to the original tokens based on the mappings between corrected POS-tagged tokens and original ones, and following the guidelines given in section 4.2. If a unique corrected token is mapped to more than one original tokens, all tokens but the last one are assigned the tag *Y*, and the last one receives the tag of the unique corrected token. If more than one corrected tokens are mapped to one original token, it is assigned a tag obtained by concatenating the tags of all corrected tokens, separated by the '+' sign. If the mapping is one-to-one, the POS tag provided by MElt for the corrected token is assigned to the corresponding original token.

This architecture is now available as part of the MElt distribution. It was also applied on English web data in the context of the SANCL shared task on parsing web data (Petrov and McDonald, 2012), with state-of-the-art results (Seddah et al., 2012).

5.2 Annotation strategy for constituency and functional annotation

Parse pre-annotation was achieved using a state-of-the-art statistical parser trained on the FTB-UC, provided with the manually validated tagging. The parser we used was the Berkeley parser (Petrov and Klein, 2007) adapted to French (Crabbé and Candito, 2008). Note that when the validated pos tags were discarded by the parser, in case of too many unknown word-pos pairs, those were reinserted.
To assess the quality of annotation, we calculated the inter annotator agreement using the

Original tokens	Gold corrected "tokens"	Automatically corrected and POS-tagged "tokens"	POS tags automatically assigned to the original tokens	Manually corrected POS tags for the original tokens

Table 4: Gold and automatic correction and POS tags for the following sentence extracted from the DOCTISSIMO file with the highest noisiness score 'Forplay have disappeared for at least 6 months, that is there is almost none.'

Parseval F-measure metric between two functionally annotated set of parses. Agreements range between 93.4 for FACEBOOK data and 97.44 for JEUXVIDEOS.COM (Table 5) and are on the same range than the DCU's Twitter corpus agreement score (Foster et al., 2011a). Similarly to that corpus, the disagreements involve fragments, interjections and the syntactic status to assign to meta-tokens elements. We note that our agreement scores are higher than those reported in other out-of-domain initiatives for French (Candito and Seddah, 2012). This small annotation error rate comes from the fact that the same team annotated both treebanks and was thus highly trained for that task. Maybe more importantly, social media sentences tend to be shorter than their edited counterparts so once POS tagging errors are solved, the annotation task is made relatively easier.

6 Preliminary experiments

Experimental Protocol In the following experiments, we used the FTB-UC as training data set, in its classical settings (test set: first 10%, dev set: next 10% and train set: the remaining.), see (Candito et al., 2009; Seddah et al., 2009) for details.

POS tagging experiments We have conducted preliminary evaluation experiments on the MElt POS-tagger(Denis and Sagot, 2009), used as such or within the normalization and correction wrapper described in the previous section. In Table 6, we provide POS-tagging accuracy results over the various subcorpora, following the DEV/TEST split described above. The results indicate that using the normalization and correction wrapper leads to significant improve-

ments in POS tagging accuracy. One can note that our accuracy results on standard TWITTER subcorpora are similar to the figures reported by Foster et al. (2011a) on English TWITTER data, although these figures are obviously not directly comparable, as they concern different languages using different tagsets. Another interesting observation is that these accuracy results are correlated with the noisiness metrics defined above.[16]

Baseline statistical parsing experiments In addition to the POS tagging experiments which showed that performance could greatly be improved using our normalization and correction wrapper, we performed a set of baseline experiments on the raw (tokenized) corpora using the PCFG-LA parser of Petrov et al. (2006) adapted to handle French morphology by (Crabbé and Candito, 2008). We used the PARSEVAL metrics applied to all sentences. Note that full scale experiments aimed at getting optimum parsing performance on this data set are out of the scope of this paper. We instead insist on providing baseline results, setting out a lower bound which assesses the difficulty of French User generated content parsing.
As expected, the results[17] provided in Table 7 show that there exists a large room for improvements. Interestingly, our user generated content data set seems even more difficult to parse than French biomedical data (67.79% vs 81.25% of F_1 score, on the Emea French test set for sentences of length lesser than 41), known to contain a high amount of unknown words and unusual phrase structures (Candito et al., 2011). Surprisingly, our parser performs poorly on FACEBOOK data, more than it does on TWITTER. In order to test their similarity, we can compare the respective noisiness scores of their subcorpora (FACEBOOK with respect to TWITTER = 1.42, TWITTER with respect to FACEBOOK 0.85). This shows that TWITTER data are more homogeneous than their FACEBOOK counterparts. Part of the reason lies in the inner nature of those social media: TWITTER is a live micro blogging platform, meaning that the content for a given trending topic shows fewer lexical divergences in a very short amount of time, whereas FACEBOOK public post are more distributed over time and posters.

The next step will involve collecting large unlabeled corpora to perform experiments with self-training techniques (McClosky and Charniak, 2008; Foster et al., 2011b) and unsupervised

[16]Simple linear regressions lead to the following results: without the normalization and correction wrapper, the slope is -4.8 and the correlation coefficient is 0.77; with the wrapper, the slope is -7.2 with a correlation coefficient as high as 0.88 (coefficients of determination are thus respectively 0.59 and 0.77).
[17]For convenience, we provide also baseline results on the FTB, see (Candito and Seddah, 2010).

Table 7: Baseline parsing results split by sub corpora and noisiness level

word clustering within a PCFG-LA framework. Indeed, we have successfully applied these techniques for French out-of-domain parsing (Candito et al., 2011), as well as for parsing *noisy* English web data (Seddah et al., 2012). On the longer term we intend to apply our normalization and correction module before parsing. The parser will then be provided with corrected tokens, closely matching our regular training data, instead of unedited ones. This will compensate the lack of user generated content large unlabeled corpora, still lacking for French.

7 Conclusion

As mentioned earlier, the *French Social Media Bank* shares with the Google web bank a common will to extend the traditional treebank domain towards user generated content. Although of a smaller scale, it constitutes one of the very first usable resources to validate social media parsing and POS tagging, among the DCU Twitter and football BBC forums treebank (Foster et al., 2011a,b) and the Twitter data set from Gimpel et al. (2011). Moreover, it is the first set of syntactically annotated data for Facebook public web text.

Regarding the Google web bank, the way annotation guidelines had to be extended to deal with user generated content is largely consistent between both treebanks. However, our treebank differs from the Google Web Treebank in several aspects. First, French not only has a morphology richer than English, entailing a tedious disambiguation process when facing *noisy* data. Although the first version of our treebank is smaller than the Google Web Treebank, it includes richer annotations (compound POS, corrected token form of contractions) and includes subcorpora exhibiting a very high level of noise.

To conclude, we presented a new data set devoted on French user generated content. We proposed a first round of evaluation showing that simple techniques could be used to improve POS tagging performance. We presented baseline statistical parsing results, showing that performance on French user generated data were lying far behind those on newspaper in-domain texts. The take home message is that despite what is commonly said, parsing and POS tagging are far from being solved and that working on real text from real users is of crucial importance.

Acknowledgments We thank the reviewers for their insightful comments and Yoav Goldberg, Reut Tsarfaty and Jennifer Foster for their remarks on an earlier version of this work. This work was partly funded by the French ANR project EDyLex (ANR-09-CORD-008).

ABSTRACT
This paper reports the highest results (95% in MUC and 92% in CoNLL metric) in the literature for Turkish named entity recognition; more specifically for the task of detecting person, location and organization entities in general news texts. We give an in depth analysis of the previous reported results and make comparisons with them whenever possible. We use conditional random fields (CRFs) as our statistical model. The paper presents initial explorations on the usage of rich morphological structure of the Turkish language as features to CRFs together with the use of some basic and generative gazetteers.

1 Introduction

Named Entity Recognition (NER) can be basically defined as identifying and categorizing certain type of data (i.e. person, location, organization names, date-time expressions). NER is an important stage for several natural language processing (NLP) tasks including machine translation, sentiment analysis and information extraction. MUC (Sundheim, 1995; Chinchor and Marsh, 1998) and CoNLL (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) conferences define three basic types of named entities; these are 1- ENAMEX (person, location and organization names), 2- TIMEX (date and time entities) and 3- NUMEX (numerical expressions like money and percentages). But NER research is not limited to only these types; different application areas concentrate to determining alternative entity types such as protein names, medicine names, book titles.

The NER research was firstly started in early 1990s for English. In 1995, with the high interest of the research community, the success rates for English achieved nearly the human annotation performance on news texts (Sundheim, 1995). Nadeau and Sekine (2007) gives a survey of the research for English NER between 1991 to 2006. The satisfaction on English NER task directed the field to new research areas such as multilingual NER systems (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), NER on informal texts (LIU et al., 2011; Rüd et al., 2011; Mohit et al., 2012), transliteration (Zhang et al., 2012) and coreference (Na and Ng, 2009) of named entities .

Conditional Random Fields (Lafferty et al., 2001) is a very popular method used in NLP. It is also widely used for named entity recognition task in various domains (LIU et al., 2011; Ekbal and Bandyopadhyay, 2009; Settles, 2004). Stanford NER (Finkel et al., 2005) which is a well-known NER tool also uses CRFs as its machine learning method.

Morphologically rich languages pose interesting challenges for NLP tasks as it is the case for NER (Hasan et al., 2009). Turkish being one of such languages attracts attention of the NLP community. Nevertheless, the results for Turkish NER remain still very behind the reported accuracies for English. The first published work on this topic is Cucerzan and Yarowsky (1999) which is a language independent system tested on Romanian, English, Greek, Turkish and Hindi. This system is trained with a small training data and learns from unannotated text using a bootstrapping algorithm. It reports an F-Measure of 53.04% for Turkish. The other studies[1] on Turkish NER are as follows: Tür et al. (2003), Bayraktar and Temizel (2008), Yeniterzi (2011), Özkaya and Diri (2011), Tatar and Cicekli (2011) and Küçük and Yazıcı (2012). Although some of these studies try to use CRFs for Turkish NER task, this is the first study which introduces a successful CRF model which beats the state of the art results for this problem. Yeniterzi (2011) uses CRFs with an IG[2] based tokenization. Özkaya and Diri (2011) reports 84% F-measure on e-mail messages by using CRFs, but since they are using features specific to email domain only (such as from, subject fields) their work may not be extended to general texts.

This is an initial study which aims to propose a successful CRF model for Turkish NER. With this purpose, we firstly focused on general news domain where there exists many reported results for comparison. We obtained the highest scores in the literature on ENAMEX types. We made an initial exploration on the use of morphological features and gazetteers. But we believe there is still room for improvement by using more expansive gazetteers and using the

[1] The studies are investigated in more detail in section §5.3 for comparison.

[2] IG is used for inflectional units smaller than words.

morphological features more efficiently. As a future work, we want to work on TIMEX and NUMEX types as well as informal texts.

This paper is organized as follows. §2 gives brief information about Turkish, §3 explains our framework, §4 gives information about datasets, evaluation metrics and features, §5 gives our experiments and evaluates the results by comparing with related work and §6 gives the conclusion.

2 Turkish

This section briefly states the characteristics of the Turkish language which we believe have impact on the NER task.

Turkish is a morphologically rich and highly agglutinative language. In most of the Turkish NLP studies, lemmas are used instead of word surface forms in order to decrease lexical sparsity. For example a Turkish verb "gitmek" (*to go*) may appear in hundreds of different surface forms[3] depending on the tense, mood and the person arguments whereas the same verb in English has only five different forms (going, go, goes, went, gone). But for the proper nouns, in formal texts, the inflectional suffixes are separated from the lemma by an apostrophe. As a result, although it seems that it is unnecessary to make an automatic morphological processing for the stemming of the proper nouns, the stemming of the surrounding words of the proper nouns has influence on the success of NER. §5 investigates the impact of using lexical information for the named entity recognition task.

Turkish person (first) names are usually selected from the words used in daily conversation such as İpek*(silk)*, Kaya*(rock)*, Pembe*(pink)*, Çiçek *(flower)*. Only the proper nouns and the initial words of the sentences start with an initial capital letter.

Turkish is a free word order language, so the position of the word in a sentence doesn't give us information about being a named entity or not. All of the three sentences: "Ahmet yarın Mehmet ile konuşmaya gidecek.", "Yarın Mehmet ile konuşmaya Ahmet gidecek" and "Yarın Ahmet, Mehmet ile konuşmaya gidecek." are valid Turkish sentences all with the English translation of "Tomorrow, Ahmet will go to talk to Mehmet".

3 Proposed Framework

This section describes our CRF based NER framework trained using morphological features and gazetteers. Figure 1 shows the outline of the framework.

3.1 Tokenization

We tokenized our data so that each word is represented as a token except for proper nouns which go under inflection. Since the suffixes separated by an apostrophe are not part of the named entities(NEs), we partitioned such proper nouns into two tokens (the tokens before and after the apostrophe.) All punctuation characters are considered as a token. Sentences are separated from each other by an empty line. Tokenization of a sample sentence can be seen in Table 2.

[3] Some surface forms of "gitmek" (only in simple present tense for different person arguments): gidiyorum, gidiyorsun, gidiyor, gidiyoruz, gidiyorsunuz, gidiyorlar.

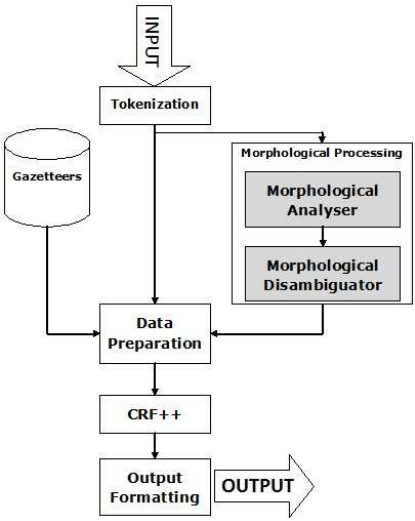

Figure 1: Proposed Framework

3.2 Morphological Processing

We used a two-level morphological analyzer (Oflazer, 1994) for producing the possible analyses for each word. We then give the output to a morphological disambiguator (Sak et al., 2008) in order to get the most probable analysis in the given context. For example, the analyzer produces three different possible analyses for the word "Teknik"(*Technical*) which corresponds to an adjective, a noun and a proper noun accordingly; the disambiguator selects most probable one for us :

Teknik teknik+Adj

Teknik teknik+Noun+A3sg+Pnon+Nom

Teknik teknik+Noun+Prop+A3sg+Pnon+Nom

The output of the analyzer both includes the stem of the word and the morphological features[4] which we use as features for our CRF model. One should keep in mind that, this is an automatic processing and it possesses its own error margin. Eryiğit (2012) gives the performance of this morphological pipeline on raw data.

[4]The abbreviations after the plus sign stand for: +Adj: Adjective, +Noun: Noun, +A3sg: 3sg number-person agreement, +Pnon: Pronoun (no overt possessive agreement), +Nom: Nominative case, +Prop: Proper noun

3.3 Gazetteers

In this work, we prepared two kind of gazetteers[5] which we call base and generator gazetteers. Table 1 gives the details for each one. Base gazetteers are the ones which include words with high probability of occurring in a named entity. These are large gazetteers with thousands of tokens. We collected person names from different sources. We split them into first name and surname gazetteers in order to be able to detect different combinations of these. We compiled the location gazetteer so that it includes all location names in Turkish postal code system[6] , all country names from international telephone code system[7], city and states of those countries[8] and geographical names from different sources.

	Gazetteer	# of tokens
Base	First names	44.048
	Surnames	138.844
	Location names	33.551
Generator	Location	44
	Organization	60
	Person	22

Table 1: # of distinct tokens in gazetteers

Our generator gazetteers are relatively small compared to the base gazetteers. They include the stems of some basic named entity generator words. To give an example: the stem "bakanlık" (*ministry*) which could come after some regular words such as spor, tarım (*sports, agriculture*) to construct organization NEs such as "Tarım Bakanlığı" (*Ministry of Agriculture*).

3.4 Data Preparation

In this stage, we use the information coming from the raw data, the gazetteers and the morphological processing in order to prepare the feature vectors for our training/test instances. For the related class labels at the training stage, we use "Raw Tags". In this format, we use the labels "PERSON", "ORGANIZATION", "LOCATION" and "O" (other - for the words which do not belong to a NE) without any position information (that is without any prefix). In §5.1, we also give the results of our experiments of using different formats for class labels.

3.5 Conditional Random Fields

Conditional random fields (CRFs) (Lafferty et al., 2001) is a framework for building probabilistic models to segment and label sequence data. CRFs offer several advantages over hidden Markov models (HMMs), stochastic grammars and maximum entropy Markov models (MEMMs). CRF is a discriminative model better suited to including rich, overlapping features focusing solely on the conditional distribution $p(\mathbf{y}|\mathbf{x})$. We use linear chain CRFs where $p(\mathbf{y}|\mathbf{x})$ is defined as:

$$p_\theta(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_\theta(\mathbf{x})} \exp\left\{\sum_{t=1}^{T}\sum_{k=1}^{K}\theta_k f_k(y_{t-1}, y_t, x_t)\right\} \quad (1)$$

[5]available from http://web.itu.edu.tr/gulsenc/ner.html
[6]https://interaktifkargo.ptt.gov.tr/posta_kodu/
[7]http://www.ttrehber.turktelekom.com.tr/trk-web/ulkekodlari.html
[8]mostly collected from wikipedia.com

where $f_k(y_{t-1}, y_t, x_t)$ is the function for the properties of transition from the state y_{t-1} to y_t with the input x_t and θ_k is the parameter optimized by the training. $Z_\theta(\mathbf{x})$ is a normalization factor calculated by:

$$Z_\theta(\mathbf{x}) = \sum_{\mathbf{y} \in Y^T} \exp \left\{ \sum_{t=1}^{T} \sum_{k=1}^{K} \theta_k f_k(y_{t-1}, y_t, x_t) \right\} \quad (2)$$

For the named entity task, each state y_t is the named entity label and each feature vector x_t contains all the components of the global observations x that are needed for computing features at time t. Sutton and McCallum (2011) gives detailed information on mathematical foundations and many examples about the usage of CRFs. In this study we used CRF++[9] which is an open source implementation of CRFs.

3.6 Output Formatting

Our system has the capability of labeling the output with two different type of tags: 1. Raw tags and 2. IOB2 tags. Raw tag format which is introduced in §3.4 is also used during the training. The experiments related to the selection of the training format is given in §5.1. IOB2 (Tjong Kim Sang, 2002) is one of the most common formats used in the literature for labeling named entities. I-O-B denotes **I**n, **O**ut and **B**egin. In this tagging format, the first token of a NE is labeled with a "B-" prefix while other words in NE are labeled with an "I-" prefix. Tokens that are not part of any NE are tagged with the label "O". Table 2 shows a sample tokenized sentence (*Mustafa Kemal Atatürk went to Samsun in 1919.*) tagged in both formats.

Token	IOB2 Tags	RAW Tags
Mustafa	B-PERSON	PERSON
Kemal	I-PERSON	PERSON
Atatürk	I-PERSON	PERSON
1919	O	O
yılında	O	O
Samsun	B-LOCATION	LOCATION
'a	O	O
çıktı	O	O
.	O	O

Table 2: IOB2 tagging vs RAW tagging

4 Configuration

This section gives detailed information about the used datasets, evaluation metrics, feature categories and feature templates. §4.3 (Feature categories) presents the features which are provided for each token in our input file. §4.4 (Feature templates) presents the templates used for creating CRF feature vectors for each instance, using the given categories for the current token and its context together with some combinations of these.

[9] http://crfpp.googlecode.com/svn/trunk/doc/index.html

4.1 Data Sets

In our experiments we used the data from Tür et al. (2003). This data consists of 500K words and is annotated only for ENAMEX types with 24,101 person names, 16,105 location names and 13,540 organization names. We reserved one tenth of the data (47,344 words) for testing and used the remaining for training purposes by exactly the same way in Yeniterzi (2011).

4.2 Evaluation Metrics

There are two main metrics in the literature for the evaluation of NER systems: CoNLL and MUC. The MUC metric is the average F-Measure of MUC TEXT and MUC TYPE. MUC TYPE evaluates the performance of assigning the correct NE type to each word without taking into account if the NE boundaries are detected correctly. MUC TEXT makes evaluation only on NE boundaries without looking if the correct NE type is assigned or not. The CoNLL metric on the other hand evaluates an assignment to be correct if both the type and the boundary of a NE is determined correctly. The details of the calculation for these metrics may be investigated from Nadeau and Sekine (2007).

Although CoNLL metric seems to be preferred in recent studies, we evaluate[10] our results using both CoNLL and MUC in order to be able to make comparisons with previous works.

4.3 Feature Categories

In our **base model (BM_surf)** we used word tokens converted to lower case in their surface form. The idea behind converting tokens to lowercase is avoiding one of the major problems of the Turkish language studies; the sparse data problem. Other features added to this model can be grouped into three main categories: morphological, lexical and gazetteer lookup features.

4.3.1 Morphological Features

The morphological features are extracted from the analysis produced after the automatic morphological processing of each word.

Stem : The stem information. For the inflected proper nouns where the inflections after the apostrophe are treated as a separate token, the same surface form after the apostrophe is assigned as the stem of the token representing inflections.

Part of Speech Tag (POS) : The final part of speech category for each word. In Turkish, with the use of derivations, words may change their part of speech categories within a single surface form. The final form of the word determines its syntactic role within a sentence. Therefore, we use the final POS form of each word. We assigned a special POS tag ("APOST") to the tokens separated by an apostrophe from the proper nouns.

Noun Case (NCS) : The case argument. This feature is 0 for non nominal tokens and one of the following values for nominals: Nominative(NOM), Accusative/Objective(ACC), Dative (DAT), Ablative(ABL), Locative(LOC), Genitive(GEN), Instrumental(INS), Equative(EQU). Ex: the value will be NOM for the word "Teknik" with the morphological analysis "teknik+Noun+Prop+A3sg+Pnon+Nom".

[10] We use the evaluation script from CoNLL 2000 shared task (http://www.cnts.ua.ac.be/conll2000/chunking/output.html) for CoNLL and MUC TYPE scores (with the option "-r").

Proper Noun (PROP) : A binary feature indication that the "+Prop" tag exists (1) in the selected morphological analysis or not (0). Ex: The value will be 1 for the word "Teknik" given above. It is useful to mention that the morphological pipeline tags all unknown words as proper nouns.

All Inflectional Features (INF) : All inflectional tags after the POS category. If a derivation exists then the inflectional tags after the last derived POS category is used. Ex: the value will be "Prop+A3sg+Pnon+Nom" for the word "Teknik" with the above morphological analysis.

4.3.2 Lexical Features

Case Feature (CS) : The information about lowercase and uppercase letters used in the current token. This feature takes 4 different values: lowercase(0), UPPERCASE(1), Proper Name Case(2) and miXEd CaSe(3)

Start of the Sentence (SS) : A binary feature indicating that the current token is the beginning of a sentence (1) or not (0).

4.3.3 Gazetteer Lookup Features

Six different features used for each of the six gazetteers introduced in §3.3. Lookup features for base gazetteers (BG) have a 1 value if the token exists in the corresponding gazetteer and 0 otherwise. Generator gazetteer lookup features (GG) are binary features as well but this time the stem of the word is checked instead of the full surface form.

4.4 Feature Templates

CRFs are log-linear models. In order to take advantage of the useful feature combinations, one needs to provide these as new features to the CRFs. In some studies, it is shown that the useful feature conjunctions may be determined incrementally and provided to the system automatically (McCallum, 2003). But, in this study, we used the approach proposed in Sha and Pereira (2003) and selected useful features manually for our initial explorations. Although this approach generally results with a huge number of features, we didn't have any memory problem by using the combinations.

We provided our atomic features within a window of {-3,+3} and some selected combinations of these as feature templates to CRF++. Two sample feature templates are given in the below example. The templates are given in [pos,col] format, where pos stands for the relative position of the token in focus and col stands for the feature column number in the input file.

$$U15 : \%x[-2,2]$$

$$U50 : \%x[0,10]/\%x[0,6]$$

U15 is the template for using the 2nd feature (part-of-speech tag) of the second previous word. U50 is the template for using the conjunction of the existence of the current word in the location name gazetteer (LG) (col=10) and its case feature (col=6) such as *exists in LG written in lowercase; exists in LG and the first letter is capitalized;...*

We use the bigram option of the CRF++ in order to automatically generate the edge features using the previous label y_{-1} and the current label y_0.

As a result, for the 14 feature categories presented in the previous section, we formulated 92 feature templates[11] in our final model which resulted to $\sim$ 20M binary features.

5 Experiments & Evaluation

This section comprises the experiments we conducted to make the decision for our training format (§5.1), to measure the impact of our proposed models (§5.2) and to compare our best model with previous studies (§5.3).

5.1 Training format experiments

We experimented with different training data formats. These are IOB, IOB2, raw labels and fictitious boundary model of Tür et al. (2003). In all of these experiments, we converted the test output to IOB-2 style and evaluated in the same manner. This conversion is made in a straightforward manner by assuming the consecutive tokens labeled with the same NE type as the part of the same NE. This is an acceptable assumption since in Turkish, words in a sentence are separated with a comma if they have the same syntactic function. And also, the subject of a sentence is written separately by the use of a comma if it appears in a confusing context. Tür et al. (2003) gives the probability of two consecutive tokens to have both "B-PERSON" tags as 0.006076. Our training and test sets do not include such NEs at all.

Our experiments show that, we obtain the highest performance by using the RAW labels whereas using the IOB formats reduces the performance by 0.4% and the fictitious boundary format by 2% in all metrics in our base model.

5.2 Feature-related experiments

	MUC TYPE				MUC TEXT	MUC
Feature	PER	ORG	LOC	Overall

Table 4: F-measure in CONNL Metric

problem. i.e. Our training data includes the name of a city "AKSARAY" as a token only one time and doesn't include "Aksaray". This usage converted both to the same token "aksaray". The disadvantage of this usage is losing the effect of an important property of proper nouns in Turkish; the first letter of a proper noun is capitalized so that the noun "gül" (rose) differs from the person name "Gül". Effect of converting all tokens to lowercase is about 1% F-Measure loss in base model in our experiments, but this loss is recoverable with added case (CS) feature. We also wanted to see the performance of using only the word stems instead of the surface form in the sentence so generated a second model (BM_stem).

Table 3 and 4 give detailed evaluation results in all metrics. A plus(+) sign before the feature name indicates that this feature is added (together with suitable feature templates) to the model at the above line. These tables also show the contribution of each feature. While adding a new feature to the model, we also made experiments using different feature template combinations for this new feature to determine the best n-gram relations and their interaction with the previously added features. These experiments are not added to the paper due to the space constraints.

From Table 3 and 4, it can be seen that BM_surf has higher performance than BM_stem. But using the stem information (+STEM) together with the BM_surf raises the performance. This supports our claim about the influence of the stemming of the surrounding words in §2.

All added morphological features raised the performance. But the performance gain acquired by the +INF feature is surprising. One should keep in mind that the +NCS and +PROP features are the atomic units extracted from the +INF feature. Since Turkish is an agglutinative language, the possible number of different values for the +INF feature is very high. For this reason, in many recent studies the usage of the inflectional features as a block[12] is not a preferred approach. We think this result indicates that there is still room for improvement using more fine grained usage of these inflectional features.

The high increase obtained by the +CS feature is as expected due to the known disadvantage of our lowercased base model. But the low performance (and some negative effects) of the feature SS is surprising.

Our base gazetteer features (+BG) performed under our expectations but added a gain of

[12] many atomic features concatenated to each other

about 1% in all metrics. An interesting observation about these features is the gain on organization name identification performance. We don't have any gazetteer of organization names, but using our gazetteers raised the number of identified person and location names. As a result, the number of false positive identifications of organization names decreased.

Impressive performance of the generator gazetteers (+GG) with their modest sizes encourages us adding more of such gazetteers for future work.

5.3 Comparison with related work

This section tries to make a detailed analysis on the related studies: At the time of writing of this paper none of the tools were publicly available so that it wasn't possible to train and test them on the same data set. Table 5 gives the reported results of each related work. We give the results of our pairwise comparisons in the running text whenever possible.

Related work	Best Result	Ev.Metr.	Domain	NE Types
Özkaya and Diri (2011)	84.24	*n/a*	E-mail texts	ENAMEX
Küçük and Yazıcı (2012)	90.13	OTHER	General news	ENAMEX,TIMEX,NUMEX
Tür et al. (2003)	91.56	MUC	General news	ENAMEX
Bayraktar and Temizel (2008)	81.97	MUC	Financial Texts	PERSON NAMES
OURS	**94.59**	**MUC**	**General news**	**ENAMEX**
Tatar and Cicekli (2011)	91.08	CoNLL	Terrorism news	ENAMEX,TIMEX
Yeniterzi (2011)	88.94	CoNLL	General news	ENAMEX
OURS	**91.94**	**CoNLL**	**General news**	**ENAMEX**

Table 5: Comparison with related work (The reported results in each paper)

The performances listed in Table 5 is organized in decreasing order of credit given to partial matches during evaluation. Most of the results are on MUC and CoNLL metrics, therefore we listed our results twice in both of these. Note that the test sets, evaluation metrics (3^{rd} column), working domain (4^{th} column) and entity types[13] (5^{th} column) in focus of each work are different from each other. Table 5 tries to give an overview of these features for each work.

The first NER work specific to Turkish is Tür et al. (2003). The study focuses on three Information Extraction (IE) tasks, namely, sentence segmentation, topic segmentation and name tagging. For name tagging task they use lexical, morphological and contextual features of the words to generate an HMM based model. They evaluate their results in MUC metrics. They use the same training data, but different test data which is not available. Their performance (91.56%) given in Table 5 are comparable with our result in MUC metrics (94.59%)

Bayraktar and Temizel (2008) work on financial texts to find person names. They apply the local grammar based approach of Traboulsi (2006) to Turkish. They construct a list of Turkish reporting verbs. Since they work on a different domain focusing only to person names, their results are not comparable with none of the related work given in this section.

Küçük and Yazıcı (2012) adds statistical methods (Rote learning- (Freitag, 2000)) to their rule based study (Küçük and Yazıcı, 2009) raising the F-measure on general news text from 87.96

[13]Detailed information on the terms ENAMEX(person, organization and location names), TIMEX(dates and times) and NUMEX(currency values and percentages) included in NE Types column can be found at (Sundheim, 1995).

to 90.13. This study is the only published work of Turkish NER comparing performances for different domains. They evaluate their system on general news texts, financial news texts, historical texts and child stories. In Table 5 we took the results on general news texts domain which sounds similar to our domain. Their evaluation metric gives more credit to partial matches and not comparable with none of our metrics. They work on ENAMEX, TIMEX and NUMEX entity types but they do not provide the scores for each of these. In order to be able to make a fair comparison between the two studies, we measure the performance of their system on our test data and calculate the overall ENAMEX performance (F-Measure) as 69.78% in CoNLL metrics and 74.59% in MUC TYPE metrics. We think the reasons of the observed difference between the performances reported in their work and on our tests are the evaluation criteria, the working test domain (our dataset consists of older news texts) and the performance drop due to the lack of TIMEX and NUMEX types (where they have higher performances).

Tatar and Cicekli (2011) propose an automatic rule learning system exploiting morphological features. Although they don't namely mention that they use the CoNLL metric, the evaluation strategy of looking for the exact match is compatible with the CoNLL metric. Their overall score includes the performance on dates and time expressions which is higher than the performance for the NE types of our interest. Their reported accuracy is 91.08% on ENAMEX and TIMEX types. The relevant F-measure for only ENAMEX types is calculated as 90.63%; this result is comparable with our reported F-measure 91.94% in CoNLL metric (except the fact that the evaluations are made on different test sets).

Yeniterzi (2011) uses CRFs and exploits the impact of morphology for Turkish NER. In this work, she uses the inflectional units (IG) as tokens. This work is the one which is most similar to ours but we use morphological features in a different way and add the use of gazetteers. We use the same training and test data, so our results given in CoNLL metrics are fully comparable with this work. One should note that our performance before adding the gazetteers (89.55%) is still higher than her best result (88.94%) which shows that the increase may not be credited to only to the use of gazetteers.

Özkaya and Diri (2011) also uses CRFs on informal texts so it is not fair to compare the results with any of the work discussed in this section all working on formal texts. They do not provide their evaluation metrics and their overall results, but we calculate overall precision, recall and F-measure values as 92.89%, 77.07% and 84.24 respectively using the token counts provided in their paper.

6 Conclusion & Future Work

In this work we presented a Turkish NER model using conditional random fields trained with morphological and lexical features. We compiled large scale person and location names gazetteers which will be available for the researchers. We obtained state of the art results which we believe will act as the baseline for future Turkish NER research. We also tried to compare the results and the evaluation metrics of recent NER work in Turkish. We believe this is also an important contribution since the results given in previous works were not comparable because of first, different evaluation metrics giving different credits to partial matches were used and second, the studies focused to different sets of named entity types and provided their results as the average of these. As future work, we will test our model in different formal and informal domains, investigate the ways to better use the morphological properties collected in the inflectional (INF) feature such as using them as atomic units. We aim to im-

prove our model extending and adding new generator gazetteers. We also aim to add NUMEX and TIMEX entity types to our system. The automatic determination of the useful features and their combinations is another subject of our future work.

ABSTRACT
In this paper, we propose a differential evolution (DE) based two-stage evolutionary approach for named entity recognition (NER). The first stage concerns with the problem of relevant feature selection for NER within the frameworks of two popular machine learning algorithms, namely Conditional Random Field (CRF) and Support Vector Machine (SVM). The solutions of the final best population provides different diverse set of classifiers; some are effective with respect to recall whereas some are effective with respect to precision. In the second stage we propose a novel technique for classifier ensemble for combining these classifiers. The approach is very general and can be applied for any classification problem. Currently we evaluate the proposed algorithm for NER in three popular Indian languages, namely Bengali, Hindi and Telugu. In order to maintain the domain-independence property the *features are selected and developed mostly without using any deep domain knowledge and/or language dependent resources*. Experimental results show that the proposed two stage technique attains the final F-measure values of 88.89%, 88.09% and 76.63% for Bengali, Hindi and Telugu, respectively. The key contributions of this work are two-fold, *viz.* (i). proposal of differential evolution (DE) based feature selection and classifier ensemble methods that can be applied to any classification problem; and (ii). scope of the development of language independent NER systems in a resource-poor scenario.

1 Introduction

Named Entity Recognition (NER) aims to identify and classify each word of a document into some predefined target categories such as person, location, organization, miscellaneous (e.g., date, time, number, percentage, monetary expressions etc.) and none-of-the-above. Over the decades, it has shown success in almost all application areas of Natural Language Processing (NLP) that includes information retrieval, information extraction, machine translation, question-answering and automatic summarization etc. Proper identification and classification of NEs are very crucial and pose a big challenge to the NLP researchers. The main challenge is due to the fact that named entity (NE) expressions are hard to analyze using traditional NLP because they belong to the open class of expressions, i.e., there is an infinite variety and new expressions are constantly being invented.

The problem of NER was actually formulated in Message Understanding Conferences (MUCs) [MUC6; MUC7] (Chinchor, 1995, 1998). The issues of correct identification of NEs were specifically addressed and benchmarked by the developers of information extraction system, such as the GATE system (Cunningham, 2002). The existing approaches for NER can be grouped into three main categories, namely rule-based, machine learning based and hybrid approach. Majority of the research focussed on machine learning (ML) approaches (Bikel et al., 1999; Borthwick, 1999; Sekine, 1998; Lafferty et al., 2001a; Yamada et al., 2001) because these are easily trainable, adaptable to different domains and languages as well as their maintenance are also being less expensive. In contrast, rule-based approaches lack the ability of dealing with the problems of robustness and portability. Each new source of text requires significant updates to the rules to maintain optimal performance and the maintenance costs could be quite steep.

Literature shows that most of the works carried out in this direction cover mostly English and European languages. There are also significant amount of works in some of the Asian languages like Chinese, Japanese and Korean. India is a multilingual country with great linguistic and cultural diversities. People speak in 22 different official languages that are derived from almost all the dominant linguistic families. Some works on NER for Indian languages can be found in (Ekbal and Saha, 2011; Ekbal and Bandyopadhyay, 2008; Ekbal et al., 2007; Ekbal and Bandyopadhyay, 2009b, 2007; Ekbal et al., 2008; Li and McCallum, 2004; Patel et al., 2009; Srikanth and Murthy, 2008; Shishtla et al., 2008; Vijayakrishna and Sobha, 2008). However, the works related to NER in Indian languages are still in the nascent stages due to the potential facts such as (Ekbal and Saha, 2011):

- Unlike English and most of the European languages, Indian languages lack capitalization information, which plays a very important role in NE identification.
- Indian person names are more diverse compared to the other languages and a lot of these words can be found in the dictionary with specific meanings.
- Indian languages are highly inflectional language providing one of the richest and most challenging sets of linguistic and statistical features resulting in long and complex word-forms.
- Indian languages do not conform to any fixed word-order.
- Indian languages are resource poor in nature- annotated corpora, name dictionaries, good morphological analyzers, Part-of-Speech (PoS) taggers etc. are not yet available in the required measure.
- Although Indian languages have a very old and rich literary history, technological devel-

opments are of recent origin.

- Web sources for name lists are available in English, but such lists are not available in Bengali, Hindi and Telugu forcing the use of transliteration.

In this paper we propose a two-stage approach for NER in Indian languages. The first step solves the problems of feature selection for NER within the frameworks of two robust machine learning algorithms, namely Conditional Random Field (CRF)(Lafferty et al., 2001a) and Support Vector Machine (SVM) (Vapnik, 1995). The performance of any classification technique depends on the features of training and test datasets. Feature selection, also known as variable selection, feature reduction, attribute selection or variable subset selection, is the technique, commonly used in machine learning, of selecting a subset of relevant features for building robust learning models. In a machine learning approach, feature selection is an optimization problem that involves choosing an appropriate feature subset. In CRF or SVM based models, relevant feature selection is a very crucial problem and also a key issue to improve the classifier's performance. Usually, heuristics are used to find the appropriate set of features in these classification models. In this paper we propose an evolutionary algorithm for automatic feature selection. The second stage deals with the problem of classifier ensemble. Classifier ensemble [1] is relatively a new direction of machine learning. The main idea behind classifier ensemble is that ensembles are often much more accurate than the individual classifiers that make them up. It is to be noted that all the existing ensemble techniques should have a way of combining the decisions of a set of classifiers. Existing approaches (e.g., stacking, AdaBoost, bagging etc.) combine the outputs of all classifiers by using either majority voting or weighted voting. The weights of votes depend on the error rate/performance of the individual classifiers. However, in reality, in an ensemble system all the classifiers are not equally efficient in detecting all types of output classes. Thus, while combining the classifiers using weighted voting, weights of voting should vary among the different output classes in each classifier. The weight should be high for that particular output class for which the classifier performs good. Otherwise, weight should be low for the output class for which its output is not very reliable. So, it is a crucial issue to select the appropriate weights of votes for all the classes in each classifier. The proposed algorithms for feature selection and classifier ensemble are based on an evolutionary algorithm, differential evolution (DE) (Storn and Price, 1997). To train and test the classifiers we use a set of features that are *mostly selected and developed without using any deep domain knowledge and/or language dependent resources*. The first stage of the algorithm produces a population that contains a set of solutions, some of them are effective with respect to recall whereas some are effective with respect to precision. In the second stage we combine the decisions of these solutions using the proposed DE based classifier ensemble technique. The proposed approach is evaluated for three resource-poor Indian languages, namely Bengali, Hindi and Telugu. Bengali is the seventh most spoken language in the world, second in India and the national language of Bangladesh. Hindi is the third most spoken language in the world and the national language of India. Results show that this two stage DE based technique attains the final F-measure values of 88.89%, 88.09% and 76.63% for Bengali, Hindi and Telugu, respectively. The proposed approach is compared with the conventional majority and weighted voting techniques, popular ensemble methods like stacking, AdaBoost and Error Correcting Output Codes. We also compare our proposed method with two ensemble techniques (Ekbal and Saha, 2010, 2011) based on evolutionary genetic algorithm. Our analysis shows that the proposed approach can attain superior performance in comparison to the exist-

[1] We use 'ensemble classifier' and 'classifier ensemble' interchangeably

ing methods. The key contributions of this work are two-fold, *viz.* (i). proposal of differential evolution (DE) based feature selection and classifier ensemble methods that can be applied to any classification problem; and (ii). scope of the development of language independent models for NER in a resource-poor scenario.

2 Overview of Differential Evolution

Differential Evolution (DE) (Storn and Price, 1997) is a parallel direct search method which performs search in complex, large and multi-modal landscapes, and provides near-optimal solutions for objective or fitness function of an optimization problem. In DE, the parameters of the search space are encoded in the form of strings called chromosomes. A collection of such strings is called a population denoted by P. It is a collection of NP number of d-dimensional parameter vectors $x_{i,G} = [x_{1,i,G}, x_{2,i,G}, \ldots, x_{D,i,G}]$ $, i = 1, 2, \ldots, NP$ for each generation G. The value of D represents the number of real parameters on which optimization or fitness function depends. The value of NP does not change during the minimization process. The initial vector population is chosen randomly which represents different points in the search space and should cover the entire parameter space. An objective or a fitness function is associated with each string that represents the degree of goodness of the string. Differential evolution generates new parameter vectors by adding the weighted difference between two population vectors to a third vector. This operation is called mutation. The mutated vector's parameters are then mixed with the parameters of another predetermined vector, the target vector, to yield the so-called trial vector. Parameter mixing is often referred to as "crossover". If the trial vector yields a lower cost function value than the target vector, the trial vector replaces the target vector in the following generation. This last operation is called selection. The process of selection, crossover and mutation continues for a fixed number of generations or till a termination condition is satisfied.

3 Proposed Method for Feature Selection

In this section we firstly formulate the problem of relevant feature selection within the framework of differential evolution, and then present the proposed approach.

3.1 Problem Formulation for Feature Selection

Suppose, the M number of available features for a given classifier are denoted by $F_1, \ldots, F_M$. Let, $\mathscr{A} = \{F_i : i = 1; M\}$. The feature selection problem is then stated as follows:

Find the appropriate subset of features $\mathscr{A}' \subseteq \mathscr{A}$ such that the classifier trained using these features should have optimized some metrics. In this work we optimize the F-measure value which is the combination of both recall and precision.

3.2 Chromosome Representation and Population Initialization

If the total number of features is F, then the length of the chromosome is F. As an example, the encoding of a particular chromosome is represented in Figure 1. Here, $\mathscr{F} = 12$ (i.e., total 12 different features are available). The chromosome represents the use of 7 features for constructing a classifier (first, third, fourth, seventh, tenth, eleventh and twelfth features). The entries of each chromosome are randomly initialized to either 0 or 1. Here, if the i^{th} position of a chromosome is 0 then it represents that i^{th} feature does not participate in constructing the classifier. Else, if it is 1 then the i^{th} feature participates in constructing the classifier.

If the population size is P then all the P number of chromosomes of this population are initialized in the above way.

3.3 Fitness Computation

For the fitness computation, the following steps are executed.

1. Suppose, there are N number of features present in a particular chromosome (i.e., there are total N number of 1's in that chromosome).
2. Construct a classifier with only these N features.
3. Here, initially the training data is divided into 3 parts. The above classifier is trained using 2/3 parts of the training data with the features encoded in that chromosome and evaluated with the remaining 1/3 part.
4. Now, the overall recall, precision and F-measure values of this classifier for the 1/3 training data are calculated.
5. Steps 3 and 4 are repeated 3 times to perform 3-fold cross validation. The average F-measure value is used as the objective function. Thus, the objective function corresponding to a particular chromosome is $f_1 = \textit{F-measure}_{avg}$. The objective is to maximize this objective function using the search capability of DE.

3.4 Mutation

For each target vector $x_{i,G}$; $i = 1,2,3,\ldots,NP$, a mutant vector/donor vector is generated according to

$$v_{i,G+1} = x_{r1,G} + F(x_{r2,G} - x_{r3,G}), \tag{1}$$

where $r1$, $r2$, $r3$ are the random indices and belong to $\{1,2,\ldots,NP\}$. These are some integer values, mutually different and $F > 0$. The randomly chosen integers $r1$, $r2$ and $r3$ are also chosen to be different from the running index i, so that NP must be greater or equal to four to allow for this condition. F is a real and constant factor 0.5 $[0,1]$ which controls the amplification of the differential variation $(x_{r2,G} - x_{r3,G})$.

3.5 Crossover

In order to increase the diversity of the perturbed parameter vectors, crossover is introduced. This is well-known as the recombination. To this end, the trial vector:

$$u_{i,G+1} = (u_{1i,G+1}, u_{2i,G+1}, \ldots, u_{Di,G+1}) \tag{2}$$

is formed, where

$$u_{j,i,G+1} = v_{j,i,G+1} \quad \text{if } (randb(j) \leq CR) \text{ or } j = rnbr(i) \tag{3}$$

$$= x_{j,i,G} \quad \text{if } (randb(j) > CR) \text{ and } j \neq rnbr(i) \tag{4}$$

for $j = 1,2,\ldots,D$,

In Equation 3, $randb(j)$ is the jth evaluation of an uniform random number generator with outcome belongs to $[0,1]$. CR is the crossover constant belongs to $[0,1]$ which has to be determined by the user. Here the value of CR is 0.5. $rnbr(i)$ is a randomly chosen index x belongs to $\{1,2,\ldots,D\}$ which ensures that $u_{i,G+1}$ gets at least one parameter from $v_{i,G+1}$.

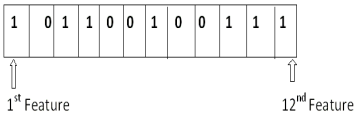

Figure 1: Chromosome representation for DE based feature selection

3.6 Selection

To decide whether or not it should become a member of generation G+1, the trial vector $u_{i,G+1}$ is compared to the target vector $x_{i,G}$ using the greedy criterion. If vector $u_{i,G+1}$ yields a smaller cost function value than $x_{i,G}$, then $x_{i,G+1}$ is set to $u_{i,G+1}$, otherwise, the old value $x_{i,G}$ is retained.

3.7 Termination Condition

In this approach, the processes of mutation, crossover (or, recombination), fitness computation and selection are executed for a maximum number of generations. The best string seen up to the last generation provides the best subset of features. Here the best string contains a set of features. This set is the optimal subset of features for NER problem for a specific language.

4 Proposed Method for Classifier Ensemble

The first step yields a set of solutions on the final best population. There is a single best solution, and along with that the population also contains many other solutions. Some of these solutions are good with respect to recall whereas some are good with respect to precision. All these solutions are equally important from the algorithmic point of view. We generate several different classifiers using these feature combinations. These are then combined using the proposed classifier ensemble creation technique in the second step. The proposed technique determines the best weights of NE classes for classifier combination.

4.1 Problem Formulation

Suppose, the N number of available classifiers be denoted by $C_1, \ldots, C_N$. Let, $\mathscr{A} = \{C_i : i = 1; N\}$ and there are M number of output classes. The proposed classifier ensemble is then stated as follows:

Find the weights of votes V per classifier which will optimize a function $F(V)$. Here, V is a real array of size $N \times M$. $V(i, j)$ denotes the weight of vote of the i^{th} classifier for the j^{th} class. More weight is assigned for that particular class for which the classifier is more confident; whereas the output class for which the classifier is less confident is given less weight. $V(i, j) \in [0, 1]$ denotes the degree of confidence of the i^{th} classifier for the j^{th} class. These weights are used while combining the outputs of classifiers using weighted voting. Here, F is a classification quality measure of the combined classifier. We choose F-measure as the objective function to optimize.

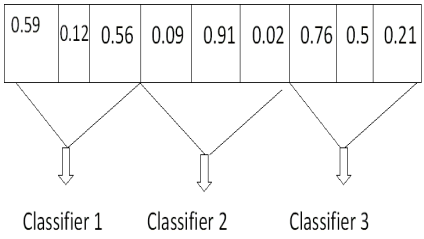

Figure 2: Chromosome Representation for Weighted Vote Based Classifier Ensemble Selection

4.1.1 Chromosome Representation and Population Initialization

If the total number of available classifiers is M and total number of output classes is O, then the length of the chromosome is $M \times O$. Each chromosome encodes the voting weights for possible O classes in each classifier. As an example, the encoding of a particular chromosome is represented in Figure 2. Here, $M = 3$ and $O = 3$ (i.e., total 9 votes can be possible). The chromosome represents the following ensemble:

The weights of votes for 3 different output classes for classifier 1 are 0.59, 0.12 and 0.56, respectively. Similarly, weights of votes for 3 different output classes are 0.09, 0.91 and 0.02, respectively for classifier 2 and 0.76, 0.5 and 0.21, respectively for classifier 3.

We use real encoding, and the entries of each chromosome are randomly initialized to a real value (r) between 0 and 1. Here, $r = \frac{rand()}{RAND\_MAX+1}$. If the population size is P then all the P number of chromosomes of this population are initialized in the above way.

4.1.2 Objective Functions Computation

Initially, the F-measure values of all the available classifiers for each of the output classes are calculated based on the development data. Thereafter, we execute the following steps to compute the objective values.

1. Suppose, there are total M number of classifiers. Let, the overall F-measure values of these M classifiers on the development data be F_i, $i = 1 \ldots M$.

2. We have M classes (each from a different classifier) for each token in the development data. Now for the ensemble classifier, the output class label for each token is determined using the weighted voting of these M classifiers' outputs. The weight of the output class provided by the i^{th} classifier is equal to F_i. The combined score of a particular class for a particular token t is:

$$f(c_i) = \sum F_m \times I(m,i),$$
$$\forall m = 1 \text{ to } M \text{ and } op(t,m) = c_i$$

   Here, $I(m,i)$ is the entry of the chromosome corresponding to the m^{th} classifier and i^{th} class; and $op(t,m)$ denotes the output class provided by the classifier m for the token t. The class receiving the maximum combined score is selected as the joint decision.

Examples: Let us consider the chromosome in Figure 2. Let the three classes be 'PER' (class 1), 'LOC' (class 2) and 'ORG' (class 3). Suppose the final F-measure values of 3 classifiers are 0.8, 0.7 and 0.85, respectively. Then let for a token *'kolkAtA* (Kolkata)' the 3 classifiers predict outputs as follows: Classifier 1: 'PER'; Classifier 2:'LOC'; Classifier 3:'LOC'. Then f('PER')=0.8*0.59=0.472; and f('LOC')=0.91*0.7+0.5*0.85=1.062. Henceforth, all the Bengali glosses are written in ITRANS notation [2]. Thus final class label selected for this particular token is 'LOC' as f('LOC')>f('PER').

3. We use the following objective function: F-measure$_{avg}$. This is maximized using the search capability of DE.

4.1.3 Operators

Other operators of this DE based ensemble approach are similar to those of the DE based feature selection technique described in the previous section.

5 Language Independent Features for NER

The main features for the NER task are identified based on the different possible combinations of available word and tag contexts. We use the following features for constructing the various models of CRF and SVM classifiers. The most important characteristics of our system is that it is both language as well as domain independent in nature. In order to maintain this property the features are *identified and generated without using any deep domain knowledge and/or language specific resources*. Due to this language independent behavior, the features can be easily obtained for almost all the languages.

1. **Context words**: These are the preceding and following tokens surrounding the current token. This is based on the observation that surrounding words carry effective information for the identification of NEs.

2. **Word suffix and prefix**: We use fixed length (say, *n*) word suffixes and prefixes as the features. Actually, these are the character strings stripped either from the rightmost (for suffix) or from the leftmost (for prefix) positions of the words. Morphological analyzers or stemmers could be more effective to extract the meaningful affixes of the wordforms. But there are no such freely available high quality tools for the Indian languages. We also wanted to build our system without using any language dependent resource or tool.

3. **First word**: This is a binary valued feature that checks whether the current token is the first word of the sentence or not. We consider this feature with the observation that the first word of the sentence is most likely a NE. This is the most useful feature for Bengali as NEs generally appear in the first position of the sentence in news-wire data.

4. **Length of the word**: This binary valued feature checks whether the number of characters in a token is less than a predetermined threshold value (here, set to 5). This feature is defined with the observation that very short words are most probably not the NEs.

5. **Infrequent word**: This is a binary valued feature that checks whether the current word appears in the training set very frequently or not. For each of the languages, we compile

[2] http://www.aczone.com/itrans/

the lists of most frequently occurring words for all the three languages. The threshold frequencies depend on the sizes of the datasets. In the present work, we consider the words to be infrequent if they have less than 10 occurrences in Bengali and Hindi datasets, and less than 5 occurrences in the Telugu dataset. A binary valued feature is then defined that fires if and only if the word does not appear in this list. We include this feature as the frequently occurring words are most likely not the NEs.

6. **Digit features**: Several digit features are defined depending upon the presence and/or the number of digits and/or symbols in a token. These features are digitComma (token contains digit and comma), digitPercentage (token contains digit and percentage), digitPeriod (token contains digit and period), digitSlash (token contains digit and slash), digitHyphen (token contains digit and hyphen) and digitFour (token consists of four digits only).

7. **Dynamic NE information**: This is the output label(s) of the previous token(s). The value of this feature is determined dynamically at run time. For CRF we use the bigram feature template that computes all the feature combinations of current and previous tokens.

8. **Content words in surrounding contexts**: At first we extract all unigrams in contexts $w_{i-3}^{i+3} = w_{i-3} \ldots w_{i+3}$ of w_i (crossing sentence boundaries) for the entire training data. Thereafter, we convert tokens to lower case, remove stopwords, numbers and punctuation symbols. We define a feature vector of length 10 using the 10 most frequent content words. Given a classification instance, the feature corresponding to token t is set to 1 iff the context w_{i-3}^{i+3} of w_i contains t. In order to compute this feature for the test set we first pass it through a NER system (Ekbal and Bandyopadhyay, 2009a) to extract the NE information of each token.

6 Datasets, Experimental Setup and Evaluation Results

In this section, we report the datasets used for the experiment, experimental setup and evaluation results with necessary discussions.

6.1 Datasets for NER

Indian languages are resource-constrained in nature. For NER, we use a Bengali news corpus (Ekbal and Bandyopadhyay, 2008), developed from the archive of a leading Bengali newspaper available in the web. One of the authors manually annotated a portion of this corpus containing approximately 250K wordforms with a coarse-grained NE tagset of four tags namely, PER (*Person name*), LOC (*Location name*), ORG (*Organization name*) and MISC (*Miscellaneous name*). The *Miscellaneous name* includes date, time, number, percentages, monetary expressions and measurement expressions. The data is collected mostly from the *National*, *States*, *Sports* domains and the various sub-domains of *District* of the particular newspaper. We also use the IJCNLP-08 NER on South and South East Asian Languages (NERSSEAL)[3] Shared Task data of around 100K wordforms that were originally annotated with a fine-grained tagset of twelve tags. This data is mostly from the agriculture and scientific domains. For Hindi and Telugu, we use approximately 502,913 and 64,026 tokens obtained from the NERSSEAL shared

[3] http://ltrc.iiit.ac.in/ner-ssea-08

Table 1: Named entity tagset for Indian languages (IJCNLP-08 NERSSEAL Shared Task Tagset)

NE Tag	Meaning	Example
NEP	Person name	*sachIna*/NEP, *sachIna ramesha tenDUlkara* / NEP
NEL	Location name	*kolkAtA*/NEL, *mahatmA gAndhi roDa* / NEL
NEO	Organization name	*yadabpUra bishVbidyAlYa*/NEO, *bhAbA eytOmika risArcha sentAra* / NEO
NED	Designation	*cheYArmAn*/NED, *sA.msada*/NED
NEA	Abbreviation	*bi e*/NEA, *ci em di a*/NEA, *bi je pi*/NEA, *Ai.bi.em*/ NEA
NEB	Brand	*fYAntA*/NEB
NETP	Title-person	*shrImAna*/NED, *shrI*/NED, *shrImati*/NED
NETO	Title-object	*AmericAn biUti*/NETO
NEN	Number	*10*/NEN, *dasha*/NEN
NEM	Measure	*tina dina*/NEM, *p.NAch keji*/NEM
NETE	Terms	*hidena markbha madela*/NETE, *kemikYAla riYYAkchYAna*/NETE
NETI	Time	*10 i mAgha 1402* / NETI, *10 ema*/NETI

Table 2: Statistics of the datasets

Language	# tokens in training	#NEs in training	#tokens in test	#NEs in test
Bengali	312,947	37,009	37,053	4,413
Hindi	444,231	43,021	58,682	3,005
Telugu	61,684	5,004	2,342	128

task. The underlying reason to adopt the finer NE tagset in the shared task is to use the NER system in various NLP applications, particularly in machine translation. The IJCNLP-08 NERSSEAL shared task tagset is shown in Table 1. One important aspect of the shared task was to identify and classify the maximal NEs as well as the nested NEs, i.e. the constituents of a larger NE. In the present work, we consider only the tags that denote person names (NEP), location names (NEL), organization names (NEO), number expressions (NEN), time expressions (NETI) and measurement expressions (NEM). The NEN, NETI and NEM tags are mapped to the *Miscellaneous name* tag that denotes miscellaneous entities. Other tags of the shared task are mapped to the 'other-than-NE' category denoted by 'O'. Statistics of the data sets in terms of the number of tokens in the training set, number of tokens in test set and number of NEs in training and test sets are given in Table 2.

6.2 Experimental Setup

The parameters of the proposed algorithm are selected by conducting a thorough sensitivity analysis on the development data. A part of the training dataset is used as the development set.

The parameters of DE are determined based on the development sets. The parameters of DE technique are as follows: population size = 100, CR (probability of crossover)=0.5, number of generations = 50 and F (mutation factor) = 0.5. We define the following *baseline* ensemble techniques:

- *Baseline 1*- This baseline is constructed by considering the following feature combination: Context of previous two and next two tokens along with all the features listed in Section 5.
- *Baseline 2*- This baseline is trained using the following feature combination: Context of previous two and next two tokens along with all the features listed in Section 5.
- *Baseline 3*- In this *baseline* model, all the individual classifiers selected from the first stage of the algorithm are combined together into a final system based on the majority voting of the output class labels. If all the outputs differ then anyone is selected randomly.
- *Baseline 4*- All the classifiers selected from the first stage of the algorithm are combined together with the help of a weighted voting approach. In each classifier, weight is calculated based on the F-measure value of the 3-fold cross validation on the training data. The final output label is selected based on the highest weighted vote.

In this work, we use CRF and SVM as the base classifiers. CRF (Lafferty et al., 2001b) considers a global exponential model. It has the freedom to include arbitrary features and the ability of feature induction to automatically construct the most useful feature combinations. For constructing CRF based classifiers, we use the C^{++} based CRF^{++} package [4], a simple, customizable, and open source implementation of CRF for segmenting or labeling sequential data. The SVM technique (Joachims, 1999; Vapnik, 1995) takes a strategy that maximizes the margin between the critical samples and the separating hyperplane. In particular, SVMs achieve high generalization even with training data of a very high dimension. Moreover, with the use of *kernel function*, SVMs can handle non-linear feature spaces, and carry out the training considering combinations of more than one feature. For constructing SVM based classifiers, we use YamCha[5] toolkit, an SVM based tool for detecting classes in documents and formulating the NER task as a sequential labeling problem. Here, we use both the *one-vs-rest* and *pairwise multi-class decision* methods, and the *polynomial kernel function* of degree 2.

At first DE based feature selection technique is used to determine the most relevant set of features for CRF and SVM. It produces a set of solutions that also includes the best solution. Based on the F-measure values we sort these solutions in the descending order. We select in total 14 solutions, 7 each for CRF and SVM. These effective classifiers are then used to construct the ensemble in the second stage. The performance of these (7+7=14) classifiers (with their feature combinations) are reported in Table 3 for Bengali. The CRF-based model exhibits the best performance (with respect to the overall F-measure value) yielding the recall, precision and F-measure values of 88.05%, 86.58% and 87.31%, respectively. Our first baseline which is constructed by including all the features in CRF model yields the recall, precision and F-measure values of 87.75%, 85.27% and 86.49%, respectively. Thus the DE based feature selection technique improves the F-measure value by 0.82 points. With SVM, the feature selection approach

[4] http://crfpp.sourceforge.net
[5] http://chasen-org/ taku/software/yamcha/

yields the recall, precision and F-measure values of 86.25%, 85.33% and 85.79%, respectively. This is an increment of 0.89 points over the second baseline where SVM is trained with all the available features. Overall evaluation results of our proposed two stage approach along with the best individual classifier and four different *baseline* ensembles are reported in Table 4. The proposed two-stage algorithm shows the recall, precision and F-measure values of 89.79%, 88.01% and 88.89%, respectively. This is an improvement of 1.58 points over the first stage, i.e. feature selection technique. It also demonstrates the overall performance increments of 1.62 and 0.78 percentage F-measure points over the third and fourth baselines, respectively.

Thereafter the proposed techniques are applied to Hindi and Telugu data sets. For both of these languages, we select 14 solutions, 7 each from CRF and SVM from the first stage, i.e. DE based feature selection approach. For Hindi, the CRF-based feature selection model exhibits the best performance with the recall, precision and F-measure values of 87.79%, 86.05% and 86.91%, respectively. Overall evaluation results of our proposed two stage approach along with the best individual classifier and four different *baseline* ensembles are reported in Table 4. The DE based feature selection approach shows an improvement of 0.59 points over the first baseline which is constructed by considering all the features into the model. The ensemble based approach attains the recall, precision and F-measure values of 88.88%, 87.35% and 88.09%, respectively. This is an improvement of 1.18 points over the feature selection approach. We clearly observe the increments of 1.28 and 1.25 points over the majority voted (i.e. Baseline-3) and weighted voted ensemble (i.e. Baseline-4) methods, respectively. For Telugu, the feature selection approach shows the recall, precision and F-measure values of 76.05%, 72.05% and 74.00%, respectively. These are the increments of 2.43 and 4.34 F-measure points over the first and second baseline, respectively. Overall evaluation results are reported in Table 4. Finally, the ensemble approach yields the overall recall, precision and F-measure values of 78.58%, 74.78% and 76.63%, respectively. This is superior to the feature selection approach as well as the other two ensemble methods. In order to show that the proposed two stage approach really outperforms the best individual classifier (i.e. feature selection approach) and four *baseline* ensembles, statistical analysis of variance (ANOVA) (Anderson and Scolve, 1978) is performed, when each is executed ten times. ANOVA tests show that for all the languages differences in mean recall, precision and F-measure are statistically significant as p value is less than 0.05 in each of the cases. We also compare the performance of our proposed approach with three state-of-the-art ensemble methods, namely stacking (Wolpert, 1992), AdaBoost (Freund and Schapire, 1995), ECOC (Error correcting Output Codes) (Dietterich and Bakiri, 1995) and two genetic algorithm (GA) based ensemble methods (Ekbal and Saha, 2010, 2011). In stacking, we used CRF as a meta-classifier. For ECOC, initially we generate binary classifiers for each NE class. Binary classifiers are generated using CRF and SVM. Thereafter, ECOC (Dietterich and Bakiri, 1995) method is applied to solve the multi-class problem. The code matrix is generated exhaustively and minimum Hamming distance based method is applied to determine the appropriate class label of each test instance. In case of AdaBoost we used CRF as a weak classifier. The GA based ensemble methods are executed on the classifiers obtained from the first stage of our proposed technique. We used the same parameter settings as used in (Ekbal and Saha, 2011) and (Ekbal and Saha, 2010). The techniques proposed in these papers were evaluated with set of features presented in this paper. Comparative evaluation results are shown in Table 5 for Bengali. In (Ekbal and Saha, 2010) authors have proposed a GA based simple classifier ensemble technique. The proper weights of votes were not determined like (Ekbal and Saha, 2011). Comparison shows that our proposed algorithm achieves superior performance compared to the previous two approaches. But approach proposed in (Ekbal and Saha, 2010) obtains better

Table 3: Evaluation results with various feature combinations for the CRF and SVM based classifiers for Bengali. Here, the following abbreviations are used: 'CW':Context words, 'PS': Size of the prefix, 'SS': Size of the suffix, 'WL': Word length, 'IW': Infrequent word, 'FW':First word, 'TD': 'Two-Digit', 'FD': 'Four-Digit', 'DH': 'Digit-Hyphen', 'DS': 'Digit-Slash', 'DD': 'Digit-Dot', 'DP': 'Digit-Percentage', 'DC': 'Digit-Comma', 'Sem': Content words, 'P', 'C' and 'N': Previous, current and next tokens, '$-i, j$': Words spanning from the i^{th} left position to the j^{th} right position, Current token is at 0^{th} position, 'X': Denotes the presence of the corresponding feature (we report in percentages), 'r': recall, 'p': precision, 'F': F-measure

F-measure values for some data sets than the proposed method. This is due to the use of many language specific features extracted from Part-of-Speech (PoS) tagger and several gazetteers. Experimental analysis suggests that errors are mostly due to boundary detection and the conflicts between the organization and location classes.

Results show that our proposed two-stage DE based technique performs better than the best individual classifier, four different baseline ensemble techniques and some other existing state-of-the-art ensemble methods (c.f. Table 4 and Table 5). It is already established in machine learning literature that proper ensemble of classifiers should always perform better in comparison to the existing base classifiers. The first stage of our algorithm that concerns with the relevant feature selection performs better than the two baseline models, where classifiers are trained with all the available features. This clearly shows the necessity of determining appropriate feature set for the problem. Our proposed DE based ensemble shows significant performance gains over all the baselines. In the third and fourth baselines, we combined the

Table 5: Comparative Evaluation Results (we report in percentages)

Classification Scheme	recall	precision	F-measure
Stacking	87.88	86.24	87.05

DE based Approach	89.79	88.01	88.89

classifiers blindly. As a result, in some cases, the combined model even shows inferior performance compared to the best individual classifier(s) that correspond to our feature selection method. The effectiveness of DE in determining proper weights of voting is also the another reason of showing better performance. The nature of performance supports our underlying hypothesis that determining appropriate weights of voting for each class in each classifier is very crucial. Results show that the proposed algorithm performs best for Bengali followed by Hindi and Telugu. The possible reasons could be (i). the ratios of positive (NEs) and negative examples (non-NEs) in the respective training data, i.e. 1:9 (Bengali), 1:9.33 (Hindi). and 1:13 (Telugu), (ii). agglutinative nature of Telugu that may possibly require some language specific rules and (iii). less amount of training data for Telugu compared to others. This may be due to the fact that all the datasets are highly imbalanced, and hence greatly biased towards the negative categories. Thus, there are not enough NE instances that could be more effective for NE identification. This observation leads to the path of investigating appropriate sampling strategy in order to make the ratios of positive and negative examples more balanced.

Conclusion

In this paper we have proposed a two stage differential evolution based technique for NER in three different languages. Here at first DE based technique is used to select relevant sets of features for different classifiers. We used CRF and SVM as the underlying classification methods. Thereafter effective classifiers were selected based on the F-measure scores, and combined using a DE based classifier ensemble technique. Evaluation results show the encouraging performance in all the settings. Comparisons with the conventional baselines and some state-of-the-art ensemble methods show the superiority of our proposed technique. The key contributions of this work are are two-fold, *viz.* (i). proposal of differential evolution (DE) based feature selection and classifier ensemble methods that can be applied to any classification problem; and (ii). scope of the development of language independent NER systems in a resource-poor scenario. In future we will study the effects of various language dependent features that can be extracted from morphological analyzers and gazetteers.

Overall evaluation results suggest that there is still the room for further improvement. In this work, we have considered the problem of feature selection and classifier ensemble as a single objective optimization problem. In future, we will develop some multi-objective DE based techniques to solve these feature selection and classifier ensemble methods.

ABSTRACT

We present algorithms for identifying Hindi Noun Groups and Verb Groups in a given text by using morphotactical constraints and sequencing that apply to the constituents of these groups. We provide a detailed repertoire of the grammatical categories and their markers and an account of their arrangement. The main motivation behind this work on word group identification is to improve the Hindi POS Tagger's performance by including strictly contextual rules. Our experiments show that the introduction of group identification rules results in improved accuracy of the tagger and in the resolution of several POS ambiguities. The analysis and implementation methods discussed here can be applied straightforwardly to other Indian languages. The linguistic features exploited here are drawn from a range of well-understood grammatical features and are not peculiar to Hindi alone.

KEYWORDS : POS tagging, chunking, noun group, verb group.

Proceedings of COLING 2012: Technical Papers, pages 2491–2506,
COLING 2012, Mumbai, December 2012.

1 Introduction

Chunking (local word grouping) is often employed to reduce the computational effort at the level of parsing by assigning partial structure to a sentence. A typical chunk, as defined by Abney (1994:257) consists of a single content word surrounded by a constellation of function words, matching a fixed template. Chunks, in computational terms are considered the truncated versions of typical phrase-structure grammar phrases that do not include arguments or adjuncts (Grover and Tobin 2006). For Abney, chunks are connected subgraphs of a sentence's parse tree. They are defined in terms of major heads and have their own syntactic structure that can be represented in the form of a tree. However a chunk does not include all the descendants of the root node that may be present in the parse-tree of the complete sentence. It only represents the root node (the head of the chunk) and its modifiers (auxiliaries in the case of verbs). Two heads of the same lexical category are not allowed inside a chunk. Consequently, 'Ram's son' in English and 'rām kā betā' in Hindi will have two chunks each [Ram's] [son] and [raam kā] [betā]. Similarly, verb complements are not grouped inside the verb chunk; they form separate chunks. The English sentence 'The bald man was sitting on his suitcase,' can be grouped into three chunks – [The bald man], [was sitting] and [on his suitcase]. The parallel sentence in Hindi 'ganjā ādmī apne sandūk pe baithā thā' will have the chunks [ganjā ādmī] [apne sandūk pe] [baithā thā] in that order.

The task of the chunker is to divide a sentence into chunks leaving out some words that are not grouped into any of the identified chunks. The output of the chunker is a shallow syntactic analysis employing simple, context sensitive grammars to detect the boundaries of syntactic groups such as a Noun Group (NG) or a Verb Group (VG). It identifies major constituents of a sentence without further identifying a hierarchical structure that connects and arranges the chunks (Abney 1991, Ramshaw and Mitchell 1995). The chunked structures (or groups, as we shall refer to them from here on) do not correspond straightforwardly to any structure in a typical phrase-structure analysis. A chunker makes use of the POS information provided by a tagger to form groups. A Noun Group consists of a head noun along with its qualifiers and modifiers (including particles). A Verb Group contains a single main verb and any auxiliaries, negation markers, and focus particles. The grammatical information of a word group depends on the order of its constituent morphemes and the information associated with those constituents. The group identification module makes use of the morphological information and the POS information provided by a morphological analyser and a POS tagger respectively. The group identification module can also be employed before POS Tagging in which case it works with possible POS tags of a given word given in a lexicon.

The focus of this work is Hindi word group identification. We performed a detailed corpus analysis and came up with word grouping rules. Local word grouping in Hindi was first discussed by Bharati et al. (1995). They built a Paninian Parser (using karaka or semantic case relations) that internally uses a morphological analyser as well as a Local word grouper (LWG). Following Bharati et al., Ray et al. (2003) attempted local word grouping using a list of regular expressions to form groups. From the list of ten possible modifier-modified structures discussed by Bharati et al., Ray et al. worked on the five structures that rely only on local modifier-modified relationships and do not need long distance dependencies. Hindi word grouping has also been attempted using statistical models including those by Baskaran (2006) using an HMM based approach and Singh A. et al. (2005) and Dalal et al. (2006) using Maximum Entropy Models. These systems rely very little on linguistic knowledge and instead use a large corpus for automatic learning. For Marathi, a close cousin of Hindi, verb group identification was deployed in a CRF based POS tagging system in Gune H. et. al. (2010). Limited noun phrase chunking has also been done for Turkish (Kutlu M. 2010) and Tamil(Vijay and Sobha 2010). While the

focus of our work is on Hindi, the analysis and implementation methods discussed here can be applied straightforwardly to other Indian languages. The linguistic features exploited here are drawn from a range of well-understood grammatical features and are not peculiar to Hindi alone.

2 Need for Group Identification in a POS Tagging System

On analysing the output a CRF (Conditional Random Fields) based POS Tagger, we discovered that most of the systems errors were due to its inability to disambiguate POS tags in the absence of large training corpora. The system needed a detailed group level analysis to resolve the ambiguities between adjective and noun, main verb and auxiliary verb or demonstrative and pronoun. In other words, a granular group level analysis was needed that made use of the morphotactical arrangement both within a word form and in between words. To motivate this further, we provide a detailed error analysis in the following.

a) Demonstrative-Personal Pronoun POS ambiguity: Data-driven learning may not help much in resolving the ambiguity because of a number of qualifiers that may appear between a demonstrative and the head noun. In most cases, a word with the demonstrative-personal pronoun ambiguity is assigned the tag PRON (pronoun) if it is not immediately followed by a noun. Hence, the tagger incorrectly tags some demonstratives (DEM) as pronouns as shown in 1a. In 1b, in contrast, *'us'* appears as a PRON and not as DEM.

1) a) *us kāl*-e ghod-e ko rok-o
that-obl black-obl horse-obl ACC stop-imp
'Stop that black horse'

b) us ko roko
He-obl ACC stop
'Stop him'

The first word in 1a should be tagged as Dem while the tagger incorrectly tags it as Pronoun because of a lack of representative training data. Similarly, sentences 2a and 2b are ambiguous for the system. In1a-b and 2a-b, *'us'* and '*ve'* are valid candidates for both DEM and PRON tags. The ambiguity arises for the system because it seeks to resolve it by looking at the words in the immediate vicinity. Note that these sentences are not ambiguous for a native speaker.

2) a) *vo kāl*-e ghod-e ko rok rəh-*ā* hai
he black-obl horse-obl ACC stop prog-masc,sg be-pres
'He is stopping the black horse'

b) vo *kālā ghodā* so rəh-*ā* hai
that black horse sleep prog-masc,sg be-pres
'That black horse is sleeping'

The TAM (tense, aspect and modality) information of the verbs in the two sentences can also help in resolving the ambiguity but requires subject-object information in the sentence along with a syntactic analysis of the sentence.

b) Adjective-Noun ambiguity: An adjective may function as a head noun if the noun is dropped, and bears the same inflection as the nominal head, as may be seen in 3 and 4.

3) *ə*cch-e *kām kā nətijā ə*cch*ā nikə*l-t-*ā hai*
good-obl deed of result good turn-hab,masc,sg be-pres
'Do good have good'

4) *ə*cch-e *kā nətijā ə*cch*ā nikə*l-t-*ā hai*
good-obl of result good turn-hab,masc,sg be-pres
'Do good have good'

If the case marker orpostposition immediately follows the adjective, it is treated as a nominal head. Since the occurrence of *ə*cche (or any other adjective) as an adjective is more likely than its occurrence as a noun in any learning corpus, this will result in incorrect learning and consequently, in incorrect tagging. NG identification rules help in resolving such ambiguity by using the featural information of the NG constituents.

d) Noun-Verb ambiguity: Many nouns may appear as verbs (even when inflected) and vice versa in Hindi[1]. Verbs may appear as verbal nouns in their infinitival form and may function as nouns. Nevertheless, a verbal noun retains many of its verbal properties. While functioning as a noun, it appears only in the 'singular, oblique' and the 'singular, direct' cases and inflects like other */ā/* ending masculine nouns in the language.

5) tair-*nā bəhut lābhkārī hai*
swim-Inf very beneficial be-pres
'Swimming is very beneficial'

6) tair-n-e ke b*əhut lābh* haĩ
swim-Inf-obl Poss many benefits be-pres,pl
'Swimming has many benefits'

Infinitival verbs as either main verbs or verbal nouns have identical forms. The POS ambiguity is easy to resolve when the verbal noun is in the oblique and is followed by a postposition as shown in 6 above. More difficult are sentences where it appears in the direct form. In 7 the verb j*ānā* appears inside a VG and should be tagged as an infinitival verb. While in 8, it appears as a verbal noun and is also modified by a possessive pronoun *merā.* These two occurrences of *jānā* as a noun and an infinitival verb yields POS ambiguity (N or V). However, when an infinitival verb is immediately preceded by a possessive pronoun or a genitive postposition, as in 8, it should be tagged as a verbal noun, and the NG information can be successfully exploited by the POS tagger.

7) mujh-*e [jā-nā hai]*
I-DAT go-Inf be-pres
'I have/want to go'

8) *[merā jā-nā] zərūrī hai*
My go-Inf important be-pres
'For me to go is important'

3 Noun Groups in Hindi

Nominal groups are defined by Halliday (1977:7) as *"...nouns plus their determi*ners and any *other modifiers...."*. Specifiers and modifiers/qualifiers are optional while the headword (noun) constitutes the obligatory element in the structure of an NG. Specifiers can be determiners, ordinals, and cardinals. Qualifiers include adjectives, prepositional, or postpositional groups or a relative clause. The idea of an NG is not far removed from that of a syntactic NP but it does not straightforwardly match the constituents of syntax. The constituents of a group always appear in a particular default order and this is subject to cross-linguistic variation. Hindi being a head-final language, the head of an NG is the rightmost constituent in the group. The head may be preceded

[1]For example, in the sentence 'mere*kə*īkh*ātehaĩ*'' the token'kh*āte'* isambiguous for NOUN (pl, direct) and VERB (habitual, pl, masc/fem).

by the words that belong to pre-nominal categories. NGs are formed around a noun or a pronoun that acts as a nucleus in the group. Types of Hindi NGs include:

- N, e.g., mez (table)
- Dem Pron+N, e.g., vo mez (that table)
- Poss pronoun+N, e.g., *merā kəmrā* (my room)
- Adj+N, e.g., sundər lə*ɽ*kī (beautiful girl)
- Dem pron+Adj+N, e.g., vo sundər lə*ɽ*kī (that beautiful girl)
- Card+N, e.g., *cār* gho*ɽ*e (four horses)
- Ord+N, e.g., *dūsrā lə*ɽ*kā* (second boy)
- Non-Spec Det+N, e.g., *kuch kitābẽ* (some books)
- Det+Adj+N, e.g., *kuch purānī kitābẽ* (some old books)
- Inten+Adj+N, e.g., b*əhut purānī kitābẽ* (very old books)
- Pron, e.g., ve (they), v*əh (he/it/she), tum (you), āp* (you-honorific)
- N or Proper N (postpositions fuse with Hindi Pronouns; they are not written as free words) followed by a simple postposition or a compound postposition, e.g. lə*ɽ*ke **ke lie** (for the boy), kəmre **m*ẽ*** (in the room), mez **p*ə*r** (on the table)
- Part/Discourse marker+N, e.g., lə*ɽ*kī **h**ī (girl only), lə*ɽ*kī *bhī (girl too), pānī tə*k (water even)

The ordering of the constituent elements of a Hindi NG can be captured using morphotactical rules and a few additional constraints. For example, the end of a Noun Group may easily be marked when the group is Oblique, i.e. when a post-position appears immediately after the head noun. NGs where the head is not directly followed by a postposition require deeper analysis to mark the group boundary. In addition to consulting standard Hindi grammar texts like Kachru(2006), we performed a detailed corpus analysis to determine the word grouping rules. Candidate constituents of the Hindi NG may be placed in five sets as shown below. Optional elements are marked by parentheses. If two or more elements always appear together, they are shown as a single unit within parentheses. Curly brackets are used to show optionality between constituents competing for a single position.

Set 1 includes possessive demonstrative pronouns. Both are optional elements of a Hindi NG and may appear in any order with or without the other. For example, both *vo tumhārī mīthī bātẽ* (those your sweet word*s), tumhārī vo mīthī bātẽ* (your those sweet words) are possible. The possessive followed by a demonstrative pronoun is the canonical order, while the reversed order is a stylistic, poetic construction. The optionality and the order of Set 1 elements is shown in 9.

9) ((Demonstrative) (Possessive)) OR ((Possessive) (Demonstrative))

Thus, any of the following outputs are valid:

- Both items are optional – (*vo tumhārī) mīthī bātẽ*
- Both items may appear together - *vo tumhārī mīthī bātẽ* or *tumhārī vo mīthī bātẽ*
- One item appears without the other - *vo mīthī bātẽ* or *tumhārī mīthī bātẽ*

Set 2 includes intensifiers and numerals. A numeral may be of the type - approximate, fractional, universal quantifier, indefinite quantifier, multiplicative, aggregative, ordinal, cardinal and measure word. Kachru (2006:133) provides the ordering among Hindi quantifiers as in 10.

10) approximate-cardinal-collective-ordinal-multiplicative/fractional-measure

We modified this ordering to capture the arrangement of numerals in a more elaborated way (in Figure 1 below).

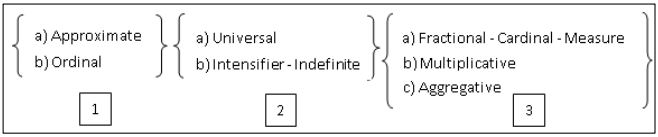

Figure 1: Ordering of quantifiers in a Hindi NG

The categories within curly braces are mutually exclusive while those separated by a hyphen '–' can appear one after another in a sequence. The ordering suggests that:

- Approximate quantifier and ordinal (e.g., *ləgbhəg *dūsrā vyə*kti *'around second man'*), universal and indefinite quantifier (e.g., *s*əbhī kuch log 'all few people'*), cardinal and aggregative (e.g., *do donõ log), aggregative and multiplicative (e.g., **donõ dugunā*), and fractional and aggregative/multiplicative quantifier (e.g., **ādhā donõ, *ādhā dugunā*) are mutually exclusive
- An intensifier may precede an indefinite quantifier but not a universal quantifier (e.g., b*ə*hut k*əm log 'very few people' (intensifier*-indefinite quantifier), b*ə*hut s*əbhī log 'very all people'* (intensifier-universal quantifier))
- Fractionals do not appear with aggregative or multiplicative quantifier (e.g., **ādhā donõ, *ādhā dugunā*)

Set 3 includes adjectives (including imperfective or perfective verbal adjectives) and are optional in an NG. Many adjectives may appear inside an NG recursively. Examples include, *bhāgtā huā kālā* gho*ɽā (running blackhorse), bhāgtā huā ghoɽā (running horse), kālā ghoɽā (black horse),* th*əkā huā kālā ghoɽā (tired black horse), thəkā huā ghoɽā (tired horse*).

11) ((Verbal Adjective) (Adjective))

The adjectives are internally ordered based on the adjective type. Those that denote shape, color, size or the origin of a noun are known as fact adjectives. Those that refer to a noun's quality or those that denote a speaker's opinion appear before fact adjectives. The order followed by different kinds of adjectives is quality-size-age-shape-color-origin material, as in l*əmbī kālī reshmī bənārəsī sā*dī *(long black silk* banarasi saree), n*əyā khushhāl bhārtiyə səmudāyə* (new happy Indian community), etc.

Set 4 includes nouns and pronouns (except the demonstrative) which are obligatory members (Heads) of an NG. They are the right most element of the group with the exception of particles and postpositions that appear after them.

Set 5 includes postpositions that form oblique NGs. Postpositions may be primary (such as ne, ko, ke, etc.) or compound (such as *'ke bā*d*', 'ke sā*t', etc.) and are optional.

Particles (focus, emphatic, etc.) may appear at many places (even at the end) within an NG and we have not put them in any set. The particles to and *bhī* may appear only at the end of an NG.

The complete ordering of constituents within a Hindi NG is given in the expression in 12 where () show optionality, [] represents a set and * stands for zero or more repetition.

12) NG = (Set 1) (Set 2) (Set 3)* Set 4 (Set 5) (Particle)

3.1 Procedure for Noun Group Identification

The Noun Group identification module attempts to isolate the basic non-recursive NG that includes only one head and its specifiers and modifiers. The input to the algorithm is the output of a morphological analyser. For each word, the morphological analyser gives the stem,andthe set of suffixes along with the associated morphological properties. A look-up is performed in a lexicon to retrieve the set of possible POS tags for each stem. The NG is built from right to left in a given sentence. As discussed in the previous section, we formulated five sets of constituents that contain different lexical categories that combine in various ways to form NGs in Hindi. Set 4, the head marks the right end of an NG (neglecting any postpositions and particles).

Sets 1, 2 and 3 contain categories which mark the left end of an NG. Processing from right to left, once the system encounters a Set 4 element, it starts to look for Set 3, Set 2 and Set 1 elements appearing to the left of the head in that order. By 'finding a Set X element', we mean 'finding a stem whose potential POS tag list in the lexicon contains a POS tag belonging to Set X.' The potential candidates are considered to be members of the NG. As soon as any word of a lexical category other than those mentioned in Sets 1, 2 and 3 is encountered, the NG is considered closed. The previous word marks the left end of the NG in such a case. The number, gender and case information for nouns, demonstratives and pronouns are required at each step to select or reject a potential POS tag. This information is extracted from the output of the morphological analyser. The pseudo code for NG identification is given below.

Steps for NG Identification

1. For all tokens, processing goes from right to left
    - 1a. Look for a post-position or a Set 4 element to start an NG
    - 1b. If Set 5 member, i.e., a postposition is found
        - 1b (i) Oblique NG has started
    - 1c. If Set 4 element is found
        - 1c (i) Direct NG has started
    - 1d. If a Demonstrative pronoun is found
        - 1d (i) Consider it as a Pronoun (head)
2. If oblique NG has just started with a Set 5 element, i.e., with a postposition
    - 2a. Look for a Set 4 element
    - 2b. If Set 4 element is not found; find the list of possible POS tags for the current word
    - 2c. If *a POS Tag appears in the possible POS Tags' list and also in Set 4*
        - 2c (i) Assign the tag which is common to both.
    - 2d. If there is no common element in the list and Set 4s
        - 2d (i) Assign the tag other than PP to the next word using the list of possible tags for it.
3. If any NG has started
    - 3a. Look for a Set 3 and/or Set 2 and/or Set 1 element
    - 3b. If Set 3, 2 and 1 elements are found
        - 3b (i) The NG includes the current word
    - 3c. If set 3, 2 and/or 1 elements are not found
        - 3c (i) The NG has already ended with the previous word
4. If any NG is completely identified
    - 4a. Apply rules to check the agreement between modifiers/qualifiers and their head and do corrections if necessary
5. Start looking for the next NG

In what follows, we give an example of how the NGI helps correct a POS Tag error.

13) *ve pūr-e māml*-e ko *suljhā-nā cāh-te haĩ*
They whole-obl matter-obl ACC solve-Inf want be-pres-pl
'they want to solve the whole matter'

For 13 the tagger produces the output as [DEM ADJ NN PP VM VAUX]. *'ve'* is tagged as a DEM instead of PRON. Scanning right to left, the NG identified is (*ve pūre māmle ko*). Now the computational rules are applied to make any POS corrections required. By the first rule for oblique NG,reading the rule from right to left, we find a PP '*ko'* followed by a noun '*māmle'* in the oblique case. '*pūre'* is allowed in the NG as its category and features warrant its being a Set 2 member. '*ve'*may be a Set 1 member and may mark the left end of the NG and may be a demonstrative or a pronoun. The tagger may tag '*ve'*as DEM 'demonstrative' but, as a demonstrative, it does not concord with the head noun for the relevant case feature. Thus, the tag DEM is rejected and PRON is selected.

4 Verb Groups (VGs) in Hindi

A Hindi VG includes a single main verb root followed by a sequence of inflectional suffixes and/or auxiliary verb sequences. The group contains various verbal morphemes that centre on a single event. The verbal morphemes occur in a fixed order and are subject to several grammatical and semantic constraints. Some examples of Hindi VGs are *[khā-yā]* (eat-past) and *[khā-yā gə-yā* hai] (eat-perf passive-perf,sg be-pres).While analysing Hindi VGs, we have not considered complex predicates such as conjunct verbs (as *ārəmbhkər 'start' (literally 'start do')*) or compound verbs (*'kəṛdāl' ('somehow finish')* (Chakrabarti et al.2007, Chakrabarti et al.2008, Begum et al. 2011). Here, a main verb is a single verb root that appears with associated inflectional morphemes.

4.1 Identifying Verb Group Boundaries

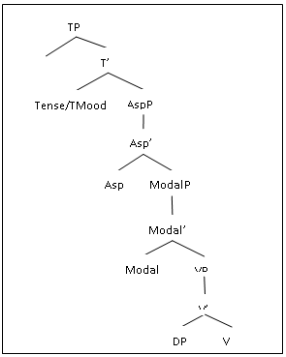

Figure 2: Order of Verbal Elements in a Hindi Verb Group

A VG boundary is marked using the order in which Hindi verbal elementsarrange themselves . The linear order of the major grammatical categories within a Hindi VG is Verb-Aspect-Tense/Mood as shown in Figure 2. The grammatical properties for which Hindi verbs inflect are tense, aspect, mood, modality, gender, number, person, honoroficity, voice and finiteness. These properties are realised analytically or periphrastically (either as suffixes or as auxiliaries). A

Hindi verb group must always begin with a main verb root with or without a suffix. Once the main verb is identified, the verb group is assumed to have begun. Scanning from left to right, the main verb may be followed by a string of intermediate verbal suffixes and auxiliaries until a must-end VG marker is encountered. These elements broadly follow the linear order in 14, though with co-occurrence constraints that are listed towards the end of this section.

14) *Verb Root*−Infinitive/*Passive*−*Modal Auxiliary*−*Aspect*−*Tense*−Mood

The three kinds of morphemes are called Start markers, Intermediate markers and Must-end Markers and are shown in Figure 3. Particles and negation markers are also allowed to appear inside a VG.

Start Marker	Intermediate Markers		Must End Markers
	Possible End Markers	Must-Continue Markers	
Main Verb (Root)	Necessity	Ability/Probability,	Present Tense
	Perfective-gen-num	Obligation/Permission	Past Tense
		Habitual/Progressive	Future+gen-num

Figure 3: Boundary Markers for Hindi VG

a) Start markers

A Hindi VG 'start' marker is always a verb root whether inflected or uninflected. All verbal auxiliaries may also be considered as start markers. Since the identification begins from left to right, the first instance of a free verbal morpheme is always the root or main verb. In rare cases (poetic constructions), verbal auxiliaries appear before the main verb in a Hindi VG, as for examplein 15, where the tense auxiliary precedes the main verb and starts a VG. This scrambling is usually seen only with tense auxiliaries. Such reordering with aspectual auxiliaries is even rarer (see 16). We exclude here the identification of these rare VGs. If such constructions are encountered, the system will identify them as two separate VGs, albeit incorrectly.

15) vo roz mujh-se [hai mil-*tā]*
he everyday I-DAT be-pres meet-hab
'He meets me everyday'

16) vo mujh-se [rəh-*ā hai mil]*
He I-DAT prog-masc,sg be-pres meet
'he is meeting me'

b) Intermediate markers

These markers include two kinds of morphemes, 1) possible-end markers and 2) 'must continue' markers. Possible end markers are those which may end a VG such as the perfective marker or the modal auxiliary for necessity (preceded by an infinitive-gender, number sequence). These morphemes, however, may be followed by other morphemes to further extend the VG. For example, the perfective marker may be followed by the past or the present tense auxiliary as in vo *āyā* 'he came', *vo āyā* hai 'he has come' and vo *āyā thā* 'he had come'. Similarly, the modal auxiliary for necessity may be followed by the past tense auxiliary, such as *usko ānā cāhiye (thā)* 'he should (have) come' and the subjunctive marker may be followed a future-person, number marker, such as *khā-ũ*-g-*ā 'eat*-subjunctive-will-*person, number'.* The 'must-continue' markers,

however, must be followed by other verbal morphemes in order to complete the VG. Details of such markers are given below in Table 1 along with their inflections.

Possible End-Markers	
Modal Auxiliary	*चाहिए (cāhie)* 'should'
Aspect: Perf+gen-num	*-या (-yā), -ा(-ā), -आ(-ā), -ी(-ī), -े(-e), -ए(-e), -ई(-ī), -ीं(-ĩ), -ईं(-ĩ)*
Subjunctive	*-ूँ(-ũ), -ऊँ(-ũ), -ें(-e), -ऍ(-e), -ं(-ŋ), -ेंं(-ẽ), -ऍं(-ẽ), -ों(-o) ,-ओ(-o)*
Must-Continue Markers	
Aspect: Habitual	*-त* (-t), Progressive *रह* (rəh), Completive *चुक* (cuk)
Modal Auxiliaries: Ability/probability	*सक* (sək), ability: *पा (pā), o*bligation: *पड़* (pəɽ), permission: *दे* (de)
Passive	*या* (-yā)/ *यी* (-yī) / *ये* (-ye)/ *जा* (-jā)
Must-End Markers	
Future+gen-num	*-गा (-gā), -गी (-gī),* -*गे* (-ge)
Mood:Imperative	null, -*ो* (-o) ,-*ओ* (-o), *िए* (-ie), *इए* (-ie), *जिए* (-jie), *–ना (-nā)*
Tense Auxiliary: Present	*है* (hai), *हैं (haĩ),* Past: *था (thā), थे* (the), *थी (thī), थीं (thĩ)*
Mood:Conditional	*-त-* (-t-)

Table 1: Intermediate Markers

As shown in 14, the verbal elements appear in a specific order. This ordering issubject to a number of constraints as listed below:

Specific Constraints within a Hindi VG

a) The modal auxiliary *chāhie* must be preceded by an infinitive (with gender-number) marker, such as *khā-nā cāhie (खा-ना चाहिए*). It may be followed neither by an aspect marker (17) nor by a present tense or future tense marker (18). It may only be followed by a past tense auxiliary (19).

17) **chāhie rəh/cuk* (aspect)
18) **chāhie hai/ chāhie-gā* (pres, future)
19) *chāhie thā* (past)

b) In the absence of a modal auxiliary, an infinitive must be followed by a mood or a tense marker (as shown in the examples below in 20 and 21). The expression in 21 where the mood or tense marker is optional is ungrammatical, as in 22.

20) *khā*-ne de-*tā hai*
21) *khā-nā pəɽ-tā hai*
22) **khā-nā (hai/thā/hogā/hotā)*

c) The modal auxiliary *sək* cannot be followed by the perfective marker, the progressive auxiliary *rə*h and the completive auxiliary cuk as shown below in 23-25. It can only be followed by a habitual aspect marker or by a subjunctive marker as in 26 and 27.

23) **khā sək rəhā hai* (progressive)

24) **khā sək-ā hai (perfective)*
25) **khā sək* cuk*ā hai (completive)*
26) *khā sək-tā hai (habitual)*
27) *khā sək*-e (subjunctive)

d) No modal auxiliary may precede the completive auxiliary cuk

28) **khā pā cukā hai*
29) **khānā pəṛ cukā hai*

e) Infinitive marker –*न*-(n), all aspectual markers, past tense auxiliary, conditional mood marker -*त*-(t) and future marker -*ग*-(g) must be followed a gender-number marker as in ता (tā), ती (tī), ते (te), रहा (rəhā), रही (rəhī), रहे (rəhe), चुका (cukā), चुकी (cukī), चुके (cuke), ना (nā), नी (nī), ने (ne), गा (gā), गी (gī), गे (ge).

4.2 Procedure for VG Identification

A VG is identified by scanning the sentence from left to right. The expression given in 30 below is used to detect VGs in a given sentence.

30) Start Marker (Intermediate marker)* Must-end marker

Thus, the start-marker and the must-end markers are obligatory to form a VG while intermediate markers are optional and may recurse (*). The three types of markers were shown in Figure 4 in the previous section. Particles and negation markers may also appear inside a VG. The VG identifier uses the root, suffixes and the morphological features supplied by the morphological analyser and the POS tags assigned by the POS tagger. A VG begins as soon as a verb is scanned and the following morphemes are marked as its suffixes or auxiliaries. The identified verb root may be locally POS ambiguous, i.e., noun or verb (*khānā*'food'and'to eat'), or main verb or auxiliary verb (rəh'live'and *'*progressive auxiliary*'*). The appropriate tag is selected by applying the regular expression on the verbal morphemes. If the sequence of the markers is allowed by the expression, they are included in the VG. The identification continues until a must-end marker is encountered. Once the end of the VG is marked, the group members are assigned fresh, disambiguated POS tags. The head of the VG is assigned VM while the auxiliaries are assigned VAUX along with the TAM features that they express. Some examples are given next.

Types of major POS ambiguity:

a. Main Verb or Auxiliary Verb
b. Main Verb or Noun
c. Main Verb or Postposition

31) [rəh *rəh-ā hai]*
live prog-masc,sg be-pres
'is living'

32) [kər cuk-*ā thā]*
do comp-masc,sg be-past
'had done'

33) kər [cuk-*ā* *de*-g-*ā]*
tax pay-masc,sg give-fut-masc,sg
'will pay the tax'

In 31, *rəh* appears as the progressive aspectual auxiliary as well as a main verb ('live'). Often a POS tagger is unable to resolve this ambiguity in the absence of contextual information. In32, *kər* is ambiguous between being a verb and a noun. As a main verb, it means 'do' and as a noun, it means 'tax'. In order to resolve this POS ambiguity, the system requires the information that when cuk appears as an auxiliary and is followed by a tense auxiliary, it requires preceding main verb. This information rules out the possible tag Noun and leaves Main Verb as the correct one. This information may yield a faulty analysis for the expression in 33. The system will consider *kər*to be a part of the VG and will output the VG as *kərcukādegā*. We require a morphotactical constraint that prevents the completive aspectual auxiliary cuk from being followed by the modal auxiliary de,. We must note that these constraints are ad-hoc and may not always produce correct POS tags.

Secondly, suffixes too may be ambiguous. For example, *'-t'* attached to the stem *ā(*come) may indicate either the habitual aspect or the conditional mood. This ambiguity may be resolved by using the regular expression and by looking at the next morpheme. For example, in 34, the suffix -t- is rejected as being a conditional mood marker as it belongs to the category of must-end markers and cannot be followed by any other verb morpheme (except for the gender-number marker). On the other hand, the habitual -t- may be followed by a tense auxiliary.

34) *bādəl roz [ā*-**te** the]
Clouds everyday come-hab be-past
'Clouds used to form everyday'

During the process of VG identification, feature agreement among elements of the group is also checked. Many invalid sequences are rejected using feature combination rules. For example, *'bhāīthā'* in 36 unlike in 35) cannot be a verb group. It is instead a noun-verb sequence since the masculine gender of the tense auxiliary *thā* does not agree in gender-number with main verb (*bhā 'like'*) marked for feminine gender using *-ī*. On the other hand, *bhāī* (brother) may be a noun with which the gender of the verb (masculine) agrees. The VG identifier thus rejects the Verb tag for the word *bhāī* and retags it as a Noun.

35) *'vo merā bhāī thā'*
he my brother be-past-masc
'He was my brother'

36) **'bhāī thā'*
like-past-fem be-past-masc
'was liked'

Another example where feature checking resolves the POS ambiguity is given in 37 below where the word *'liye'* is POS-ambiguous between a Verb (take-past-pl) and a Postposition (for). If a verb, the form liye should be plural but the tense auxiliary does not agree with it for number(singular, in this case). Thus, it cannot form a VG. By discarding the Verb tag, it is instead assigned the Postposition tag. The VG is formed only with hai 'is'. For the sentence in 38, the word *pāī* may belong to one of two POS categories - Noun (penny) or Verb (found-fem, sg). According to the VG identification rules, negation may appear inside a VG but the perfective must be followed by either a tense marker or a mood marker. The given sequence does not conform to the rule and thus the tag Verb for *pāī*is rejected and a tag Noun is assigned instead.

37) un-*kī* *yojnā shāntipūrnə* uddeshy-õ ke **liye** hai
their plan peaceful aims-obl for be-pres
'Their plan is for peaceful aims'

38) ve ek ***pāī*** nəhĩ *le*-te the
they one penny not take-hab be-past
'They would not take a single penny'

5 Performance Evaluation

We use a CRF based POS Tagger. Without NGI/VGI, the features used for the POS-Tagger include (a) Tag ambiguity scheme from the dictionary, (b) suffix given by the stemmer, (c) prefix and suffix character streams of size one and two, (d) previous word's suffix and (e) tag ambiguity scheme for previous and next word. We tried NG and VG identification at two different places, before and after CRF. When the NGI/VGI module is run before CRF, its output is used as features supplied to CRF and the tags assigned by CRF are considered final. The tag ambiguity scheme of the NG/VG members is simply replaced by the tags given by NGI/VGI modules. On the other hand, when NGI/VGI follows CRF, then NGI/VGI overwrites the tags assigned by CRF.

The Hindi POS Tagger was tested on a corpus of 66,990 words, which is a subset of the BBC Hindi news corpus (downloaded from http://www.bbc.co.uk/hindi) and the IIIT Hyderabad corpus. We partitioned the corpus into four testing folds. The accuracy of the CRF based POS Tag system using Verb Group and Noun Group Identification rules for the four folds are as follows:

Experiment	**Average Accuracy of 4 folds**
CRF	95.18%
CRF + NGI after	95.67%
CRF + VGI after	95.73%
CRF + NGI after + VGI before	95.87%
CRF + NGI after + VGI after	95.26%

Table 2: Experimental Results

We find that while both NGI and VGI help improve accuracy, the best performance is obtained when VGI is applied before CRF and NGI is applied after CRF. It is interesting that applying both NGI and VGI after CRF does not help very much since the errors from one module result in multiple, cascading errors in the second module as the tags given by the first module are considered final. When we apply one module before CRF, then the CRF still gets a chance to overwrite the wrong tags as CRF treats VGI tags as features rather than as final tags.

While a 15% error reduction (from 4.72% to 4.1%) may not appear much numerically large, it should be noted that removing the final 5% of errors is an uphill task with corpus inaccuracies, annotator disagreement, and long distance dependencies dominating. Some of the challenging examples are:

39) mæt∫ 48-48 ovərõ kā kər diyā gəyā hai
match 48-48 overs of do has been be-pres
'Match has been made of 48-48 overs'

Here, the verb group is identified as (diyā gəyā hai). (kər) is marked as a verb whereas in 40, it appears as a noun.

40) mætʃ kā kər diyā gəyā hai
match of tax give-past has been
'Tax has been given/paid for the match'

Another example is that of long distance dependency of the possessive marker:

41) unkā yeh bhī kehnā hai ki
They-ACC this also saying be-pres that
'They also said that'

The verb group is identified as (kehnāhai), whereas (kehnā) is a noun which should co-occur with the preceding possessive. But the possessive pronoun (unkā) is not adjacent to (kehnā).

42) tīm ne spænish līg lā līg kā khitāb jītā
Team-ERG Spanish League Lā Liga of prize win-past
'The team won the Spanish League La Liga title*'*

In 42 (La Liga) is a proper name but as per the morphological analysis (lā) only qualifies to be a verb.

In summary, even with detailed rules for NG and VG identification, there is little improvement in the accuracy of the tagger as (1) our Morphological Analyzer is not able to analyze Compounds (both Verbs and Nouns) and Conjunct verbs as single units unless they are stored in the lexicon,(2) because some of the tags show real ambiguity in a given sentence and 3) because the MA fails to recognize and analyse unknown or foreign words that are not listed in the lexicon.
Our results compare favourably with the 93.45% accuracy reported in Singhet al. (2006) for a CN2 based tagger forthe Hindi BBC news corpus. Guneet al. (2010) report 94% accuracy for CRF on Marathi using a corpus of size 20K. They did not implement NGI but only VGI. They found that use of VGI did not improve the accuracy since not much VM-VAUX ambiguity (their main focus) remained after applying CRF.

6 Conclusions

We have presented algorithms to identify Hindi Noun and Verb Groups by using morphotactical information and the constraints that apply to the constituents of these groups. We also provided the list of grammatical categories and their markers that may appear inside a group and discussed ways in which these markers may be arranged. Group Identification enabled the resolution of major POS ambiguities. The identified groups may also be used at a later stage, i.e., in parsing or in language generation. We cannot handle all the POS ambiguous cases (that involve scrambling or those that are structurally ambiguous) where immediate contextual rules do not help. However, using the ordering among the major categories and their possible combinations, we have tried to present ways that can be applied to other languages equally well. The methods are especially beneficial for languages with meagre corpora or other NLP resources. Since a system will not be able to learn patterns that might be absent in small training corpora, with the useof morphological patterns that govern the ordering of the elements inside a group, a large number of ambiguities and errors may be avoided at a first pass.

Acknowledgements: We would like to thank Nikhilesh Sharma and Neha Gupta for implementing the group identification system discussed here.

ABSTRACT

Named Entity Recognition (NER) is a task which helps in finding out Persons name, Location names, Brand names, Abbreviations, Date, Time etc and classifies them into predefined different categories. NER plays a major role in various Natural Language Processing (NLP) fields like Information Extraction, Machine Translations and Question Answering. This paper describes the problems of NER in the context of Urdu Language and provides relevant solutions. The system is developed to tag thirteen different Named Entities (NE), twelve NE proposed by IJCNLP-08 and Izaafats. We have used the Rule Based approach and developed the various rules to extract the Named Entities in the given Urdu text.

Keywords: NER, Urdu NER, Urdu, Rule Based

Proceedings of COLING 2012: Technical Papers, pages 2507–2518,
COLING 2012, Mumbai, December 2012.

1. Introduction

Named Entity Recognition (NER) is a subtask of Information Extraction (IE). NER extracts and classifies the true Named Entities in text. NER system is widely used in different tasks of Natural Language Processing (NLP) and in many commercial applications on internet like Search Engine. Accuracy of NER system is directly reflected in NLP applications. So, accurate working of NER system is very important. NER system can be used for one's personal interest like company manager wants to know all the names involved in specific text document.

S.No:	Tag Name	Example
1	Person Name	ارشد(Arshad)
2	Location	پٹیالا (Patiala)
3	Organizations	رلاینس (Reliance)
4	Terms	سپنڈلائٹس (Spondylitis)
5	Designation	وزیر اعظم (President)
6	Title Person	جناب (Mr.)
7	Title Object	ہندوستان ٹائمز (Hindustan Time)
8	Brand	سیمسنگ (Samsung)
9	Measure	10 سال (10 Years)
10	Number	ایک، دو (One, Two)
11	Date/Time	12 اکتوبر (12 October)
12	Abbreviation	بی بی سی (BBC)

TABLE 1- Different Named Entity Tags

Named Entities mentioned above were proposed at IJCNLP-08 workshop [17]. Named Entities can be domain specifics like NER system to identify entities in scientific data.

The NER system can be developed using three approaches, 'Rule-Based', 'Machine Learning' (HMM, SVM, CRF, Decision Tree) and 'Hybrid' approach. The Rule-Based system is difficult to develop as one should know the language and grammar rules. These kinds of systems are domain specific. Machine learning approach provides different Statistical NLP tools to train NER system. Statistical tools provide fast way to develop NER system but the accuracy of the system is dependent on annotated training data. For greater accuracy we need to train the NER system with large amount of annotated data. Hybrid approach is a combination of both Rule Base and Statistical based.

2. Related Work

NER system came in focus during the sixth Message Understanding Conference (MUC-6) [6]. After that many NER systems were developed. Most of these systems were developed for European languages and all systems were highly accurate. For south Asian languages, NER systems yet in developing phase. IJCNLP-08 workshop played a major role in development of NER Systems for Indian languages. This Workshop focused on five languages i.e. Hindi, Bengali, Oriya, Telugu and Urdu. All the systems were developed using Statistical approaches or Hybrid approach. Hybrid NER system for five languages was developed by (Sujan Kumar saha et al. 2008) [2]. Rules were developed only for Hindi and Bengali. The system was developed

using MaxEnt model. Accuracy for Urdu was Maximal, Nested and lexical were 27.79, 28.59 and 35.47 respectively.

Karhik Gali et al.2008 [18] had developed the system for five languages Telugu, Hindi, Bengali, Urdu and Oriya. The system was developed using CRF based machine learning model. This system also used some heuristic rules. The system was specific for Telugu and Hindi. Accuracy for Urdu was Maximal, Nested and lexical, were 39.86, 39.01 and 43.46 respectively. Asif Ekbal et al 2008 [1] had developed the system using CRF Machine learning approach. The system was trained for Bengali, Hindi, Telugu, Oriya and Urdu. The system also used language dependent and language independent rules. Accuracy of the system for Urdu was Maximal nested and lexical, were 30.35, 28.55 and 35.52 respectively. Praveen Kumar P et al 2008[3] had developed the system for Hindi, Bengali, Oriya, Telugu and Urdu languages. The system was developed using Hybrid approach which was a combination of CRF and HMM models. Accuracy of the system for Urdu by using CRF, Maximal Nested and Lexical were 33.17, 31.78 and 38.25 respectively and by using HMM 34.48,36.83 and 44.73 respectively . Amit Goyal 2008[10] had developed the system using CRF machine learning model for Hindi language. Accuracy of the system was 58.85. Shilpi Srivastava et al. 2011 had developed the NER system for Hindi language based on CRF and MaxEnt models of Machine Learning approach and rules were developed for Hindi language. The system used voting method to improve the accuracy. Accuracy of the system was 82.95. Kashif Riaz et al. 2010[4] had developed the system using the Rule Based approach. Rules were developed for Person name, Location, Date, Numbers, Organizations and Person's designations tags. The system used very small gazetteer for person names and locations. Recall of the system was 90.7%, precision 91.5 and F1-measure was 91.1%. which was better than all the NER systems developed in IJCNLP-2008 workshop for Urdu? We can see that sufficient work was not done for Urdu NER system and work which is available does not show satisfactory results. Only Kashif Riaz's work shows good results.

3. Approaches to NER

3.1 Rule Based approach: Rules are developed to identify NE in text. This approach takes much time in development and one should have good knowledge of target language. Heuristic based rules are used to identify tags and these rules are language specific. Good rules always yield good results. Development of these kinds of systems is always a time consuming task.
3.2 Statistical approach: Statistical approach is also known as Machine Learning approach. This is a fast way to develop a NER system. The system is trained using annotated training data set in specified format. Accuracy of statistical approach is dependent upon the training data. So, we always train the system with a large set of annotated data. Various Machine Learning models like HMM, CRF, MaxEnt, are used for NER system.
3.3 Hybrid system: Hybrid system is combination of Rule Based approach and Statistical approach. To develop the Hybrid system we use Statistical tools as well as linguistic rules. Combinations of both approaches make a system more accurate and efficient.

4. Issues in Urdu NER System

No capitalization: Urdu and other Asian Languages do not have concept of capitalization. In European language like English this feature is widely used to recognize Named Entity in text because all the names in text always begin with capital letter. Absence of capitalization feature makes the NER task hard for Urdu language.

Ambiguous Name: Urdu language has lots of ambiguous names that can be used as proper noun as well as common noun. Main challenge of any NER system is to separate or extract proper noun in place of common noun. Example: برکت (barkat) or سلامت (slaamat) can be the name of a person or it can be used as common noun.

Spelling variations: Lack of standardization in Urdu language can be seen in spelling as well. There are different spellings that can be used for same word. Like word Hospital can be written in two ways in Urdu اسپتال/ہسپتال (hasptaal/asptaal) which makes the task difficult for NER. We are unable to collect the standard spelling of foreign language. Example: انسٹیچیوٹ/انسٹیٹوٹ (institutes/instichutes).

Non-availability of resources: Language Resources are must for any approach whether it is Rule Based or Statistical. There is no large gazetteer and annotated data available for Urdu language.

5. Why Rule Based Approach

Rule Based approach is time consuming task to develop any NER system. Rule based approach is used only when you know the target language well and have sufficient knowledge about the linguistic rules like knowledge of grammar. The system developed using Rule Based approach always yields the good results. On the another hand, Statistical approach which provide us with many Statistical tools, to develop NER system like HMM, CRF, SVM, MaxEnt etc, with the help of these tools development process of the system is rapid as compared to Rule Based approach. We have studied that in IJCNLP-2008 that all the NER systems were developed using different Statistical approaches. But none of the system provides good results for Urdu text because annotated data provided by the workshop is only 36000 Urdu tokens which is not sufficient to train Urdu NER system. New Statistical techniques like CRF not perform well for Urdu. Absence of any large Urdu gazetteers is also one of the reasons for low accuracy. These kinds of gazetteers boost the accuracy of Statistical approaches. Rule Based approach used by (Kashif Riaz 2010[4]) for Urdu language shows good results. Rules are used to identify six tags. Workshop on NER system by IJCNLP 2008 focused on twelve NER tags. By studying various research papers we concluded that we should follow Rule Based approach though it is a time consuming approach but this approach will give us promising results as we have seen in Kashif Riaz's[4] system. We did not try Hybrid Approach because the absence of large annotated corpus for Statistical part. We have tried to develop different rules for all 12 NE tags which are used in IJCNLP-08 workshop.

6. Rule Based Model

Following Rules are used to identify different tags in Urdu text.

1. Rules are applied to identify date and time tags. These kinds of tags are easily identified by Regular Expressions that are created for specific patterns like 01.01.2012 or 01/01/2012 and time is also identified as 11:20 or 01:22. The system is able to identify the date like 01 May 2012 or 01 May and year 2012.

2. Suffix matching is used to identify various locations and types of names and terms. In Urdu language and other south Asian languages, there are many location names that end with 'pur' (Kishanpur, Rampur), 'stan' (Pakistan, Hindustan) 'ghar' (Chandighar, Ramghar), 'nagar'

(Sonagar) and words that end with 'abad' (Fridabad, Hardabad). Suffix matching is also used for persons name, terms and org Like, person name that ends with 'dev' (Ramdev, Shamdev), 'das' (Sumitvadas, Charndas). Terms that ends with 'logy' (biology), person's last name ends with 'brown' or 'wood' then we can identify them as person's name or it may be organization like Hollywood and Bollywood.

3. The system uses gazetteer of most common person names to identify 'Person Names tag'. The system is able to tag words of maximum three lengths as one Named Entity like محمد شفیق تھند (mahmad saphīk thindh). For person names we have collected 4500 Urdu names and 1500 Hindu person names.

4. We have collected the surname of Muslim and Hindu religions. With the help of surnames the system is able to identify his/her first name, like surname (khān)خان helps the system to check one word before the surname which may be the first name of person like (shāhrukh khān) شاہ رُخ خان

5. Title person and Designations helps the system to identify person name like Title Person وزیر اعظم (vajīr-ē-ājam) and مسٹر (miṣtar) that may have proper name next to it. With the help of Title Person and surname, the system is able to detect Person Named Entities easily. The system is also able to identify those person names which are not part of the gazetteer. We have collected 34 Title Persons and 102 Designations.

6. The NER system performs well when it can identify true Named Entities by resolving the ambiguities. Our NER System is able to identity true Person Named Entity based on various rules like if the system encounters any ambiguity in person name it will treat it as a special case and apply different rules to make sure that it is a true person name. For example when system encounter the word کمل (kamal) then system try to resolve the ambiguity of this word with help of postposition as surname or preposition where it may found Title Person or Designation. If there is no clue to identify as Named Entity then at last it check out the post position of ambiguity word likeکمل کو گھر پے کام تھا (kamal kō ghar pe kam tha.) the word (kō) کو give us clue that it may be the person name , So the system tag it as Person Named Entity(PNE).

7. Rule is also used to identify numbers that are non numerals like 'چار'چھے'پانچ' (Four, Five, and Six). The system able to tags three words as one Number Entity likeسو پانچ تین (Three Hundred Five).

8. Person name may have abbreviations in the place of first name of person like کلام اے جے پی اے (A P J A Klam). If the system is able to identify surname alone then it always try to find it as abbreviation name.

9. The system is able to find out and tag abbreviations like (C P U) سی پی زو (B B C) بی بی سی etc.

10. Organizations are tagged during gazetteer look up. We have insufficient data related to organizations so we have used some heuristics to identify ORG tags. For Example if text includes Org (vō pañjābī yūnīvrasiṭī kā ṭālī-ē-ilam hai.)وہ پنجابی یونیورسٹی کا طالب علم ہے and we don't have this Organization in gazetteer then system apply rules to find and tag org as "Punjabi university".

7. Algorithm for Urdu NER

We have developed the system on Windows platform using Dot Net framework 4. System is using other available classes of framework to implement all features of our NER system. Like Tokenizer and Linked List class and its functions. We have developed many other modules for different rules used by the system. The system works in linear complexity.

1. Input text, through file upload or user may type text in given Text Field.
2. Normalization of Input Text
   1.1 Remove Extra spaces to single space.
   1.2 Remove special chars from end of the strings.
3. Gazetteer lookup
   3.1. Gazetteer lookup up for Locations, Terms, Brands, Abbreviations and Organizations Tags.
4. Tokenized and Normalized
   4.1. Tokenized the input Text word by word and search against the Gazetteer
5. Search for Date and Time tags
   5.1 Search for Number (numeral), Date, Time, Email and URL Tags.
6. Rule to tag Person Names
   6.1 Rule to detect Person Name with the help of Title Person Name, Designation and Surname without using Gazetteer.
7. Suffix stripping is used
   7.1 Suffix Striping Rules are used to Detect Location Names, Organizations, Izaafats, and Some types of Person names.
8. Find Person Names and Numbers
   8.1 Find more Person Names through Various rules and Gazetteer lookup.
   8.2 Rules are applied for names up to three words of length.
   8.3 Rule to detect Abbreviation Names.
   8.4 Rule is applied to resolve ambiguity in names.
   8.5 Rule is applied to find Numbers in non numerals form.
9. Rule is applied to find out Abbreviations which were not found during Gazetteer search.
10. Rules are applied to find out Organizations
    10.1 Those Organizations entity which were not found during Gazetteer lookup, rule will try to find out and tag them as organization entities.
11. Show tagged output to user along with untagged data.

Algorithm is self explained; still lightening some of its steps regarding Gazetteer look up. Gazetteer lookup is used to find out various Named Entities in text. We have collected Named Entities related to various fields i.e. Politics, Business etc. In algorithm's step 3 gazetteer look up is used for Locations, Terms, Brands, Abbreviations and Organizations Tags. All these tags are less ambiguous so the system tags them without applying any rule. System have gazetteer list related to these tags which are not ambiguous. In Step 4 system tokenized the input text and normalized the tokens for further processing. Step 6, 7 and 8 are used to tag Person Names. In Step 6, algorithm finds out person names based on Title Person, Designation and Surname. In this step system is able find out Person Named Entities without any gazetteer list. In Step 8, system used gazetteer list to find out person names and apply various rules to resolve their ambiguity. Some person names have patterns in its suffix or in prefix of the word. So, Step 6 of algorithm finds out this kind of person name by using suffix stripping.

8. Evaluation Metrics

Standard evaluation metrics for Information Retrieval includes Precisions, Recall and F-measure.

Recall: Relevant information extracted from text. Recall defined as:

Recall: = No. of correct answers given by system / Total No. of possible correct answers in text.

Precision: Actual correct answers returned by system. Precision defined as:

Precision: = No. of correct answer/No. of answers given

F-Measure: Balances of Recall and Precision by using a parameters **β**. The F-measure is defined as:

F-*measure=(β*^{2}*+1)RP/(β*^{2}P+R)**

β is weighted as **β**=1. When **β**=1 F-measure is called F1-measure. The F1-measure is defined as:-

F1-measure=2*RP/P+R

9. Evaluation and Results

We have constructed two sets of test data. Test data is collected from different websites [19] of Urdu. Test data mainly include News from different fields like Politics, Sports, Business and Science. The reason of collecting News data is that because News data is always full of Named Entities. So, it gives challenging job to our NER system to identify all different kinds of NE tags accurately. Test data also include ambiguous data, our NER system tried to resolve ambiguities and tag only true entities. Mainly ambiguities are in person names and the system resolves them by applying different rules. For evaluating the system we have tested the system on two different test data sets. Both test data sets have news and articles related to different domain. Test data set 1 have data related to political news, some articles and short stories. Test data set 2 mainly have news related to science and business.

Test Case	Number of tokens	Domain
Test set 1	12032 tokens	News and articles related to politics.
Test set 2	150243 tokens	News data related to science topics, business news.

TABLE 2-Test Sets and along with number of tokens and their domain

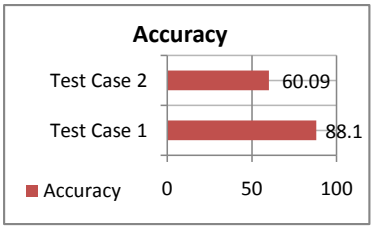

FIGURE 1- Performance of different test cases

Test Sets	Precision	Recall	F1-Measure
Test set 1	58.15	62.05	60.09
Test set 2	86.17	90.40	88.1

TABLE 3- Result of Test cases

Accuracy of Test set 1 is 88.1% and Test set 2 is 60.09%. Note that the frequency of occurrence of tags like Terms, Title Object, Brand Name are very less and we have not sufficient collected data related to these tags. Accuracy without all these four tags is shown below.

NE Tags	Precision	Recall	F1-Measure
NEP(Person Name)	92.85	93.37	93.10
NEL(Location)	85.00	90.00	87.28
NEO(Organizations)	77.70	81.30	80.37
NED(Designation)	86.80	89.21	87.98
NETP(Title Person)	85.33	88.45	86.85
NEM(Measure)	88.24	89.59	88.87
NEN(Number)	92.84	93.50	93.16
NETI(Time)	90.36	91.32	90.83
NEA(Abbreviation)	89.85	91.59	90.71

TABLE 4- Individual results of Nine NE tags

NE Tags	Precision	Recall	F1-Measure
NETE(Terms)	32.20	34.49	33.30
NEB(Brand Name)	43.45	47.28	45.34
NETO(Title Object)	51.49	53.22	52.35
NEIZ(Izaafats)	31.25	35.29	33.14

TABLE 5- Individual results of Four NE tags

Results shown in Table 5 for four tags are not good as compared to other tags because these tags need more time to collect accurate data. If we consider accuracy of all the thirteen tags then accuracy is 74.09%. Accuracy of the system also depends upon the domain of testing data. Test set 2 includes scientific and business terms so that system was not able to perform well. We have considered thirteen tag as compared to twelve tags used in IJCNLP-08. The system tagged Izaafat words because in Urdu, Izaafats are used very frequently and when we translate Urdu to target languages then we need to translate these Izaafats in specific target language words. Like (aab-e-hayat) آب حیات izaafat meaning in English is sacred water. But some time izaafat plays the role as NE for example وراثت خالصہ (vīrāsat-ē-khālsā) name of a place and it should not be translate in target language but transliterate it.

Conclusion and Future Work

We have developed the system to tag different Named Entities and system is able to find out and tag them all. But system has some limitations too.

1. We have developed the rule to tag person's name having length of three words. If person name has longer string of words like four words in a name then it will tag three words as one Named Entity and fourth one as another Named Entity. For Example in محمد أصف علی زرداری (mohmad āsīph alī jardārī) person name, زرداری (jardārī)will be tagged separately and محمد آصف علی (mohmad āsīph alī)will be tagged as another Named Entity. Count of Entities will be two in place of one.

2. Same is the case with Number tag. Like: دو سو چوّن (Two Hundred fifty four) tagged as one named entity but if we have longer string having more than three words like دو ارب چوّن لاکھ (Two Thousand Fifty Four Lakh) will be tagged as two separate entities. Where (Lakh) لاکھ will be tagged as a separately.

3. Partial tagging problem in Org tag like (انڈین انسٹیوٹ آف ٹیکنالوجی) Indian Institute of Technology will tagged partially as (Institute of Technology) word Indian will not be tagged with that Org tag.

4. Problem in Date tag, some time Date is written in word form like: بیس جنوری دویار گیارہ (Twenty January Two Thousand Eleven.) This kind of string will not be tagged as Date tag but will be treated as separate tags like January as Time tag and Twenty as Number tag and Two Thousand Eleven as one Number tag.

5. System is not using any kind of technique to resolve the segmentation problem in given Urdu text. Like other Asian languages Urdu has problem of space omission and space insertion. We will try to improve our NER system by using effective segmentation technique in near future.

6. System is not using POS Tagger or POS tagged data. So system always has to do larger number of comparisons to find out entities in given text. It is difficult to make any decisions for system based on rules because system compares only words but not their part of speech. Due to large numbers of comparisons system is little bit slowly when we gave large amount of input text to system. POS tagged data and stemmer is very essential for NER system and we have not used any POS tagger for our NER. So, we will develop POS tagger to include it in our system.

7. There is a problem to resolve ambiguity of person's name. We have collected the data of ambiguous person names and system treats them as special case to resolve its ambiguity but some time all the rules fail to remove its ambiguity. For example فتح کو بلاوا دو (phatah kō būlāva dō) here word فتح (phatah) can be proper noun or common noun. We do not have any clue to find out whether it is a person name or not. Rule checked Title Person, Designations or surname if all these conditions are not present in given sentence then we need to check out postpositions, but some time these postpositions come along with common name.

We have collected 6000 person names gazetteer. We will collect more number of person names and will try to include surname of other languages. Main problem is gazetteers of terms related to various domains. Collected data is not sufficient. We do not have standard spelling of terms related to various fields. We will try to collect standard spellings of different terms.

To develop the Urdu NER system we have insufficient resources as we discussed earlier but still we are able to get good accuracy. In future we will try to develop other essential tools for Urdu NER.

Abstract

We describe an approach to coreference resolution that relies on the intuition that easy decisions should be made early, while harder decisions should be left for later when more information is available. We are inspired by the recent success of the rule-based system of Raghunathan et al. (2010), which relies on the same intuition. Our system, however, automatically learns from training data what constitutes an easy decision. Thus, we can utilize more features, learn more precise weights, and adapt to any dataset for which training data is available. Experiments show that our system outperforms recent state-of-the-art coreference systems including Raghunathan et al.'s system as well as a competitive baseline that uses a pairwise classifier.

KEYWORDS: coreference resolution, discourse processing, supervised clustering, greedy approaches.

Proceedings of COLING 2012: Technical Papers, pages 2519–2534,
COLING 2012, Mumbai, December 2012.

1 Introduction

Coreference resolution has traditionally benefited from machine learning approaches (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2009). Surprisingly, however, recent work has shown that simple rule-based coreference systems can compete with the state-of-the-art machine-learning-based systems if provided with rich lexical, syntactic, semantic and discourse information (Haghighi and Klein, 2010; Raghunathan et al., 2010). In fact, the rule-based system of Raghunathan et al. (2010) exhibited the top score in the recent CoNLL evaluation (Pradhan et al., 2011). This system's innovation is to build the coreference clusters incrementally, starting with the most precise rules (dubbed *sieves* by Raghunathan et al. (2010)) and use the available coreference information to guide the less precise sieves.

Coreference resolution is inherently a global task: for example, discovering that *Smith* and *she* corefer makes it more probable that *Smith* corefers with *Jane Smith* (i.e., a female name) rather than *Jason Smith*. Furthermore, grouping *Jane Smith*, *she* and *Jason Smith* in the same cluster should be rejected by the clustering algorithm because it results in poor gender and proper name agreement. Yet incorporating such structured information in coreference has proven challenging. There have been several successful attempts to incorporate structured information through joint inference such as Culotta et al. (2007) and Poon and Domingos (2008), but they do not explicitly learn parameters tuned to the inference algorithm used at test time (and the latter relies on a complicated and expensive inference procedures). The difficulty of inferring globally consistent clusterings lies in the fact that there are exponentially many clusterings and producing an "optimal" clustering according to most measures of global coherence is NP-hard. In this context, the approach of Raghunathan et al. (2010) can be seen as a rule-based greedy search for a globally consistent clustering.

We propose a coreference resolution approach that like Raghunathan et al. (2010) aims to consider global consistency while performing fast and deterministic greedy search. Similar to Raghunathan et al. (2010), our algorithm operates by making the easy (most confident) decisions first. It builds up coreference clusters as it goes and uses the information from these clusters in the form of features to make later decisions. However, while Raghunathan et al. (2010) use hand-written rules for their system, we learn feature weights from training data.

What do the learned weights *mean*? They tell our system how to make the merging decisions as it performs greedy agglomerative clustering. And how do we *learn* the weights? Inspired by Goldberg and Elhadad's (2010) approach to easy-first dependency parsing, we utilize a learning method that performs supervised perceptron-style updates as it carries out clustering. Thus, during training, the learner observes partially completed clusterings similar to those that are likely to be encountered during testing.

Our approach inherits all of the advantages of discriminatively trained systems: tuning of parameters based on the empirical properties of training data (instead of hand-tuning weights); an ability to easily adapt to different datasets for which training data is available; an ability to utilize arbitrary overlapping features of the data. In addition, like Raghunathan et al. (2010), we are able to utilize information from earlier, more certain steps when making later, less certain decisions. Our experimental section compares both to traditional ML-based approaches that do not utilize incremental information and to the approach of Raghunathan et al. (2010), which is incremental but utilizes no ML. Under the same evaluation settings, our algorithm outperforms a competitive machine-learning baseline that uses a pairwise classifier, under 9 out of the 10 evaluation settings. Additionally, our system outperforms that of Raghunathan et al.

by more than 2 points on all 4 evaluation settings in which we are able to compare directly.

2 Coreference Resolution

Noun phrase coreference resolution is the task of determining whether two noun phrases (NPs) refer to the same real-world entity or concept. In this paper we will be concerned with determining coreference only within a document. Following established terminology, we use the term **mention** to refer to a linguistic expression that may participate in the coreference relation, as defined for the particular task. Typically mentions are noun phrases, but definitions vary by dataset and may include nested nouns, gerunds, etc. (see Stoyanov et al. (2009) for details). Our method is agnostic to the particular definition of what constitutes a mention, provided that it can rely on a component that extracts mentions with reasonable accuracy. We will use the terms **coreference chain** (or just **chain**) and **cluster** interchangeably to mean a set of mentions that have been posited to refer to the same entity.

The field of coreference resolution has been dominated by the mention-pair model (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2009). This approach trains a classifier to decide whether a pair of distinct mentions is coreferent or not. The quadratically many decisions about all pairs are then reconciled using a clustering algorithm to form the predicted coreference chains. Different features, learners, and clustering algorithms have been employed in the literature. Surprisingly, the mention-pair model with a simple clustering algorithm such as single-link clustering (i.e., transitive closure) performs on par with state-of-the-art systems (Bengtson and Roth, 2008; Stoyanov et al., 2009).

The pitfall of the mention-pair model and other algorithms that rely only on "local" information between pairs of mentions is that they cannot consolidate structured information. In fact, it is common in practice that some chains produced by such algorithms exhibit low coherency. (E.g., a cluster may consist of [*Jason Smith*, *Smith*, *Smith*, *she*], which looks good to the clustering algorithm because 5 of its 6 pairs are plausible. See section 4.4 for other examples.) In addition to negatively impacting evaluation scores, such clusters are especially irritating to human users of the system output.[1] Recent work has attempted to overcome the limitation of local models. Culotta et al. (2007) and Poon and Domingos (2008) perform global clustering of all mentions in a document by using first-order probabilistic models in the supervised and unsupervised settings respectively. However, these models do not specifically tune their weights to their respective test-time inference procedures – the method of Poon and Domingos (2008) is unsupervised, while Culotta et al. (2007) learn a scoring function that can judge the goodness of an overall clustering, but it is not trained to judge goodness incrementally as the algorithm progresses.

The model of Raghunathan et al. (2010) uses an approach based on *multiple sieves* of decreasing precision and increasing recall. It begins by creating a coreference chain for each mention in the document. Each sieve consists of deterministic tests that are applied to pairs of chains in the current clustering. When the tests succeed, the coreference chains in the pair are joined together. The sieves are manually designed and tuned manually on development data.

Another approach has considered a set of hand crafted rules — the multi-agent method of Zhou and Su (2004). Like Raghunathan et al., it relies on multiple agents that filter potential antecedent candidates. However, the system of Raghunathan et al. differs in that coreference

[1] Based on our personal experience deploying coreference resolution systems.

decisions are not made sequentially but in order of the precision of the corresponding sieves, with later (less precise) sieves relying on the information from earlier sieves.

3 Easy-first Coreference

The intuition behind the multi-pass sieve coreference system is that some decisions are easier than others. For instance, the first sieve joins together mentions that constitute the exact same string, while the second sieve looks for high-precision constructs such as appositives and predicate-nominal relations. The later sieves that make harder decisions (for instance, pronoun resolution is done by the last sieve) are joining larger clusters and so can exploit more complete information about the entities being referred to. We rely on the same intuition, but we allow the system to automatically learn what constitutes easy decisions based on features of the clusters that are to be joined. We hope that the system will learn based on the statistics of the training data, in addition to the human intuition that goes into designing the features. For example, we hope that our algorithm can learn to link *Smith* and *she* early in certain contexts (e.g., if *Smith* is the only possible antecedent for the pronoun *she*). Additionally, in contrast to a system for which rules are designed manually, our approach can utilize a large number of features, using the learned weights to aggregate evidence from different features.

We will describe our algorithm by first discussing the test-time system and then the learning algorithm that we use. We face a reinforcement learning setting. Our agglomerative clustering "agent" observes a current *state*, which consists of all current partially formed coreference chains. In the *start state*, each mention is a separate, single-element chain. At each step, the agent will select some action of the form JOIN_{ij}, which joins existing chains i and j (changing the state and the set of actions available at the next time step). Alternatively , the agent may select the special action HALT, which stops the computation and returns the current coreference chains.

3.1 Test-time Inference

At test time our agent operates greedily (without lookahead), choosing its action at each step according to a linear model. The main loop of the test-time algorithm without optimizations discussed below is shown in Algorithm 1. For each action JOIN_{ij} that is available in the current state C, we compute a feature vector $\phi(\text{JOIN}_{ij}, C)$. In this work, ϕ ignores most of C and extracts only features that depend only on the two clusters i and j. However, in the future work section we discuss features that express the relative confidence of linking clusters i and j as *compared to* the alternatives (i.e., is i the only reasonable antecedent for cluster j?). Similarly, $\phi(\text{HALT}, C)$ defines a feature vector for the HALT action. At present, there is a single dedicated feature that always fires on this action, but in future work we can use additional features that consider whether it is a good idea to HALT in the current state or to continue merging clusters.

The score of an action a in state s is given by a linear combination of the features, $w \cdot \phi(a, s)$, where w is a weight vector (coefficient) that specifies a weight for each feature. We learn w using a perceptron-style procedure (described in the next section).

Given the feature weights, inference is easy: we keep picking the action a with the highest score. If the action is HALT, we stop and return the current clustering. Otherwise, the action has the form JOIN_{ij} and we merge the clusters i and j. For the sake of efficiency, we maintain a priority queue containing all currently available actions and their current scores. At a state that has n clusters, the priority queue contains $O(n^2)$ actions.[2] When we pop JOIN_{ij} and merge i

[2]In Section 3.2 we describe a method for limiting the number of actions that we consider, so the true number of

Input: document d; weight vector w
Output: clustering C
$C =$ initial clustering with each mention in d in its own cluster ;
$A =$ empty priority queue ;
A.insert(HALT, $w \cdot \phi(\text{HALT}, C)$) ;
foreach *pair of mentions* i, j **in** d **do**
  A.insert(JOIN_{ij}, $w \cdot \phi(\text{JOIN}_{ij}, C)$) ;
end
repeat
  $a_{max} = A$.popMax() ;
  if a_{max} *has the form* JOIN_{ij} **then**
    performJoin(i, j, C, A) ; /* modifies C and A as described in text */
until $a_{max} ==$ HALT ;
return C ;

Algorithm 1: *Inference method: "easy-first" agglomerative clustering.*

and j, we update the queue accordingly, which involves removing the $O(n)$ actions that use the old i and j, and adding $O(n)$ new actions involving the new cluster ij. To quickly identify the actions to remove, each cluster stores pointers to the enqueued actions that involve it.

Additionally, each cluster stores a best-guess description of the *properties* of the entity to which the cluster refers. These properties include the *gender*, *animacy* and *number* of the entity, its *semantic type* (i.e., *person*, *organization*, etc.) as well as the set of *proper names* used to refer to the entity. When joining two clusters we consolidate the property values, which may be in conflict (i.e., the *number* of cluster i is *single*, while the *the number* of cluster j is *plural*). In principle, the cluster should store a probability distribution over the values of its properties, using this distribution both to score the compatibility with other clusters and to compute a consensus distribution when clusters are merged. Our clusters instead use a simpler approach of storing a single value for each property together with a confidence in that value. We employ manually assigned confidences consisting of three tiers. Pronouns induce the most confident properties (confidence=3), followed by proper names (confidence=2) and common nouns (confidence=1). When two clusters are merged, we resolve conflicting values of a property by choosing the more confident value, or in the case a tie, the value contributed by the larger cluster. In case of a further tie, we use the value of the cluster whose first mention is earlier in the document.

If n is the number of mentions in the document, then there are $\leq n$ clusters at any time. Furthermore the algorithm must HALT after at most n JOIN steps—and usually halts much sooner since it would be incorrect to merge all mentions into a single large cluster. Each step of the algorithm involves:

- popping the highest-scoring action JOIN_{ij} from the priority queue (runtime $O(\log n)$),
- performing the merge action (runtime $O(1)$ by having the new cluster ij point back to the old clusters i and j),
- computing the properties of the newly merged cluster (total runtime $O(1)$),
- deleting $O(n)$ old actions (total runtime $O(n \log n)$),
- computing the scores of $O(n)$ new actions (runtime $O(n)$),[3]
- and inserting these (runtime $O(n \log n)$ or $O(n)$ depending on the type of priority queue).

actions is $O(Cn)$, where C is a constant.

[3]One might think that computing the score of each new JOIN_{ij} action would be expensive (because one might have

Thus, the total runtime is $O(n^2 \log n) + O(sn \log n)$, where $s \leq n$ is the number of actions popped before HALT and tends to be small. The initial $O(n^2 \log n)$ term is for initializing the priority queue by pushing all actions JOIN_{ij}. We will speed this up below by pruning the set of actions.

Note that this easy-first algorithm essentially has the same structure as Kruskal's (1956) minimum spanning tree algorithm on a complete graph of $O(n^2)$ edges, except that as the connected components grow and merge, the weights of the edges between them are recomputed. In addition, the easy-first algorithm may HALT early, outputting a forest of several components rather than a single spanning tree. Many agglomerative clustering algorithms have this structure. The key difference here is that we are going to *learn* a linear function that weights the old and new edges—we will learn to define "easiness" such that the easy-first algorithm will achieve good scores on a coreference task.

3.2 Pair Selection

In the name of efficiency, we apply several rules to limit the number of pairs of mentions that our algorithm considers. (That is, we run our Kruskal's-like algorithm on a sparse graph rather than a complete graph with $O(n^2)$ edges.) For each mention, we only consider some of the preceding mentions as possible antecedents. The number of preceding antecedents we consider is based on the type of each mention and relies on linguistic intuitions. The following describes the possible antecedents that we consider for each mention type.[4]

- **Proper Name (Named Entity):** A proper name is compared against all proper names in the current sentence and the 40 preceding sentences. In addition, it is compared to all other mentions in the 3 preceding sentences.
- **Definite noun phrase:** Compared to all mentions in the 4 preceding sentences.
- **Common noun phrase:** Compared to all mentions in the 2 preceding sentences.
- **Pronoun:** Compared to all mentions in the three preceding sentences unless a first person pronoun. First person pronouns are additionally compared to first person pronouns in the preceding 40 sentences.

These simple rules cover almost all positive pairwise links in our corpora while effectively reducing the runtime of our algorithm from $O(n^2 \log n)$ to $O(Cn \log n)$. Technically, C as defined above is not a constant since the k preceding sentences could be arbitrarily long and thus could contain up to $n-1$ mentions. So we set a limit of at most 500 preceding mentions that we consider. This limit is never achieved in our experiments.

3.3 Features

As mentioned before, an advantage of our approach over the pairwise model is that it is not "edge-factored." Each greedy decision can rely on all of the information contained in the coreference chains built so far. In particular, we can rely on features that attempt to capture agreement between entire clusters. We will refer to such features as *cluster features*. Our cluster features include features that fire when the two clusters have the *same* gender, animacy, number,

to score all pairs of mentions in the clusters being joined). However, we explain in the next section how to do it in $O(1)$ time for the particular set of features that we use.

[4]The numbers that appear in our pair selection heuristics could, of course, be automatically tuned on development data to achieve a user's desired balance between speed and accuracy on a particular domain. We do not do this in the present paper, which focuses on a different kind of automatic tuning.

head noun or semantic class. Similarly, we have features that fire when the two clusters have the *same* or *compatible* gender, animacy, number, head noun or semantic class (i.e., one cluster has *gender* value *feminine* while the other has value *unknown*). We also have features that are *true* when the set of heads of the two clusters overlap or the set of proper names overlap. Another highly effective feature that we use detects when there is a conflict between person names—for instance, this feature will fire if we try to match *John Smith* and *Jane Smith*.

Additionally, each cluster stores a bit that indicates whether the cluster's first mention is a pronoun (where "first" refers to the order in which the mentions appear in the text). If it is, additional features indicate whether the other cluster is a potential antecedent for the pronoun (i.e., whether it agrees in gender, number, and/or animacy and has a non-conflicting semantic type and has at least one mention that appears earlier). Additional features indicate whether the noun phrase is the only such potential antecedent in the sentence in which the pronoun appears; the only potential antecedent in the preceding sentence; or the only potential antecedent that is a verbal subject in the preceding three sentences. This special handling is necessary to assure pronouns to get a single antecedent.

In addition to the cluster features, our system utilizes the rich set of features developed for mention-pair systems that capture local configurations indicative of coreference. These *local features* operate on pairs of mentions. We include features that capture when the two mentions are in an appositive relation, a predicate-nominal relation or are aliases of each other (see Ng and Cardie (2002) and Raghunathan et al. (2010) for descriptions of these features). We also introduce in the local feature set some features that capture the textual overlap of two mentions. We use most of the local features utilized by Stoyanov et al. (2009), with the exception of the ones that duplicate our cluster features. Details about the local features that we use can be found in Stoyanov et al. (2009) and Raghunathan et al. (2010). As discussed later in the paper, the code for our system is available upon request; it documents both the feature names as they relate to the corresponding papers, as well as their semantics.

Again, each local feature evaluates a *pair of mentions*. However, what we are evaluating is a JOIN_{ij} action that merges a *pair of clusters*. Thus, when we consider joining two clusters i and j at least one of which contains more than one mention, we have a choice of all local vectors between mentions in i and j to score the local compatibility. After some experimentation on development data, we decided to select the local cluster vector which results in the highest overall local score. In other words, we pick the single local vector that scores highest under w. This resembles single-link clustering. For example, to create a long chain of mentions that runs through the text, it would suffice for each pair of *adjacent* mentions (for example) to be locally compatible (e.g., syntactically related or proximate). Even though other mention pairs in the chain might not receive a high pairwise score (because they are not *directly* related), these lower pairwise scores would not be able to veto the chain. Thus, we effectively have a division of labor where positive evidence is contributed mainly by local pairwise features and negative evidence is given only by cluster features that detect global incompatibilities.

At test time, maintaining the local feature vectors takes time $O(1)$ since both the local features and the weight vector w are fixed. Thus, we can maintain a single local feature vector for each action. When joining two clusters i and j into ij, for each k, the local feature vector of the new action $\text{JOIN}_{(ij)k}$ becomes the maximum of the local feature vectors of actions JOIN_{ik} and JOIN_{jk}. At training time, w is not fixed, so we need to maintain local vectors for all pairs of mentions and recompute the maximum every time w changes.

3.4 Learning

The goal of training is to find a weight vector w that leads our easy-first algorithm to good clusterings. Goodness is defined in terms of a task-specific evaluation function (we consider MUC score and the BCubed evaluation metrics described in Section 4). We face a typical reinforcement learning problem in that in effect, our training set depends on our weight vector w—if we choose our actions differently or choose a different input document, we end up in previously unvisited states, which offer new sets of actions to choose among. During training we need to act in the environment to generate states that present the kinds of choices among actions that we are likely to encounter during testing. We cannot practically enumerate every possible state even for a single training example, because there are exponentially many clusterings; and of course test examples will give rise to entirely new states.

In early experiments we attempted using standard reinforcement learning algorithms such as Q-learning (Watkins and Dayan, 1992) and policy gradient (Sutton et al., 2000), but the learned weights did not lead to accurate predictions. We believe that this is due to the large variation of the values of our actions. Thus, we settled on a variant of the structured perceptron with early updates (Collins and Roark, 2004) with beam width 1. Our algorithm was inspired by the successful use of a similar algorithm by Goldberg and Elhadad (2010) for training an easy-first dependency parser. The nature of our task necessitates certain differences from both the structured perceptron and the "easy-first" algorithm of Goldberg and Elhadad. Those differences are described bellow.

Algorithm 2 is our training algorithm. Overall, the algorithm monitors the agent's behavior, and performs perceptron-style updates when the current weights would result in a mistake. Learning starts from a vector of initial weights $w^{(0)}$ (initialization is discussed below) and iterates over all training documents. For each document d training begins at the start state, where each mention is in its own cluster (we use C to refer to the current set of clusters and A to refer to the current set of available actions). A state s is specified by C and A. At each time step, t, the algorithm finds the highest weighted action a_{max} according to the current weights $w^{(t)}$. If a_{max} is positive (we say that an action is positive if it results in an immediate increase of the evaluation metric for which we train), w is not updated. If a_{max} is negative (i.e., results in an immediate decrease in evaluation score), the algorithm performs a perceptron update by subtracting the features of a_{max} and adding the features of the highest scoring positive action a_{pos} scaled by a learning rate η: $w \mathrel{+}= \eta \cdot (\phi(a_{pos}, C) - \phi(a_{max}, C))$. We repeat this update k times or until a_{max} is a positive action. Note that the highest-scoring positive action a_{pos} may be different in each iteration as the feature weights are changing. Once the weights have been updated, the algorithm selects the (new) highest-scoring action a_{max} (which may be positive or negative at this point) and performs it. The procedure is repeated in the new state, and so on. When the selected action is the HALT action, we stop clustering the document and move on to the start state for the next document. After iterating over the corpus a specified number of times, the learner returns the average of all the weight vectors that were actually used to choose actions.

The above algorithm learns a weight for the HALT action. Nevertheless, in an additional step after running Algorithm 1, we fine-tune the weight of the single identity feature associated with the HALT action. We are essentially learning a *threshold* on when to stop resolution. Stopping earlier will improve precision at the expense of recall, so the ideal time to stop depends on our evaluation metric. We freeze all other feature values and pick the weight of the HALT feature

Input: set D of coreference-annotated documents; initial weight vector w; learning rate η;
number of iterations *numIter*; max number of updates per error, k
Output: new weight vector w
$w_{sum} = \vec{0}$; $wcount = 0$;
for $i = 1$ **to** *numIter* **do**
  foreach *document* $d \in D$ **do**
    initialize C and A from d as in the first 5 lines of Algorithm 1 ;
    repeat
      for *tries* $= 1$ **to** k **do**
        $a_{max} = A$.peekMax() ; /* highest-scoring action */
        if a_{max}.isPositive() **then break** ; /* proceed with it if it's positive */
        $a_{pos} = A$.peekMaxPositive() ; /* highest-scoring pos action (or Halt if none) */
        $w \mathrel{+}= \eta \cdot (\phi(a_{pos}, C) - \phi(a_{max}, C))$; /* update toward a_{pos} */
        recompute scores in A using new w ;
      end
      $w_{sum} \mathrel{+}= w$; $wcount$++;
      $a_{max} = A$.popMax() ;
      if a_{max} *has the form* JOIN_{ij} **then**
        performJoin(i, j, C, A) ;
    until $a_{max} ==$ HALT ;
  end
end
return $w_{sum}/wcount$;

Algorithm 2: *A training method for easy-first clustering.*

that maximizes the desired evaluation metric on the training data. Experiments on development data showed that this step results in rather small but consistent improvements in our domain.

As noted above, our algorithm is a slight modification of the structured perceptron with early updates (Collins and Roark, 2004) for beam width 1. The difference is that upon making a mistake on a training example (in our case a training example is a document), the structured perceptron updates the weights and moves onto the next example. In contrast, we update the weights and continue working on the current example. Our subsequent updates on the example may thus have to update from one incorrect clustering to another—unlike the structured perceptron or violation-fixing perceptrons in general (Huang et al., 2012) (but like DAgger (Ross et al., 2011)). The difference is motivated by the fact that our data is highly non-separable—it is extremely rare to get all of the coreference decisions right in a document. Thus, the algorithm needs to operate in states in which some errors were previously made. Additionally, there is a significant overhead in initializing the necessary data structures for each document. Thus, a straightforward implementation of the structured perceptron with early updates is inefficient.

Goldberg and Elhadad (2010) use an update strategy similar to the structured perceptron, but keep updating until the next move will not result in an error ($k = \infty$).[5] For the reasons discussed above, such an update is not suitable for our problem—we want the algorithm to learn to operate as well as possible in states that contain errors, as such states will inevitably be encountered during testing.

[5] Because it was unclear to them at the time how to supervise the parser beyond its first error (Goldberg, p.c.).

Novel features:
DeterminerHeadMatch, Longer2, LongerPN2, ShorterPN2, Halt

Table 1: Names of the local features used. Global features are described at start of section 3.3.

In the experiments described in the next section, we use for all runs $\eta = .01$ and $numIter = 5$ iterations of training and a single update to the training vector ($k = 1$). These parameters were tuned on additional development data (namely, the corpus described in Hasler et al. (2006)).

For our baseline (described in more detail in the next section) we train a "flat" classifier that implements the traditional mention-pair model. The baseline does not maintain clusters incrementally, but instead, it makes pairwise decisions up front and forms clusters by transitive closure. As in the easy-first case, we utilize a linear classifier trained using the perceptron algorithm on the set of initial clusters C. Weights are trained to recognize whether two clusters are coreferent or not. This training regime is equivalent to using easy-first training on the initial state without ever performing any action, but iterating over all possible actions and updating when a positive action would be classified as negative and vice versa. Our easy-first learning algorithm is initialized with the weights obtained from a single iteration of baseline training.

4 Experiments

We implemented our algorithm in Reconcile, a research platform for coreference resolution (Stoyanov et al., 2010b,a). We used the same set of preprocessing components as Stoyanov et al. (2009) and took a subset of their features for our local features. The names of the features that we use are listed in Table 1 and are documented in our code. The code of our system is available upon request. We can also provide a trained version of our easy-first algorithm that can be used as a resolver.

4.1 Data

We experiment with five of the most commonly used coreference resolution data sets. Those include two corpora from the MUC conferences (MUC-6, 1995; MUC-7, 1997) and three from the Automatic Content Evaluation (ACE) Program (NIST, 2004). We use the training and test splits previously used by Stoyanov et al. (2009).

We first evaluate an end-to-end coreference system that automatically discovers mentions. We measure system performance using two common scoring algorithms—MUC (Vilain et al., 1995) and BCubed (Bagga and Baldwin, 1998). When working with automatically extracted mentions, rather than gold-standard mentions, we use the BCubed variant proposed by Stoyanov et al. (2009), which they label BCubed_{all}.

We also compare to two unsupervised systems that have claimed the best scores on recent evaluations: the systems of Haghighi and Klein (2010) and Raghunathan et al. (2010). In order to compare to those, we also train and test a version of our system that uses gold-standard mentions on the MUC6 and ACE04 corpora. For training on the MUC6 corpus we follow the standard training/test split and report results on the test part. Unsupervised systems (Haghighi and Klein, 2010; Raghunathan et al., 2010) test on the entire newswire portion of the ACE04 corpus. In order to test the supervised methods on the same corpus, we randomly split it in two, and test on each half when training on only the other half (two-fold cross validation).

4.2 Baselines

We compare to a baseline that trains a pairwise classifier and then performs transitive closure. This setting is similar to the state-of-the-art systems of Bengtson and Roth (2008) and Stoyanov et al. (2009). The baseline system uses the same linear scoring function and the same feature set as our easy-first system, including global features. However, it only scores the pairwise joins of the initial single-mention clusters. It then simply performs transitive closure on the pairs whose scores are above the halting threshold, rather than computing new join scores during agglomerative clustering. As noted previously, the baseline is trained using the standard averaged perceptron (Freund and Schapire, 1999) and the positive decision threshold is tuned on training data as in the easy-first system.

Our pairwise baseline uses the same data splits and pre-processing components as Stoyanov et al. (2009). Thus, our results are directly comparable. In fact, our baseline can be considered a re-implementation of Stoyanov et al. (2009), except for the feature set. Our local features are a subset of the features used by Stoyanov et al. (2009), but we have also added some of the features described by Raghunathan et al. (2010) (as discussed in Section 4.3). We will use *Pairwise* to refer to this baseline in the results.

Our *Easy-first*$_{percep}$ setting runs our easy-first inference algorithm (Algorithm 1) but using the same perceptron-trained weights as the baseline system while still utilizing the global features. Finally, *Easy-first*$_{struct}$ also runs easy-first inference, but after training with the full algorithm described in Section 3.4 and Algorithm 2.

4.3 Results

Results of our fully automatic, end-to-end coreference resolution system are shown in Table 2. Results using gold standard mentions are shown in Table 3.

Comparison to Stoyanov et al. (2009). As previously mentioned, our *Pairwise* baseline (the second result line in Table 2) is a reimplementation of Stoyanov et al. (2009) (the first result line) with a different feature set. The results are quite different—*Pairwise* performs slightly worse than Stoyanov et al. on the MUC6 corpus and substantially worse on MUC7, while it shows substantial gains across the three ACE corpora. For instance, we gain 6 points of MUC F1-score on the ACE04 corpus. We attribute these differences to the different features and resources that we used. The main differences are outlined below.

First, *Pairwise* drops several of the features used by Stoyanov et al. (2009). Most notably, we drop the *RuleResolve* and *ProResolve* features that they utilize. Those features rely on an internal rule-based coreference and anaphora resolution systems, respectively, and indicate whether the respective rule based system clustered the noun-phrases together. We chose not to utilize these

	MUC6		MUC7		ACE03		ACE04		ACE05

Easy-First$_{struct}$	**72.1**	68.2	64.6	57.7	**83.1**	**74.5**	**80.9**	**68.8**	75.9	**70.9**

Table 2: Results for "end-to-end" coreference resolution, where mentions are automatically extracted. The best result in each column is boldfaced.

	MUC6		ACE04	
	B^3	*MUC*	B^3	*MUC*
Haghighi and Klein	75.0	81.9	76.9	76.5
Raghunathan et al.	73.2	77.7	78.9	78.1
Stoyanov et al.	76.1	**88.2***	*77.8*	*76.2*
Pairwise baseline	72.7	**88.2***	75.9	78.9
Easy-First$_{percep}$	73.3	**88.2***	78.4	**79.8**
Easy-First$_{struct}$	**77.5**	**88.2***	**81.8**	**80.1**

Table 3: Results with gold-standard mentions. In each column, the best result is boldfaced along with all statistically indistinguishable results (paired permutation test, $p < .01$). A star indicates that the result was achieved by a degenerate clustering—the algorithm learns a threshold that groups all mentions in a single cluster.[5] Italics indicate that result are not comparable to the rest, because Stoyanov et al. (2009) use a different test/train split and evaluate on only a subset of the ACE04 documents. Note also that the first two systems are unsupervised.

features because the rule-based systems are computationally expensive. They also appear to be engineered with significant amounts of knowledge and seem to be targeted toward the MUC corpora. We confirmed empirically that the decrease of performance on the MUC7 corpus is due to the absence of these features.

Second, as noted earlier, *Pairwise* introduces several new features inspired by Raghunathan et al. (2010). Below we list the most useful new features as shown through ablation studies:

- **Demonyms** – this feature is true if one of the two mentions is a demonym of the other, e.g. *Holland* and *Dutch*. We utilize the list of demonyms from Raghunathan et al. (2010).
- **WhoResolve** and **WhichResolve** – true for mentions that are animate/inanimate relative pronouns and the preceding mention in the text. This features can help resolve construct such as "*Smith*, *who* was present . . . ".
- **CountryCapital** – true if one mention is a country and the other is the capital of that country. This feature is useful since capitals are often used to refer to the country governments, e.g. "*London* issued a statement." This feature is novel to this work. We used a list of country capitals that we mined from Wikipedia.

Third, following Raghunathan et al. (2010), we use the list of name/gender associations provided by Bergsma and Lin (2006). This list is more comprehensive and more precise than the list that comes with the Reconcile system.

[5] Previous work (Stoyanov et al., 2009) has pointed out that because MUC annotates only anaphoric mentions, such a baseline results in a surprisingly strong performance when evaluating on MUC data with gold-standard mentions and using the MUC score.

Effectiveness of the Easy-First approach. Table 2 shows that easy-first inference, when trained using either our full algorithm or the perceptron algorithm, performs better than the pairwise baseline in 9 out of the 10 end-to-end evaluations. This suggests that it may also work better in other evaluations.[6] In general, the advantage of easy-first is stronger on the more precision-conscious BCubed score, which can be expected since easy-first mainly aims to correct precision errors (see section 4.4 for examples).

The improvements are more pronounced when we evaluate our system on gold-standard mentions as shown in Table 3. Compared to the unsupervised systems of Haghighi and Klein (2010) and Raghunathan et al. (2010), our system shows improvements of at least 2 points on all evaluation metrics on both datasets. When evaluated on BCubed score, easy-first outperforms the pairwise baseline by 5–6 points on both corpora, and Algorithm 2 now helps substantially.

For the gold-standard experiments, we test the statistical significance of these measured improvements, treating each test document as an independent observation. A paired permutation test ($p < .01$) reveals that improvements of Easy-first$_{struct}$ over Raghunathan et al. (2010) are statistically significant in all four settings. Additionally, Easy-first$_{struct}$ improvements over the pairwise baseline are statistically significant in the two settings that use BCubed score for evaluation. For the two settings using MUC score, the pairwise baselines as well as our methods find a degenerate solution that works well for that evaluation measure—the algorithm learns a threshold that groups all mentions in a single cluster.

To the best of our knowledge, the results presented in Table 3 represent a new state-of-the-art for systems using gold-standard mentions. For end-to-end coreference systems, our results in Table 2 represent a new state-of-the-art for the three ACE corpora.

4.4 Qualitative Evaluation

The cold hard numbers behind our evaluation tell only half of the story. Looking at the output of the end-to-end system reveals that the easy-first system produces results that look more consistent with human expectations. Consider, for instance the following sentence from an ACE05 document: *"The court order was requested by Jack Welch's attorney, Daniel K. Webb, who said Welch would likely be asked about his business dealings, his health and entries in his personal diary."*

The pairwise baseline is confused by the evidence that suggests that *his* should be linked to both *Welch* and *Daniel K. Webb* and incorrectly assigns all eight of the underlined mentions to the same cluster. Our easy-first approach, in contrast, does not attempt to join clusters that contain conflicting person names. Thus, it correctly separates {*Jack Welch's attorney, Daniel K. Webb* and *who*} into one cluster and all other mentions into another cluster.

Another example from the ACE04 corpus concerns resolving the following sentence: *"Tamara Maschino, for example, a resident of the Clear Lake area of Houston, criticizes Bush for his lack of attention to pollution problems from chemical plants near her home."*

Here the pairwise baseline resolves the pronoun *her* to *Bush*, grouping together {*George Bush* (an earlier occurrence), *Bush*, *his*, *her*}. The easy-first system, in contrast, first links the mention *Bush* to *George Bush*, and then correctly links *her* not to this male cluster but to *Tamara Maschino*.

[6] Indeed, 9 improvements out of 10 would be significant under a sign test ($p < 0.025$), if the 10 settings were independent. They are not, though, since the BCubed and MUC scores on a given corpus are presumably correlated.

5 Related Work

Related work on coreference resolution is discussed throughout the paper. As previously mentioned, our learning algorithm follows the easy-first approach to dependency parsing proposed by Goldberg and Elhadad (2010). Our learning method is also inspired by the structured perceptron and its application to incremental parsing (Collins and Roark, 2004). Our algorithm is an instance of learning parameters for a fixed approximate inference method (i.e., greedy search). Other approaches that learn for a fixed greedy inference method include SEARN (Daumé et al., 2009) and LaSO (Daumé III and Marcu, 2005). Other work proposes methods for learning parameters for fixed approximate methods beyond greedy search. Stoyanov et al. (2011) propose a back-propagation-based algorithm for learning the weights of Markov Random Fields and Conditional Random Fields for a fixed variational inference algorithm (they experiment with loopy belief propagation). Experiments on three NLP problems show that this regime of learning leads to more accurate system performance than traditional approximate maximum-likelihood training (Stoyanov and Eisner, 2012).

Concurrent to us, Jain et al. (2011) propose a method for learning features to guide a greedy agglomerative clustering algorithm. They apply their algorithm to a very different problem – image segmentation by clustering superpixels. Their learning algorithm is inspired by on-policy reinforcement learning and it differs from ours. Initial experiments with several reinforcement learning approaches on our problem (including Q-learning (Watkins and Dayan, 1992) and policy gradient (Sutton et al., 2000)) did not lead to improvements in our setting.

6 Conclusions and Future Work

We presented a novel algorithm for coreference resolution that capitalizes on the idea that early "easier" decisions can be used to guide later, "harder" decisions. We presented a training algorithm based on the structured perceptron for automatically learning feature weights. When evaluated on coreference data, our algorithm outperformed a competitive baseline as well as previously published state-of-the-art methods under most evaluation conditions.

Our model is still missing the opportunity to compare each action to alternatives. For instance, the algorithm should be able to learn that it is "easy" to join clusters i and j when i is the only reasonable antecedent cluster for j (there are no strong competitors). For instance, if j is headed by a pronoun and cluster i contains the only reasonable antecedent for J, the algorithm can have more confidence that i and j should be joined. Thus, it would learn to perform such actions sooner. Since actions can rely on any features of the current state, we could augment our model with such competition-style features, as used by Yang et al. (2003).[7]

Our easy-first approach is suitable for performing coreference resolution jointly with other tasks. We are particularly interested in jointly performing within-document coreference and cross-document coreference (or entity linking). An easy-first approach will allow us to trade-off decisions on the document and intra-document level. For example, linking *Obama* to the appropriate database entity may help us link it to the mention *president* later in the document.

Acknowledgments

Thanks to the anonymous reviewers, and to Yoav Goldberg, for their thoughtful comments on an earlier version. Also thanks to the JHU NLP group and especially Shane Bergsma for early

[7] We do already use competition-style features to evaluate pronoun antecedents, as described in section 3.3.

discussions of the approach. This work was supported by the the Human Language Technology Center of Excellence at Johns Hopkins University, and by National Science Foundation under Grant No. 0964681 to the second author.

ABSTRACT

In this article, we present a novel approach towards the detection and modeling of complex social phenomena in multi-party discourse, including leadership, influence, pursuit of power and group cohesion. We have developed a two-tier approach that relies on observable and computable linguistic features of conversational text to make predictions about sociolinguistic behaviors such as Topic Control and Disagreement, that speakers deploy in order to achieve and maintain certain positions and roles in a group. These sociolinguistic behaviors are then used to infer higher-level social phenomena such as Leadership and Influence, which is the focus of this paper. We show robust performance results by comparing our automatically computed results to participants' own perceptions and rankings. We use weights learnt from correlations with training examples known leadership and influence rankings of participants to optimize our models and to show performance significantly above baseline for two different languages – English and Mandarin Chinese.

1 Introduction and Related Work

Our objective is to model high-level sociolinguistic phenomena such as Leadership, Influence, Pursuit of Power and Group Cohesion in discourse. This research project aims to develop a computational approach that uses linguistic features of conversational text to detect and model sociolinguistic behaviors of conversation participants in small group discussions. Given a representative dialogue of multi-party conversation, our prototype system automatically classifies the participants by the degree to which they engage in such sociolinguistic behaviors as Topic Control, Task Control, Disagreement, and several others discussed in this paper. These mid-level sociolinguistic behaviors are deployed by discourse participants in order to assert higher-level social roles such as Leadership. Our approach to this problem combines robust computational linguistics methods and established empirical social science techniques. The focus in this paper is on online multi-party conversations in chat rooms; however, the models we are developing are intended to be universal and are applicable to other conversational situations: informal face-to-face interactions, formal meetings, moderated discussions, asynchronous threaded discussions as well as interactions conducted in languages other than English, e.g., Urdu and Mandarin. We shall discuss the robust detection of Leadership and Influence in discourse in this paper; we defer the discussion of remaining phenomena to a separate, larger publication.

Proceedings of COLING 2012: Technical Papers, pages 2535–2552,
COLING 2012, Mumbai, December 2012.

Social science theory indicates that leadership may be manifested in various ways (Bradford, 1978, Huffaker, 2010). We define leadership in the following terms: A leader is someone who guides group toward an outcome, controls group discussion, manages actions of the group and whom members recognize as the task leader. Such a leader is a skilled *task* leader, which corresponds to the social science theory put forth in Beebe and Masterson (2006). On the other hand, a *thought* leader in the group is someone who has credibility in the group and introduces ideas or thoughts that others pick up on or support. Such a person is a participant but need not be active in the portion of discussion where others credit or support him. This definition corresponds to the Initiator-Contributor type of leadership outlined in Bradford (1978). For ease of presentation and understanding – we shall refer to task or skilled leadership as *Leadership* and thought leadership as *Influence*, henceforth in this paper.

Since leadership and influence are manifested differently and may be deployed by distinct participants in a discussion, it is important for an automatic system to recognize the distinction and make a determination of who is deploying such roles. Consider as an example, a debate with panel of experts hosted by a facilitator. Here, the facilitator will exhibit sociolinguistic behavior consistent with being a task leader, by controlling the agenda, putting forth questions to individual panelists, beginning and ending the discussion and so on. However, she will not be a thought leader, or influencer, as she does not contribute much actual content to the discussion apart from asking questions. Any member of the expert panel may exhibit the sociolinguistic behavior consistent with being an influencer. In a peer-oriented group discussion however, it could occur that the task and thought leader (leader and influencer) are the same person.

Human-human interaction affords a rich resource for research. Much prior work has been done in communication that focuses on the communicative dimension of discourse. For example, the Speech Act theory (Austin, 1962; Searle 1969) provides a generalized framework of multiple levels of discourse analysis; work on dialogue analysis (Blaylock, 2002; Carberry and Lambert, 1999; Stolcke et al., 2000) focuses on information content and structure of dialogues. Somewhat more relevant to social roles is research that models sequences of dialogue acts (Bunt, 1994), in order to predict the next dialogue act (Samuel et al. 1998; Stolcke, et al., 2000; Ji & Bilmes, 2006, inter alia) or to map them onto subsequences or "dialogue games" (Carlson 1983; Levin et al., 1998), from which participants' functional roles in conversation (though not social roles) may be extrapolated (e.g., Linell, 1990; Poesio and Mikheev, 1998; Field et al., 2008). However, the effects of speech acts on social behaviors and roles of conversation participants have not been systematically studied. Research in anthropology and communication has concentrated on how certain social norms and behaviors may be reflected in language (e.g., Scollon and Scollon, 2001; Agar, 1994). But, there are few systematic studies in the current literature that explore the way in which language may be used to make predictions of social roles in groups where (a) these roles are not known a priori, or (b) these roles do not exist prior to the beginning of the discourse and only emerge through interaction.

Internet-enabled conversation is particularly interesting because in this reduced-cue environment, the only means of engaging in and conveying social behaviors is through written language. As such, studying online chat relies on the more explicit linguistic devices necessary to convey social and cultural nuances than is typical in face-to-face or telephonic conversations. The use of language by participants as a feature to determine interpersonal relations has been studied by Bracewell et al. (2011) who developed a learning framework to determine collegiality between discourse participants. Their approach, however, looks at singular instances of linguistic markers or single utterances rather than a sustained demonstration of sociolinguistic behavior over the

course of entire discourse. Freedman et al. (2011) have developed an approach that takes into account the entire discourse to detect behaviors such as persuasion; however their analysis is conducted on and models developed upon online discussion threads where the social phenomena of interest may be rare. By contrast, we build our models based on analysis of a data corpus of online chat discourse, where data collection experiments were specifically designed so that the resulting corpus may be rich in sociolinguistic phenomena.

Our research extends the work of Strzalkowski et al. (2010) and Broadwell et al. (2012), who first proposed the two-tiered approach to sociolinguistic modeling and have demonstrated that a subset of mid-level sociolinguistic behaviors may be accurately inferred by a combination of low-level language features. We have adopted their approach and extended it to modeling of leadership and influence. Furthermore, we enhanced the method by adding the evidence learnt from correlations of indices and measures to compute weights through which sociolinguistic behaviors may be combined appropriately to infer higher-level social phenomena.

In this paper, we describe our approach to model Leadership and Influence in online multi-party task-oriented chat dialogues. We show how our models were developed on evidence from online English and Mandarin chat dialogues. Performance on both languages is very encouraging.

2 Sociolinguistic Behaviors to Model Leadership and Influence

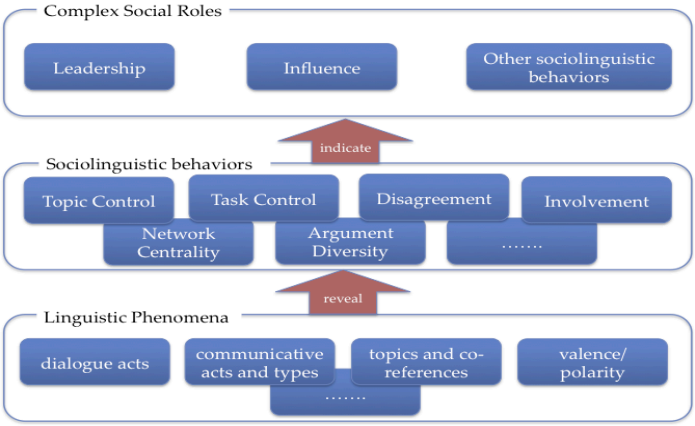

FIGURE 1 – Two-tier approach applied to model social roles in discourse.

In our two-tier approach, we use linguistic elements of discourse to first unravel sociolinguistic behaviors, and then, use the behaviors, in turn, to determine social roles, as shown in Figure 1. It is important to note that, at both levels, our analyses are solidly grounded on sociolinguistic theory. Mid-level behaviors that we shall discuss in this article are Topic Control, Task Control, Disagreement, Involvement, Argument Diversity and Network Centrality that are computed using *indices*. These indices are directly obtained from linguistic elements of discourse, which are described in Section 3. For each participant in the discourse, we compute the degree to which

they engage in sociolinguistic behaviors, using *measures,* which are a linear combination of indices. We describe behaviors, component indices and corresponding measures in this section.

2.1 Topic Control Measure (TCM)

Topic Control is defined as attempts of participants to impose a topic of conversation. This sociolinguistic behaviour is consistent with both Leadership and Influence. In any conversation, whether it is focused on a particular issue or task or is just a social conversation, the participants continuously introduce multiple topics and subtopics. These are called *local topics*. Local topics, following the notion put forth by Givon (1983), may be equated with any substantive noun phrases introduced into discourse that are subsequently mentioned again via repetitions, synonyms, or pronouns. Who introduces local topics, who continues to talk about them, and for how long are some of the indicators of topic control in dialogue. We have developed four indices for Topic Control. Participants who introduce more local topics exert more topic control in dialogue. The first index, called the **Local Topic Introductions Index (LTI)** calculates the proportion of local topics introduced by each participant, by counting the number of first mentions of local topics by each participant as percentage of all local topics in a discourse. The **Subsequent Mentions of Local Topics (SMT)** index calculates the percentage of discourse utterances where the local topics introduced by each participant are being mentioned (by themselves or others) through repetition, synonym, or pronoun. The **Cite Score (CS)** index calculates the percentage of subsequent mentions of local topics first introduced by each participant, but excluding the self-mentions by this participant. The final measure of topic control is the average **Turn Length (TL)** per participant. This index calculates the average utterance length (words) for each participant, relative to other participants.

We shall explain the calculation of one index – Local Topic Introductions (LTI) - in detail. Figure 2 shows a fragment of an actual chat conversation from our corpus with selected local topic references to illustrate how the constructed indices model the concept of Topic Control. In this small excerpt, a few local topics are introduced, including *Carla*, *nanny* and *horses*, as well as possibly others (*record, car,* etc). These local topics are underlined in different ways, with the first mention set in boldface. For example, *Carla* is introduced by speaker JR in turn 1, and is subsequently mentioned by KN (turn 2), LE and KN (via *she*) in turns 3 and 4. Similarly, KN introduces horses in turn 4, and then self-mentions it again in turn 6.

1. **JR**: *wanna go thru **Carlas** resume first ?*
2. **KN**: *i wonder how old carla is*
3. **LE**: *Ha, yeah, when I hear nanny I think she is someone older.*
4. **KN**: *she's got a perfect driving record and rides **horses**! coincidence?*
5. **JR**: *'06 high school grad*
6. **KN**: *i think she rides a horse and not a car!*

FIGURE 2 – Fragment of chat with a few selected local topics highligted.

Once we have computed the scores for each participant on each index, we combine them to compute a single score on the corresponding measure. In Figure 2, we only highlight a few local topics, to illustrate the process. Nouns such as *resume* and *high school*, are not marked for ease of presentation.

In this case, the LTI, SMT, CS and TL indices are combined to get a Topic Control Measure (TCM) for each participant. For instance, suppose we discover the following in a conversation with 7 participants and over 600 total turns:

1. *There are 90 distinct local topics introduced in the conversation.*
2. *The mean rate of local topic introduction is 14.29%.*
3. *Participant LE introduces 23 local topics. Thus, LTI index for LE is 23/90, that is, 23.6%.*
4. *Participant LE scores the highest amongst all on the LTI index in this conversation.*

Using the above information, we can assert that participant LE has the highest topic control in the conversation *based on the LTI index*. This is evidence based on just one index; we compute the index measures for all participants on all component indices to build additional evidence. In our current system prototype, TCM score is computed as the mean of component index scores.

2.2 Task (or Skilled) Control Measure (SCM)

Task Control is an effort by one or more members of a group to define the group's project or goal and/or steer the group towards it. Task Control is gained by telling others to perform certain tasks, or subtasks, or to accept certain decisions about the task. It can also be gained by the speaker offering to perform a task. This sociolinguistic behaviour is primarily consistent with Leadership. One index of Task Control is the number of directives (done as statements or questions) made by each participant as a percentage of all directives in discourse, known as **Directive Index (DI)**. In other words, a participant who tells others what to do (whether overtly or more subtly) is attempting to control the task that the group is performing. Other indices have been developed to support Task Control; these will be explained in future publication.

2.3 Cumulative Disagreement Measure (CDM)

Disagreement has a role to play with regard to leadership and influence in that it is possible that a person in a small group engages in disagreements with others in order to control the topic by way of identifying or correcting what they see as a problem (Ellis and Fisher, 1994; Sanders, Pomerantz and Stromer-Galley, 2010). While each utterance where a participant disagrees with another is a vivid of expression of disagreement, we are interested in a sustained phenomenon where participants repeatedly disagree, thus revealing a social relationship between them. One of the indices we have developed to measure disagreement is the proportion of disagree and/or reject turns produced by a participant that are directed at any other participants in the discourse. This index is called the **Disagree-Reject Index (DRI)**.

2.4 Involvement Measure (INVX)

Involvement is defined as a degree of engagement or participation in the discussion of a group. This behavior is consistent primarily with Leadership. A degree of involvement may be estimated by how much a speaker contributes to the discourse in terms of substantive content. Contributing substantive content to discourse includes introduction of new local topics, taking up the topics introduced by others, as well as taking sides on the topics being discussed. By topics here, we mean the local topics described previously. We have defined five indices in support of Involvement, we shall expand on three of them here. The **Noun Phrase Index (NPI)** is the amount of information content that each speaker contributes to discourse. The NPI measure is calculated by counting the number of content words (e.g., all occurrences of nouns and pronouns referring to people, objects, etc.) in each speaker's utterances as a percentage of all content words

in discourse. The **Turn Index (TI)** is the frequency of turns that different speakers have during a conversation. The **Topic Chain Index (TCI)** is computed by identifying the most frequently mentioned topics in a discourse, i.*e.,* topics chains (i.e., with gaps no longer than 10 turns and then by computing the percentages of mentions of these persistent topics by each participant.

2.5 Network Centrality Measure (NCM)

Another measure is the degree to which a participant is a "center hub" of the communication within the group. In other words, someone whom most others direct their comments to as well as whose topics are most widely cited by others. This behavior is consistent mainly with Influence. Two of the indices used to compute this measure are described. **Communication Links Measure (CLM)** index calculates a degree of Network Centrality for a participant by counting the utterances that are addressed to this participant as a percentage of all utterances in discourse. **Citation Rate Index (CRI)** calculates the degree of Network Centrality for a participant by counting the number of times that the local topics introduced by this participant are cited by other participants. Unlike the Subsequent Mentions measure (SMT) of Topic Control Measure, we calculate CRI by normalizing the citation count by the number of topics introduced by the participant, thus obtaining an average citation rate per topic.

2.6 (Measure of) Argument Diversity (MAD)

Argument Diversity, a behavior consistent with Influence, is displayed by the speakers who deploy a broader range of arguments in conversation. This behavior is signaled by the use of more varied vocabulary, including specialized terms and citations of authoritative sources, among others. A person who uses more varied vocabulary and introduces more unique words into a conversation is considered to have a higher degree of Argument Diversity, which can be measured using the two indices: the **Vocabulary Introduction Measure (VIM)** which is calculated as a proportion of new content words introduced by each participant to all distinct content words in discourse; and the **Vocabulary Range Index (VRI)** which is the number of distinct words used by this participant as a percentage of all distinct words in discourse.

2.7 Combining Indices and Measures

As outlined briefly at the end of Section 2.1, we compute the score of each *measure* by taking linear combination of scores obtained on each *index*. We can thus obtain a full ranking of participants on each sociolinguistic behavior. The measures used to compute Leadership are Topic Control, Task Control, Disagreement, and Involvement. These are indicated in Beebe and Masterson (2006) and borne out in our research. Measures used to compute Influence are Topic Control, Disagreement, Network Centrality and Argument Diversity. Since we have defined Influence as the Initiator-Contributor type of leadership (Bradford, 1978), we shall use those sociolinguistic behaviors that pertain to initiating discussion and contributing substantively in the group. On the other hand, Task Control and Involvement have little or minor role to play in computing Influence, and hence we do not include them while combining behaviors. Similarly, while Task Control and Disagreement are most indicative of Task Leadership, other behaviours such as Network Centrality and Argument Diversity do not correlate with this role. Hence, we do not include them in computation of Leadership. We shall elaborate on this in Section 5, Evaluation and Results.

3 Corpus, Annotation and Computational Modules

The models described in this paper are derived from online chat dialogues. The corpus we use for this analysis is the MPC chat corpus (Shaikh et al., 2010, Liu et al., 2012). This is a corpus of over 90 hours of online chat dialogues in English, Urdu and Mandarin. Participants in these chats are native speakers of these languages. Each chat session is a task-oriented dialogue around 90 minutes in length, with at least 4 participants. This corpus is particularly useful for the type of sociolinguistic analysis we are interested in due to the characteristics of interaction in each chat session – the participants are focused on some task, they form a fairly stable group and the dynamics of conversation unfold naturally through discourse. Other corpora exist such as the ICSI-MRDA corpus (Shriberg et al., 2004) and the AMI meeting corpus (Carletta, 2007), however these are spoken language resources rather than online chat. Where other corpora of online chat do exist, like the NPS Internet chat corpus (Forsyth and Martell, 2007) and StrikeCom corpus (Twitchell et al., 2004), they do not contain any information about the participants themselves or their reactions to the discussion. In order to create a ground truth of assessments of sociolinguistic behavior, we needed certain information to be captured through questionnaires or survey following each data collection session. In the data that comprise MPC corpus, at the conclusion of each chat session, participants were asked to fill out a survey consisting of a series of questions about their perceptions of and reactions to conversation that had freshly participated in. The questions were focused on eliciting responses about sociolinguistic behavior. Questions pertaining to Leadership and Influence are shown in Figure 3. Participants may interpret the notions of socio-linguistic phenomena intuitively, and may rank themselves and other participants accordingly. We refer the reader to the Conclusion section where we address this issue. There are similar questions regarding other behaviors we are interested in modeling and we refer the reader to the cited paper (Shaikh et al., 2010) for a detailed discussion of these.

- *During the discussion, some of the people talking are more influential than others. For the conversation you just took part in, please rate each of the participants in terms of how influential they seemed to you? Scale: Not Influential --- Very Influential.*
- *Below is a list of participants including yourself. Please rank order the participants with regards to leadership.*

FIGURE 3 – Questions regarding sociolinguistic phenomena in post-discussion survey.

We developed a multi-layer annotation process so that automatic modules may be trained to detect and classify social behaviors from discourse. A substantial subset of the MPC corpus was annotated using trained annotators who are native speakers of the respective language. Annotators were trained extensively so that inter-annotator agreement level was sufficiently high (0.8 or higher Krippendorf's alpha). We briefly explain three of the categories that annotation was performed on:

3.1 Communication Links

It is important and very challenging to determine automatically who speaks to whom in multi-party discourse. In our annotation process, we ask annotators to classify each utterance in the chat by marking it as either a) addressed to someone or everyone; b) a response to someone else's specific prior utterance; or c) a continuation of one's own prior utterance. Using annotated data from this layer of annotation; we can train a communication link classification module, which

uses context, inter-utterance similarity and proximity of utterances as some of the features in a Naïve Bayes classifier to automatically classify utterances in one of the above-mentioned three categories. The current performance of this module is 61% accuracy as measured against annotated ground truth data. Indices that are calculated using this automatic module include the Communication Links Measure (CLM).

3.2 Dialogue Acts

We have developed a hierarchy of 15 dialogue acts in order to annotate the functional aspect of an utterance in discourse. The tag set adopted is based on DAMSL (Allen and Core, 1997) and SWBD-DAMSL (Jurafsky et al., 1997), but compressed to 15 tags tuned towards dialogue pragmatics and away from more surface characteristics of utterances. A detailed description of dialogue act tags and annotation procedure has been described in a separate publication. Some dialogue acts that are note-worthy are: Assertion-Opinion, Disagree-Reject, Agree-Accept, Offer-Commit, Information-Request and Action-Directive. Annotated data from this process is used to train a cue-phrase based dialogue act classifier adapted from Webb and Ferguson's (2010) approach, which currently performs at 64% accuracy. Our Cumulative Disagreement Measure (CDM) is calculated using the proportion of disagreement dialogue act utterances detected for each participant by this automatic module. Directive Index (DI) for Task Control is also computed by counting the number of Action-Directive and Offer-Commit types of dialogue acts made by participants.

3.3 Local Topics

Local topics are defined as nouns or noun phrases introduced into discourse that are subsequently mentioned again via repetition, synonym, or pronoun. Annotators were asked to mark all nouns and noun phrases of import from the discussion. We use Stanford part-of-speech tagger (Toutanova et al., 2003) to automatically detect nouns from text. Princeton's Wordnet (Miller et al., 1990) is consulted to identify synonyms commonly used in co-references. Since POS taggers are typically trained on well-formed text, performance of POS tagging on chat text – where grammar may be disorganized, use of abbreviations and symbols etc. may be quite frequent – would affect the accuracy of POS tagging. Our automatic local topic detection module performance is at 70% in the current system prototype. Several indices including Local Topic Introductions (LTI) and Citation Rate Index (CRI) are computed using this module.

We note here that it is not the goal of this research to develop the best POS tagger or the most accurately performing dialogue act classifier. In spite of the shortcomings in the computational modules that support our index calculations, we are able to achieve very robust performance in our intended task of modelling complex social roles. This is because we base our claims of sociolinguistic behaviors on repeated counts of each linguistic phenomenon over the length of entire discourse. When computational modules such as local topic detection fail, such errors are systematic, and would be replicated for each participant in their index scores. If the count for each participant were not fully accurate, nevertheless, the *distribution* of counts for all participants would still hold, thus giving us the desired ranking or the degree of sociolinguistic behaviour for each participant.

Having multiple indices for each behavior helps us account for error introduced from automatic modules. If the predictions on individual indices are not always consistent, we can still combine them into a single output by using different weighting schemes, albeit with lesser confidence. In

order to validate our proposed indices and measures, we analyzed their correlation with each other, both from human annotated data as well as our automatic process, as we shall discuss next.

4 Correlations

4.1 Correlations between proposed indices and behaviors

We compute the scores for each participant of a dialogue for each proposed index. For example, in Table 1, we show the correlation between component indices for Topic Control measure computed for a sample chat session from the MPC corpus – Turn Length (TL), Subsequent Mentions of Local Topics (SMT) and Local Topic Introductions (LTI). If the proposed indices indeed measure the same phenomena, then the correlation between them should be very high. The Cronbach's alpha (1951, 2003) for the scores shown in Table 1 is 0.96, which is extremely high. In Table 2, we show the correlation among selected indices used to compute Involvement measure (INVX). These are Noun Phrase Index (NPI), Turn Index (TI) and Topic Chain Index (TCI). The Cronbach's alpha for this table is also extremely high.

	TL	SMT	LTI	TCM
TL	1.0			
SMT	0.96	1.0		
LTI	0.78	0.80	1.0	
TCM	0.92	0.95	0.88	1.0
α	0.96			

	NPI	TI	TCI	INVX
NPI	1.0			
TI	0.76	1.0		
TCI	0.97	0.83	1.0	
INVX	0.96	0.83	0.98	1.0
α	0.98			

TABLES 1, 2 – Correlation among selected Topic Control and Involvement indices for a sample online chat dialogue

For all sessions we looked at, the correlation among indices of all proposed measures is quite strong, averaging above 0.93 for the Cronbach's alpha reliability statistic. Thus, strong correlations were seen among the index scores both for annotated data as well as automatic computation.

4.2 Correlations between proposed measures and human assessments

In addition to the correlation among indices within a proposed measure, we also computed the correlations among our proposed measures of Leadership and Influence. Figure 4 displays the correlations between the four measures of Leadership – Topic Control Measure (TCM), Skilled Control Measure (SCM), Involvement Measure (INVX) and Cumulative Disagreement Measure (CDM) on an actual 10-participant chat session from MPC corpus. Figure 5 shows the correlations between four measures – Topic Control Measure (TCM), Cumulative Disagreement Measure (CDM), Network Centrality Measure (NCM) and Measure of Argument Diversity (MAD). These measures were calculated for an actual 9-person chat session from the MPC corpus. For both Figures 4 and 5, the x-axes are the anonymized participant names DE, NT and so on and the y-axes are the scores on each of the measures, normalized as percentages.

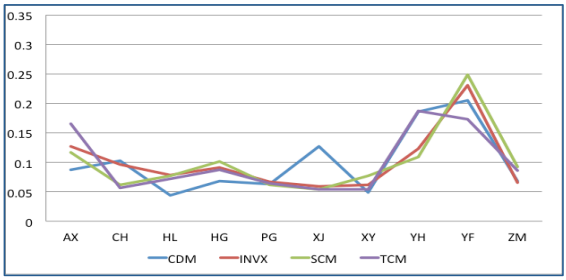

FIGURE 4 – Correlation between selected Leadership measures for a typical chat dialogue

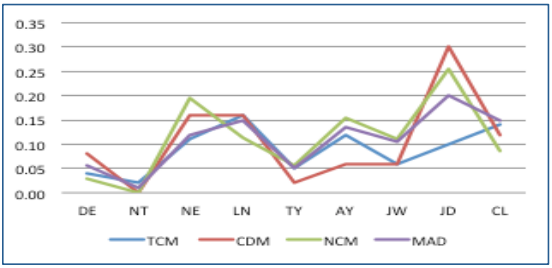

FIGURE 5 – Correlation between selected Influence measures for a typical chat dialogue.

Additionally, we show the correlations between all proposed Leadership and Influencer measures in Tables 3 and 4, to note one important finding. We note that Cumulative Disagreement Measure correlations are lower than the other measures, pointing to evidence of it being the discriminant variable. We have observed similar correlation patterns across the sessions we have looked at.

Leader-ship	SCM	TCM	INVX	CDM
SCM	1.0			
TCM	0.72	1.0		
INVX	0.95	0.77	1.0	
CDM	0.66	0.71	0.76	1.0

Infl-uence	NCM	MAD	TCM	CDM
NCM	1.0			
MAD	0.86	1.0		
TCM	0.98	0.86	1.0	
CDM	0.58	0.59	0.48	1.0

TABLE 3, 4 – Correlation among measures of Leadership and Influence for sample chat dialogue

Computing the correlation against human rankings elicited using survey questionnaire provides us with evidence that indeed the proposed behaviors are measuring the correct phenomena. The correlation between rankings produced by annotated data and ranking induced by participant ratings holds quite strongly across a significant proportion of data sets in our corpus with an average of over 0.80 Cronbach's alpha. Using this evidence of high correlations among indices, among behaviors and their measures, as well as measures against human survey ratings, we can be confident about our approach in measuring and detecting Leadership and Influence.

5 Evaluation and Results

In Table 5, we show how Leadership and Influence are present across different sessions in the MPC corpus. This is determined from participant ratings on post-discussion survey. On average, across both English and Chinese data, in 44.8% of dialogues different participants held the roles of the (task) Leader and the Influencer. Consequently, a significant portion of the MPC corpus has distinct participants exhibiting sociolinguistic behaviors consistent with either Leadership or Influence but not both. In the remaining dialogues, the same person was the leader and the influencer, thus exhibiting both types of behaviors at the same time. An automatic system should be able to distinguish between cases where the leader and influencer are the same person or different; the MPC corpus has a sufficient number of sessions for both cases.

Leader and Influencer are the same participant	Leader and Influencer are different participants
55.2%	44.8%

TABLE 5 – Number of sessions in MPC corpus where Leadership and Influence are exhibited by same or different participants (in percentages)

We compute the scores for each participant for all proposed measures. Although we have a full ranking of participants, both from survey ratings as well as system output, we are only interested in participants who have the highest Leadership and Influence. This means, the top-ranking participant on both rankings should match in order evaluate system performance. In cases where the top two individuals are quite close in the survey scores, we may consider top two participants.

We calculate the Leadership and Influencer score for all participants by taking the mean of our measures and deriving a Leadership and Influencer score for each participant. Using this simple weighting scheme of taking an average across all measures of the corresponding behavior, our accuracy is ~51% in predicting the top Leader and ~70% in predicting the top Influencer across our test data set. However, this scheme does not take into account the evidence found using correlations among measures. We have found that, on average, TCM measure correlates higher than other measures for Influence with survey ratings. We also discovered that SCM (Skilled Control Measure) correlates higher in Chinese dialogues than in English for Leadership. Consequently, we devised a weighting scheme that reflects the evidence found from our analysis of correlations against survey ratings.

So, the weighting scheme for English chat dialogues is:

Leader score = $(\alpha_{TCM} * TCM) + (\alpha_{SCM} * SCM) + (\alpha_{INVX} * INVX) + (\alpha_{CDM} * CDM)$

Where $\alpha_{TCM} > \alpha_{SCM} > \alpha_{CDM} > \alpha_{INVX}$

Influencer score = $(\alpha_{TCM} * TCM) + (\alpha_{CDM} * CDM) + (\alpha_{NCM} * NCM) + (\alpha_{MAD} * MAD)$

Where $\alpha_{TCM} > \alpha_{NCM} > \alpha_{MAD} > \alpha_{CDM}$

Similar combinations are derived for Chinese chat dialogues as well. Using this weighting scheme, we compute the Leadership and Influencer scores again. We illustrate this for Leadership in Table 6; the corresponding analysis is also applied for Influence in Table 7. In Table 6, we see that participant CC has the highest score on leadership from survey rating (4.33), followed by AA (score of 4). If we combine the scores computed automatically by our system on Leadership measures, TCM, SCM, INVX and CDM by taking an average, participant AA scores the highest (0.28). However, using the weights learnt from correlations, these scores can be correctly combined to get a score of 0.59 for CC.

Partici -pant	Survey Score	TCM	SCM	INVX	CDM	Leadership without weights	Leadership with weights
AA	4	0.23	0.25	0.31	0.33	0.28	0.48
BB	1.67	0.15	0.13	0.12	0.09	0.12	0.30
CC	4.33	0.27	0.43	0.21	0.14	0.26	0.59
DD	0.67	0.09	0.06	0.09	0.12	0.09	0.20
EE	1	0.10	0.06	0.13	0.09	0.09	0.22
FF	3.33	0.16	0.08	0.15	0.23	0.16	0.29

TABLE 6 – Leadership score computed using linear combination with weights on a sample English chat dialogue

Participant	Survey Score	TCM	CDM	NCM	MAD	Influencer w/ weights
AA	5.5	0.11	0.15	0.06	0.17	0.20
BB	5	0.13	0.15	0.19	0.11	0.28
CC	6.84	0.26	0.25	0.33	0.13	0.49
DD	4.67	0.23	0.25	0.21	0.28	0.44
EE	5	0.15	0.1	0.16	0.14	0.28

TABLE 7 – Influence score computed using linear combination with weights on a sample English chat dialogue

The accuracy of our predictions on our test data set improves to 80% for both Leadership and Influence after factoring in the weights. For different data types and different languages, we have learnt different weighting schemes where the sociolinguistic behaviors may be combined differently to compute scores. In essence, the higher the correlation, the greater the weight given to the measure. As expected and shown in Table 8, different correlations hold across languages – hence possibly cultures, since the participants are native speakers. We can see from the weighting schemes that different behaviors account for Leadership and Influence in different cultures. The Measure of Argument Diversity (MAD) has a higher correlation with Influence in Chinese chat as compared to English chat dialogues. Where the scores are 0, it signifies that the behavior is found to not correlate well with the other measures that comprise the phenomena being modeled; hence we do not include these behaviors while taking linear combinations. They may be either negatively correlated or demonstrate very low correlation; in both cases, the evidence from those behavior should not be included while predicting that sociolinguistic phenomena.

Weights	TCM	SCM	CDM	INVX	NCM	MAD
English Chat Leadership	0.75	0.6	0.3	0.23	0	0
Chinese Chat Leadership	0.68	0.73	0.36	0.45	0	0
English Chat Influence	0.75	0	0.15	0	0.5	0.4
Chinese Chat Influence	0.75	0	0.1	0	0.34	0.75

TABLE 8 – Weighting schemes for combining behaviors learnt from correlation analyses

Illustrated in Table 9, are the correlations between Measure of Argument Diversity (MAD) and Network Centrality Measure (NCM), which are behaviors that are consistent with Influence; and Involvement (INVX) and Skilled Control Measure (SCM) which are the behaviors consistent

with Leadership. We can see that MAD and NCM correlate quite highly with each other; as do INVX and SCM. By contrast, NCM and INVX correlation is very low, as is SCM and MAD. Topic Control Measure (TCM) and Cumulative Disagreement Measure (CDM) are common to both social phenomena; they exhibit high correlations and are not included in Table 9.

Correlation	MAD	NCM	INVX	SCM
MAD	1			
NCM	0.78	1		
INVX	-0.15	0.14	1	
SCM	-0.25	0.11	0.97	1

Table 9. Correlations between Leadership and Influencer measures on sample chat dialogue

In Tables 10 and 11, we show performance of detecting the top leader and influential participant across languages for the two methods we proposed, when compared to baseline. The baseline we have chosen is to pick a participant at random to be top influential person. In a small group discussion found in our corpus, this is a reasonable baseline given the limited number of participants. We could choose another baseline, such as selecting the participant with the most number of turns as the Leader or Influencer. However, we see similar performance for such baselines as the random one.

Performance Leadership	Baseline	Without Weights	With Weights	Including TFM
English Chat	17.85%	37.5%	80%	80%
Chinese Chat	12.5%	64%	72.7%	90.9%
Average	15.65%	50.75%	76.35%	85.45%

TABLE 10 – Performance of system against random baseline, with and without weighting scheme, for Leadership

Performance Influence	Baseline	Without Weights	With Weights
English Chat	17.85%	71.40%	78.50%
Chinese Chat	12.5%	69%	90%
Average	15.65%	70.2%	84.25%

TABLE 11 – Performance of system against random baseline, with and without weighting scheme, for Influence

In a separate publication (Taylor et al., 2012), we have discussed the development of an additional sociolinguistic behavior to predict Leadership in Chinese dialogues – called the **Tension Focus Measure (TFM)**. This behavior is defined as the degree to which a speaker is someone at whom others direct their disagreement, or with whose topics they disagree the most. Using this additional measure, our performance on detecting the top leader goes up to 85% average for English and Mandarin test data set.

Conclusion and perspectives

We have shown a novel, robust method for modeling social phenomena in multi-party discourse. We have combined established social science theories with computational modeling to create a two-tier approach that can detect high-level sociolinguistic phenomena such as Leadership and Influence in language with a high degree of accuracy. In future work, we have planned for a

larger scale evaluation, testing index stability, and resilience to errors in automated language processing, including topic detection, coreference resolution, and dialogue act classification. Current performance of the system is based on versions of these linguistic modules, which perform at about 70% accuracy, so these need to be improved as well. We could also experiment with training a classifier to learn the weights automatically, which we plan to report in a future publication.

The advantage of applying a two-tier approach is that we can add or remove mid-level sociolinguistic behaviors efficiently when applying our models to different data types and languages. As we have noted, we can insert additional sociolinguistic behaviors such as Tension Focus Measure, if our existing models do not completely account for Leadership in certain data sets. Such sociolinguistic analysis is impractical in a straight-forward machine-learning approach where one can add all features to a learning algorithm to decide how features may best be combined. A machine-learning approach modeled directly on linguistic features would not be easily transferable to other data types and could prove brittle. Some measures turn out to be more predictive in a given data genre, and when applied appropriately, perform well at predicting phenomena as rated and understood by human assessors. We note that there may be some variance as to how humans perceive the concept of Leadership and Influence and rate a participant based on their intuitive notion of the concept. The fact that we have multiple indicators in the form of indices and measures helps us overcome the potential variance in this perception. Another advantage of a two-tier approach is that some of the existing measures can be combined differently as we have demonstrated using the CDM and TCM measures. These behaviors are consistent with both Leadership and Influence. When trying to model additional higher-level sociolinguistic phenomena beyond Leadership and Influence, we can use existing measures in a manner that is substantiated by social science theory as well as revealed in our computational analyses.

ABSTRACT
High impact events, political changes and new technologies are reflected in our language and lead to constant evolution of terms, expressions and names. Not knowing about names used in the past for referring to a named entity can severely decrease the performance of many computational linguistic algorithms. We propose NEER, an unsupervised method for named entity evolution recognition independent of external knowledge sources. We find time periods with high likelihood of evolution. By analyzing only these time periods using a sliding window co-occurrence method we capture evolving terms in the same context. We thus avoid comparing terms from widely different periods in time and overcome a severe limitation of existing methods for named entity evolution, as shown by the high recall of 90% on the New York Times corpus. We compare several relatedness measures for filtering to improve precision. Furthermore, using machine learning with minimal supervision improves precision to 94%.

TITLE AND ABSTRACT IN GERMAN

NEER: Eine nichtüberwachte Methode zur Erkennung von Namensevolution

Wichtige Ereignisse, politische Veränderungen und neue Technologien spiegeln sich in unserer Sprache wieder und führen zu einer ständigen Evolution von Begriffen, Ausdrücken und Namen. Mangelndes Wissen über frühere Namen einer Entität kann die Leistungsfähigkeit vieler computerlinguistischer Methoden deutlich verringern. In diesem Papier präsentieren wir unsere nichtüberwachte Methode namens NEER zur Erkennung von Namensevolution, die unabhängig von externen Datenquellen arbeitet. Indem wir Zeiträume mit erhöhter Evolutionswahrscheinlichkeit mit Hilfe einer Kookkurrenzmethode basierend auf *Sliding Windows*-Verfahren untersuchen, erfassen wir evolvierende Terme im selben Kontext. Dadurch vermeiden wir es, Terme aus weit auseinander liegenden Zeiträumen zu vergleichen und umgehen damit eine schwerwiegende Beschränkung vorhandener Methoden. Dieses zeigt sich an einer gemessenen Sensitivität von 90% auf dem Korpus der New York Times. Um die Genauigkeit zu erhöhen, vergleichen wir mehrere Ähnlichkeitsmaße zur Filterung. Mit Hilfe von maschinellem Lernen mit minimaler Überwachung verbessern wir die Genauigkeit auf 94%.

1 Introduction

Do you remember the bright yellow Walkman, Joseph Ratzinger or Andersen Consulting? Chances are you do not, because as the world around us changes, new terms are created and old ones are forgotten. High impact events, political changes and new technologies are reflected in our language and lead to constant evolution of terms, expressions and names. Most everyday tasks, like web search, have so far relied on the good memory of users or been restricted only to the current names of entities. As the web and its content grow older than some of its users, new challenges arise for natural language tasks like information retrieval and knowledge consolidation to automatically determine relevant information, even when it is expressed using forgotten terms.

Language evolution is reflected in documents available on the web or in document archives but is not sufficiently considered by current applications. Therefore, not knowing about different names referencing the same entity severely compromises system effectiveness. This can partially be addressed by using external knowledge sources like DBpedia. The limitation of this approach is that these resources do not cover all entities and are not able to capture ephemeral names or jargon used in everyday language or social media.

There are several kinds of language evolution, among others spelling variations, name changes and concept changes. We focus on named entity evolution, the detection of name changes, as it has a high impact, for example in information retrieval. This research field is becoming increasingly important. However, most previous work depend on the availability of external knowledge sources or assume a static context around terms and expect the names to be the only changing factor. We follow a statistical approach to eliminate the dependency on external resources and use a context based method that considers only periods with a high likelihood of name change, thereby capturing evolving names with less computational effort. This independence opens the possibility to apply the method to any corpus, including historical collections or those in different languages, and to identify undocumented named entity evolution.

The main contributions of this paper are:

- We propose the use of change periods (i.e., periods with high likelihood of name change) to capture the evolution of one name into another instead of comparing names and their contexts from vastly different periods in time.
- We propose NEER, a method for named entity evolution recognition that analyzes the context of entities during time periods of evolution. The proposed method is independent from external knowledge sources and is able to find name changes.
- We describe and compare named entity evolution filtering methods, statistical as well as machine learning based, that capture relatedness between different names used to reference the same entity at different points in time in order to increase accuracy.
- We apply NEER on a standard dataset (New York Times corpus) to identify named entity evolution and evaluate using precision and recall. We make our test set publicly available to encourage comparison of results.

The rest of the paper is organized as follows: In the next section we review related work in areas relevant to named entity evolution. In Section 3 we define terminology needed for our work. We describe our approach and highlight the limitations of previous work in Section 4 and present the NEER method in Section 5. We introduce our data and test sets in Section 6 and present our experimental results. We discuss our findings in Section 7 and finally present our conclusions and future work.

2 Related Work

Previous work on automatic detection of term evolution has been very limited and mainly focused on named entity evolution. The interest has largely been from an information retrieval point of view as named entity evolution makes finding relevant documents more challenging.

Berberich et al. (2009) propose reformulating a query into terms prevalent in the past; they measure the degree of relatedness between two terms when used at different times by comparing the contexts as captured by co-occurrence statistics. This approach requires a recurrent computation each time a query is submitted as it requires a target time point for the query reformulations which reduces efficiency and scalability. The results presented in this paper are "anecdotal" (to use the words of the authors) and thus cannot be used for direct comparison. However, because of the promising results we use the same method for defining a context.

Kaluarachchi et al. (2010) propose to discover semantically identical concepts (or named entities) used at different time periods using association rule mining to associate distinct entities to events. Sentences containing any subject, verbs, objects, and nouns are targeted and the verb is interpreted as an event. Two entities are considered semantically related if their associated event is the same and the event occurs multiple times in a document archive. The temporally related term of a given named entity is used for query translation (or reformulation) and results are retrieved appropriately w.r.t. specified time criteria. They present precision and recall for very few queries and evaluate only indirectly on the basis of retrieved documents.

Kanhabua and Nørvåg (2010) define a time-based synonym as a term semantically related to a named entity at a particular time period. They extract synonyms of named entities from link anchor texts in Wikipedia articles using the full history. Unfortunately, link information, such as anchor text, is rarely available and thus limits the method to hypertext collections. They evaluate the precision and recall of the time-based synonyms by measuring increased precision and recall in search results rather than directly evaluating the quality of the found synonyms.

3 Definitions and Terminology

Language evolution is a broad concept which can be divided into several sub-classes including spelling variations (Ernst-Gerlach and Fuhr, 2007; Hauser et al., 2007; Gotscharek et al., 2009) and word sense evolution (Tahmasebi et al., 2011). The general class of **term to term evolution** contains terms of any part of speech that have been used to mean the same thing at different points in time. The shift between terms typically occurs over a long period of time, e.g., one sense of the term *cool* was previously expressed with the term *collected*. In this paper, we focus on a special case of term to term evolution namely **named entity evolution** which considers a given entity and the different lexical names for the same entity. Here, the entity is fixed while the name changes over time.

Named entity changes do not need to have any lexical overlap between two representations, for example *Joseph Ratzinger* was the birth name of *Pope Benedict XVI* and *Hillary Rodham* was *Hillary Clinton*'s maiden name. The latter is an easier case of evolution because of the overlapping first name and can be targeted using entity consolidation or linking techniques (Shen et al., 2012; Ioannou et al., 2010). However, most existing techniques do not take historic changes into account and only focus on merging concurrent representations of the same entity.

We consider a term w_i to be a single or multi-word lexical representation of an entity at time t_i. The **context** C_{w_i} is the set of all terms related to w_i at time t_i. Similar to Berberich et al. (2009)

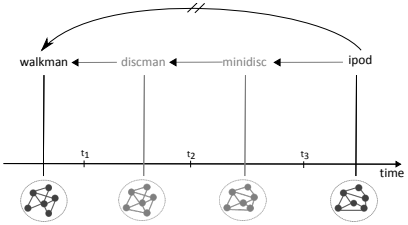

FIGURE 1: Existing methods detect evolution by comparing term contexts from different times. E.g., by directly comparing *walkman* to *ipod*.

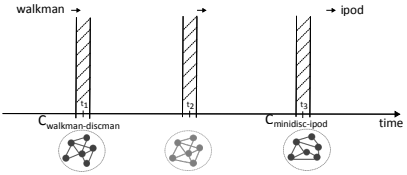

FIGURE 2: NEER detects by creating one context for each change period, thus eliminating the need to compare contexts.

we consider the most frequently co-occurring terms within a distance of k words as the context, however, other contexts can be used. We consider a **change period** to be a period of time in which one term evolves into another.

Co-references are expressions that refer to the same entity. In the sentence "The president said he had discussed the issue" the words *the president* and *he* refer to the same person. In this paper, we consider **temporal co-references** to be different lexical representations that have been used to reference the same concept or entity at the different periods in time.

We have two variations of temporal co-references, direct and indirect. **Direct temporal co-references** are temporal co-references that are variations of each other with some lexical overlap. **Indirect temporal co-references** are temporal co-references that lack lexical overlap on the token level. *Hillary Clinton* and *Hillary Rodham* are examples of direct temporal co-references while *Pope Benedict XVI* and *Joseph Ratzinger* are examples of indirect temporal co-references. All introduced terms will be used with and without *temporal* interchangeably.

A **temporal co-reference class** contains all direct temporal co-references for a given named entity, denoted as $\text{coref}_r\{w_1, w_2, \ldots\}$. Each temporal co-reference class is represented by a **class representative** r which is also a member of the class. For example, *Joseph Ratzinger* is the representative of the co-reference class containing the terms {*Joseph Ratzinger, Cardinal Ratzinger, Cardinal Joseph Ratzinger,* ... }.

4 Approach

Previous work in the area can be generalized as shown in Figure 1. A word w_i (*walkman*) is mapped to its context and compared to word w_j (*ipod*) by comparing contexts. If the corresponding contexts are similar it is concluded that w_i and w_j are temporal co-references. These methods have severe drawbacks because they assume that the queried entity is the only evolving factor and that contexts stay stable over time. This is however not the case. Comparing the term *walkman* and *ipod* (an example given by Berberich et al. (2009)[1]) directly by means of contexts from the New York Times corpus ($C_{walkman}$, C_{ipod}) we find that the majority of the context terms have changed. In Table 1 we can see the contexts of related terms *discman, minidisc* and *mp3 player* during the year when each term was introduced[2].

[1]We do not consider *walkman* and *ipod* to be co-references as they do not correspond to the same named entity. We use this example to illustrate the difficulties that arise with state of the art and the differences to NEER.

[2]The *walkman* was already introduced in 1979, so we chose the first year of the corpus' time span (1987).

$C_{walkman}$	$C_{discman}$	$C_{minidisc}$	$C_{mp3\ player}$	C_{ipod}
cassette	walkman	compact	music	apple
audio	stillvideo	disc	digital	mp3
video	sony	sony	internet	roqit
tape	portable	digital	audio	player
music	cd	cassette	player	music
sony	kodac	phillips	files	geeks
digital	video	walkman	cd	jukebox
stereo	priestly	dcc	computer	portable
earphones	digital	prerecorded	mp3	macintosh
recorders	camera	video	portable	dlink

TABLE 1: Five terms and their contexts in the New York Times corpus.

We find that the only overlap between $C_{walkman}$ and C_{ipod} is the term *music*. By comparing the intermediate contexts pairwise instead we find that there is a much larger overlap between the contexts. For instance, $C_{walkman}$ has a 40% overlap with $C_{discman}$ which in turn has a 30% overlap with $C_{minidisc}$. The same properties hold when we compare the 20 most frequent terms and we find that the overlap between $C_{mp3player}$ and C_{ipod} increases further. From this we deduce that comparing contexts pairwise where the contexts are closer in time is more effective than comparing two contexts far apart in time.

The same observation holds for Kaluarachchi et al. (2010). They consider nouns to have evolved into each other if they point to the same event (represented by a verb) at different points in time. Over long periods of time also the verb undergoes evolution and hence the method is limited only to those terms where the corresponding event has not changed over time.

In this paper we make use of the typical characteristics of named entity evolution. Unlike with other types of evolution, such as word sense evolution, named entity changes typically occur during a short time span. There are few concept shifts where the term slowly changes, instead name changes occur due to special events like being elected pope, getting married or merging/splitting a company. If the named entity is of general interest, these name changes will also be announced to the public repeatedly during the change period with sentences like "The day after Cardinal Joseph Ratzinger became Pope Benedict XVI"[3].

By first identifying candidate change periods and then creating a context around a term, we believe that we can capture both the old and the new co-reference in the same context. We thus eliminate the risk of comparing contexts that are vastly different. Figure 2 illustrates our method. By identifying change periods t_1, t_2, t_3 we can create contexts around a term which contain both co-references and do not have to compare largely different contexts like those of *walkman* and *ipod*.

5 The NEER Method

To find temporal co-references we use the pipeline depicted in Figure 3. We start by detecting change periods for a query term over the entire collection. We make use of the identified change periods to find the subsets in which we look for evolution. We extract single and multi-word nouns and find named entities mentioned in the text.

We create contexts around extracted terms by applying co-occurrence analysis and use the context and the extracted terms to find direct co-references. Finally we apply frequency analysis as well as machine learning to identify direct and indirect co-references and to filter out noise.

[3]The New York Times, April 21, 2005.

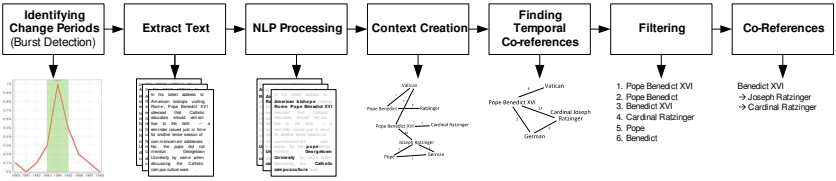

FIGURE 3: Pipeline used to detect temporal co-references.

5.1 Identifying Change Periods

Named entity changes are typically associated with significant events concerning the entities which lead to increased attention. We use this property to pinpoint change periods and detect those using a **burst detection algorithm**.

We use the Kleinberg algorithm (Kleinberg, 2003) to find bursts from the entire document collection $\mathbf{D}$. The algorithm models the frequency of documents $\mathbf{D}_w$ containing term w using a series of probability distributions. Each distribution represents an increasing degree of burstiness. A set of states indicates which distribution is active. By assigning a cost to state transitions the algorithm ensures that an optimal state sequence creates bursts that end only if they are followed by a sufficiently large period of lower activity. This avoids splitting bursts for example around weekends when the number of articles drops.

We detect bursts related to an entity by retrieving all documents in the corpus containing the query term, grouping them into monthly bins and running the burst detection on the relative frequency of the documents in each bin. Each resulting burst corresponds to a significant event involving the entity. However, these bursts do not necessarily correspond to a name change. By choosing the `topB` strongest bursts we expect to find a subset of bursts which also captures change periods. We denote each change period p_i for $i = 1, \ldots, \texttt{topB}$.

5.2 Creating Contexts

After identifying change periods p_i for an entity w we create a context for each period by extracting all documents $\mathbf{D}_{w_i}$ that mention the entity or any part of it and are published in the year corresponding to p_i. We extract nouns, noun phrases and named entities. We use noun phrases to capture more information and create richer contexts around entities. All extracted terms are added to a **dictionary** and used for creating a co-occurrence graph. The co-occurrence graph is an undirected weighted graph which links two dictionary terms if and only if they are present in $\mathbf{D}_{w_i}$ within k terms of each other. The weight of each link is the frequency with which the two terms co-occur in $\mathbf{D}_{w_i}$. The context of entity w is considered as all terms co-occurring with w. The context of a co-reference class is considered to be all terms co-occurring with any of the terms in the co-reference class.

5.3 Finding Temporal Co-references

To find *direct co-reference classes* we need to consolidate the extracted terms by recognizing all variants of each term. As an initial step each term from the dictionary with a frequency above `minFr` is placed in its own co-reference class where the term acts as the representative as well as the only co-reference: $\text{coref}_{\text{Benedict}}\{\text{Benedict}\}$.

Merging: The procedure for merging terms and co-reference classes is shared between all three rules described below; each co-reference class is represented by the term with the highest frequency. A frequency is stored in the co-reference class for the representative r as the sum frequency of all terms in the class. If two co-reference classes have the same representative, they are merged into one. Each co-reference class carries with it all co-occurrences that belong to any of the terms in the co-reference class. These are considered as the context C_r. When terms are merged, the context is updated accordingly.

Next we will describe the main rules used for finding all direct co-reference classes. In the initial iteration the first rule works on the dictionary terms and populates an index with co-reference representatives. In the second and all subsequent iterations the first rule makes use of the terms in the index. This index is passed through all the rules. The rules are iterated until there are no more terms in the index that can be merged.

1. **Prefix/suffix rule:** This rule creates co-reference classes by merging dictionary terms that differ only by a prefix or suffix. For example, the co-reference classes of *Pope Benedict* and *Benedict* as well as *Pope* and *Pope Benedict* are merged. In both cases the co-reference class has *Pope Benedict* as representative and these co-reference classes are therefore merged and result in $\text{coref}_{\text{Pope Benedict}}$*{Pope, Pope Benedict, Benedict}*.
2. **Sub-term rule:** This rule merges classes that are represented by terms that can be considered sub-terms. For a term to be a sub-term of another we require the longer term to contain all terms from the shorter term in the correct order. For example, the co-reference classes represented by *Cardinal Joseph Ratzinger* and *Cardinal Ratzinger* are merged.
3. **Prolong rule:** The third rule is used to create longer terms than might be found in the dictionary. It merges two representatives from the index into one longer term if the terms have an overlapping part and there exists a co-occurrence between the remaining terms. E.g., *Pope John Paul* and *John Paul II* are merged if there is a co-occurrence (*Pope John Paul , II*) or (*Pope , John Paul II*); the representative of the merged co-reference class is *Pope John Paul II*. The third rule also merges terms that differ due to plural of the prefixes assuming that the prefix is not considered a stopword. E.g., *Senator Barack Obama* and *Senators Barack Obama* are merged but *Mr Obama* and *Mrs Obama* are not.

Final merging When the terms in the index cannot be merged further, a final round of merging takes place. In this round we apply a *soft* sub-term rule where we drop the requirement that the terms should be in the same order but require them to be similar in frequency. This way terms like *Illinois Democrat* and *Democrat of Illinois* are merged.

Consolidation When all terms are merged we create a mapping from each term to the co-reference class representative that has the highest frequency. Using this map we consolidate all terms in the context of each class.

An example is shown in Figure 4 (original context in 4a). Using the three rules we find

$$\text{coref}_{\textit{Cardinal Joseph Ratzinger}}\{\textit{Cardinal Joseph Ratzinger, Joseph Ratzinger, Ratzinger}\}$$
$$\text{coref}_{\textit{Pope Benedict XVI}}\{\textit{Pope Benedict XVI, Pope Benedict,Pope}\}$$
$$\text{coref}_{Vatican}\{\textit{Vatican}\}$$
$$\text{coref}_{German}\{\textit{German}\}.$$

Next a mapping is created: [*Joseph Ratzinger* → *Cardinal Joseph Ratzinger*, *Ratzinger* → *Cardinal*

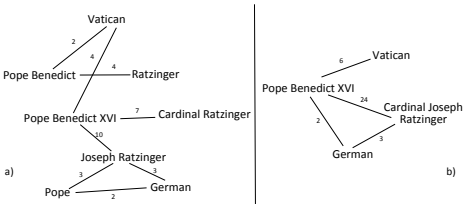

FIGURE 4: a) Example graph after creating context. b) After consolidating and merging all direct co-references.

Joseph Ratzinger, *Pope Benedict* → *Pope Benedict XVI*, *Pope* → *Pope Benedict XVI*]. Additionally, all co-reference class representatives map to themselves. Then each term in the co-reference class context is consolidated and replaced using the map. If two co-occurrences share a term they are merged into one and the frequency of the co-occurrence is updated as shown in Figure 4b.

Ranking The term frequencies and the merging steps offer a natural ranking of co-references. When two terms are merged like *Pope Benedict* and *Pope Benedict XVI* we update the frequency of the class representative by summing up the frequencies. During merging all co-occurrences are updated with the sum of the frequencies of all participating terms. In Figure 4b we see that the co-occurrence frequencies of (*Vatican* , *Pope Benedict XVI*) is 6 because the frequency of (*Vatican , Pope Benedict*) is 2 and (*Vatican , Pope Benedict XVI*) is 4. The term frequencies and co-occurrence frequencies are stored in each co-reference class. The frequency of *Pope Benedict* and *Pope Benedict XVI* is much higher than that of *Benedict XVI* and *Eggs Benedict* and during consolidation the term *Benedict* is replaced with *Pope Benedict XVI* rather than *Eggs Benedict*.

Indirect Co-references Indirect co-references are found implicitly by means of the direct co-references. After consolidation, all terms in the context of a co-reference class are considered candidate indirect co-references. These are a mix between true indirect co-references, highly related co-occurrence phrases as well as noise. The quality of the indirect co-references is dependent on the named entity extraction, co-occurrence graph creation and filtering of the co-occurrence graph. The choice of including single token terms in addition to multi-token terms has a high influence on the quality of the resulting co-occurrences. In Figure 4b *Vatican*, *German* and *Cardinal Joseph Ratzinger* are candidate co-references for *Pope Benedict XVI*.

If NEER does not find any co-references for a term, all direct co-occurrences from the co-occurrence graphs (derived from the union of the change periods) are returned instead.

5.4 Filtering Temporal Co-references

To remove noise and identify the true direct and indirect co-references we make use of the term frequencies as well as the document frequencies for the filtering. We start by describing similarity measures between terms and continue with the filtering techniques.

Similarity measures To keep true co-references we need to measure the temporal relatedness of terms. Unlike previous works that take temporal features into account it is not sufficient to consider relatedness over the entire time span of a collection. In Radinsky et al. (2011) time series of terms are used to capture the relatedness of terms like *war* and *peace* or *stock* and *oil*.

These terms are considered related because they have similar frequencies over time.

For temporal co-references, capturing the overall relatedness is not sufficient. Both direct and indirect co-references can be related only for a certain period in time and then lose their relation. To give an example: Both *Senator Clinton* as well as *Hillary Clinton* have been used to refer to the same person at different periods in time. As the latter name was only valid for a certain period in time, measuring the relatedness between *Hillary Clinton* and *Senator Clinton* using global term frequencies (i.e. term frequency over the entire corpus) will not yield the correct results. However, global measures can help to find direct co-references such as *Barack Obama* and *Barack Hussein Obama*.

Therefore, to fully capture temporal co-references we need, in addition to global relatedness measures, a relatedness measure that captures how related terms are during the time periods where they can be related at all. To this end we allow a relatedness measure to consider only periods where both terms occur. In all cases we use the normalized frequencies.

We consider four relatedness measures: (1) Pearson's Correlation ($corr$) (Weisstein, 2012a), (2) Covariance (cov) (Weisstein, 2012b), (3) Rank correlation (rc) and (4) Normalized rank correlation (nrc).

The two first measures are standard relatedness measures where $corr$ measures linear dependence between random variables while cov measures correlation between two random variables. The two last measures are rank correlation measures and inspired by the Kendall's tau coefficient that considers the number of pairwise disagreements between two lists. Our rank correlation coefficient counts an agreement between the frequencies of two terms for each time period where both terms experience an increase or decrease in frequency without taking into consideration the absolute values. The rank correlation is normalized by the total number of time periods. The normalized rank correlation considers the same agreements but is normalized with the total number of time periods where both terms have a non-zero term frequency.

Filtering Co-references using Pearson's Correlation The first filtering makes use of the correlation measure to determine which co-references are related to the query term and filter out the rest. This measure is used by Radinsky et al. (2011) to measure similarity between terms and serves as a comparison for our filtering mechanisms. We keep a co-reference if its correlation to the query term exceeds the threshold corr_{min}. An increase in the filtering threshold would lead to the same or decreased recall while the precision could be affected either way. A decrease in the threshold would lead to a lower precision. Therefore a low threshold is sufficient to get an upper bound of the recall while maintaining precision.

Filtering Co-references using Document Frequency The second filtering is based on the document frequencies (df) of co-references. We filter out all co-references that differ largely in document frequency from the document frequency of the query term. The filtering depends on the document frequency of the most frequent term in the dictionary corresponding to a change period ($\text{df}_{\texttt{max}}$), the document frequency of the query term ($\text{df}_{\texttt{query}}$) and a *scaling factor* (sc). We filter out all co-references that have a document frequency $\text{df} \geqslant \text{df}_{\texttt{query}} \cdot \text{sc}(\text{df}_{\texttt{max}})$, i.e., which are frequently used in different contexts.

Filtering Co-references using Machine Learning Our third and final filtering method is based on machine learning. We use a random forest classifier (Breiman, 2001) consisting of a combination of decision trees where features are randomly extracted to build each decision

tree. In total ten trees with three features each are constructed. We choose features from the similarity measures presented above. This means that for each term–co-reference pair (w , w_c) found by NEER we calculate the $corr$, cov, rc and nrc measures. We also use the average of all four measures as a fifth feature. Finally we classify the pair as either 1 for w_c being a correct co-reference of w or 0 otherwise.

6 Experiments

The aim of our experiments was to measure how well NEER can detect names used during different time periods to refer to the same entity. We did this by (1) investigating how well burst detection can be used to capture change periods, and (2) measuring precision and recall of the co-references found using NEER. Each experiment in (2) was performed using two settings: (a) the first made use of the known change periods (denoted **known periods**), (b) the second used the detected bursts (denoted **found periods**). We used the known change periods to measure how well the method works assuming that we can find the correct change periods.

As there are no available baselines to compare our methods to, we defined our own baseline and named it **co-occurrence**. This considers all terms that co-occur with the queried named entity within a sliding window for all change periods, for (a) and (b) separately. This provided a baseline that shows what can be achieved with minimal computational effort.

We considered $precision = \frac{\text{\# correctly captured co-references}}{\text{\# all captured co-references}}$ and $recall = \frac{\text{\# captured co-references}}{\text{\# known name changes}}$ for our evaluation. For a term we required all direct co-references and at least one indirect co-reference for each name change to achieve full recall. That means that for *Joseph Ratzinger* we required all direct forms {*Cardinal Joseph Ratzinger, Cardinal Ratzinger*} but only one of the indirect {*Pope Benedict XVI, Pope Benedict*} to achieve a recall of 100%.

6.1 Experimental Setup

Dataset and Test Set For our experiments we used the New York Times Annotated Corpus (NYTimes). The dataset contains around 1.8 million articles published between 1987 and 2007.

We devised a test set of named entities, based on Kanhabua and Nørvåg (2010), with direct as well as indirect co-references and divided them into three categories: People, Locations and Companies. We identified all relevant name changes and the year in which they occur. Each co-reference pair was verified using three judges and kept if at least two judges agreed. If the change occurs in January of a year also the previous year was added. Change periods are available in the released test set. We mirrored all the entities so that *Pope Benedict* → *Cardinal Ratzinger* and *Cardinal Ratzinger* → *Pope Benedict* both exist as separate entries.

The final test set was devised by keeping all terms that (1) exist in the NYTimes, (2) have a change period in the NYTimes time span and (3) occur at least 5 times in at least one change period. The dataset is available in Tahmasebi et al. (2012). We started with 75 distinct names and 294 co-references. After filtering there were 16 distinct entities corresponding to 33 names and 86 co-references (44 indirect and 42 direct).

Setup We used the NYTimes API to extract documents from the NYTimes corpus. To extract terms we used Lingua English Tagger (Coburn, 2008) for finding single and multi-token nouns and the Stanford Named Entity Recognizer (NER, Finkel et al., 2005) to extract named entities. NERs typically consider names but not the role as a part of the name. For example *Barack Obama* is extracted but not *Senator Barack Obama*. Therefore we used the Lingua tagger which

	Found periods			Known periods		
Method	**Precision**	**Recall**	**avr # co-ref**	**Precision**	**Recall**	**avr #co-ref**
co-occurrence	8%	51%	120	20%	59%	16
NEER	8%	90%	128	13%	89%	64
NEER + Corr	20 %	61%	107	17%	74%	43
NEER + DF	33%	86%	28	50%	81%	10
NEER + ML	91 %	81%	6	94%	92%	5

TABLE 2: Precision and recall for the baseline and the different filtering techniques.

recognizes also terms like *Senator Barack Obama*. Named entities recognized by both methods are counted twice and thus receive a higher frequency. This procedure helps to choose good representatives for the co-reference classes.

In order to increase precision we filtered out infrequent terms. During graph creation we required a term to occur at least three times in the collection used for creating the graphs. If the most common terms in the dictionary occured more than 800 times, we required at least five occurrences. For finding direct co-references we required that each term occur at least five times. However, if the most common term in the dictionary occured more than 3000 times we increased the threshold to 10 occurrences. We also filtered out terms containing lowercase tokens. For this reason the term *Union of Myanmar* could not be found by the system.

For the relatedness calculations we used normalized term frequencies that are calculated as the fraction of term occurrences in all documents published per month divided by the total number of tokens in these documents.

To find the bursts we used the Java implementation from CIShell (Alencar, 2012) with 3 burst states, a transition probability γ of 0.8 and a density of 1.9. Using these parameters we detected on average 3.2 bursts for each term in our test set.

6.2 Results

Burst Detection We approximated change periods using burst detection. Considering all found bursts for an entity we were able to capture 73% of all change periods. This indicates that burst detection works well for capturing change periods but that there is room for improvement and parameter tuning. To reduce complexity and false positives, we limited the number of bursts to $\texttt{topB} = 6$. Using the $\texttt{topB}$ bursts we were able to capture 66% of all change periods.

If a name is ambiguous the bursts are less suitable for capturing correct change periods as the burst detection algorithm cannot distinguish between entities. This is the case for *George Bush* where the top bursts are 1988, 1989 and 1990 and correspond to *George Bush Senior*. *George W Bush* is not ambiguous and the found bursts are 1999, 2000 and 2001.

The results for the named entity evolution detection presented next are summarized in Table 2.

Baseline – Co-occurrence For comparison we chose a baseline consisting of all terms that co-occur with the query term in the datasets corresponding to the known and found burst periods. This naive baseline serves as a lower bound on recall. We used precision and recall for direct and indirect co-references found by our method and the corresponding entries from the test set. In Table 2 we find that the recall for the baseline is 59% using known periods and 51% using found periods. When considering the co-occurrences for the query term very few

or no direct co-references were found for the terms. Instead most indirect co-references were found. The precision differs largely between known and found periods; for the latter precision is surprisingly high with 20% compared to the found bursts (8%). This shows that the known periods help to find better co-references without introducing too much noise.

To mimick other methods where the user chooses a target time, we randomly chose three years per query term (corresponding to the average number of bursts per term) and created co-occurrence graphs for these years. We repeated the experiment three times and got an average recall of 36% which is statically significantly lower than the recall for known burst showing the power of using change periods for finding temporal co-references. As a comparison, a baseline method that chooses all terms that have lexical overlaps with the query term, can maximally achieve a recall of 49% ($= 42/86$) because no indirect co-references can be found.

NEER In this experiment we kept all co-references found by NEER without any filtering. This experiment provides an upper bound on the recall for the subsequent experiments. We found that for known periods as well as for found periods recall is high with 89% and 90% respectively. Only very few true co-references were missed and we found at least one correct co-reference for all but two terms. The precision is much lower for known bursts in comparison to the baseline which is a consequence of the higher average number of co-references found. However the recall is statistically significantly higher. The precision of the found bursts is comparable to the baseline and again the recall is significantly higher.

Out of 22 terms with indirect co-references our method was able to find at least one indirect co-reference for 21 terms for both known burst and found bursts. For found bursts no indirect co-reference could be found for *Airtran* because no bursts could be detected. For known bursts no indirect co-references could be found for *Andersen Consulting*.

Some sample queries and their five most frequent direct and indirect co-references for known bursts are shown in Table 3. As we can see the results contain co-references of high quality. For *Vladimir Putin* NEER found four roles *President-elect, Minister, Acting President* and *President*. For *Sean Combs* all but one of his names are present in the top five co-references, missing is only *Puff Daddy* which appears with a lower frequency. *Sean Combs Ruiz* is an error caused by the term extraction. The term *Ruiz* is a name of a movie character that was played by Sean Combs in 2001.

Considering names with only a single token typically decreases the precision for people because it increase the number of co-occurrences with first names. However, for companies and locations it is necessary to keep single token names as otherwise many names would be missed, e.g. *Burma*. To further improve results an extension to NEER could classify names into different categories. The extended NEER can then keep or discard single token names accordingly as well as allow different name patterns such as names with non-capital tokens (e.g., *Union of Myanmar*).

NEER + Correlation filtering Using correlation as a filtering, with $\text{corr}_{\text{min}} = 0.4$, precision increased over the NEER results while recall decreased. For both known and found periods the decrease in recall corresponds to a statistically significant decrease. The recall is higher than that of the baselines but is not competitive to the NEER results and shows that global correlation is not an appropriate similarity measure for temporal co-references.

Barack Obama	Vladimir Putin	Sean Combs
Senator	President-elect Vladimir V Putin	Puffy
State Senator Barack Obama	Minister Vladimir Putin	Sean John
Senator-elect Barack Obama	Acting President Vladimir V Putin	Diddy
Senator Barack Obama	President Vladimir V Putin	Sean Combs Ruiz
Illinois Democrat	Vladimirovich	Sean John Combs

TABLE 3: Terms and their top temporal co-references. Gray cells are considered incorrect.

NEER + Document Frequency filtering In this experiment co-references were removed if they occured in more documents than the query term times a scaling factor (sc), as described in Section 5.4. The filtering provides a good recall for both found and known periods. The decrease in recall compared to the NEER results is not statistically significant for either found nor known periods. With regards to precision both found and known periods show the most competitive performance compared to the baseline and the NEER results.

We used sc $= 10$ for $\mathrm{df}_{\mathtt{max}} \leqslant 300$, 5 for $\mathrm{df}_{\mathtt{max}} \leqslant 800$ and 3 for $\mathrm{df}_{\mathtt{max}} > 800$. These filtering thresholds as well as the scaling factors were found empirically. Learning these could improve the results for document filtering further.

NEER + Machine Learning We showed that unsupervised filtering can perform well for filtering out erroneous co-references found by NEER. In this experiment we investigated if the results could be further improved by using a limited amount of supervision for training a classifier. We used WEKA (Hall et al., 2009) and the random forest classifier. We trained our classifier on the dataset and used 15 fold stratified cross fold validation to determine precision and recall. We classified each term–co-reference pair produced by NEER. For known burst we got in total 2963 instances where 170 were correct co-references (we accepted combinations of correct names, e.g., *Sean Diddy Combs*). Using the classifier we were able to achieve a 94% precision and only 11 false co-references were classified as correct. The recall of the filter is 92%, however, it was only applied to the output of the NEER. For the known bursts this corresponds to a true recall of $92\% \cdot 89\% = 82\%$. This shows the true potential of the machine learning approach and the features chosen for the classification (see relatedness measures, Section 5.4). Assuming that the NEER results can be improved further the classification is a powerful tool.

For the found bursts there were 7048 instances with 204 correct co-references. The precision of 92% is comparable to that of the known bursts and only 16 false co-references were classified as true co-references. The recall is 81% compared to 92%, likely a consequence of the ratio between the two classes with 204 vs 6844 instances. Adding learning instances could help boost the results, e.g., adding the entire test set to the training set could further improve the recall.

7 Discussion

Our experiments show that we are able to find temporal co-references with high recall without depending on external knowledge sources. We found that, even though not all change periods could be found using burst detection (recall 66%), we still managed to get a recall that is comparable to the high recall for the known (correct) change periods. Because every change period captures two co-references, it is possible to capture more co-references than the number of found change periods suggests.

There can be several reasons for a change period not to occur as a burst. In some cases the name change is discussed before the change takes place and thus there is a discrepancy between

Accenture	Comcast	Czech Republic	Myanmar
Accenture Match Play Championship	Comcast Corporation	Hungary	Burma
Andersen Consulting	AT&T Comcast	Slovakia	

TABLE 4: Top co-references from the categories *Location* and *Company* after document frequency filtering for known bursts. For *Myanmar* only *Burma* remains after filtering.

the found burst and the 'true' change period. It is also possible for a name change to correspond to a smaller increase in frequency than other events (possibly such leading up to and causing the name change). Future work is to learn thresholds to find bursts that correspond to change periods or find other methods better suited for change period detection.

We found that co-references cannot be detected in a symmetric way: Finding w_i as a co-reference for w_j does not imply that we can find w_j as a co-reference for w_i. E.g., NEER found *Slovakia* and *Czech Republic* as co-references for *Czechoslovakia*. However, for *Czech Republic* NEER could not find *Czechoslovakia* (using found or known bursts).

Our experiments show that co-references found for terms from the category *People* have a good accuracy among the top co-references also without filtering. However, for the category *Locations* and *Companies* filtering is needed for achieving high accuracy among the top results. Some examples for companies and locations can be found in Table 4. For *Accenture*, *Czech Republic* and *Myanmar* we found an indirect co-reference among the top two terms.

By making use of terms from the dataset we ensure that all found temporal co-references can be used for information retrieval on the dataset. The results of Kanhabua and Nørvåg (2010) contain co-references of high quality like *Senator Barack H. Obama Jr*, but many of these do not appear in the NYTimes and thus cannot be used to retrieve documents. By not relying on external resources we enable a robust method that can be applied on any corpus and finds ephemeral co-references like *President-elect George Bush* or *Senator-elect Barack Obama*. NEER can also be applied to heterogeneous data such as long-term archives as well as web data and can mix content from several sources.

Conclusions and Future Work

In this paper we presented NEER, an unsupervised approach for named entity evolution recognition that overcomes limitations of existing approaches and does not depend on external knowledge sources. We made use of change periods to create term contexts to capture co-references in the same context, thereby avoiding to compare term contexts from vastly different periods in time. Burst detection was used to detect change periods and captured 66% of all change periods. Because term contexts created in change periods capture more than one co-reference, 90% of all name changes were found. We used frequency analysis to find direct and indirect co-references by filtering on document frequency as well as using machine learning to classify correct co-references. Using a random forest classifier we achieved a precision of 94% on known periods and 91% on found periods. All name changes used in our test set are released to encourage further research in this area (Tahmasebi et al., 2012).

In this paper we focused on change periods for one term and searched for temporal co-references. This means that for terms with indirect co-references, we can find at most one change at a time. In future work we will focus on automatically creating chains of evolution to handle terms with many changes and to associate validity period to each co-references, e.g.,

$$\textit{ipod} \xrightarrow[2012-2001]{} \textit{mp3 player} \xrightarrow[2001-1996]{} \textit{minidisc} \xrightarrow[1996-1992]{} \textit{discman} \xrightarrow[1984-1979]{} \textit{walkman}.$$

ABSTRACT

The current paper evaluates the performance of the PRESEMT methodology, which facilitates the creation of machine translation (MT) systems for different language pairs. This methodology aims to develop a hybrid MT system that extracts translation information from large, predominantly monolingual corpora, using pattern recognition techniques. PRESEMT has been designed to have the lowest possible requirements on specialised resources and tools, given that for many languages (especially less widely used ones) only limited linguistic resources are available. In PRESEMT, the main translation process is divided into two phases, the first determining the overall structure of a target language (TL) sentence, and the second disambiguating between alternative translations for words or phrases and establishing local word order. This paper describes the latest version of the system and evaluates its translation accuracy, while also benchmarking the PRESEMT performance by comparing it with other established MT systems using objective measures.

KEYWORDS: hybrid machine translation; language-independent methodology; MT evaluation

Proceedings of COLING 2012: Technical Papers, pages 2569–2584,
COLING 2012, Mumbai, December 2012.

1 Introduction

The Machine Translation (MT) task has been studied for a number of decades, but still remains to a large extent an issue unresolved, as the performance delivered by the best current systems still falls short of the required quality. Since the number of texts available over the World Wide Web is ever increasing, and these texts may be written in one of several hundred languages, the requirement for automatically performing translation of an acceptable quality remains a prime objective. A number of MT paradigms have been proposed, the main ones including Rule-Based MT (RBMT), Statistical MT (SMT) and Example-Based MT (EBMT). Furthermore, the requirement for covering an ever increasing combination of Source to Target language (SL to TL) combinations necessitates the development of language-independent methodologies.

Currently most MT approaches are based on the SMT paradigm (Koehn, 2010). SMT uses dedicated algorithms that do not employ language-specific rules and is thus portable to new language pairs, provided the necessary training data are available. The main SMT constraint is the need for SL-TL bilingual corpora of a sufficient size (of the order of a million parallel sentences) to allow the building of accurate translation models. Such corpora are hard to obtain, particularly when less widely-used languages are involved. Besides, the process of compiling and verifying such corpora is expensive in terms of both manpower and time.

In EBMT, translations are generated by analogy, where the system has available a set of known pairs of input sentence (in SL) and corresponding translation (in TL). Then, each new input sentence is broken down to non-overlapping phrases, which are translated using the translation examples as a reference. The translated sentence is finally composed by combining the translated phrases.

Another paradigm is hybrid MT, which combines ideas and techniques from more than one approaches, like for example EBMT and SMT techniques (cf. Groves & Way, 2005 and Phillips, 2011). Such approaches have been proposed for creating MT systems using more limited but easily obtainable resources. Even if these methods do not achieve accuracy as high as that of SMT systems, their ability to develop MT systems with limited resources is an advantage in the case of less-widely used languages. The PRESEMT system is based on such a methodology, as detailed below, its main characteristics being the use of only very small bilingual corpora and the employment of large monolingual corpora for extracting most of the necessary linguistic information.

A number of methods for the automatic inference of templates for the structural transfer from SL to TL have been proposed. For instance, Sanchez-Martinez et al. (2009) suggest using small parallel corpora only to extract transfer rules, assuming that a sufficient bilingual dictionary is already available. Carbonell et al. (2006) propose an MT method that requires no parallel corpora, but relies on a translation model utilising a full-form bilingual dictionary and a decoder using long-range context via large n-grams.

Another family of systems are METIS (Dologlou et al., 2003) and METIS-II (Markantonatou et al., 2009), both of which rely solely on extensive monolingual resources in order to generate translations employing pattern recognition-based algorithms. The METIS family represents the ancestor of PRESEMT, which has built

upon the past experience, by (i) adding a small bilingual corpus to improve translation accuracy and (ii) using more advanced algorithms for pattern matching to provide a measurable increase in both speed and accuracy of the generated translations.

2 The principles of the PRESEMT system

In terms of resources, similarly to METIS-II, PRESEMT uses a bilingual dictionary providing SL – TL lexical correspondences and an extensive TL monolingual corpus collected automatically from the web. A small bilingual corpus containing parallel sentences is added in PRESEMT, in order to (a) reduce the number of possible translations that need to be evaluated by the system and (b) define examples of SL – TL structural modifications, thus improving the translation quality. The bilingual corpus need not cover a particular domain and only numbers a few hundred sentences (typically ~200) for determining structural equivalences between sentences in the source and target languages. Hence, in comparison to SMT systems, the size of the parallel corpus required is reduced by more than three orders of magnitude. Evidently, for a bilingual corpus of only a few hundred sentences, not all linguistic phenomena are likely to occur. However, it is expected that the most frequent ones will be covered and thus a sufficient coverage of the structure transformations from SL to TL can be achieved.

Both the bilingual and the monolingual corpora are annotated[1] with lemma and Part-of-Speech (PoS) information and, depending on the language, with additional morphological features (e.g. case, number, tense etc.). Furthermore, they are segmented into non-recursive syntactic phrases (e.g. noun phrase, verb phrase etc.). The next subsections describe the kind of information extracted.

2.1 Processing the bilingual corpus

The processing of the bilingual corpus involves the use of a pair of modules, namely the Phrase aligner module (PAM) and the Phrasing model generator (PMG). PAM operates on the bilingual corpus to achieve the establishment of matching phrasing schemes in the SL and TL sides. This is achieved by aligning the bilingual sentences initially at a word level and then porting these alignments at a phrase level. PAM aims at identifying how the SL structure is modified towards the TL one, allowing the deduction of a phrasing model for the source language. During initialisation, PAM takes as input a parsed text in the TL-side of the parallel corpus, via a chosen TL parser. It is assumed that in this corpus there is a high level of fidelity between the SL-side and TL-side, which extends to the phrasing schemes of the two languages. Then, PAM algorithmically segments the SL-side sentence into phrases in accordance to the TL side. To achieve that, PAM takes into account alignment information in the form of (a) lexicon-based correspondences, (b) alignment on the basis of grammatical feature similarity and PoS tag correspondence and (c) alignment information provided by already aligned neighbouring words in the SL and TL sides. Within this sequence, in each consecutive step additional SL words are aligned to TL words, the aim being for all words to be assigned to SL phrases that correspond to the TL phrasing, these phrases then being mapped to the TL phrases.

[1] For the annotation task readily available tools are employed, including statistical taggers and (to some extent) chunkers that provide shallow parsing. This alleviates the need for developing new linguistic tools.

The SL side of the aligned corpus is subsequently processed by PMG, with a two-fold purpose, namely to (i) deduce a phrasing model based on conditional random fields (CRF) (Lafferty et al., 2001) and (ii) employ this model for parsing any SL text submitted for translation. During the derivation of a phrasing model, the SL side of the aligned bilingual corpus is used to train a CRF model via a standard iterative process. During operation, this model is used to segment new sentences to be translated into their constituent phrases. Details on the algorithmic design and individual accuracy of PAM and PMG are provided in Tambouratzis et al. (2012a).

2.2 Extracting information from the monolingual corpus

The TL monolingual corpus is processed to create two distinct models, which are employed during the translation process. The first model is used solely for disambiguation purposes, when two or more translations are proposed for a word or set of words. In this account, different models have been studied, including a SOM-based model (Tsimboukakis et al., 2011 and Tambouratzis et al., 2012b) and an n-gram-based model. The second one is a phrase model that provides the micro-structural information on the translation output, to determine intra-phrasal word order. The model is stored in a file structure, where a separate file is created for phrases according to their (i) phrase type, (ii) phrase head and (iii) phrase head PoS tag. As most of the progress has involved developments in the second model, this is the one discussed in more detail in the remainder of the present section.

The number of files created as a result of this process is very large (of the order of millions of files), as for each combination of the three aforementioned criteria, a different file needs to be created; yet each of the files is of a small size and thus can be retrieved and loaded quickly. Due to the very large number of files, the actual data structure and implementation becomes very important. Currently PRESEMT uses a simple string representation to store the phrases in each file, ordered by their frequencies of occurrence. Initially the phrases were stored as serializable objects in hash tables, based on their order of appearance in the corpus. This redesigned model occupies substantially less disk space and provides faster retrieval. Also the ordered storage of phrases provides the algorithm a way to stop the search as soon as a relevant phrase has been retrieved. On the whole, the aforementioned revisions in the modelling of the phrases have led in a reduction in the translation time of approximately 40%, when averaged over a set of 200 sentences being translated (to avoid bias due to sentence-specific phenomena. Regarding the disk requirements, the use of the revised mapping has resulted in a substantial drop in the required space for storing the model (for a corpus of 80 Gbytes, the model size has been reduced by approximately 58%, from 22 Gbytes to 9.3 Gbytes).

2.3 Main translation engine

The translation process is split into two phases. Phase 1 (**Structure selection**) uses the bilingual corpus to determine, for a given input SL sentence, the appropriate TL structure in terms of the sequence of phrases and their order. The output of the Structure selection phase is the SL sentence with a TL structure, created by reordering the phrases according to the archetypes contained in the parallel corpus, and all words replaced by the TL lemmas and tag information as retrieved from the bilingual dictionary.

Phase 2 (**Translation equivalent selection**) uses the models extracted from the TL monolingual corpus as described in section 2 so as to specify the most likely word order within phrases, to handle functional words such as articles and prepositions and to resolve lexical ambiguities emerging from the possible translations provided by the bilingual dictionary. Finally, a token generator component generates tokens out of lemmas. Therefore, the first PRESEMT translation phase is closely related to EBMT, while the second phase is reliant upon information of a statistical nature (but extracted from monolingual corpora), resulting in a hybrid nature.

3 Phase 1: Structure selection

The task of Structure selection is to determine for each input sentence the type of TL phrases to which the SL ones translate and to order them in the TL sentence. To this end it consults the patterns of SL – TL structural modifications to be found in the parallel corpus, thus resembling EBMT (Hutchins, 2005).

Translation phase 1 receives as input an SL sentence (termed **ISS** – Input Source Sentence), bearing lexical translations from the dictionary, annotated with tag and lemma information and segmented into phrases by PMG. A dynamic programming algorithm is applied to determine for each ISS the most similar, in terms of phrase structure, SL sentence found in the bilingual corpus (termed **ACS** – Aligned Corpus Sentence)[2].

The similarity is determined on the basis of structural information such as phrase type, phrase head PoS tag, phrase functional head info and phrase head case. The phrases within ISS are reordered in accordance to the TL side of the chosen ACS by replicating the SL-TL phrase alignment mapping. The dynamic programming algorithm evaluates the similarity in the SL language. The most similar SL structure of the bilingual corpus, that determines the TL structure of the sentence to be translated, is thus selected purely on SL properties. The implemented method is based on the Smith-Waterman algorithm (Smith and Waterman, 1981), initially proposed for aligning DNA and RNA sequences. This algorithm is guaranteed to find the optimal local alignment between two input sequences.

The structural similarity between ISS and ACS is reflected on the similarity score, for the calculation of which a two-dimensional matrix is created with the ISS phrases along the top row and the ACS along the left side. As is standard practice in Dynamic Time Warping, movement across this matrix is from the top left corner towards the bottom right-hand side. The similarity for cell (i,j) is determined by examining the predecessor cells located directly to the left $(i, j-1)$, directly above $(i-1, j)$ and above-left $(i-1, j-1)$,, and is calculated iteratively as the maximum of the three similarities. The similarity of two phrases results by the weighted sum of the similarities of (a) the phrase type, (b) the phrase head PoS tag, (c) the phrase head case and (d) the functional phrase head PoS tag.

The similarity score ranges from *100* to *0*, these limits denoting respectively exact match and total dissimilarity between elements of ISS and ACS. In case of a zero similarity score,

[2] If the most similar ACS retrieved from the parallel corpus is very dissimilar, then ISS does not undergo any reordering. It is notable that in our experiments never did such an occasion appear, the similarity always reaching a high percentage (above 70%). The fact that comparisons involve sentences of the same language (SL) contributes to a high similarity score.

a penalty weight (-50) is employed, to further penalise the establishment of a mapping between dissimilar items.

After calculating the final similarity score between sentences, the comparison matrix indicates the optimal phrase alignment between the two SL sentences. By combining the SL sentence alignment from the algorithm with the alignment information between the ACS and the attached TL sentence, ISS phrases are reordered accordingly.

4 Phase 2: Translation equivalent selection

Following the completion of Phase 1, remaining translation issues include (i) establishing word order within phrases, (ii) handling functional words and (iii) resolving translation ambiguities. To establish the correct word order, the monolingual TL corpus is searched to determine the most similar phrase to each phrase in the SL sentence. The similarity measure takes into account the phrase type and the words contained in terms of lemma, PoS tag and morphological features. These factors enter the comparison with different weights, the relative magnitudes of which are the subject of an optimisation process.

The main issue at this stage is word reordering within each phrase. This entails that the words of a given phrase of the input sentence (denoted as **ISP** – Input Sentence Phrase) and the words of a retrieved TL phrase (denoted as **MCP** – Monolingual Corpus Phrase) are close to each other in terms of number of words and type.

When initiating Phase 2 of the translation process, the matching algorithm accesses the indexed TL phrase corpus (created as described in section 2) to retrieve similar phrases and select the most similar one through a comparison process, which is viewed as an assignment problem. This problem can be solved via both exact algorithms that guarantee the identification of the optimal solution and sub-optimal ones. Experiments when developing METIS-II have shown that the solution of the assignment problem is computationally-intensive. Consequently, to conform to the strict translation time constraints set for PRESEMT, the Gale-Shapley algorithm is used (Gale and Shapley, 1962 and Mairson, 1992), which solves the assignment problem in a reduced time. This process is possibly non-optimal but allows a substantial reduction in the computation time.

After the completion of this comparison process, the selected phrase from the monolingual corpus serves as a basis for resolving other issues such as the handling of functional words (e.g. insertion / deletion of articles). In this process, the TL information prevails over the SL entries, based on initial experiments performed, to provide a translation closer to the TL-provided information.

Translation equivalent selection receives as input the output of Structure selection, which contains sets of candidate translations for each SL lemma. One translation needs to be chosen from each set, thus disambiguating amongst the possible translations. The disambiguation process uses the semantic similarities between words as evidenced by the monolingual corpus. Different approaches are evaluated within PRESEMT for selecting the most appropriate translation, including Vector Space Modelling (Marsi et al., 2010) and Self-Organising Maps, following the work by Tsimboukakis et al. (2011).

Rather than employing these disambiguation processes, a simpler, corpus-based approach is proposed in the PRESEMT configuration discussed here, which relies on the

extraction of statistical information with only limited pre-processing. This method reuses and enhances the indexed sets of the monolingual corpus phrases, by exploiting information on the frequency of occurrence of each TL phrase. When searching for the best matching TL phrase for each combination of lexical alternatives, the frequency of the TL phrase is taken into account. Notably, not all combinations are examined for lexical disambiguation; instead only the phrase mapped to the most frequent TL phrase is retained. A formula is used for selecting the most appropriate phrase based on both the similarity score and the frequency of the TL phrase. This formula ensures that even though one TL might achieve a higher comparison score than another, if its frequency is significantly lower, then the second phrase - which has a lower absolute score - will be selected, due to its substantially higher frequency of occurrence. This enables the algorithm to delete or add a word such as an article in the final translation of the phrase. This scoring mechanism can be easier to understand with a Greek to English translation example where the article in the Greek phrase needs to be removed from the English translation, for instance the Greek noun phrase '*Η Γαλλία*', which translates to "*France*" in English. When searching for relevant phrases in the TL model, the phrase "*the France*" scores *100* and appears in the corpus *34* times, while the phrase "*France*" scores *85* and appears *5,030* times. Using the aforementioned method and a threshold value of the score ratio being equal to 90% in this case, the ratio between the two scores is not high enough, so the selection will be based on the frequency of occurrence ratio between the two phrases, where the correct phrase (the one without the article) has a substantially higher number of occurrences in the corpus.

5 Example of the PRESEMT translation process

In this section a simple example is used to illustrate the translation process of the PRESEMT system in a step-wise manner. An SL sentence as the one in (1) is being input for translation:

(1) Εδραιώνονται σχέσεις καλής γειτονίας στις χώρες των Βαλκανίων
"Good neighbourhood relations are established in the Balkan countries"

Annotation at various levels [tagging & lemmatising; PMG-based segmentation to phrases (VC: verb chunk, PC: prepositional chunk); output of the lexicon look-up]

SL sentence annotated after being input for translation			
Phrase	**VC**	**PC**	**PC**
Word	εδραιώνονται	σχέσεις καλής γειτονίας	στις χώρες των Βαλκανίων
Lemma	εδραιώνω	σχέση, καλός, γειτονία	στου, χώρα, ο, Βαλκάνια
Tag	**vb**o3pl	**no**feplnm, **aj**fesgge, **no**fesgge	**as**feplac, **no**feplac, **at**neplge, **no**neplge
Lexicon	{consolidate; establish}	{relation; relationship} {nice; decent; good} {adjacency; neighbourhood}	{on; at; to; into; in; upon} {country} {the} {Balkan}

1st translation phase: Search the bilingual corpus for the most similar SL sentence in structural terms, find the corresponding TL one and reorder the input SL sentence on the basis of TL; output an intermediate result (2).

Most similar SL sentence of the bilingual parallel corpus			
Phrase	**VC**	**PC**	**PC**
Word	σημειώνονται	διαμαρτυρίες φοιτητών	σε άλλες χώρες της ΕΕ
Lemma	σημειώνω	διαμαρτυρία, φοιτητής	σε, άλλος, χώρα, ο, ΕΕ
Tag	**vb**o3pl	**no**feplnm, **no**maplge	**asppsp**, **pn**fe03plac, **no**feplac, **at**fesgge, **abbr**
Corresponding TL sentence of the bilingual parallel corpus			
Phrase	**VC**	**PC**	**PC**
Word	student protests	occur	in other EU countries
Lemma	student, protest	occur	in, other, EU, country
Tag	nn, nns	vv	in, jj, np, nns

(2) Output of the 1st translation phase (expressed as list of phrases and lemmas):

[PC {relation; relationship}; {nice; decent; good}; {adjacency; neighbourhood}]
[VC {consolidate; establish}]
[PC {on; at; to; into; in; upon}; {country}; {the}; {Balkan}]

2nd translation phase: Identify the correct word order within each phrase (3); disambiguate the translations (4); generate tokens out of lemmas (5); produce final translation (6).

(3) **Word reordering results:**

[PC {nice; decent; good}; {adjacency; neighbourhood}; {relation; relationship}]
[VC {consolidate; establish}]
[PC {on; at; to; into; in; upon}; {the}; {Balkan}; {country}]

(4) **Disambiguation results:**

[PC {good}; {neighbourhood}; {relation}]
[VC {establish}]
[PC {in}; {the}; {Balkan}; {country}]

(5) **Token generation:**

[PC {good}; { neighbourhood}; {relations }]
[VC {are established}]
[PC {in}; {the}; {Balkan}; {countries}]

(6) **Final translation:** Good neighbourhood relations are established in the Balkan countries

6 Experimental Results

The evaluation results reported here concern the Greek – English language pair [3] and are based on the development datasets used in PRESEMT for studying the system performance. For each SL, these datasets contain 1,000 sentences, collected via web-crawling. Sentence length ranges from 7 to 40 words.

[3] PRESEMT currently handles 8 language pairs: SL {Czech, English, German, Greek, Norwegian} – TL {English, German}.

From these datasets, 200 sentences were randomly chosen, and manually translated into each of the target languages. The correctness of these reference translations was checked independently by native speakers. For the current evaluation phase four automatic evaluation metrics have been employed, i.e. BLEU (Papineni et al., 2002), NIST (NIST 2002), Meteor (Denkowski and Lavie, 2011) and TER (Snover et al., 2006).

For the bilingual corpus, 200 sentences were used. The Greek-English dictionary contained a total of just over 40,000 entries. For PRESEMT, two versions are evaluated. The first one (PRESEMT-1) indicates the state of the system on April 2012 (i.e. after almost 28 months of development of the system, including the system specifications definition). PRESEMT-1 includes the basic configuration of the system as described in Sofianopoulos et al. (2012). PRESEMT-2 encompasses a number of improvements in comparison to PRESEMT-1, including refined algorithms for the two translation phases, an improved method of using the indexed monolingual corpus and later enhanced versions of the PAM/PMG modules (reflecting the current state in October 2012). Table 1 summarises indicative scores obtained together with scores achieved by four MT systems available online for the same set of data.

	BLEU	NIST	Meteor	TER
Google	0.5544	8.8051	0.4665	29.791
Systran	0.2930	6.4664	0.3830	49.721
WorldLingo	0.2659	5.9978	0.3666	50.627
Bing	0.4600	7.9409	0.4281	37.631
METIS-II	0.1222	3.1655	0.2698	82.8780
PRESEMT-1	0.1683	5.7389	0.3203	68.4670
PRESEMT-2	0.3011	6.6878	0.3733	54.5990

TABLE 1 – Comparison to other MT systems for the Greek-to-English language pair

In comparison to METIS-II[4], the latest version of PRESEMT offers a substantial improvement for all metrics, with for instance BLEU and NIST scores both being increased by more than 145%. This illustrates the improvements conferred by the new translation methodology as compared to the METIS-II family.

It is noteworthy that PRESEMT outperforms two of the other MT systems, Systran and WorldLingo, with scores increased by 2.7% and 13% respectively. As noted, PRESEMT is still under development and it is anticipated that more extensive experiments involving additional language pairs will provide improvements in the translation quality.

6.1 Detailed analysis of the evaluation results

In the present section, the aim is to visualise the evaluation results for the development set. In Figure 1 the BLEU results of the earlier PRESEMT prototype are indicated in a

[4] http://www.ilsp.gr/metis2/

scatter plot, as a function of the sentence size for the language pair Greek-to-English. It can be seen that, as the input sentence size increases in terms of words, the score shows a trend of reducing. Also, it can be noted that for most sentences, the BLUE score is less than 0.2, indicating a less than satisfactory translation.

The highest BLEU score of PRESEMT-1 is equal to 0.56 and is obtained for a relatively short sentence of 12 words, while for only a few medium to long sentences (of 15 words or more) is a BLEU score of 0.4 or more achieved. Finally, for sentences with length of 20 words or more the BLEU score rarely exceeds 0.2.

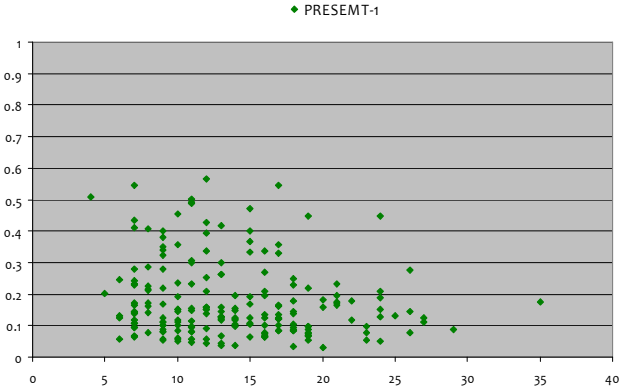

FIGURE 1 – Scatter plot of BLEU results for the EL-EN language pair (PRESEMT-1)

In Figure 2, the BLEU results for the PRESEMT-2 are indicated in a scatter plot, as a function of the sentence size for the language pair Greek-to-English. It is evident that the translation quality is improved, with BLEU scores exceeding 0.5 for a number of sentences. In addition, even for large input sentence sizes, relatively high BLEU scores are achieved (for instance, for the largest sentence of 35 words, a score of almost 0.6 is achieved). Furthermore, even for sentences of more than 25 words, the majority of translations approximate or exceed a score of 0.5, whilst when using PRESEMT-1 (cf. Figure 1) no sentences of this length manage a BLEU score exceeding 0.3.

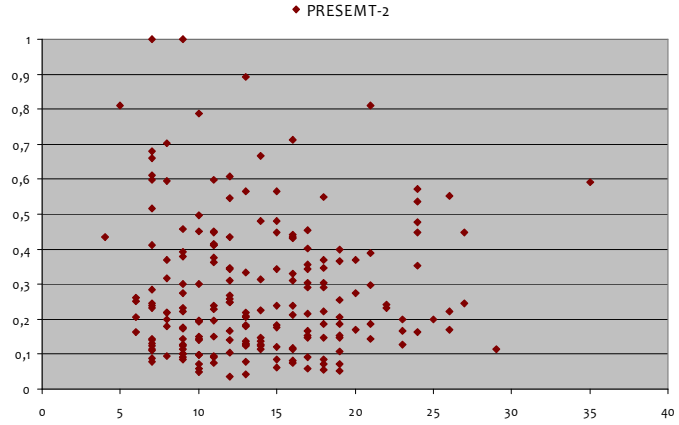

FIGURE 2 – Scatter plot of BLEU results for the EL-EN language pair (PRESEMT-2)

To perform a more systematic analysis, the different sentence sizes have been organised by defining bins, each of which spans 8 sentence sizes (i.e. the first bin concerns sentences of between 4 and 7 words, bin 2 comprises sentences between 8 and 10 words etc.). A boxplot diagram is used to indicate for each of the aforementioned bins the characteristics of BLEU scores, as shown in Figure 3 for PRESEMT-1 and in Figure 4 for PRESEMT-2.

By comparing the boxplots of the two PRESEMT versions for BLEU, it can be seen that boxplots for PRESEMT-1 occupy similar ranges of the score range to those of PRESEMT-2. However, the range for PRESEMT-1 is displaced towards lower values of BLEU in comparison to PRESEMT-2, while also a larger number of outliers exist for PRESEMT-1. Thus, most median values of PRESEMT-1 for different sentence sizes are placed at lower BLEU levels, below the 0.15 mark, with only a few outliers exceeding the limited range of the boxplots.

On the contrary, when turning to PRESEMT-2, the median values are higher, exceeding 0.200 in most cases and even reaching 0.400 in some of the cases. Besides, when comparing the median values, these are increased by 50% or more for most sentence sizes for PRESEMT-2 in comparison to PRESEMT-1. Also, for longer sentences (for instance bin6, which comprises sentences of 24 to 27 words), the improvement in BLEU score is substantial, increasing by a factor of approximately 2.5. This applies to the value corresponding to the 50% level (i.e. the median value) as well as to the levels of 25% and 75%.

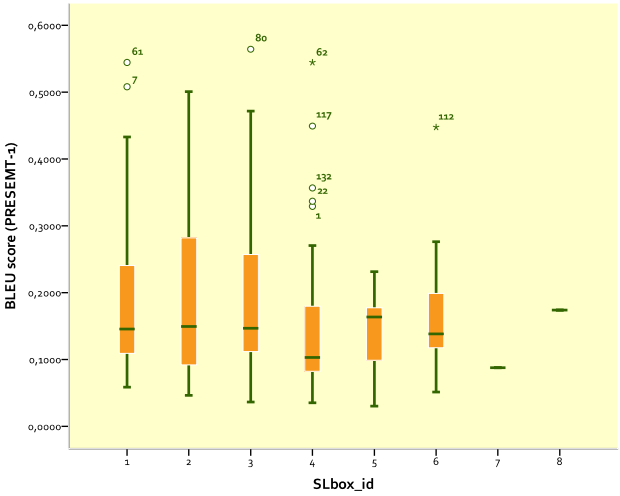

FIGURE 3 – Box plot of BLEU results for the EL-EN language pair (PRESEMT-1)

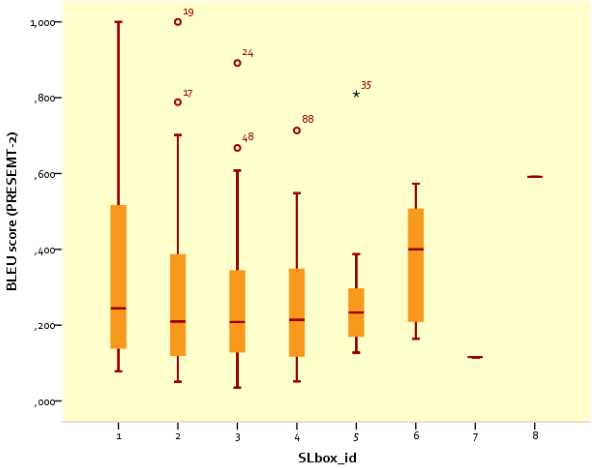

FIGURE 4 – Box plot of BLEU results for the EL-EN language pair (PRESEMT-2)

Furthermore, even though the y-axis scale is larger in Figure 4 than that of Figure 3 the population of solutions covers a much wider range and in several cases translations of a substantially higher quality are achieved. Though the variances are substantially higher for Figure 4 as compared to Figure 3, this is due to several sentences being translated much more accurately, thus reflecting a better translation performance. In addition, the boxplot outliers are fewer in the case of PRESEMT-2, while the variance does not appear to increase as the sentence size increases.

Finally, the BLEU score does not appear to reduce substantially as the sentence size increases, promising scalability of the PRESEMT system for more complex sentences (though this would need to be confirmed via more extensive experiments), with a dependable level of performance. This indicates that the algorithmic improvements integrated when transitioning from PRESEMT-1 to PRESEMT-2 result in a higher translation quality and also contribute to a more predictable performance.

Conclusions

In the present article the principles and the implementation of a novel language-independent methodology have been presented. The PRESEMT methodology draws on information residing in a large monolingual corpus and a small bilingual one for creating MT systems readily portable to new language pairs. Most of this information is extracted in an automated manner using pattern recognition techniques.

First experimental results and comparisons to established systems have been reported. These results are promising, especially taking into account the fact that several PRESEMT modules are still under development and the translation process is being refined, in particular with respect to the handling of internal phrasal structure. Initial studies of the PRESEMT translations have indicated that the handling of the bilingual corpus and the structure selection phase possess the greatest potential for further improvements. The outcome of these efforts will be reported in future articles.

ABSTRACT
In this paper we present work on the task of Native Language Identification (NLI). We present an alternative corpus to the ICLE which has been used in most work up until now. We believe that our corpus, TOEFL11, is more suitable for the task of NLI and will allow researchers to better compare systems and results. We show that many of the features that have been commonly used in this task generalize to new and larger corpora. In addition, we examine possible ways of increasing current system performance (e.g., additional features and feature combination methods), and achieve overall state-of-the-art results (accuracy of 90.1%) on the ICLE corpus using an ensemble classifier that includes previously examined features and a novel feature (n-gram language models). We also show that training on a large corpus and testing on a smaller one works well, but not vice versa. Finally, we show that system performance varies across proficiency scores.

KEYWORDS: Native Language Identification, Text Classification, Corpora.

COLING 2012, Mumbai, December 2012.

1 Introduction

One growing NLP field is that of Native Language Identification (NLI), which is the task of automatically identifying a speaker's first language based solely on the speaker's writing in another language. NLI can be useful for a number of applications. Native language is often used as a feature in machine learning approaches to authorship profiling (Estival et al., 2007), which is frequently used in forensic linguistics. NLI can also be used in educational settings to provide more targeted feedback to language learners about their errors (Chang et al., 2008; Dahlmeier and Ng, 2011; Rozovskaya and Roth, 2011). It is well known that speakers of different languages make different kinds of errors when learning a language (Swan and Smith, 2001). For example, a French speaker learning English might write sentence (1), which contains a verb tense error. On the other hand, a Japanese speaker learning English might make the verb tense error shown in (2). A writing tutor system which can detect the native language of the learner will be able to tailor the feedback about the error and contrast it with common properties of the learner's language.

(1) She knows that she hasn't achieve it completely.

(2) They also said to have great curiosity.

There has been a great deal of work on NLI in recent years. The methods employed have ranged from some combination of lexical, part-of-speech and n-gram features (Koppel et al., 2005), to syntactic features (Wong and Dras, 2011) including Tree Substitution Grammars (TSGs) (Swanson and Charniak, 2012), to topic models (Wong et al., 2011). Despite these research efforts, it has been somewhat hard to compare different approaches for a number of reasons.

The first difficulty is with the evaluation data set. Evaluating an NLI system requires a corpus containing texts in a language other than the native language of the writer. Because of a scarcity of such corpora, most work[1] has used the ICLEv2[2] for training and evaluation since it contains several hundred essays written by college-level English language learners. However, this corpus is quite small for training and testing statistical systems which makes it difficult to tell whether the systems that are developed can scale well to larger data sets or to different domains. The usability of the corpus is further compromised by idiosyncrasies in the data such as topic bias (as shown by Brooke and Hirst, 2011) and the occurrence of characters which only appear in essays written by speakers of certain languages. As a result, it is hard to draw conclusions about which features actually perform best.

A second problem is that there is no consensus on the scope of the evaluation. The ICLE contains English essays written by native speakers of 16 languages. Typically a subset of 7 languages is used in the evaluations, although more recently some work has reported results for a larger set. Moreover, when researchers report results for 7 languages, they are not always reporting on the same 7 languages. For example, in the work of Wong and Dras (2011) the 7 native languages (L1s) are Bulgarian, Chinese, Czech, French, Japanese, Russian, and Spanish. Whereas in Brooke and Hirst (2012), Italian and Polish are used instead of Bulgarian and Czech. In addition, different researchers have split the corpus in different ways when training and evaluating their systems, making it even more difficult to compare results across experiments.

[1] Note that Kochmar (2011) used a subsection of the Cambridge Learner Corpus.
[2] Throughout this paper, we will refer to ICLE version 2 as ICLE.

In this paper, we first provide an automatic method for extracting data from the ICLE corpus to remove some of the corpus-specific idiosyncracies that automatic Native Language Identification classifiers currently learn from. We call this modified version of the ICLEv2, ICLE-NLI. Second, we introduce a new data set, TOEFL11 (Blanchard et al., to appear), which is roughly twice the size of the ICLE and has more essays per L1 than the ICLE. We argue for the use of TOEFL11, which will be made publicly available, as a common evaluation resource for this task. Next, we use these two new resources (ICLE-NLI and TOEFL11) to address the following research questions:

1. Are there methods previously unexplored in the literature that can be used to improve performance? (Section 5.1)
2. Do features commonly used in prior work generalize to different corpora? (Section 5.1)
3. What is the effect of training on one corpus and then testing on another? (Section 5.2)
4. What is the effect of larger training data on the performance of these features? (Section 5.3)
5. How widely do results vary across levels of writing proficiency? (Section 5.4)

In Section 2, we discuss previous approaches to NLI and also how there is a need for greater standardization of corpora used and evaluation practices. We present the corpora used in this study in Section 3, and our system and the features we investigate in Section 4. In Section 5 we discuss the results and the five research questions above. Our best system achieves state-of-the-art accuracy (90.1%) on the ICLE-NLI corpus, surpassing the previously reported best accuracy of 81.7% (Wong and Dras, 2011) on ICLE.

2 Related Work

The work of Koppel et al. (2005) set the stage (and probably a high bar as well in terms of performance) for much of the NLI research in the past few years. Their work investigated features from NLP and Second Language Acquisition including character and POS n-grams, content and function words, and spelling and grammatical errors. The features were evaluated on a subsection of the ICLE corpus consisting of essays sampled from 5 L1s (Russian, Czech, Bulgarian, French and Spanish) with 10-fold cross validation. The researchers found that by combining all of the features using a SVM, they could achieve an accuracy of 80.2%. Tsur and Rappoport (2007) continued this work by investigating why character n-grams alone performed so well (66%). As in the work of Wong and Dras (2011), we use an approximation of the Koppel et al. (2005) features both as a baseline system and as a base feature set to which we add our own features.

The notion that different learners tend to exhibit different grammatical error patterns was further explored by Kochmar (2011). Instead of the ICLE corpus, English learner essays from the Cambridge Learner Corpus[3] were used, specifically essays written by test-takers with Romance and Germanic native languages. In this work, a SVM was used to classify these essays on the basis of lexical and parse features as well as manually marked grammatical and spelling errors.

[3] http://www.cup.cam.ac.uk/gb/elt/catalogue/subject/custom/item3646603/Cambridge-International-Corpus-Cambridge-Learner-Corpus

One of the main conclusions was that character and POS n-grams were the most powerful features. Since this work used a different evaluation corpus and different L1s, it is hard to compare to other studies.

Wong and Dras (2009) based their NLI system on the contrastive analysis hypothesis: that differences between a writer's L1 and the language they are trying to write in are caused by differences between the two languages. Often, characteristics of the writer's L1 are carried over into the target language. They investigated the impact of three common ESL error types: subject-verb agreement, noun-number agreement and determiner errors and used 7 languages from ICLE: the 5 used in the Koppel et al. (2005) study in addition to Chinese and Japanese. While the determiner error feature did seem informative, performance did not improve when it was combined with a baseline model of lexical features.

Recently, more complex syntactic features have been proposed to better model the structural differences in learner writing. Wong and Dras (2011) extended the Koppel et al. work by incorporating production rules from two parsers as well as reranking features into the classification framework. In line with their prior work, they address the 7-way NLI task (Bulgarian, Chinese, Czech, French, Japanese, Russian and Spanish) by selecting 95 essays for each L1 and doing 5-fold cross validation with 70 essays selected for training and 25 for testing. This particular evaluation framework has been adopted by others in the field, such as Swanson and Charniak (2012). The combination of parse production rules with the Koppel et al. lexical features achieved a performance of 81.71% on the 7-way NLI task, currently the highest reported in the literature for that set of 7 in the ICLE. Swanson and Charniak (2012) experiment with various Tree Substitution Grammars (TSGs) on the 7-way NLI task and achieve an accuracy of 78.4%. In our work, we also experiment with the use of the Post and Gildea (2009) TSG fragments for the NLI task. Bergsma et al. (2012) tackled the related problem of classifying text as either written by a native speaker or a non native speaker of English. They used TSGs in conjunction with other stylometric features to achieve an F-score of 91.6.

Wong et al. (2011) also investigated the use of Latent Dirichlet Analysis (LDA) to cluster features and then adaptor grammars (Wong et al., 2012) to better capture arbitrary length n-gram sequences over tags and words. While the LDA approach did not improve performance over a baseline model of lexical features, the adaptor grammar approach scored close to state-of-the-art, around 75% accuracy.

Finally, Brooke and Hirst (2012) explored the effect of adding more training data on NLI classifier performance. In one experiment, English sentences written by Chinese and Japanese native speakers were scraped from a language-exchange social networking website (lang8)[4] and used to augment a classifier which used different n-gram features and function words. The effect was that for those two languages, increasing the training data from 200 texts to 5,000 improved overall performance by 30% (from 59.8% to 89.8%). This work sets the tone for the resource contribution of this paper: the creation of a publicly available corpus of ESL essays.

3 Data

In this work, we evaluated our NLI systems on four corpora: a subset of the ICLE (Granger et al., 2009) and three samples from a collection of essays written by non native English speakers as part of a high stakes college-entrance test (TOEFL®). Each corpus is described in detail below.

[4] http://www.lang-8.com/

3.1 ICLE Corpus Description

Currently, the only widely available corpus of non native English that is annotated for native language is the International Corpus of Learner English (ICLE) (Granger et al., 2009). It is a large collection of 6,085 essays written by university undergraduates of advanced proficiency.[5] The intent of the project was to produce for corpus linguistics a relatively large corpus that "shared a large number of task variables, notably in terms of medium (writing), genre (academic essay), field (general English rather than English for Specific Purposes) and length (between 500 and 1,000 words)" (Granger et al., 2009). Because these were the only factors the designers controlled for, there is substantial variation of other factors such as the number of essays per L1 and the number of languages covering each topic (see Table 1). The current version of the corpus, ICLEv2, consists of 6,085 essays for 1,302 prompts, which we have manually clustered into 736 topics.

Language	Unique Topics	Total Topics	Essays on Unique Topics	Total Essays
Bulgarian (Bul.)	0	4	0	302
Chinese (Chi.)	16	27	542	982
Czech (Cze.)	29	49	46	243
French (Fre.)	6	21	33	347
Japanese (Jap.)	119	132	336	366
Russian (Rus.)	2	17	2	276
Spanish (Spa.)	14	32	60	251

Table 1: ICLE counts of topics and essays for seven L1s commonly used in the NLI task.

3.2 Using the ICLE for NLI

Because techniques for NLI have looked for patterns in the data not only at the lexical level but also at the character level, any unintended lexical or character patterns correlated with L1 are likely to be weighted heavily by a statistical classifier. Therefore, it is important that the corpus is free of such patterns.[6] After examining the ICLE in detail, we discovered that there are two classes of confounding patterns for the task of NLI:

1. A variety of character encoding errors and annotations (both erroneous and correct) occur predominantly in certain languages and not in others. Because of the techniques and features commonly used for NLI, these issues can impact system evaluation.

2. The topics the authors write about are not evenly distributed across languages. In fact, there are many topics for which all the authors are native speakers of a single L1 (see Table 1). This topic bias is also observed and discussed in Brooke and Hirst (2011). The bias is problematic for machine learning approaches to NLI because it could cause classifiers to conflate the tasks of topic identification and NLI. For example, only Chinese

[5] http://www.uclouvain.be/en-cecl-icle.html

[6] We do acknowledge that there are two ways of evaluating NLI systems. The first one, and the approach we are taking here, is that all characters are encoded in the same way. The second way of evaluating is to actually include any patterns that may arise from using a certain keyboard or encoding scheme that writers with a certain L1 tend to use. The first method essentially focuses on solely on linguistic patterns, while the second is more application-driven and focuses on both linguistic and extra-linguistic patterns.

authors responded to the prompt "Discuss the advantages and disadvantages of using credit cards," and consequently all of those essays contain the $ character, whereas almost no other languages' essays do.

To address the first set of problems we (a) removed the header information from all documents, (b) removed all instances of the codes used by the annotators to indicate deleted references, quotations, or illegible words, (c) converted all non-ASCII characters to their closest ASCII equivalent using the Unidecode Python module,[7] (d) fixed characters that resulted from encoding errors by replacing them with the appropriate character, (e) deleted long quotes that were surrounded by <</>> instead of the usual English quote character ", and (f) removed the duplicate essay from `RUMO7057.txt`

To remove as much topic bias as possible from our ICLE dataset, we used a specific sample of the corpus that did not contain any topics that were found in one and only one native language group. The only exception to this was the sample for Japanese, where most of the topics were unique to that language group. We chose to leave the unique Japanese prompts in the sample because the alternative would have been to remove all of the Japanese essays from consideration. For the evaluations with ICLE discussed later in this paper (Section 5), we use this modified version of the ICLE. We provide a script which will automatically modify ICLE to address the issues above. The transformed version of this corpus is called ICLE-NLI.

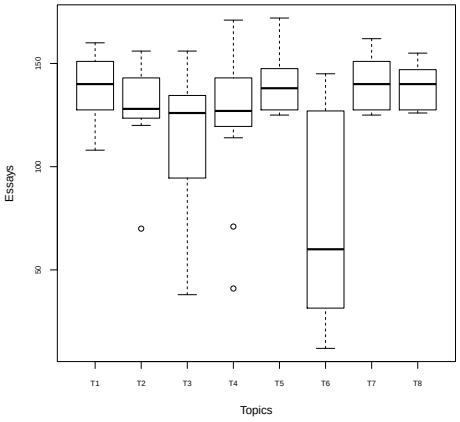

Figure 1: TOEFL11: Language distribution for each topic

3.3 TOEFL11: A New Corpus for NLI

While the modifications do address many of the issues with the ICLE corpus, it still has problems of small data size and some remaining topic bias. We constructed a new corpus of non native English writing called TOEFL11 which will be released through the LDC in 2013.

[7] http://code.zemanta.com/tsolc/unidecode/

This corpus consists of essays written by non native English speakers during a high stakes college-entrance test. It contains 1,000 essays per language sampled as evenly as possible from 8 topics along with author proficiency scores (low/medium/high) for each essay determined by assessment specialists. The distributions of the number of essays from each L1 group for each topic are shown in Figure 1. The 11 native languages covered by our corpus are: Arabic (Ara.), Chinese (Chi.), French (Fre.), German (Ger.), Hindi (Hin.), Italian (Ita.), Japanese (Jap.), Korean (Kor.), Spanish (Spa.), Telugu (Tel.), and Turkish (Tur.).

Corpus	**Languages (bold = common)**	**Essays per L1**	**Total Essays**	**Topics**	**Avg. Langs per Topic**	**Avg. Words per Essay**
ICLE-NLI	Bul., **Chi.**, Cze., **Fre.**, **Jap.**, Rus., and **Spa.**	110	770	76	1.4	666
TOEFL7	Bul., **Chi.**, Cze., **Fre.**, **Jap.**, Rus., and **Spa.**	659	4,613	79	6.5	252
TOEFL11	Ara., **Chi.**, **Fre.**, Ger., Hin., Ita., **Jap.**, Kor., **Spa.**, Tel., Tur.	1,000	11,000	8	11	315
TOEFL11-Big	Ara., **Chi.**, **Fre.**, Ger., Hin., Ita., **Jap.**, Kor., **Spa.**, Tel., Tur.	7,954	87,502	76	11	256

Table 2: Properties of NLI Corpora

We also compiled a larger dataset to investigate the effects of large amounts of training data on NLI accuracy. This corpus, which we will refer to as TOEFL11-Big, contains 87,502 essays from the same 11 languages as our public corpus, with between 7,900 and 7,983 essays per language. Again we sampled as evenly as possible across topics, but this time from a larger pool of 76 topics. There is no overlap in data between TOEFL11 and TOEFL11-Big.

To allow for a more direct comparison with previous ICLE results, we compiled a third corpus, henceforth TOEFL7, that uses the same 7 native languages that are most frequently used for NLI with the ICLE: Bulgarian, Chinese, Czech, French, Japanese, Russian, and Spanish. We used 659 essays per L1, sampled from a pool of 79 topics. In comparison, ICLE work typically uses 70 or 110 essays per L1.

Table 2 summarizes the four corpora to be used for training and testing in this paper. Of the three new corpora introduced in this paper, TOEFL11 will be made public.

4 System

Following previous work, we treat the problem of native language identification as a classification task. We train a native language identification system using a logistic regression model with L1-regularization.[8] We carry out 10-fold cross validation on all of the TOEFL® corpora and 5-fold cross-validation on the ICLE-NLI corpus (following Wong and Dras (2011)). In addition to building individual classifiers for each of our features, we also experiment with two ways of combining them. **Simple Combination** involves combining the features into one large set. In

[8]For all of our experiments we use the liblinear implementation (Fan et al., 2008) available from `http://www.csie.ntu.edu.tw/~cjlin/liblinear/` with the L1-regularized logistic regression solver and default parameters.

Character n-grams	All unigrams and bigrams present in each essay.
Function words	Function word counts based on the same list used by Koppel et al. (2005).
Part-Of-Speech (POS) bigrams	All POS bigrams present in each essay. Tags were obtained using the Stanford Tagger (Toutanova et al., 2003).
Spelling errors	Spelling errors returned by MS Word 2007 based on the list of error types used by Koppel et al. (2005). In the Koppel et al. (2005) work, spelling errors were derived using a pre-2003 version of MS Word.
Word n-grams	For unigrams, we restrict the list to correctly-spelled content words to prevent overlap with other features. For word bigrams, we do not filter the list.
Writing quality features	Counts and binary features quantifying different aspects of writing quality such as grammatical errors, style, discourse and vocabulary level. These features were derived using a proprietary automatic essay scoring engine (Attali and Burstein, 2006). Koppel et al. (2005) used a pre-2003 version of MS Word to find grammatical errors.
Tree Substitution Grammar Fragments	Counts and binary features corresponding to TSG fragments. These were extracted using the software described by Post and Gildea (2009) available from `https://github.com/mjpost/dptsg`.
Stanford Dependencies	Counts of basic dependencies extracted using the Stanford Parser (de Marneffe et al., 2006). Also included are variations of dependencies where lemmas were replaced by POS tags.
Language Model	Perplexity scores from 5-gram language models, one for each language in the corpus. Language Models were trained using the IRSTLM toolkit (Federico et al., 2008) .

Figure 2: A summary of all features used in our classifier

Ensemble Combination, which has not been explored for this task, each individual feature is trained as its own classification system and the predictions from that system, along with the scores (either probabilities or perplexity scores) are used in the final ensemble model to predict the native language.[9]

4.1 Features Used

The features used in our system are summarized in Figure 2. In order to be able to examine the performance of features across corpora, we implemented many of the features commonly used in the literature, as well as a novel language-model-based feature.

To begin with, we implement the features described by Koppel et al. (2005). The main classes of features in that paper were: character n-grams, function words, parts of speech, spelling errors, and writing quality features. We implement these features, roughly corresponding to the original work. One key difference is that we do not restrict our n-gram features to only include n-grams that occurred a certain number of times; we include all n-gram features as input to the classifier unless otherwise specified. For each feature, we implement both the binary and frequency variants. This set of binary and frequency features is combined to form the "Koppel Baseline."

We also combine Koppel's features with content words and word bigrams to produce a model

[9]Note that the splits used for all the individual classifier training and testing were identical.

that includes most of the simple features previous researchers have used for NLI. We only include counts of correctly spelled content words for the unigrams to avoid overlap with the other Koppel Baseline features.

Tree Substitution Grammar features have been used by previous researchers for this task (e.g., Swanson and Charniak, 2012). We take the fragments as generated by the Post and Gildea (2009) system and use those as fragments in our classification system. The Stanford dependency features are a variation on the syntactic features proposed previously (e.g., Kochmar, 2011; Wong and Dras, 2011; Post, 2011). We automatically extract all basic dependencies for each essay and consider each dependency to be a feature. This yields features of the form `nsubj(saw, dog)`, `dobj(saw, cat)`. We also carry out a backoff transformation based on part-of-speech, and for the two dependencies previously listed, would also consider the following features: `nsubj(VBD, dog)`, `dobj(VBD, cat)`, `nsubj(saw, NN)`, `dobj(saw, NN)`, `nsubj(VBD, NN)`, `dobj(VBD, NN)`.[10] We also consider the corresponding unlabeled dependencies as features. For almost all features we use both count-based (relative frequency for all but the writing quality features) and binary (presence/absence) features. We do not use binary features for the Stanford dependencies.

In addition to the previously described features, we also propose the use of language model perplexity scores. Surprisingly, language models, to our knowledge, have not been used for native language identification. We hypothesize that previous researchers may have avoided them because of the topic bias inherent in the ICLE or because there may not be enough data to build reliable models. Jarvis et al. (2012) showed that using higher-order *n*-gram features did not help for the task of L1 identification in the ICLE with 12 L1s and 10-fold cross-validation. We take a slightly different approach and train a 5-gram language model (with Witten-Bell smoothing) for *each* language in the corpus. We then apply each language model to each essay in the test data and choose as the prediction, the language model with the lowest perplexity.

5 Results

In this section, we discuss evaluations of different NLI systems under a variety of conditions to best answer the original research questions. In Section 5.1, we address the first two research questions by investigating the effectiveness of typical NLI features, as well as a novel feature (n-gram language models) across different corpora. In addition, we show that different feature combination methods can further improve system performance. In Section 5.2, we discuss the impact of training on one corpora and testing another. In Section 5.3, we discuss the impact of increasing the amount of training data on system performance. Finally, in Section 5.4 we show that the proficiency level of a writer should be taken into account when designing features and reporting results.

5.1 General Feature Discussion

This section reports the results of our experiments on the four corpora described in Section 3 to address the first two research questions posed. For each experiment we carried out cross validation, training on one portion of the data and testing on the remainder. We measure the performance of the classifier in terms of accuracy, i.e. the percentage of correctly classified languages in the corpus. Table 3 gives the results for all experiments. As a baseline, we take

[10] We ignore the index information provided by the Stanford Parser when storing the dependencies, however they are used when applying the part-of-speech backoff transformation.

our approximation of the Koppel et al. (2005) features. We also report results for features derived from Tree Substitution Grammar fragments, Stanford dependencies, and our novel language model feature. Finally the table shows that the ensemble method of combining features performs best, often significantly better than the simple combination of all features into one model.

On the ICLE-NLI corpus, our best ensemble model achieves an accuracy of 90.1% for a 7-way classification task. This is substantially higher than any previously reported results on the ICLE. Note that our experiments were carried out on a cleaned up version of the ICLE corpus (in an attempt to remove some of the biases, making the task more difficult). As noted in Section 2, it is very difficult to compare results for this task on the ICLE corpus because of the many different experimental procedures used by different researchers. However, despite these caveats, we believe that our system achieves state-of-the-art performance on this corpus for this task. Looking at the results for individual features, it is clear that the Koppel features alone do a very good job at predicting. Interestingly, the language model-based classifier also performs very well. The syntax-based features alone are also quite predictive, and our experiments show that the slightly more abstract representation of the syntactic structures within essays that can be captured by the Stanford dependencies is also a powerful predictor.

The results for TOEFL7, which contains the same languages as the ICLE-NLI corpus with a similar number of total topics but is around 6 times larger, show that the features and combinations that worked extremely well for the ICLE-NLI corpus, do not perform as well on this new corpus. The best result is achieved by our ensemble model with an accuracy of 70.9%. Again we see that the baseline Koppel features are very strong, although the language model-based classifier does not outperform the syntax-based models on this corpus. We believe that this indicates that while we may be reaching the upper bounds of performance on the ICLE-NLI corpus, there still remains plenty of room to improve current models and develop them to be able to perform well across corpora.

Interestingly, all of the combined models (and most of the individual ones) perform substantially worse on TOEFL7 than on any of the other corpora. There are two properties of the TOEFL7 corpus that are likely the cause for this performance disparity: (a) essay length and (b) topic distribution. The essays in the ICLE-NLI are on average 666 words long (see Table 2), whereas the TOEFL7 essays are an average of 252 words long. Therefore, while there are more total essays in the TOEFL7 corpus to use for training than in the ICLE-NLI sample, there are fewer potential occurrences of each useful feature per essay, which means the binary versions of the features are less helpful. This length disparity does not exist between the TOEFL7 and TOEFL11 data sets, but the distribution of topics is very different, which may contribute to the difference in performance. The topic distributions for TOEFL11 and TOEFL11-Big were made as even as possible, but we did not have access to enough of some of the ICLE-NLI languages to be able to sample TOEFL7 as evenly.

Our performance on the TOEFL11 corpus, developed specifically for the task of native language identification, are encouraging. Our best ensemble model achieves 80.9% accuracy, and the performance of the individual features follows a pattern similar to the ICLE-NLI and TOEFL7 evaluations. These results show that the features and their combinations do scale to larger corpora (1000 essays per language, 11 native languages)

Finally, on our largest corpus, TOEFL11-Big we see the same patterns as on the other corpora. Here, the increased data size does seem to lead to some small improvements in performance

Features	ICLE-NLI (7-way)	TOEFL7 (7-way)	TOEFL11 (11-way)	TOEFL11-Big (11-way)
Random baseline	14.3	14.3	9.1	9.1
Koppel baseline	80.0	58.0	65.9	67.3
character unigrams	20.1	23.2	23.8	28.1
character unigrams (binary)	46.1	29.2	26.6	24.3
character bigrams	14.5	26.0	25.0	39.2
character bigrams (binary)	70.3	44.4	52.2	51.9

Table 3: Cross-validation results for all systems on each corpus; accuracy in %

for some features, but not all. Particularly, some of the binary features perform worse on the TOEFL11-Big corpus compared to the smaller TOEFL11 corpus. The syntax-based features do seem to be one of the stronger features given the extra data.

We notice that the performance of the language-model feature is inconsistent across corpora. It remains unclear why this is the case, but we hypothesize that it is partly due to topic distributions. We will continue to explore the cause of this inconsistency. Noteworthy, is the fact that word unigrams/bigrams are generally one of the strongest baselines. Our language-model feature is a more complex version of these features. These simple features alone perform about as well as the entire set of features that goes into the Koppel baseline. One reason previous researchers had given for avoiding these word-level features was because it was felt that they were unfairly advantaged because of the topic bias in ICLE. Our experiments show, however, that even in corpora where there is no topic bias (TOEFL11), these word-level features remain predictive.

5.2 Cross-Corpus Evaluation

The experiments in Section 5.1 all involved cross-validation on one corpus. A remaining issue to address is the question of whether a system trained on one corpus can generalize to another. Brooke and Hirst (2011) reject cross-validation as a means of evaluating NLI systems on corpora that are heavily topic biased and instead train their system on a large amount of web-scraped data.

In our study of the effect of training on one corpus and testing on another, we carry out experiments on pairs of corpora that consist of the same sets of languages. We evaluate first on the ICLE-NLI vs TOEFL7 corpora (7 languages) and second on the TOEFL11 vs TOEFL11-Big corpora (11 languages). The main argument for carrying out this evaluation as proposed by Brooke and Hirst (2011) is to circumvent the issue of topic bias. We believe that these pairs of corpora are composed of sufficiently different topics that there should not be significant overlap.

For the ICLE-NLI vs TOEFL7 experiment, we train a classifier using the combined set of features listed in Figure 2 apart from the language model features. The results are reported in Table 4. The results generally show lower performance than the cross-validation experiments. In particular, the system trained on the ICLE-NLI data set does not generalize at all to the TOEFL7 data set. Training on TOEFL-Big and testing on TOEFL11 shows that the large amount of training data available in the TOEFL11-Big corpus leads to similar performance as the cross-validation result on TOEFL11. In general it seems that training on a larger corpus and testing on a smaller one works reasonably well, however training on a small corpus and testing on a larger one does not yield good results with our feature set. It remains for future work to determine which individual features can generalize well in this scenario.

Train	**Test**	**Accuracy(%)**
ICLE-NLI	TOEFL7	26.6
TOEFL7	ICLE-NLI	67.4
TOEFL11	TOEFL11-Big	35.4
TOEFL11-Big	TOEFL11	79.2

Table 4: Results for Cross-corpus evaluation

5.3 Corpus size

The relatively small size of the portion of the ICLE corpus traditionally used for the task of NLI has been a major criticism (Brooke and Hirst, 2011). Since our TOEFL11-Big corpus is several orders of magnitude larger than this, we are in a favorable position to be able to examine the impact of adding additional training data to NLI classifiers. In Brooke and Hirst (2011), they automatically gleaned additional training data by scraping online blogs. Our large data set is composed of essays written by learners of English and the native language self-reported by the learners.

Figure 3 shows the learning curve for an ensemble classifier on our TOEFL11-Big data set. When increasing the size of the data set, we add the same number of essays for each language, where possible. The graph shows a steep rise at the beginning, but as more data is added, the increase in performance is low and appears to be leveling off. The graph shows that the 11,000 essays in our publicly available data set should be a large enough number to be able to train classifiers with high accuracy, but that there could also be performance improvements with a somewhat larger dataset.

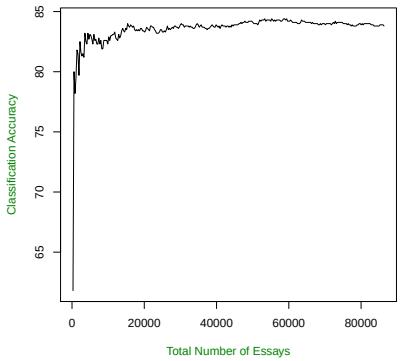

Figure 3: 11-way Classifier accuracy when trained on increasing amounts of data

5.4 Proficiency-based Evaluation

One issue that has not been thoroughly addressed in the field is the effect of writer proficiency on system performance. If a corpus is composed of highly proficient writers, then one would expect the effects of features such as spelling and grammatical errors to be less useful since they would be less common. Conversely, if the writer is of moderate or low proficiency, error features may be a larger contributor to classifier performance while more complex features may be less so due to data sparsity. So, when designing an NLI system and evaluating it, it is important to take into account the proficiency of the writer. In a pilot study, Jarvis and Paquot (2012) found that it is necessary to control for proficiency since it impacts the final discriminative analysis. They used trained assessment specialists to manually rate 223 ICLE essays written by learners of 3 L1s: Spanish, German and French. They found that the Spanish essays tended to have lower proficiency scores than the other two and were thus more easily distinguishable using the standard error techniques.

To investigate the influence of author proficiency on classification accuracy, we examined the performance of our best ensemble model at the three proficiency scores. As can be seen in Table 5, accuracy is highest for essays with a medium proficiency score. One possible reason for this is that medium proficiency essays feature a significant number of errors that many of the features (e.g. spelling errors, POS bigrams, and writing quality) can be used for prediction, but not so many that the sentences are seriously ungrammatical and difficult to interpret, as is the case with low-scoring essays. It is not surprising that high-score essays are difficult for NLI because their near-native writing would contain substantially fewer predictive errors. An alternative explanation for the results in Table 5 is that they simply reflect the score distribution in the corpus. We will continue to examine these hypotheses in future work.

We believe that proficiency reporting should be a necessary “best practice” in the NLI field. As more learner corpora become available, such as TOEFL11, Cambridge Learner Corpus and lang8, including a breakdown of classifier performance by proficiency score will make it easier to compare and discuss results across corpora.

Proficiency Score	Accuracy (%)	Number of Essays
Low	82.8	1,201
Medium	86.1	5,964
High	79.8	3,835

Table 5: TOEFL11 Accuracy for Best Model by Proficiency Score

Conclusion

To date, it has been hard to interpret results or compare systems because of the reliance on the ICLE corpus. In this paper, we addressed these issues by providing two resources: a modified version of the ICLEv2 (ICLE-NLI) and a larger corpus of essays that is more balanced across topics (TOEFL11). It is our hope that making these resources publicly available will help foster better standardization in the growing field of NLI.

Using these two corpora, we were able to draw the following conclusions:

1. Many of the trends found in previous work on the ICLE do generalize to other corpora, such as the power of the Koppel et al. (2005) features and word n-gram frequencies.
2. N-gram language models, which had been heretofore unexplored in this work, perform comparatively well for all corpora we examine.
3. Training on a large corpus and testing on a smaller corpus works well, but classifiers trained on smaller corpora do not appear to generalize well.
4. Combining multiple features in an ensemble classifier yields significantly greater classification accuracy than simply using including all of the features in one large classifier for all corpora we examine.
5. For the ICLE, the ensemble method has an accuracy of 90.1%, which is higher than the previously reported best accuracy of 81.7%.
6. Classification accuracy varies across proficiency levels, however further research is required in order to be able to explain the reasons for this.

Acknowledgments

The authors wish to thank Ben Swanson, Julian Brooke, Matt Post, Jojo Wong and Sylviane Granger for stimulating discussions related to this work. We would also like to thank the anonymous COLING reviewers, Jill Burstein and Nitin Madnani for their helpful comments and suggestions for improving earlier versions of this paper. We are grateful to Derrick Higgins, Anthony Ostrander, Xiaoming Xi and Robbie Kantor for their help in making the public release of the TOEFL11 dataset possible.

ABSTRACT
The advent and recent popularity of location-enabled social media services like Twitter and Foursquare has brought a dataset of immense value to researchers in several domains ranging from theory validation in computational sociology, over market analysis, to situation awareness in disaster management. Many of these applications, however, require evaluating the a priori relevance of trends, topics and terms in given regions of interest. Inspired by the well-known notion of the *tf-idf* weight combined with kernel density methods we present a smooth measure that utilizes large corpora of social media data to facilitate scalable, real-time and highly interactive analysis of geolocated text. We describe the implementation specifics of our measure, which are grounded in aggregation and preprocessing strategies, and we demonstrate its practical usefulness with two case studies within a sophisticated visual analysis system.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE, L_2 (OPTIONAL, AND ON SAME PAGE)

Inverse Dokumentdichte: Ein glattes Maß für ortsbezogene Termnutzungsunregelmäßigkeiten

Das Aufkommen und die derzeitige Beliebtheit von ortsbezogenen Diensten der Sozialen Medien wie Twitter und Foursquare haben einen Datensatz von immensem Wert für Forscher verschiedener Domänen, von der Aussagenvalidierung in der Soziologie, über Marktanalysen, bis zur Situationseinschätzung im Katastrophenschutz, geschaffen. Viele dieser Anwendungen erfordern jedoch eine Einschätzung der a priori Relevanz von Trends, Themen und Termen für gegebene geographische Regionen. Basierend auf der Idee hinter dem bekannten Tf-idf-Maß, präsentieren wir eine geglättetes Maß, welches, durch die Ausnutzung großer Korpora bestehend aus Daten der Sozialen Medien, die skalierbare, echtzeitfähige und voll interaktive Analyse von geokodierten Texten ermöglicht. Wir beschreiben die Details der Umsetzung unseres Maßes, welche auf Aggregations- und Vorverarbeitungsstrategien beruht, und wir zeigen seine praktische Anwendbarkeit durch zwei Fallbeispiele mit Hilfe eines elaborierten Systems zur visuellen Analyse.

KEYWORDS: tf-idf, term density, geolocated corpora, Visual Analytics, Twitter, social media.

Right: Cluster analysis is used to detect spatiotemporal clusters of similar topic usage to display them on a map.

1 Introduction

Every time Twitter users write a message on their GPS-enabled mobile device, they can attach precise location information. Each day more than 3 million documents are produced this way. Within one year, people from all over the world have generated a corpus comprising more than 1.3 billion[1] geolocated messages. Such location-enriched text data has tremendous value for researchers and analysts in several fields ranging from theory validation in computer sociology to location aware market analysis. Most notably, this data source has opened important application domains for research in situation awareness and disaster management, since the community of social media users can serve as a global 'sensor network' of potential incident reporters of critical events (Sakaki et al., 2010).

Due to the high complexity and volume of data, automated means for language processing and information mining are often complemented by highly interactive visualization tools (MacEachren et al., 2011; Marcus et al., 2011) that help analysts to explore and filter relevant messages and detect important localized events like river floods, wildfires, typhoons, hurricanes, infectious diseases or shooting incidents (Starbird and Palen, 2010; Mendoza et al., 2010; Sakaki et al., 2010; Hughes and Palen, 2009; Chew and Eysenbach, 2010; Palen et al., 2009; Heverin and Zach, 2010). Several of these tools have shown that aggregated representations of keywords and topics of large message volumes from selected or automatically determined spatiotemporal ranges can be of great value for precise situation assessment and large scale anomaly indication. For example, the ScatterBlogs Visual Analytics system (Bosch et al., 2011; Thom et al., 2012), depicted in Figure 1, provides means to aggregate large volumes of textual data in selected areas and indicates spatiotemporal topic clusters with geolocated Term Clouds.

Relevant keywords in such systems are often detected through their high term-occurrence counts compared to the counts of other terms in the vicinity. It has been a challenge, however, to evaluate whether documents or even individual terms are actually anomalous outliers within the specified area and timespan or just perennially prominent terms like stopwords or certain keywords that are frequently used in the examined region or throughout the whole Twitter

[1]Tweets can either have a user defined geotag (e.g. `London`) or precise latitude/longitude coordinates. In this work we only consider the latter ones, comprising a subset of 0.7 billion messages.

network. As a result, relevant and anomalous documents and keywords are often obscured by falsely highlighted keywords resulting from regular day-to-day chatter. Conventional solutions for this problem rely on the use of *tf-idf* and similar measures, which indicate whether a keyword is specifically important within a selected document set or whether it is also frequent within the corpus of all documents. However, when looking at geolocated documents the situation is quite different. Besides globally prominent terms, which can easily be detected by *tf-idf*, there are also many terms that are only prominent within a certain region. Thus, when examining a certain geospatial area and timeframe of documents, the importance of certain prominent and unusual terms can still be easily obscured by numerous and ordinary terms for the area.

To address this problem we present a smooth and scalable technique for geospatial term relevance normalization. Based on the combination of *tf-idf* with kernel density methods, a complete one-year corpus of geolocated Twitter messages is evaluated to determine the a priori probability that a given term is contained in a document composed at a given location. The intuition behind our measure is quite simple: In the *idf* part of the *tf-idf* measure, the number of documents in which a term appears is counted in order to put the term frequency in relation to the sum of documents in the corpus. In contrast, our measure sums for a given location the derived probabilities that a document containing the term could have appeared at this point and puts it in relation to the sum of derived probabilities that any document could have appeared at this point. The outcome of this is the (im)probability that a term is contained in a message appearing at any given point, allowing to assess the abnormality of observed term occurrences in examined document sets.

The details and a formal definition of this concept will be given in Section 3. An important contribution of our paper is a scalable implementation to calculate, store and quickly retrieve the normalization values based on adaptive grid aggregation techniques, described in Section 4. Since the proposed technique was particularly developed for large scale interactive document exploration, the performance details are discussed in Section 5 and its practical applicability is evaluated in Section 6. We conclude with a discussion of the results, final remarks and an outlook on future work.

2 Related Work

Work related to the described approach can be found mainly in two areas, which will be addressed in this section. First, geolocated resources can be used to create meta-documents for specific locations in order to geographically tag new resources according to their similarity to these meta-documents. Second, the geographic information of resources can be exploited to establish a 'geo-ranking' of search results lists.

Several approaches propose a prediction of a resource's geolocation inferred from the textual content or associated tags by features such as toponyms, geographic and cultural features, and stylistic and dialectic differences. Wing & Baldridge (2011) discretize the world with a regular grid of equal degree and calculate the term probabilities per document, grid cell and corpus using different geolocated document collections, i.e. Wikipedia articles and Twitter messages. Given a new and unlocated document, they can calculate the similarity between the document term-distribution and the cells' term-probabilities and choose the closest cell as the probable document location. Roller et al. (2012) follow the same approach but construct an adaptive grid from a space-partitioning k-d-tree trained on the same document collections for efficiency and higher resolutions in densely populated regions. For each grid cell, a pseudo-document is assembled from all training documents that lie within the cell and again their similarities

to documents of unknown origin are calculated. This can lead to a decreasing quality of the measure when the resolution is increasing, due to an overfitting of the data when the pseudo-documents will become small and specific for the high resolution cells. In contrast, our approach uses a smoothing kernel, such that the measure's quality is increasing with higher resolutions. Serdyukov et al. (2009) present a similar approach related to the tags associated with user uploaded photos. They consider a bag-of-tags model for each grid cell and combine it with a smoothing strategy and additional codified knowledge about geolocations from services such as GeoNames[2]. However, all these approaches examine the situation where an unknown document is given and the most probable location of its origin has to be found. Therefore it is reasonable to estimate the probability that a certain term or document *appears* at a certain location. In contrast, our approach estimates the probability that a document written at a certain location *contains* a certain term. What seems to be just a slight difference, leads to a completely new application domain, as will be demonstrated in our case studies.

Zhang et al. (2010) also present a geospatial extension of the *tf-idf* measure in the context of tag centric query processing for geolocated web 2.0 resources. The approach tries to identify regions where each of the query tags is covered by at least one nearby web 2.0 resource. The purpose of the measure is to rank regions within the result set according to how characteristic the tags are for each region. Due to the focus on querying, their use case and therefore the measure itself and its implementation differs from ours in the following aspects. The geospatial extension can be seen as replacing documents by regions and the corpus by the set of all regions. A term is therefore characteristic for a region when it is *frequently* observed in the region but *infrequently* used globally. As our work focuses on exploring large data sets with potentially huge amounts of frequent but irrelevant chatter, we need a measure for normalization with respect to long-term keyword densities. Our approach contrasts term densities with document densities for each individual point of the world. Therefore, a term can still achieve a high score for a specific region even if it is a globally common word. Furthermore, the approach of Zhan et al. utilizes a fixed grid in order to approximate a smooth measure and a tagged resource can only influence directly neighboring cells by a two-step degradation function. This limits the spatial scalability and allows only rough resolutions when dealing with global data.

The World Explorer visualization tool (Ahern et al., 2007) identifies representative labels for geolocated photo collections. The available photos are geospatially clustered, independent of their associated tags, to form potential map label locations for each zoom level and map tile individually. Afterwards, a representative tag is selected for each cluster by evaluating an adapted *tf-idf* measure. Similarly to Zhang et al., the tag frequency within a cluster is related to its overall frequency within one tile. With this approach, tags like *San Francisco* are relevant on the scale of the state of California, but insignificant on a detailed tile of San Francisco itself. Eisenstein et al. (2010) present a latent geographic topic model to identify words with high regional affinity, geographically coherent linguistic regions, and regional variations of general topics. The model can be seen as a latent Dirichlet allocation with regional corruptions of the base topics. The model was applied to 380k twitter messages and achieved a good performance in locating users by their allocation to a regional topic.

3 Model

In information retrieval and language processing, the *tf-idf* measure is used to evaluate the relevance of a term for a given document within a given corpus (Jones, 1972; Manning et al.,

[2] `http://www.geonames.org`

2008). Given a document d and a term t, the number of occurrences $tc_{t,d}$ of t in d is determined and normalized by document length to compute the term frequency $tf_{t,d} = \frac{1}{|d|} tc_{t,d}$. This results in the relative prominence of t within d. A high term prominence, however, is no indicator that the term is also important to the document, since common terms like `the`, `she` or `like` are prominent within most documents. Therefore, one also has to compute the inverse document frequency based on the corpus D of all documents, from which d was taken:

$$idf_{t,D} = \log \frac{|D|}{|\{d|d \in D \wedge t \in d\}|} \tag{1}$$

The *idf* can be seen as an indicator for the a priori probability that t appears in documents drawn from D - the higher the probability, the lower the value. The *tf-idf* is computed by simply multiplying the values:

$$tfidf_{t,d,D} = tf_{t,d} * idf_{t,D} \tag{2}$$

Moving from regular document sets to the domain of geolocated messages, we find a very diverse corpus with contents ranging over several different regional topics, characteristics and languages. For example, in most major cities around the globe the city's own name as well as the names of individual districts are usually mentioned in hundreds of Twitter messages every day. The same is true for regional points of interest or words from languages and dialects which are only used in distinct parts of the world. In order to estimate, whether a term is actually important or anomalous for a particular map area and time span, it is not sufficient to compare its local term frequency against the global *idf* value. Globally, the term `Denver` could have a similar or even lower *idf* value as `shooter`. What is needed instead is a measure that compares the term count of the examined message set with the estimated inverse document frequency of all messages that have been written in the appropriate region and in a larger timeframe than that of the message set.

To estimate this inverse document density for arbitrary map locations from the sparsely distributed message corpus, we utilize kernel based density estimation (KDE), which approximates probability distributions from discrete point data, and integrate it with the traditional *tf-idf* measure. Characteristics of the KDE and the formal definition of the new measure will be detailed in the following two subsections.

3.1 Kernel Density Estimation

It is a well-known problem to derive a continuous probability density f from a finite sample data set $X = \{x_1 \dots x_n\}$. For example, X could be a list of locations of crime reports for a major city. In KDE techniques (Rosenblatt, 1956; Parzen, 1962), the so-called density estimator for the data set is constructed as follows:

$$\hat{f}(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{d(x, x_i)}{h}\right) \tag{3}$$

In this equation, $d(x, y)$ is a distance metric, e.g. the Euclidean distance in case of samples from $\mathbb{R}^n$. The function K is the kernel and it is used together with the bandwidth h to assign a weighted value to each x_i depending on its distance from x. For the sake of simplicity one can also write the equation using subscript notation $K_h(u) = \frac{1}{h} K(\frac{u}{h})$. Selected kernel functions

usually have their maximum at $u = 0$, are rapidly decreasing with higher u, and integrate to 1. A Gaussian kernel is used in our implementation but other choices are also conceivable:

$$K(u) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{u^2}{2}\right) \tag{4}$$

The purpose of using these functions is to reflect the probability that a given sample could deviate a given distance u from its actual location. For example, if a crime was committed somewhere along a street at point x, without prior knowledge, it could as well have happened 5, 10 or 100 meters farther away with decreasing probabilities. By summing and normalizing all these spatially decreasing probabilities from all samples, the constructed function $\hat{f}(x)$ gives us a relative estimate of the probability that a crime can happen at an arbitrary location.

3.2 Measure Definition

Similar to the crime example above, the KDE principle can be applied to a sample of term occurrences from Twitter messages m_t containing term t at location x to inspire the estimation of term occurrence densities at arbitrary map locations. In the presented measure, KDE is employed to define the localized version of the inverse document frequency *idf* as basis for the localized *tf-idf* measure. It is assumed, that a given corpus G of geolocated messages has been collected over a large temporal range, e.g., one year, to stabilize the corpus against seasonal characteristics. We first define a measure for local term density and normalize it by the corresponding local document density to calculate the local inverse document density:

For a given term t let $G_t = \{m \in G : t \in m\}$ be the subset of messages from G that contain t and let $loc(m) \in \mathbb{R}$ be the location of message m in the coordinate space. Furthermore, let K_h be a kernel with fixed bandwidth h. For a given location $x \in \mathbb{R}$ we call

$$td_t(x) = \sum_{m \in G_t} K_h(d(x, loc(m))) \tag{5}$$

the term density of t at x. Note that these are absolute and not relative densities as they are not normalized with $\frac{1}{|G_t|}$. In order to allow a cross-comparison of different terms, the terms' densities are normalized at each location using the term independent document density at the same location:

$$dd(x) = \sum_{m \in G} K_h(d(x, loc(m))) \tag{6}$$

Finally, and analogous to the *idf*, we call

$$idd_t(x) = \log \frac{dd(x)}{td_t(x)} \tag{7}$$

the inverse document density of t at x.

In these equations the distance function must be matched to the coordinate space that has been chosen to represent message locations. For the example in Section 3.1, we assumed a uniform grid coordinate system and thus the Euclidean metric was an appropriate choice. However, since Twitter messages are usually given in graticule coordinates (latitude, longitude), one can convert them to a uniform grid or use the haversine formula (Sinnott, 1984) to approximate the distance.

For the term frequency value *tf* there is a natural analogue in most application cases. However, compared to the *idd* these values cannot be precomputed, since we want to apply the measure to new messages as they arrive from a continuous real-time data stream. Furthermore, in the case of Twitter messages, which are bound to 140 characters, there will rarely be more than one occurrence of a specific term and it is thus not meaningful to calculate the term frequency for a single message. However, if a set of messages M is examined - e.g. within a user selected region and timeframe - one can build a localized *tf-idf* value for any term t by calculating the sum

$$\sum_{m \in M} tc_{t,m} * idd_t(loc(m)) \tag{8}$$

This equation properly reflects the relation of current prominence of the term versus its commonness at the message locations. For the sake of simplicity and computational cost, the value can be approximated by calculating the term frequency for a pseudo-document, generated by concatenating all documents in M, and multiplying it with the $idd_t(mean)$ at the centroid location $mean = \frac{1}{|M|} \sum_{m \in M} loc(m)$ of the documents.

4 Implementation

For the traditional *tf-idf* measure, it is expensive to compute the *idf*-part, as the whole corpus has to be analyzed. Therefore, the values are usually precomputed at once by iterating through the complete set of documents and terms within the corpus. Once this is done, one can quickly compute a *tf-idf*-vector for any given document by computing a term frequency value for each term $t \in d$ and multiplying it with its precomputed $idf_{t,D}$ value.

The computation of the $idd_t(x)$ values is even more expensive, because for any point x the sum of kernel-weighted distances between x and $loc(m)$ for all messages $m \in G$, and for the messages $m \in G_t$ respectively, has to be calculated. Furthermore, as we are looking at a continuous and thus infinite coordinate space, it is not feasible to precompute and store an $idd_t(x)$ value for every possible t and x.

For practical applications, however, there is no need to have an infinitely high spatial resolution of values. Therefore, a high resolution regular grid can be laid over the globe and the $td_t(x)$ and $dd_t(x)$ values can be compute at every cell center or vertex. Missing values between these points could then be calculated at runtime through interpolation. Nevertheless, to achieve cell-sizes below 0.5 kilometer at the equator line, a grid resolution of at least 80 000 × 40 000 cells would be needed for global coverage. If we assume that each value takes 4 Bytes of storage, this amounts to approximately 12 Gigabytes of data for every single term in the corpus. To counter these problems, we adhere to a grid construction strategy that is adaptive to regional requirements resulting from population density. This will be detailed in the next subsection. Section 4.2 explains how the *idd* values are actually computed for each generated grid cell using a technique called Splatting. Finally, we explain in Section 4.3 how the values are stored and quickly retrieved once they are needed by the application.

4.1 Grid Creation

In many regions of the world, like oceans, deserts or large rural areas, the occurrence of Twitter messages is sparse. At the same time a high Tweet frequency in major cities can be observed. Instead of using a regular grid with a fixed resolution, it is reasonable to use an adaptive grid with high resolution in densely populated areas and lower resolution elsewhere. This grid is

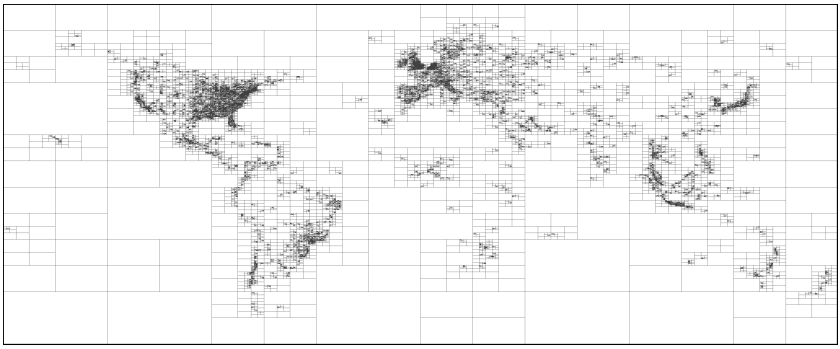

Figure 2: The result of adaptive grid creation, generated with a maximum depth of 16 and cell splitting as long as more than 50 messages were contained within a cell.

constructed by a recursive splitting mechanism generating a quadtree data structure (Finkel and Bentley, 1974). Since only Twitter users are of interest for this data set, the relevant 'Twitter population' density can be directly derived from message densities in the observed corpus. A data sample of 10 days taken uniformly distributed from one year of recorded Twitter messages was used for the construction of the grid. The initial, single cell comprises the complete coordinate space with $lat \in [-90, 90]$ and $lon \in [-180, 180]$. As long as more messages than a fixed threshold fall within one cell, we split it into four equally sized sub-cells and recursively apply the algorithm to each. A recursive path is terminated as soon as a predefined minimum cell-size of 0.5 kilometers is reached. The result of this method can be seen in Figure 2. For further computation, the complete recursive tree structure with the leaves representing the grid cells is stored. This way we can quickly ($O(\log|leaves|)$) find cells containing a given location x by recursively searching through the tree. Furthermore, a unique cell ID c_i is assigned to each cell and we use $loc(c_i)$ to denote the center-location of the cell.

4.2 Fast Value Computation

In a Gaussian kernel K_h, more than 99% of the area beneath the curve is within a $3h$-radius from the center. During the computation of the $td_t(x)$ and $dd(x)$ values, messages which are further away from x than this radius can be ignored, as they add little to nothing to the sum. Based on this observation, we chose a strategy called Splatting to realize a fast *idd* precomputation. The technique originates from volume rendering for 3D graphics (Westover, 1991). The concept can be considered as 'throwing ink balls' onto the grid at every message location, which results in a Gaussian footprint, a so-called *splat*. The local sums of the footprints at each grid-cell add up to the *td* and *dd* values. The concept is illustrated in Figure 3.

The algorithm works as follows. Let $grid = \{c_1, ..., c_i\}$ be the set of cell IDs of a grid data structure as created in Section 4.1. Furthermore, let $DD : grid \rightarrow \mathbb{R}$ and $TD_t : grid \rightarrow \mathbb{R}$ be initially empty Hash tables that map cell-ids to computed *dd* and td_t values. A given corpus G is processed according to the `splat` procedure of Listing 1. Thus, instead of iterating through the whole corpus for each grid-cell, to calculate the kernel weighted distances, we iterate through

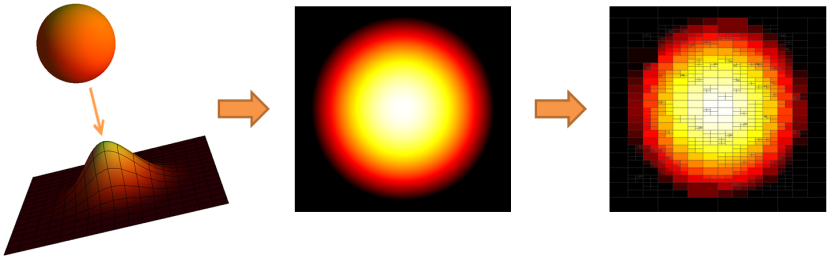

Figure 3: Left: Splatting process can be imagined as throwing ink balls onto the grid, resulting in a Gaussian signature. Middle, Right: The continuous splat is applied to the discrete grid. Each cell value is computed based on the distance from cell center to splat center.

G just once and add for each $m \in G$ and $m \in G_t$ a Gaussian splat value to all affected hash table entries $DD(c)$ and $TD_t(c)$, where the center location $loc(c)$ is within a $3h$-distance from m.

```
procedure splat(G,TD,DD,grid) is
begin
  for each m∈G do
    impact_area ← {c∈grid : d(loc(c),loc(m)) ≤ 3h}
    for each c∈impact_area do
      if DD(c)=empty then
        DD(c) ← K_h(d(loc(c),loc(m)))
      else
        DD(c) ← K_h(d(loc(c),loc(m))) + DD(c)
      end if
    end for
    for each t∈m do
      for each c∈impact_area do
        if TD_t(c)=empty then
          TD_t(c) ← K_h(d(loc(c),loc(m)))
        else
          TD_t(c) ← K_h(d(loc(c),loc(m))) + TD_t(c)
        end if
      end for
    end for
  end for
end
```

Listing 1: Splatting Algorithm

As mentioned in Section 4.1 this 'impact area' can be found quickly using the quadtree data structure. Assuming a constant upper bound for the number of terms inside a Twitter message as well as the number of cells within a splat radius, the algorithm runtime can be estimated by $O(|G| * \log(|grid|))$. Also, in terms of memory management the hash tables provide an efficient means to store the data, as large volumes of grid cells in oceans and rural areas will be unaffected by the splats of most terms. For these areas, we avoid to redundantly storing the information $idd_t(c) = 0.0$.

To limit the duration of the precomputation phase (e.g. one day instead of three) it is reasonable

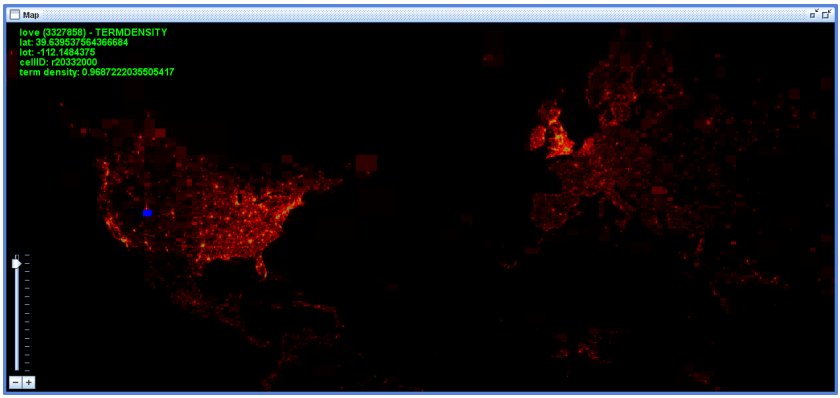

Figure 4: To evaluate the computed *TD* and *DD* results, we implemented a zoomable visualization, where individual values can be interactively examined by mouseover (blue rectangle). The result for the term density map of `love` can be seen in the window.

to restrict the computation to terms that have a certain minimum frequency. For example, in our case we included only terms that have at least 1000 mentions within a year — at application runtime, all other terms are then handled as if they occur for the first time with a default minimum term density of $td_t(x) = 1 * K_h(0)$. For evaluation purposes, the outcome of the splatting algorithm can be visualized by mapping the computed values to a color palette. The results for TD_{love} can be seen in Figure 4.

4.3 Fast Value Retrieval

The output of the splatting procedure will be a large set of filled hash tables TD_t for each term and *DD* for all documents, which can then be used for ad-hoc interpolation of the $idd_t(x)$ values at arbitrary points on the map. To actually apply the measure, two different modes were implemented. The first mode attaches the computed *idd* values directly to the twitter message as soon as it is stored. Currently, geolocated messages are collected from a continuous stream of approximately 3 – 4 million messages per day. Assuming that the number of terms per messages can be bounded by 20 terms, this means that the computation of one $idd_t(x)$ value has to be achieved in less than approx. 20 to 30 milliseconds. For future implementations the computation needs to be even faster, due to the still heavily increasing number of Twitter users.

The second mode is to retrieve the *idd* values only when they are needed inside an interactive application. In this case the retrieval from memory has to be fast enough to avoid interrupting fluid interactivity for the user. Thus it depends on the application what this means in terms of retrieval speed, i.e. for how many messages the value has to be computed in one interaction step. To actually store and fetch the values we used Apache Lucene[3], a widely known text search and storage system, and a custom built storage and query management. These methods will be reviewed in the next section.

[3] `http://lucene.apache.org/core/`

5 Implementation Performance

To evaluate its performance, the implementation was tested on a compute server driven by four Intel Xeon processors totaling to 40 physical cores, 128GB RAM, and SAS hard drives in a RAID 50 configuration. The *idd* values were precomputed based on a set of 732 895 428 geolocated Twitter messages collected between August 2011 and August 2012. The splatting algorithm described in Section 4.2 can easily be modified for parallel execution, such that it could fully benefit from the multicore capabilities of the test system. For a maximum depth of 18, the adaptive grid, described in Section 4.1, was created in less than 30 minutes and has about 300 000 cells. Based on this configuration, the complete precomputation process for the *TD* and *DD* tables was performed in less than 35 hours and it took approximately 200 Gigabytes to store the raw output.

A set of 1000 terms, drawn according to their overall frequency in the corpus, and 1000 randomly chosen cells of the grid were used to measure the retrieval speed of our storage solution. The adaptive grid tries to keep the amount of documents in each cell relatively constant; therefore the random cell node selection roughly reflects the document distribution. Because all terms share the same grid, only one instance of the quadtree needs to be held in memory for computing the cell ID for a given point x. The actual data is stored as mappings from cell IDs to term density values. We use Apache Lucene for storage and fast access to the precomputed $td_t(x)$ map. Each combination of term, cell ID, and *td* value was indexed by Lucene as a standalone *document*[4]. In order to access a value, the index for the term and cell ID combination is used to retrieve the document containing the value. This process takes 46ms on average (48ms for hits, 35ms for misses). Using parallelization with twenty threads, our implementation achieves an average of 4.8ms per value retrieval.

6 Case Studies and Evaluation

The practical usefulness of our measure was evaluated with scenario studies based on actual events and real world Twitter data. For this purpose the measure was integrated into existing tools for spatiotemporal text analysis and aggregation. In the following case studies we demonstrate how an analyst can employ and benefit from improved highlighting and term filtering based on the term normalization. Furthermore, we examine how our measure performs compared to traditional approaches.

6.1 Comic-Con 2012

The San Diego Comic-Con International is one of the largest annual conventions for comic books, science fiction/fantasy and other popular arts. From July 12 to July 15 2012 the main event was held at the San Diego Convention Center and several smaller events were co-located in nearby hotels and other venues. With more than 130 000 visitors swarming the area, observing and reporting show acts, autograph signings, meetings and other activity in the metropolitan area, the collected social media data is a perfect playground for large scale situation analysis.

For our case study we examined a set of 37 937 geolocated messages that were written in the San Diego area between 07/12 and 07/15 using the Visual Analytics system ScatterBlogs. Some of the system's core features integrate automated NLP methods for interactive visual analysis of aggregated text data. Here, we employed the *content lens*, a movable circle used to explore spatially plotted message contents by visualizing the most prominent terms. The

[4]Lucene stores documents as individually indexed string or numeric fields

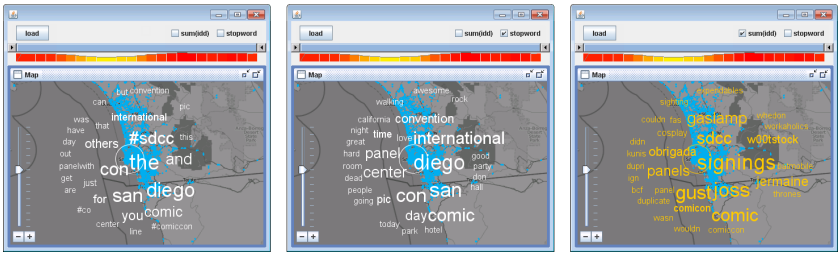

Figure 5: In ScatterBlogs a circular lens can be dragged over the map to spatially explore aggregated message contents. Left: Terms from messages inside the lens are shown according to descending occurrences. Middle: An English stopword list is used to remove irrelevant terms. Right: The *idd*-sum is used to weight the terms.

result of applying this technique to the San Diego area can be seen in Figure 5. The screenshot on the left shows the lens operating in standard mode, i.e. all terms from messages within the selected spatial and temporal frame are extracted, counted, and then arranged with descending popularity. By fixing the lens to a specific location and selecting one of the labels, the corresponding messages are shown in a table and can be further investigated by the user. In most cases, however, the standard mode will not be very useful, as it is dominated by high frequency stopwords like `the` and `you`. The user can thus activate two filtered operating modes by selecting one of the checkboxes. In *stopword*-mode, as depicted on the image in the middle, a list of English stopwords is used to remove them from the aggregation. In this mode, at least some terms related to the event (`panel`, `international`, `comic`) achieve a high ranking and can be seen in the visualization. However, the top ranking terms are still dominated by terms of regional prominence (`san`, `diego`, `center`).

The image on the right shows the *content lens* with activated measure as described in Sections 3 and 4. Here one can see several terms indicating individual smaller sub-events and activities in connection with Comic-Con. Some selected examples are:

- `w00tstock` - The music and arts show `w00tstock` was co-located with the event.
- `signings` - Artists, authors and actors gave autographs in special signing sessions.
- `joss` - Joss Whedon (an American screenwriter) gave a press conference at that day.
- `batmobile` - Props from the batman movies were on display near the convention center.

Between the hundreds of high frequency terms, these terms only achieve such a high ranking because their high prominence for the spatiotemporal frame contrasts their average prominence within the region. Such sub-event indicators are often what an analyst is interested in, when examining localized large scale events and catastrophes.

6.2 Virginia Earthquake

In August 2011 the US state Virginia was hit by a magnitude 5.8 earthquake near Richmond. The first Tweets reporting the incident were written just seconds after the shockwave occurred.

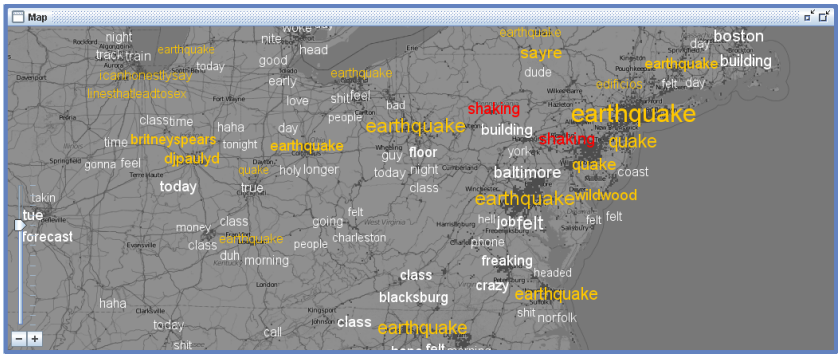

Figure 6: The *tag map* visualization: A k-means clustering scheme is employed to detect and display message clusters with similar timestamp, location and topic. Orange highlighting shows clusters/terms with high average *idd*.

To analyze this event, we use another tool of ScatterBlogs called *tag map*. It detects spatiotemporally dense clusters of messages with similar term usage and visualizes them by placing representative labels on the map. It follows the intuition that messages written by groups of local event observers will often result in this kind of *spatiotemporal content anomalies* (Thom et al., 2012) in the message streams. These anomalies can be used as an overview of the dataset and help to indicate suitable entry points for deeper investigation. Although the mechanism helps to detect many localized characteristics, it cannot distinguish whether a cluster results from a sudden and unexpected incident or from a regular venue - e.g. there could be a daily occurring cluster of messages containing `apple` at the location of an Apple store. Thus the overview showing several relevant terms is heavily cluttered with irrelevant terms that hinder the analysis.

To enhance the technique with our measure, a color coding was introduced that highlights topic clusters with high average *idd* values in orange. The threshold for highlighting is predefined based on the z-score of the *idd* value for all events. However, the analysts can also configure it to their needs using interactive controls. The result of applying the measure to a frame around the 23th of August can be seen in Figure 6. One can observe that relevant terms like `quake` and `shaking`, which are related to the sudden earthquake event, clearly stand out, while other prominent terms like `baltimore` and `blacksburg` are shown in the default color white. Besides the earthquake related terms one can also observe that `britneyspears` and `djpaulyd` are highlighted, because the artists happened to perform in Indianapolis during the examined timeframe.

6.3 Evaluation

We compared the results of our location aware measure against raw prominence and global *tf-idf* based term rankings for our observed scenario studies. For each scenario we used all messages within a predefined timeframe and area and computed the three measures for every term. For the 1000 most frequent terms a decision was made, whether they are specifically relevant for

the examined scenario. Based on this labeling, we determined incremental precision/recall curves by ranking the terms according to the respective measure's values. An example for the Comic-Con case can be seen in Figure 7.

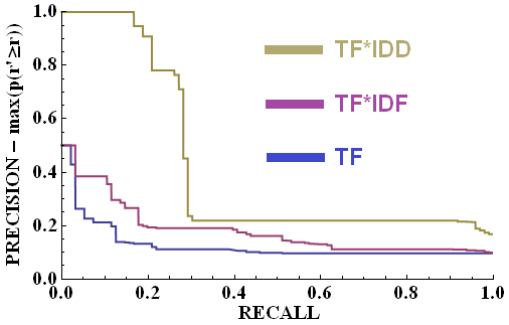

Figure 7: The graph shows interpolated precision ($p_{interp}(r) = \max_{r' \geq r} p(r')$) versus recall for Comic-Con 2012. From the messages written in the San Diego area the 1000 most prominent terms had to be ranked (96 were labeled as being relevant).

Our results show that our measure usually performs better in terms of precision for the top ranked terms and equally well or better for the lower ranked terms.[5] It is thus well suited for relevance based visualizations, where an analyst must quickly find interesting query-terms that could qualify for further investigation.

Conclusion and Perspectives

In this work a smooth measure for estimating term occurrence probabilities on a global scale was presented. Based on density adaptive large data aggregation, our measure can be employed in highly interactive environments and is suitable for real-time processing of streaming data. Because of the focus on term densities, our approach can be used in multilingual scenarios like the global Twitter corpus, as it is mostly language independent. It therefore eliminated the need for language specific stopword lists in the presented scenarios. Our case studies and evaluation have shown that the integration of the measure can lead to significant improvements for visual analysis systems.

Future work will encompass research in filtering techniques like loess smoothing to distinguish between seasonal, trending and unusual aspects of the data. In this context we will also examine means for explorative parameter steering to allow an interactive adaption of the measure's influence to tune results to the analysts' needs.

ABSTRACT
In this paper, we revisit the problem of language identification with the focus on proper discrimination between closely related languages. Strong similarities between certain languages make it very hard to classify them correctly using standard methods that have been proposed in the literature. Dedicated models that focus on specific discrimination tasks help to improve the accuracy of general-purpose language identification tools. We propose and compare methods based on simple document classification techniques trained on parallel corpora of closely related languages and methods that emphasize discriminating features in terms of blacklisted words. Our experiments demonstrate that these techniques are highly accurate for the difficult task of discriminating between Bosnian, Croatian and Serbian. The best setup yields an absolute improvement of over 9% in accuracy over the best performing baseline using a state-of-the-art language identification tool.

KEYWORDS: language identification, language discrimination, closely related languages.

Proceedings of COLING 2012: Technical Papers, pages 2619–2634,
COLING 2012, Mumbai, December 2012.

1 Introduction

Language identification becomes increasingly important in applications and research that rely on data collected from the web and user contributed content. The increased interest in automatic classification of texts can be seen in the number of tools and publications related to this task. Rather simple statistical techniques based on character N-grams and other orthographic features have been shown to be very effective even for the distinction of quite a large number of different languages. However, closely related languages are much harder to distinguish (even for humans) and standard approaches usually fail badly. Furthermore, low-density languages that are strongly related to other languages with larger resources are often not supported by language identifiers with pre-trained models. Some popular tools, such as the language detector integrated in the Google Chromium project, cannot be trained at all and, therefore, cannot be extended easily.

For these reasons, we consider in this paper the specific task of discriminating between closely related languages as a sub-task in automatic language identification. We will show that dedicated, yet simple models can greatly contribute to a better classification of those languages and, in this way, can help to build up resources for low-density languages. In our experiments, we focus on three related south-slavic languages: Bosnian, Croatian and Serbian. They represent a prototypical example for the problem we like to concentrate our work on. Their genetical closeness and lexical similarities make it very hard to distinguish between texts written in either language, which we will see further down in our initial experiments with standard language identification tools.

2 Related work

The problem of language identification was for quite some time considered a rather easy one and mostly solved. One of the most frequently used system in the academic world was TextCat based on the algorithm described in (Cavnar and Trenkle, 1994). This system uses character n-grams as features of length 1<=n<=4 that are most frequent in the specific language. Beside character N-grams, some systems also use the most frequent words as features (Batchelder, 1992).

With the dramatic increase of multilingual data on the web, the language identification problem has received new attention. Additionally, with the rise of new domains, such as microblogging, domain adaptation for language identification has become an important problem. Lui and Baldwin (2011), for example, tackle the problem by calculating information gain over multiple domains choosing those character n-gram features that are the most domain independent ones.

A harder problem emerging with the availability of data in many languages is the problem of discriminating between closely related languages. However, only a few researchers dealt with that problem in the past. Padró and Padró (2004) report problems with the distinction of Catalan and Spanish when using standard language identification methods showing that a character-based Markov chain is the least erroneous one having an error rate of roughly 6% on very short texts and 1% on longer ones, This accounts for 40% of errors on a task of discriminating between six languages. Furthermore, the inability to discriminate Portugese and Brazilian Portuguese with TextCat has been reported by Martins and Silva (2005). Finally, in our previous work (Ljubešić et al., 2007) we discuss the identification of Croatian in a pool of Slovenian, Croatian and Serbian documents showing very good results with a second-order Markov chain with 100% accurate discrimination of Slovene and a 96% accurate discrimination

between Croatian and Serbian. We also show that the latter could be improved by using simple lists of forbidden words to achieve up to 99% accuracy. These findings, in particular, motivated us to further explore the identification of these three languages with the techniques we present below.

Let us first have a quick look at the differences between the languages we focus on before introducing our approaches for language discrimination.

2.1 Differences between Bosnian, Croatian and Serbian

The three languages are considered very similar and until recently there was an open discussion if these languages should be considered linguistically separate.

If we consider the usage of Latin script only,[1] the largest difference between Croatian and Serbian is the present form of the proto-Slavic vowel *jat*, resulting in Serbian following more the ekavian and Croatian the ijekavian reflex which introduces many lexical differences (*child* – *dete* (sr) vs. *dijete* (hr, bs)). In this feature, Bosnian generally follows Croatian.

Internationalisms and proper nouns are handled differently as well with transliterations being frequent in Serbian, less frequent in Bosnian while in Croatian foreign proper names from Latin-script languages are written in the original orthography (*Nju Jork* (sr,bs) vs. *New York* (hr)).

In morphology the most important difference is the existence of synthetic future tense in Serbian (*videću*) beside the analytical one (*vidjet ću* or *ću vidjeti*) while Croatian and Bosnian only use the analytical form. There are also systematic differences in the derivation of nouns, adjectives and verbs (*organizovati*, *organizovan* (sr,bs) vs. *organizirati*, *organiziran* (hr,bs)) with Bosnian using both again.

There are some syntactic differences as well. The most visible one is the structure *modal verb + da + present* in Serbian and *modal verb + infinitive* in Croatian (*hoću da radim* (sr, bs) vs. *hoću raditi* (hr, bs)), Bosnian allowing both. Finally, Croatian and Serbian show a series of differences in the general vocabulary (*fabrika* (sr, bs) vs. *tvornica* (hr,bs)), Bosnian again allowing both, but additionally introducing a lot of lexical units culturally bound with the Moslem world. Apart from the fact that these three languages have common origins, today they are three distinct and codified standards, and texts in these standard languages appear regularly.[2]

Being aware that this is an oversimplification, we conclude that Croatian and Serbian are visibly different languages while Bosnian is a mixture of the two with a tendency towards Croatian. To support this claim, we present in table 1 the overlap of lowercased tokens calculated on the parallel corpus used later on for training our classifiers. We can observe that Croatian and Serbian are the most different languages, Bosnian and Serbian coming second and Bosnian and Croatian being the most similar ones. By not calculating type, but token intersections, we are also able to observe the amount of symmetry in the token overlap inside language pairs. The largest difference in the token overlap is shown between Croatian and Serbian showing 5%

[1] In contemporary Serbian around 50% of texts appear written in Cyrillc, Bosnian much less, while Croatian doesn't use the Cyrillc script at all.

[2] In our research we did not take into account the appearance of a new Montenegrin standard, with its reformed orthography that makes it distinct from any of these three languages. This development appeared only recently and this language should be considered as an extremely low-density language (total number of speakers is less than half a million).

more tokens of Serbian appearing in Croatian texts than vice versa. The most likely reason for this phenomenon is the tendency of Croatian language to break from the tradition of language unification efforts that existed in Yugoslavian times.

	bs	hr	sr
bs		0.952	0.915
hr	0.950		0.857
sr	0.930	0.902	

Table 1: Overlap of lowercased tokens between languages in the parallel corpus of Bosnian (bs), Croatian (hr) and Serbian (sr). Rows represent tokens, columns corpora of specific languages.

In order to stress the problems in automatic discrimination between these languages, we trained models using three popular tools (TextCat[3], Lingua::Identify[4] and langid.py[5]) with data taken from SETimes[6], a collection of parallel texts from an on-line news portal for the Southeast European region that publishes "news and views from Southeast Europe" in ten languages.[7] The trilingual parallel corpus we extracted from the dataset contains 5,536 parallel documents and roughly 2.7 million words per language. We trained models for only the three languages of interest in order to avoid any further confusions of the classifiers. For evaluation purposes, we extracted and manually verified 600 documents (200 per language) from three on-line resources, one in each language.[8] Table 2 shows the confusion matrices produced by these tools.

TextCat

langid.py
Overall accuracy: 87.7%

	bs	hr	sr
bs	139	56	5
hr	11	187	2
sr	0	0	200

Accuracy for Bosnian: 69.5%

Table 2: Special-purpose classifiers trained with standard tools for language identification: bs (Bosnian), hr (Croatian) and Serbian (sr).

As we can see, there is significant difference between the results of the three classifiers. langid.py performs much better than the other two, which is most probably due to the more sophisticated learning algorithm used in that approach (Lui and Baldwin, 2012). Namely, it uses information gain for the selection of features that discriminate best between languages. An additional remark should be made that this system focuses on domain robustness and not the problem of discriminating similar languages. On the other hand TextCat only uses the most frequent N-grams per language and Lingua::Identify uses prefixes, suffixes and frequent words and, apparently, none of these features can well discriminate similar languages such as the ones we

deal with. Although langid.py performs much better than the other two systems, the overall accuracy is still much below general language identification performances reported in the literature. This is especially true for the discrimination between Bosnian and Croatian. The accuracy of 0.695 for the recognition of Bosnian texts is just not acceptable.[9]

3 Discriminating Between Closely Related Languages

In this section, we will discuss two approaches to language discrimination: One is based on a document classification method and the other one focuses on the identification of indicator features in terms of blacklisted words. Both approaches are in their essence quite similar, but they show a different performance on various amounts of training data and on data which is not entirely parallel, but comparable.

3.1 Learning a Document Classifier

The idea of using document classification techniques for language identification relies on the prerequisite of possessing parallel data of closely related languages. Since parallel texts communicate identical content, the differences in the bitext of closely related languages are exactly the differences between these two languages. By learning to discriminate between these datasets we actually learn the difference between the languages. Using document classification techniques on non-parallel data would model content alongside language specificities and is expected to perform worse than the models built on parallel data.

We chose to use the multinomial Naive Bayes classifier (McCallum and Nigam, 1998) because of its general good performance and speed. Additionally, because its parameters are actually probabilities of words given the category, i.e. language, this makes the model easily readable for humans. We estimate the model parameters as probabilities of words given the class

$$\hat{P}(w_i|c_j) = \frac{c(w_i, c_j)}{c(w_i)}$$

where $c(w_i, c_j)$ is the count for word w_i in texts of class c_j and $c(w_i)$ is the count of word w in the whole corpus.

We predict the language by maximum a posteriori class c_{map}

$$c_{map} = \arg\max_c \sum_w \log \hat{P}(w_i|c_j)$$

by summing over logarithms of probabilities of words given the class for each word in the document to be classified. We use simple add-one smoothing to take care of unseen events. Since we consider all languages equiprobable, we omit the prior probability in the procedure.

[9] We decided to refer to the performance on individual languages in terms of accuracy when applying only that subset of the data to the classifier. Alternatively, one could look at precision and recall values for individual languages computed over the entire data set. In that case, our language-specific accuracy values correspond to recall. Using the example of langid.py, precision of Bosnian would then be 0.927 and for Croatian as low as 0.77.

3.2 Learning "Blacklisted Words"

The difference between related languages can often be explained by some distinctive words that occur quite frequently in one language but never in the other language (at least not with exactly the same spelling). The use of "forbidden words" in language identification has already been shown in Ljubešić et al. (2007) as discussed in the introduction. This observation leads to the idea of building a classifier entirely based on those distinctive features that clearly discriminate between two languages. One could say that these words are on a "blacklist" for the language in which they should not appear. Observing one of those words should give very strong evidence against the language they are blacklisted for. We consider this idea to be strictly binary between two well-defined classes. Blacklists should only provide evidence to distinguish one language from exactly one other one.

Blacklists could be built manually using linguistic intuitions by native speakers. However, it is also possible to derive such data sets from corpora simply by comparing word frequencies. As stated above, we are looking for words that are (rather) common in one language but forbidden in the other. The most simplistic approach would use raw frequencies to find relatively frequent words that do not appear in texts of the other language. A simple frequency threshold could be sufficient for this purpose.

$$w \in B_2 \;\; if \;\; c_1(w) > \theta \wedge c_2(w) = 0$$

where B_2 is the set of blacklisted words for language L_2, $c_1(w)$ and $c_2(w)$ are the frequency counts of word w in language L_1 and L_2, respectively, and θ is the threshold to filter out infrequent words. These blacklists could be used as strict filters (as in spam filtering) but this would lead to (possibly a lot) of documents that are blacklisted for both languages as some of the words may still be valid for a language in which they do not appear in the training data. Certainly, it is again important to focus on texts from similar domains in order to avoid spurious signals indicating domain differences instead of language differences.

One possibility to make the classifier more robust is to use counts of matching blacklist words to, for example, classify document D:

$$lang(D) = \begin{cases} L_2 & if \;\; \sum_{w \in D \wedge w \in B_1} 1 \; > \sum_{w \in D \wedge w \in B_2} 1 \\ L_1 & \text{otherwise} \end{cases}$$

However, in this approach each blacklisted word has the same impact on the final classification and the frequency threshold θ becomes very important when collecting the data sets. Furthermore, it may not be wise to restrict the blacklists to words that do not appear at all in the other language. Certain elements (quoted expressions, names, titles) may spoil the data and useful discriminators will be missed by this strict approach.

Hence, another idea is to use the difference of relative frequencies (as an MLE-based approximation of unigram probabilities) between words appearing in one or both languages. In order to measure the difference, we define the following ratio (N_1 and N_2 are the total word counts in language L_1 and L_2, respectively):

$$\delta(w, L_1, L_2) = \frac{c_1(w)/N_1 - c_2(w)/N_2}{c_1(w)/N_1 + c_2(w)/N_2} = \frac{c_1(w)N_2 - c_2(w)N_1}{c_1(w)N_2 + c_2(w)N_1}$$

Furthermore, we restrict the candidates to words that appear less than a certain frequency threshold α in one language and more than another frequency threshold β in the other language. Yet another threshold (γ) can be set to restrict the set to the most discriminating words by adding the constraint $|\delta(w, L_1, L_2)| > \gamma$. Negative scores indicate a feature supporting L_2 and positive scores support L_1.

Using this set of weighted features, we can now define an adjusted decision rule in the following way:

$$lang(D) = \begin{cases} L_2 & if \ \sum_{w \in D} \delta(w, L_1, L_2) < 0 \\ L_1 & \text{otherwise} \end{cases}$$

Using this definition, the Blacklist classifier becomes quite similar to a two-class Naive Bayes approach but with heavy feature selection using only the most promising discriminating tokens for classification. We could even introduce yet another threshold to define a margin that describes the grey area of uncertain decisions. In that case, we would end up with a classifier that uses the following decision rule:

$$lang(D) = \begin{cases} L_1 & if \ \sum_{w \in D} \delta(w, L_1, L_2) > \mu \\ L_2 & if \ \sum_{w \in D} \delta(w, L_1, L_2) < -\mu \end{cases}$$

However, we do not apply this method in the present paper as this introduces yet another free parameter that needs to be adjusted.

Another practical consideration is to avoid spurious tokens such as proper names or tokens containing non-alphabetic characters. Some texts may frequently mention certain names, numbers, dates or other named entities that do not appear in texts of the other language. In that case, they would easily end up in blacklists without being appropriate for language discrimination. On the other hand, certain punctuation differences may also work quite well for distinguishing between languages. However, in our experiments we simply dismiss all tokens containing non-alphabetic characters.

For the discrimination between more than two languages, we can use a simple cascaded setup of pairwise classifications. The disadvantage of this procedure is that the order of classification steps may influence the final result. However, we could not see any significant impact on our results in the experiments described below. We, therefore, did not try to optimize this procedure for better discrimination.

4 Experiments

Our experiments are based on the same data sets as we have used for our baseline approaches presented in section 1. In particular, we used the portion of the parallel SETimes corpus containing Bosnian, Croatian and Serbian with its 2.7 million words per language. The evaluation data contains 200 documents per language with about 78 thousand words of Bosnian, 70 thousand words of Croatian and 113 thousand words of Serbian. Hence, the average document length is rather short – between 350 and 500 tokens per document.

In order to compare our approaches to a strong baseline, we built a second-order Markov chain as described in (Ljubešić et al., 2007) that has been proven to be very efficient for the

	bs	hr	sr	accuracy
bs	173	17	10	0.865
hr	30	170	0	0.850
sr	1	0	199	0.995

Table 3: Applying a second-order Markov chain to our test data.

discrimination between related languages such as Slovene, Croatian and Serbian. The confusion matrix of classifying our test set using this method is shown in table 3.

The overall accuracy of this approach is 90.3%. As expected, it still has major problems with distinguishing Bosnian and Croatian.

Table 4 shows the results of our proposed classifiers when applied to the test data.

Naive Bayes: overall accuracy: 95.7%

	bs	hr	sr	accuracy
bs	181	11	8	0.905
hr	7	193	0	0.965
sr	0	0	200	1.000

Blacklist Classifier: overall accuracy: 97%

	bs	hr	sr	accuracy
bs	187	12	1	0.935
hr	5	195	0	0.975
sr	0	0	200	1.000

Table 4: The confusion matrices of applying our classifiers to the test data.

For the blacklist approach, we always apply Serbian-Croatian discrimination before discriminating between the preferred language from the first step and Bosnian. The blacklisted word extraction parameters are set to intuitively chosen values: $c_{low}(w) < \alpha = 4$, $c_{high}(w) > \beta = 9$ and $|\delta| > \gamma = 0.8$. We did not perform any optimization of these settings so far, which we, however, plan to do in future work.

We can see that the overall accuracy is much higher than for the general-purpose tools even when trained for this specific task. The difference is especially striking for the case of Bosnian which could be identified with over 90% accuracy in both cases. To test the statistical significance of the differences in performance of the classifiers we use the approximate randomization procedure (Hoeffding, 1952; Yeh, 2000) with 1000 repetitions. The obtained p-values are presented in Table 5.

classifier 1	classifier 2	difference in accuracy	p-value
Naive Bayes	TextCat	0.401	**0.001**
Naive Bayes	Lingua::Identify	0.468	**0.001**
Naive Bayes	langid.py	0.080	**0.001**
Naive Bayes	Markov chain	0.053	**0.001**
Blacklist	TextCat	0.415	**0.001**
Blacklist	Lingua::Identify	0.482	**0.001**
Blacklist	langid.py	0.093	**0.001**
Blacklist	Markov chain	0.067	**0.001**
Naive Bayes	Blacklist	0.013	0.188

Table 5: Comparison of the presented approaches in terms of overall accuracy.

The difference between the Naive Bayes and Blacklist classifiers has shown not to be statistically

significant on this size of the evaluation set ($p = 0.188$), but the difference is an interesting fact that should be looked into in future work. However, the difference between the Naive Bayes and Blacklist classifiers to the other classifiers is highly statistically significant ($p < 0.001$) while the difference between our baseline Markov chain and the langid.py classifier (0.027) is marginal ($p = 0.094$).

4.1 Size of Training Data

Despite their higher performance, a possible disadvantage of our token-based classifiers (compared to classifiers based on character sequences) is that they may have larger problems when trained on limited amount of data, non-parallel texts and non-comparable domains. Figure 1 plots the learning curves for our two methods when training with various amounts of parallel data.

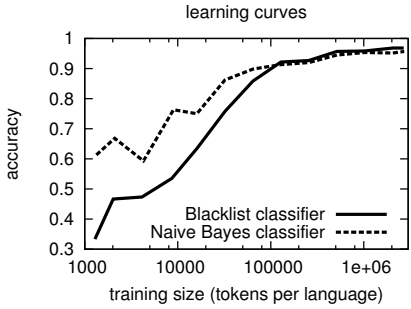

Figure 1: Learning curves of the proposed classifiers with various amounts of training data.

The figure shows that Naive Bayes is learning much quicker to distinguish between the three languages. This is not very surprising as the blacklist classifier only considers a fraction of the possible features included in the training data (see Table 6). However, after about 100,000 tokens per language, it surpasses the accuracy of the Naive Bayes classifier and performs consequently better thereafter.

It is also interesting to consider the learning curves for the individual languages. Looking a bit closer at the blacklist classifier (Figure 2), we can see that the main problem is the identification of Bosnian. It takes much more data to train a decent classifier for Bosnian than required for distinguishing the other two languages.

Interesting are also the drops in performance when recognizing Serbian in the beginning and when recognizing Croatian after about 10,000 tokens of training data. This development is due to our cascaded setup and the lack of evidence in the learned classification models. In the beginning, no (or only a few) blacklisted words are found and the classifier cannot discriminate between the three languages. Our method simply classifies every document as Serbian. After a few thousand tokens, the classifier learns to identify Croatian quickly but starts confusing it with Serbian and later with Bosnian. At about 10,000 tokens, the classifier improves significantly for Serbian again but seems to be more confused about Bosnian and Croatian before fixing most of

these problems with larger amounts of training data.

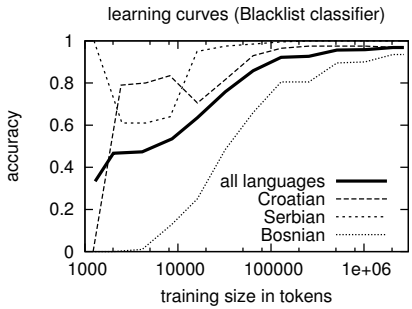

Figure 2: Learning curves for individual languages in the Blacklist classifier.

The learning curves above reveal one of the main weaknesses of the blacklist approach. It is not reliable with very little amounts of training data and the results will significantly depend on the setup of the binary decisions in that case. Table 6 lists the total number of tokens included in the blacklists when using default settings. For example, after about 32,000 tokens only a few hundred words are selected, which does not seem to be sufficient according to Figure 1. However, only a few thousand words selected at about 128,000 tokens of training material perform pretty well for all three languages. This is a very promising result. Furthermore, the amount of selected words for classification can certainly be adjusted by the extraction parameters α, β and γ. Initial experiments show that less restrictive parameters lead to better accuracies with small amounts of training data but lower overall performance when using the entire training set. This is also expected as the classifier becomes more similar to the Naive Bayes classifier and its parameters. We will leave a proper optimization of these model parameters to future work.

size in number of tokens		CPU time in seconds	
train data	blacklists	training	classification
1k	2	0.06	1.35
2k	5	0.08	1.38
4k	10	0.14	1.39
8k	32	0.27	1.40
16k	95	0.53	1.41
32k	361	1.01	1.40
64k	867	2.08	1.44
128k	1766	4.08	1.46
256k	3463	8.25	1.49
512k	6280	16.72	1.53
1M	10522	32.96	1.50
2M	16707	66.60	1.61
2.5M	19261	93.93	1.70

Table 6: Size of the learned blacklists and time spent for training and classification.

Table 6 also lists the time spent for training blacklist models with various amounts of training data and the time required for classifying our test set with those models. We can see that training is fast[10] even with our unoptimized code (based on a scripting language) and classification time is almost constant with some overhead because of the increasing size of the extracted models. The simplicity of the blacklist approach allows very efficient computation and produces compact models with high accuracy. This is certainly one of the major advantages of this approach compared to more sophisticated machine learning techniques.

4.2 Parallel versus Comparable Training Data

An additional question we like to consider in this paper is how robust our classifiers are with respect to non-parallel data. To simulate a loss in comparability we have split our trilingual dataset into three folds. In the first setting we train three models on parallel data while in the second setting we train models on the six permutations of non-parallel data so that for neither language there is any parallel data in the training set[11].

We evaluated each of the 3+6 models for both classifiers on our standard test set. The results are given in Table 7. With a loss of comparability of the training data we see an average decrease in performance of 1.6 points for the Naive Bayes classifier while there is no decrease in the case of the Blacklist classifier. The difference in the results of the two settings when using the Naive Bayes classifier is statistically significant according to the one-sided Student's t-test with unequal variance (p-value is 0.029). Furthermore, the difference between the results of the two classifiers on comparable corpora has become highly statistically significant (p-value below 0.001). Here we have identified a strong point of the Blacklist classifier – it is much more resistant to non-parallelity of the data when compared to the Naive Bayes classifier.

	Naive Bayes	Blacklist	p-value
parallel	0.953	0.963	0.233
comparable	0.937	0.963	**0.001**
p-value	**0.029**	0.875	

Table 7: Results for parallel and comparable training sets for both classifiers with the p-value from the Student's t-test.

The reason for such results can be sought in the fact that the Blacklist classifier does generalize more by selecting only the most informative features while this implementation of the Naive Bayes classifier does not perform any feature selection at all.

4.3 Sensitivity with Respect to Document Size

Finally, we would also like to investigate the influence of document size on classification performance. We expect that our word-based classifiers require larger amounts of input data for reliable classification. This is especially true for the blacklist approach that relies on strong discriminative features that might not be very frequent in all kinds of documents. Figure 3 illustrates the overall accuracy with varying document sizes. For this experiment, we selected all documents with more than 300 words from our initial test set (giving us 100 Bosnian

[10] Note that training speed is not as essential as classification speed as training is usually done once only.

[11] In the first setting we train on folds (0,0,0), (1,1,1) and (2,2,2) while in the second one we train on (0,1,2), (1,2,0) etc.

documents, 89 Croatian documents and 182 Serbian documents) and used the initial N words of each of them for classification.

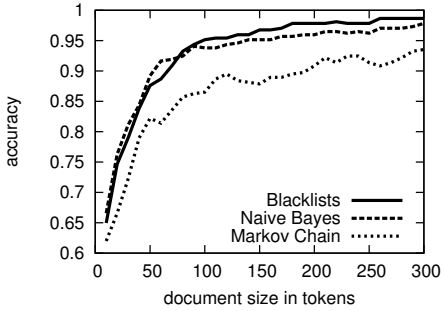

Figure 3: Classification performance with various text sizes.

As expected, we can see a significant decline of the accuracy with very short documents. However, already at about 70 words we have an overall performance of over 90%. Again, proper identification of Bosnian texts is the hardest task and about double as many words are needed to reach 90% accuracy for the Bosnian test set (not shown in Figure 3). In general, a modest document size of 150–200 words seems to be quite sufficient for our difficult task.

Another important result is that both classification approaches outperform our strongest baseline (the character-based Markov chain model) at all points. Furthermore, the blacklist approach is slightly worse on short documents, which was also to be expected.

4.4 Inspecting Language Discriminators

An interesting byproduct of both language identification approaches described above is that the parameters of their models are actually conditional probabilities and weights calculated on words and categories. This gives us the opportunity to inspect the strongest discriminators between these three languages and to classify them by the differences described in subsection 2.1.

In table 8 we list the twenty five highest conditional probabilities (and thereby strongest discriminators) of the final Naive Bayes classifier. In Bosnian there are only five conditional probabilities with a maximum value while in Croatian there are 34 of such words that do not appear in training corpora of other languages. In the Serbian model we have 21 maximum probabilities. This is in line with the previous claim from subsection 2.1 and table 1 that Croatian is the most specific language while Bosnian is a mixture of the other two.

The twenty five strongest Bosnian discriminators contain seven lexemes where Bosnian differs from Serbian regarding the ijekavian reflex like *obezbijediti* (*obezbediti* in Serbian) and *posjetioc* (*posetioc*). The latter form is written in Croatian with a different suffix morpheme – *posjetitelj*. Another difference to Serbian is the internationalism *historija* written *istorija* in Serbian while Croatian has its own word – *povijest*.

Table 8: Twenty five highest conditional probabilities of the Naive Bayes classifier for each language

Croatian's strongest discriminators contain ten month names (*listopad*, *veljača* etc.) since Croatian uses its own names and Bosnian and Serbian use the international forms. The word *priopćiti* shows a difference in derivational morphology compared to Bosnian where we have *saopćiti*. The list contains also many words of Croatian origin like *ravnatelj*, *gospodarstvo* and *tvrtka* where in Bosnian and Serbian internationalisms or terms from the Yugoslav era are used.

The Serbian list contains many ekavian variants like *sreda* (written *srijeda* in Bosnian and Croatian), *savet* (*savjet*) and *vest* (*vijest*). A frequent morphological difference to Croatian and Bosnian is present in the word *organizovan* that would be formed as *organiziran* in these two languages.

It is important to note that not all differences caught by these models are actual differences in language use or language norm, but are sometimes just the result of the language policy applied on the website the dataset comes from. A good example is the word *izvještaj* from the Bosnian list that obviously never appears in any other language although it is regularly used in Croatian language and Croatian dictionaries define it as standard as well.

Conclusion and Future Work

In this paper, we have shown that language discrimination between closely related languages deserves special attention. Standard tools based on character sequence features are not sufficient for distinguishing languages with a large lexical overlap. We propose two token-based approaches, one based on a Naive Bayes classifier and one based on weighted lists of blacklisted words. Both perform very well and significantly outperform state-of-the-art approaches to language identification. Another conclusion from our experiments is that a Naive Bayes model performs better for smaller amounts of data but highly depends on the comparability of the language data it is trained on. The blacklist approach is similar in essence but includes heavy feature selection. This leads to a larger generalization of the model and makes it perform better on less parallel data sets. The overall performance of the blacklist approach is also higher given the entire data set we train on and improves the best baseline created using public language identification tools by over 9% absolute accuracy. The implementations of the two approaches along with the datasets used in the paper can be retrieved from `http://www.nljubesic.net/resources/tools/bs-hr-sr-language-identifier/` and `http://bitbucket.org/tiedemann/blacklist-classifier`.

In this work we were using parallel data, but did not exploit all the benefits one can expect from such a dataset. We did not use sentence and word alignments, but just the corpora as a whole having in mind that the frequencies of identical language elements across languages will agree very well. Using alignments from parallel corpora is one direction for future work.

Another direction is the opposite one: using weakly comparable, but larger corpora to obtain the same or better results. We have shown that the blacklist approach is very robust on strongly comparable corpora, but additional experiments are necessary to examine how it copes with lower comparability of the training data. On the other hand, the Naive Bayes classifier could be made less prone to non-parallelity as well by applying different feature selection methods.

Furthermore, using very large web corpora such as the hrWaC corpus (Ljubešić and Erjavec, 2011) 1.2 billion words in size and the bsWaC and srWaC corpora (under construction) opens the door for catching most of the token and N-gram domain-independent variation between closely related languages that could yield extremely high results we are used to for more distinct languages.

Finally, we would also like to look at recently proposed character-based language models that have successfully been used for the discrimination between language varieties (Zampieri and Gebre, 2012). Their approach is similar to our Markov chain baseline but uses larger character N-grams that often cover entire words. One of the disadvantages of this approach is the increase of the number of model parameters, blowing up the model size and causing a slower classification speed. However, one could hope for higher generalization and resistance to non-parallelity of the training data.

Semi-Supervised Semantic Role Labeling: Approaching from an Unsupervised Perspective

Ivan Titov *Alexandre Klementiev*
Saarland University, Saarbrücken, Germany
{titov, aklement}@mmci.uni-saarland.de

ABSTRACT
Reducing the reliance of semantic role labeling (SRL) methods on human-annotated data has become an active area of research. However, the prior work has largely focused on either (1) looking into ways to improve supervised SRL systems by producing surrogate annotated data and reducing sparsity of lexical features or (2) considering completely unsupervised semantic role induction settings. In this work, we aim to link these two veins of research by studying how unsupervised techniques can be improved by exploiting small amounts of labeled data. We extend a state-of-the-art Bayesian model for unsupervised semantic role induction to better accommodate for annotated sentences. Our semi-supervised method outperforms a strong supervised baseline when only a small amount of labeled data is available.

KEYWORDS: semantic role labeling, semi-supervised learning, shallow semantics, Bayesian model.

COLING 2012, Mumbai, December 2012.

1 Introduction

Shallow representations of meaning, and semantic role labels in particular, have a long history in linguistics (Fillmore, 1968). More recently, with the emergence of large annotated resources such as PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998), automatic semantic role labeling (SRL) has attracted a lot of attention (Gildea and Jurafsky, 2002; Carreras and Màrquez, 2005; Surdeanu et al., 2008; Hajič et al., 2009).

SRL representations encode the underlying predicate-argument structure of sentences, or, more specifically, for every predicate in a sentence they identify a set of arguments and associate each argument with an underlying *semantic role*, such as an agent (an initiator or doer of the action) or a patient (an affected entity). SRL representations have many potential applications in NLP and have been shown to benefit question answering (Shen and Lapata, 2007; Kaisser and Webber, 2007), textual entailment (Sammons et al., 2009), machine translation (Wu and Fung, 2009; Liu and Gildea, 2010; Wu et al., 2011; Gao and Vogel, 2011), and dialogue systems (Basili et al., 2009; van der Plas et al., 2009), among others.

Most of the current statistical approaches to SRL are supervised, requiring large quantities of human annotated data to estimate model parameters. However, such resources are expensive to create and only available for a small number of languages and domains. Moreover, when moved to a new domain, performance of these models tends to degrade substantially (Pradhan et al., 2008). Scarcity of annotated data has motivated the research into techniques capable of exploiting unlabeled data, that is, semi-supervised and unsupervised learning.

The existing semi-supervised approaches to SRL can largely be regarded as extensions to supervised techniques, as they use supervised learning as sub-routines in the estimation process. These include self-training and co-training methods (He and Gildea, 2006b; Lee et al., 2007; Kaljahi and Samad, 2010), mono-lingual and cross-lingual annotation projection (Fürstenau and Lapata, 2009; Pado and Lapata, 2009; van der Plas et al., 2011), and methods which exploit or induce word representations to reduce the sparsity of lexicalized features (He and Gildea, 2006a; Deschacht and Moens, 2009; Collobert et al., 2011). Most of these approaches, especially the bootstrapping-style methods (He and Gildea, 2006b; Lee et al., 2007; Kaljahi and Samad, 2010; Fürstenau and Lapata, 2009), have achieved minimal or even no improvement from using unlabeled data. Consequently, the development of effective semi-supervised techniques remains an important and largely unresolved problem.

Another vein of research exploiting unlabeled data for shallow semantic parsing has focused on purely unsupervised set-ups (Swier and Stevenson, 2004; Grenager and Manning, 2006; Lang and Lapata, 2010, 2011a,b; Titov and Klementiev, 2012; Garg and Henderson, 2012; Fürstenau and Rambow, 2012). The unsupervised setting is important in itself, and the development of these methods arguably provides interesting insights into modeling implicit supervision signals present in unlabeled data. However, given that small amounts of labeled data are often easy to obtain, it is surprising that no previous work that we are aware of looked into integration of labeled data into unsupervised SRL systems.[1] Moreover, due to the inherent difference in the clustering metrics used for unsupervised SRL and the labeled accuracy scores used to evaluate supervised SRL methods, they have so far never been properly compared. These are the gaps addressed by this paper.

In this work, we show how a state-of-the-art unsupervised Bayesian model (BayesSRL) (Titov

[1] This semi-supervised learning setting is sometimes referred to as semi-*un*supervised (Daumé III, 2009).

and Klementiev, 2012) can be used in a semi-supervised set-up. BayesSRL is especially appropriate for our study as it automatically induces a common representation encoding properties of the syntax-semantics interface that are valid across predicates, contrasting much of other research on unsupervised SRL where separate models were induced for each predicate (Grenager and Manning, 2006; Lang and Lapata, 2010, 2011a,b; Garg and Henderson, 2012; Fürstenau and Rambow, 2012). These models would not be able exploit sparse labeled data effectively, as they would essentially split this scarce data into even smaller (and often empty) training sets.

A straightforward way of integrating labeled data into learning of a generative model would amount to maximizing joint probability of labeled and unlabeled data. However, due to hard constraints in the BayesSRL model and the great disbalance between the amount of labeled and unlabeled data, we argue that a different approach is preferred. Namely, we use labeled data to construct an informed prior over the potential semantic representations and also modify the model to integrate the labels as soft constraints on admissible semantic structures.

We compare the semi-supervised approach we propose to a state-of-the-art supervised method (Johansson and Nugues, 2008a). Though the BayesSRL model exploits a cross-predicate representation, it does not align roles across predicates which prevents us from using supervised evaluation metrics. Consequently, we evaluate the methods using clustering measures: the harmonic mean of purity and collocation, a common metric for unsupervised SRL evaluation (Lang and Lapata, 2010), and the information-theoretic V-Measure (Rosenberg and Hirschberg, 2007).

The semi-supervised method outperforms its supervised counterpart when the amount of labeled data is small. Unsurprisingly, it does not fare as well when the amount of data increases. We believe that this is primarily due to the overly coarse modeling of the syntax-semantics interface, as it is optimized for the unsupervised setting. Nevertheless, these results strongly suggest that approaching the semi-supervised learning setting for SRL from an unsupervised perspective is a promising research direction and that the existing unsupervised SRL methods are already mature enough to be useful for low resource languages with little or no labeled data available.

2 Background

In this section, we begin by formally defining the semantic role labeling task, and then discuss the distance-dependent Chinese Restaurant process (Blei and Frazier, 2011), used as a component in the BayesSRL model and crucial for effective learning in the semi-supervised setting. We conclude the section with a short description of the BayesSRL model.

2.1 Task Definition

The SRL task involves prediction of predicate argument structure, i.e. both identification of arguments as well as assignment of labels according to their underlying semantic role. For example, in the following sentences:

(a) [$_{A0}$ Mary] opened [$_{A1}$ the door].
(b) [$_{A1}$ The door] opened.
(c) [$_{A1}$ The door] was opened [$_{A0}$ by Mary].

Mary always takes an agent role (*A*0 in the PropBank notation (Palmer et al., 2005)) for the predicate *open*, and *door* is always a patient (*A*1).

In this work we focus on the labeling stage of semantic role labeling. Identification, though an important problem, can be tackled with heuristics (Lang and Lapata, 2011a; Grenager and Manning, 2006; de Marneffe et al., 2006), with unsupervised techniques (Abend et al., 2009) or potentially by using a supervised classifier trained on a small amount of data. In our experiments we use the heuristic identifier of Lang and Lapata (2011a). Also, as in much of the previous work on supervised and unsupervised SRL, we rely on automatically generated syntactic dependency trees.

In the labeling stage, semantic roles are represented by clusters of arguments, and labeling a particular argument corresponds to deciding on its role cluster. However, instead of dealing with argument occurrences directly, in BayesSRL they are represented as predicate-specific syntactic signatures, called *argument keys*. The following syntactic features are used to form the argument key representation:

- Active or passive verb voice (`ACT/PASS`).
- Argument position relative to predicate (`LEFT/RIGHT`).
- Syntactic relation to its governor.
- Preposition used for argument realization.

In the above example, the argument keys for candidate arguments *Mary* for sentences (a) and (c) would be `ACT:LEFT:SBJ` and `PASS:RIGHT:LGS->by`,[2] respectively. While aiming to increase the purity of argument key clusters, this particular representation will not always produce a good match: e.g. *door* in sentence (b) will have the same key as *Mary* in sentence (a). Consequently, this introduces an upper bound on the model performance: in our experimental set-up the upper bound on the purity of clustering was equal to 91.7%.

Increasing the expressiveness of the argument key representation by using features of the syntactic frame would enable us to distinguish that pair of arguments. However, we keep this representation, in part to compare with previous work and in part because we are primarily interested in set-ups with little annotated data where this upper bound would not be as limiting.

The clustering implicitly defines the set of permissible *alternations*, or changes in the syntactic realization of the argument structure of the verb. For example, passivization can be roughly represented with the clustering of the key `ACT:LEFT:SBJ` with `PASS:RIGHT:LGS->by` and `ACT:RIGHT:OBJ` with `PASS:LEFT:SBJ`.

In sum, BayesSRL treats the unsupervised semantic role labeling task as clustering of argument keys. Thus, argument occurrences in the corpus whose keys are clustered together are assigned to the same semantic role. The objective of this work is to study how argument key clusterings can be improved by using small amounts of annotated data.

2.2 Distance-dependent CRPs

The Chinese Restaurant Process (CRP), a standard component in non-parametric Bayesian modeling, defines a probability distributions over partitions of a set of objects. It encodes general rich-get-richer dynamics and, as such, is often useful in modeling long tail distributions. CRPs do not distinguish between individual objects and, consequently, prior probability that two objects would end up in the same subset is constant for any choice of objects. Distant-dependent

[2] `LGS` denotes a logical subject in a passive construction (Surdeanu et al., 2008).

CRPs (dd-CRPs) (Blei and Frazier, 2011) use a similarity function d_{ij} in generating partitions: they prefer to place pairs (i, j) with larger similarity d_{ij} in a single subset. More formally, each object i chooses itself a partner c_i with the probability

$$p(c_i = j|D, \alpha) \propto \begin{cases} d_{ij}, & i \neq j \\ \alpha, & i = j \end{cases} \quad (1)$$

where α is a non-negative concentration parameter. The resulting partition is defined by connected components in the directed graph encoded by the partnership relation c. Unlike normal CRP, dd-CRP lacks the exchangeability property and the probability of a given partition cannot be efficiently computed. Nevertheless, efficient inference is possible with MCMC techniques or approximate MAP search methods.

The prior is invariant under joint rescaling of the concentration parameter and the similarity scores, and the proportion of the concentration parameter to the distance parameters can be regarded as a parameter controlling granularity of clustering. We use a slight extension to the original dd-CRP by allowing the concentration parameter to be different for every example and, therefore, write it as $\alpha_i = d_{ii}$.

The similarities D can be fixed and used to encode prior knowledge about the problem (Blei and Frazier, 2011; Socher et al., 2011; Duan et al., 2007; Jensen and Shore, 2011) or can be induced automatically by sharing them across several instances of the clustering problem in a multi-task setting (Titov and Klementiev, 2012). In this work, as discussed in Section 3.2, we use the dd-CRP priors to fill both of these roles.

2.3 BayesSRL Model

In this section we describe the Bayesian model which we use as a basis for our semi-supervised learning approach. For more detailed and formal description of the model we refer the reader to Titov and Klementiev (2012). In this work we use the *coupled* version of the BayesSRL model, that is the model which induces cross-predicate representations.

In Section 2.1 we defined our task as clustering of argument keys, where each cluster corresponds to a semantic role. If an argument key k is assigned to a role r ($k \in r$), all of its occurrences are labeled r.

The Bayesian model encodes two common assumptions about semantic roles. First, it enforces the selectional restriction assumption: namely it stipulates that the distribution over potential argument fillers is sparse for every role, implying that 'peaky' distributions of arguments for each role r are preferred to flat distributions. Second, each role normally appears at most once per predicate occurrence. The inference algorithm will search for a clustering which meets the above requirements to the maximal extent.

As we argued in Section 2.1, clusterings of argument keys implicitly encode the pattern of alternations for a predicate. The set of permissible alternations is predicate-specific,[3] but still most of the alternation are shared across several or many predicates (e.g., passivization or dativization). Consequently, BayesSRL regards semantic role induction as a multi-task clustering problem and encodes the relative 'popularity' of alternations by quantifying how likely a pair of keys is to be clustered. These scores (d_{ij} for every pair of argument keys i and j) are induced automatically within the model, and treated as latent variables shared across predicates.

[3] Or, at least specific to a class of predicates (Levin, 1993).

Parameters:

$D \sim NonInform$ [similarity graph]
for each predicate $p = 1, 2, \ldots$:
  $B_p \sim dd\text{-}CRP(\alpha, D)$ [partition of arg keys]
  for each role $r \in B_p$:
    $\theta_{p,r} \sim DP(\beta, H^{(A)})$ [distrib of arg fillers] $\psi_{p,r} \sim Beta(\eta_0, \eta_1)$ [geom distr for dup roles]

Data generation:

for each predicate $p = 1, 2, \ldots$:
  for each occurrence s of p:
    for every role $r \in B_p$:
      if $[n \sim Unif(0, 1)] = 1$: [role appears at least once]
        GenArgument(p, r) [draw one arg]
        while $[n \sim \psi_{p,r}] = 1$: [continue generation]
          GenArgument(p, r) [draw more args]

GenArgument(p, r):
  $k_{p,r} \sim Unif(1, \ldots, |r|)$ [draw arg key]
  $x_{p,r} \sim \theta_{p,r}$ [draw arg filler]

Figure 1: The BayesSRL model.

The model associates two distributions with each predicate: one governs the selection of argument fillers for each semantic role, and the other models (and penalizes) duplicate occurrence of roles. Each predicate occurrence is generated independently given these distributions. Let us describe the model by first defining how the set of model parameters and an argument key clustering are drawn, and then explaining the generation of individual predicate and argument instances. The generative story is formally presented in Figure 1.

The generation starts by choosing a graph D with non-negative weights $d_{i,j}$ on edges from a non-informative prior, in other words, uniformly over the space of such graphs. Then for each predicate p, a partition of argument keys B_p is drawn from a distance-dependent Chinese Restaurant Process dd-CRP(α, D), with each subset $r \in B_p$ representing a single semantic role.

Next, the parameters are generated from the corresponding prior distributions. For details, we refer the reader to Titov and Klementiev (2012).

Now, when parameters and argument key clusterings are chosen, we can summarize the remainder of the generative story as follows. We begin by independently drawing occurrences for each predicate. For each predicate role we independently decide on the number of role occurrences. Then each of the arguments is generated (see **GenArgument**) by choosing an argument key $k_{p,r}$ uniformly from the set of argument keys assigned to the cluster r, and finally choosing its filler $x_{p,r}$, where the filler is the lemma of the syntactic head of the argument.

In sum, the properties of the BayesSRL model most relevant to the discussion of the semi-supervised extension are (1) induction of predicate-specific hard clustering of argument keys and (2) learning of a cross-predicate similarity measure D over pairs of argument keys.

GenArgument(p, r):
  $b \sim Bernoulli(\epsilon)$
  if $b = 1$:
    $k_{p,r} \sim H^{(K)}$ [noisy arg key]
  else
    $k_{p,r} \sim Unif(1, \ldots, |r|)$ [true arg key]
    $x_{p,r} \sim \theta_{p,r}$ [draw arg filler]

Figure 2: A modified model of argument generation.

3 Semi-Supervised Extension

In this section, we discuss two ways that the labeled data can be exploited in estimating the BayesSRL model. In practice, we found that their combination yields the best result.

3.1 Adding Labels

The integration of labeled data in a generative model is usually trivial and amounts to maximizing the joint likelihood of the observable data. In practice, it implies that the observable labels will be clamped in the estimation process. The straightforward application of this idea to our set-up is problematic. The BayesSRL method makes hard decisions about the clustering of argument keys, and, given the imperfect purity of argument keys and potential annotation errors, no single clustering would be entirely compatible with the labeled data, resulting in zero probability for any model state. Intuitively, one would want to relax this compatibility assumption by allowing for some inconsistency between induced clusterings and labeled data, while still favoring more compatible configurations.

A standard trick to achieve this behavior within the generative framework is to assume that with some small probability ϵ the true outcome is substituted with a random pick. The parameter ϵ would serve as a penalty for inconsistency, the smaller the probability ϵ, the more severe is the penalty. In our case, it translates into modifying the **GenArgument**(p, r) by introducing the possibility of drawing the random argument key from some base distribution $H^{(K)}$, instead of choosing it from the set of keys associated with r (See Figure 2). We use the normalized counts of argument keys in the corpus as the base distribution $H^{(K)}$.

Labeled data integrated in this relaxed BayesSRL model would affect the induced shared prior D and, consequently, the information present in the labeled data would be propagated across different predicates. Unfortunately, there are two problems with using this approach which negatively affect practical results.

The first deficiency is connected with the fact that in practice the amount of unlabeled data vastly exceeds the amount of labeled data nullifying the effect of the latter during estimation. A standard heuristic approach to mitigate this deficiency is to reweigh the data to put an extra emphasis on the labeled part. This technique is unlikely to be very effective here as the argument key clusterings are drawn from dd-CRP(α, D) once for each predicate, not once per predicate occurrence, and the proportion of predicates in labeled and unlabeled data would remain unaffected by instance reweighting.

Another problem is more subtle. As discussed in Titov and Klementiev (2012), their method induces the pairwise clustering preferences D but does not attempt to learn the concentration

parameters α_k and also enforces a form of normalization on the pairwise similarity, effectively 'freezing' the granularity of clusterings. This is fairly natural for an unsupervised setting where the model designer should have some form of control over the granularity but not as desirable in the semi-supervised setting where the granularity should be learned from the annotated data. In fact, as we will see in Section 4, labeled data mostly provides evidence for combining clusters (thus increasing collocation), and, consequently, the ability to learn granularity is crucial.

Thus, a compromise is necessary between (a) learning the granularity from labeled data and (b) limiting the influence of unlabeled data on cluster granularity. We implement this idea by using annotated examples to construct an informed prior.

3.2 Constructing Informed Priors

An alternative approach to directly incorporating the labeled data in the objective function would be to use the data to define an informed 'prior' over argument key clusterings. To this end, we estimate from the labeled data how likely argument keys k and k' are to belong to the same role and how likely a specific key k is to be left unclustered. We use the former to set the similarity $\hat{d}_{kk'}$, and the latter to set the concentration parameter α_k for the dd-CRP model. More precisely, we estimate both the predicate-specific similarities $\hat{d}^{(p)}$ and the cross-predicate similarities $\hat{d}$. When generating partitions B_p (see Figure 1), we multiply $\hat{d}^{(p)}$, $\hat{d}$, and the automatically induced prior d and use the resulting combined similarity in the dd-CRP process. The concentration parameters are combined in the same way as similarities. This techniques corresponds to the standard product-of-expert combination approach (Hinton, 2002). The remaining part of the section describes this idea more formally.

Initially we will consider individual predicates and then we will generalize the approach to cross-predicate similarities. Consider a predicate p, and assume that we have K different argument keys and R different roles,[4] and that each argument key k appears N_k times in the labeled data, and is annotated $N_{k,r}$ times with role r. In order to estimate the required probabilities we need to make assumptions about the joint generation of labels and argument keys.

We assume that there exists a fixed latent mapping g from argument keys to semantic roles and any such mapping is a-priori equiprobable, $P(g) = const$. However, when generating a label $g(k)$ for a key k, we assume that it can be replaced by any of the remaining $R-1$ roles with small probability γ. The probability of the set of labeled examples X_k associated with the key k given a mapping g can be written as

$$P(X_k|g(k)=r) = (1-\gamma)^{N_{k,r}} \left(\frac{\gamma}{R-1}\right)^{N_k - N_{k,r}}.$$

The joint probability of the sets of labeled examples X_k and $X_{k'}$ under the assumptions that either (1) the two keys belong to the same (any) role or (2) belong to two different roles can

[4] In our experiments we set R to 21, the number of distinct roles in PropBank, and K to the number of argument keys appearing both in labeled and unlabeled data for the considered predicate.

be computed by summing over the roles:[5]

$$
\begin{aligned}
&P(X_k, X_{k'} | g(k) = g(k')) \\
&\quad = \sum_r P(X_k | g(k) = r) P(X_{k'} | g(k') = r) \\
&P(X_k, X_{k'} | g(k) \neq g(k')) \\
&\quad = \sum_r P(X_k | g(k) = r) \sum_{r' \neq r} P(X_{k'} | g(k') = r')
\end{aligned}
$$

The posterior probability that two keys belong to the same role $P(g(k) = g(k')|X)$, where X is the entire labeled dataset, is given by renormalizing the two likelihoods above. As the distance $d^{(p)}_{kk'}$ in dd-CRP essentially encodes how much more likely the two keys are clustered together than by random chance, we compute the similarity as

$$
\hat{d}^{(p)}_{kk'} = \frac{P(g(k) = g(k')|X)}{P(g(k) = g(k'))}, \tag{2}
$$

where $P(g(k) = g(k'))$ is the prior probability that two keys are labeled with the same role, equal to $1/R$.

A very similar algebra is used to derive the probability that an argument key k is the only key assigned to some role $P(\nexists k', k \neq k' : g(k) = g(k')|X)$. The concentration parameter $\hat{\alpha}_k$ is set to

$$
\hat{\alpha}^{(p)}_k = \frac{P(\nexists k', k \neq k' : g(k) = g(k')|X)}{P(\nexists k', k \neq k' : g(k) = g(k'))}, \tag{3}
$$

where the denominator is the prior probability of not sharing the role with any other argument key, $(R-1)^{k-1}/R^{k-1}$. Note that if no labeled data is available for the considered predicate p, equations (2) and (3) would yield 1 and, as desired, the prior would not affect prediction of other experts in the product-of-expert combination.

The above approach induces predicate specific priors but this is insufficient for all but very frequent predicates. Consequently, we use a similar approach to define cross-predicate similarities $\hat{d}$ but with a larger γ', thus penalizing less severely for violations. For the cross-predicate similarities, the assumption is that (independently over pairs of keys) each pair of keys either shares a role in all the predicates or the two keys are labeled with a different role in all the predicates. This implies that the similarities can be computed by multiplying the results of computations (2) over all the predicates, while using the parameter γ' instead of the original γ. The same multiplication is done for the concentration parameter.

Note that in this approach we never attempted to encode cross-predicate correspondence between labeled semantic roles, the prior (and the model as whole) is invariant under any renaming of roles for individual predicates.

Admittedly, this method is not a proper estimation method for the BayesSRL model but rather the use of an extrinsic probabilistic model to set the similarity scores in the dd-CRP prior. This is in line with much of the work on using dd-CRPs where the similarities were used to encode prior or external knowledge (Blei and Frazier, 2011; Socher et al., 2011; Duan et al., 2007;

[5] Note that we use here the fact that the mappings are equiprobable.

Jensen and Shore, 2011) rather than estimated as in the multi-tasking set-up of Titov and Klementiev (2012).

To induce the model in the semi-supervised set-up, we use the same approximate MAP search algorithm, as originally proposed in Titov and Klementiev (2012) for the unsupervised setting.

4 Experiments

4.1 Data

Datasets. We evaluate our semi-supervised approach on the CoNLL 2009 distribution (Hajič et al., 2009) of the Penn Treebank WSJ corpus (Marcus et al., 1993). We split the CoNLL training set roughly in half: we draw annotated sentences from the first part (20,000 sentences), and evaluate on the remaining 19,279 sentences. All, but the drawn annotated sentences are used as unsupervised training data as standard for unsupervised SRL.

Syntactic annotation. We annotate the data with dependency structures predicted by the syntactic component of the LTH system (Johansson and Nugues, 2008b), a more realistic setup than making use of the gold syntactic annotation.

Predicate and argument identification. We select all non-auxiliary verbs as predicates.[6] We identify their arguments using a heuristic proposed in (Lang and Lapata, 2011a). Since our goal is to evaluate the argument labeling stage of semantic role labeling, we use this argument identification procedure for all of the systems in our experiments. The quality of argument identification on CoNLL 2009 using predicted syntactic analyses was F1 82.7% (P 83.3% / R 82.0%).

4.2 Evaluation Metrics

We cannot use supervised metrics to evaluate our models, since we do not have an alignment between gold labels and clusters induced in the unsupervised and semi-supervised set-up.[7] Instead, we use the following two standard sets of clustering metrics for our evaluation:

Purity, Collocation, and F1. We use the standard purity (PU) and collocation (CO) metrics as well as their harmonic mean (F1) to measure the quality of the resulting clusters. Purity measures the degree to which each cluster contains arguments sharing the same gold role and collocation evaluates the degree to which arguments with the same gold roles are assigned to a single cluster, see (Lang and Lapata, 2010).

Homogeneity, Completeness, and V-Measure. Additionally, we also evaluate with the information-theoretic V-Measure (V) (Rosenberg and Hirschberg, 2007). It is defined as the harmonic mean of homogeneity (H) and completeness (C) scores, which attempt to measure similar characteristics of the induced clustering as purity and collocation, respectively.

We compute the aggregate scores for all metrics over all predicates in the same way as Lang and Lapata (2011a) by weighting the scores of each predicate by the number of its argument occurrences. Since our goal is to evaluate the clustering algorithms, we *do not* include incorrectly identified arguments when computing these metrics.

[6] In this work we do not disambiguate predicate senses.

[7] Our BayesSRL extension does not propagate role labels between predicates which we would need to compute supervised metrics.

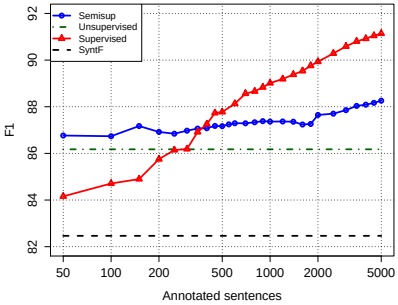

Figure 3: Performance (F1) of supervised (*Supervised*) and semi-supervised (*SemiSup*) systems vs. the number of annotated sentences, along with the original unsupervised model (*Unsupervised*) and the syntactic baseline (*SyntF*).

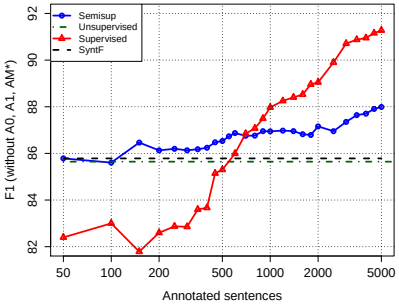

Figure 4: Performance (F1) evaluated on all roles except *A*0, *A*1, and *AM*∗ (modifier arguments) vs. the number of annotated sentences.

4.3 Model Parameters

The unsupervised model and the semi-supervised extension are robust to parameter settings. While they could be tuned by visual inspection of the induced argument roles, as in much of the previous work, we instead tuned them on the standard CoNLL held-out set primarily for replicability reasons.

4.4 Systems

In our experiments, we compare the performance of three systems: our semi-supervised extension (*SemiSup*) to the original state-of-the-art unsupervised model (*Unsupervised*) of Titov and Klementiev (2012), as well as the best CoNLL-08 shared task supervised SRL system (*Supervised*) of Johansson and Nugues (2008b). We also compare against the syntactic function baseline (*SyntF*), which is considered difficult to outperform in the unsupervised setting (Grenager and Manning, 2006; Lang and Lapata, 2010). It simply clusters predicate arguments according to the dependency relation to their head. As in previous work, we allocate a cluster for each of 20 most frequent relations in the CoNLL dataset and one cluster for all other relations.

4.5 Discussion

Figure 3 summarizes the results for the three systems and the syntactic baseline. The semi-supervised model outperforms the supervised counterpart when up to about 350 annotated sentences are available for training. It also continues to improve over the original unsupervised model as more annotated sentences are used for training. Table 1 details the single point of 300 labeled sentences on Figure 3 and breaks up the evaluation of the three systems and the syntactic baseline. It also shows the effect of the two ways of exploiting labeled data we

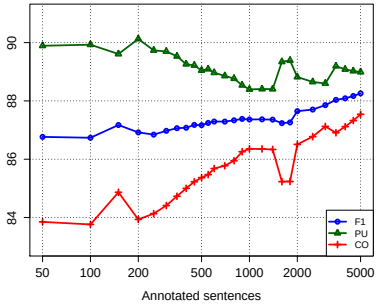

Figure 5: Purity, Collocation, and F1 of our semi-supervised extension (*SemiSup*) vs. the number of annotated sentences.

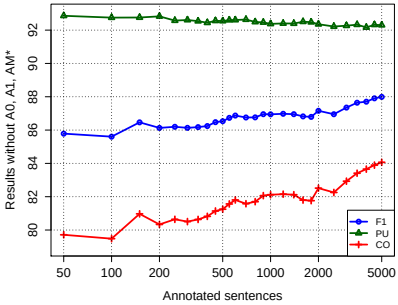

Figure 6: Purity, Collocation, and F1 of our semi-supervised extension (*SemiSup*) evaluated on all roles except *A*0, *A*1, and *AM*∗ vs. the number of annotated sentences.

	PU	CO	**F1**	H	C	**V**
Supervised	88.0	84.5	**86.2**	79.6	74.7	**77.0**
Unsupervised	89.6	83.0	**86.2**	83.8	73.3	**78.2**
SemiSup	89.7	84.4	**87.0**	83.6	74.9	**79.0**
SemiSup-l	89.5	84.2	**86.8**	83.3	74.6	**78.7**
SemiSup-p	90.0	82.5	**86.1**	84.4	72.8	**78.2**
SyntF	83.3	81.6	**82.5**	73.4	70.4	**71.9**

Table 1: Purity (PU), Collocation (CO), and F1, as well as Homogeneity (H), Completeness (C), and V-Measure (V) for for a single point (300 labeled sentences) on Figure 3. Results are for the syntactic baseline (*SyntF*), the supervised system (*Supervised*), the unsupervised model (*Unsupervised*), our semi-supervised extension (*SemiSup*), as well as our extension without adding labeled data to the generative story (*SemiSup-l*), and without the informed prior (*SemiSup-p*).

proposed in Section 3. *SemiSup-l* and *SemiSup-p* is our semi-supervised (*SemiSup*) method without adding labeled data to the generative story, and without informed priors, respectively. Note, that while adding labeled data alone does not improve over the performance of the unsupervised model for this number of labeled examples, the combination of the two methods yields a substantial improvement both in terms of F1 and V-Measure.

*A*0 and *A*1 arguments are annotated in PropBank based on the proto-role theory presented in (Dowty, 1991) and correspond to proto-agents and proto-patients, respectively, while arguments receiving an *AM*∗ label are supposed to be adjuncts, and the roles they express are consistent across all verbs. In order to evaluate the model performance on arguments which do not necessarily express consistent semantic roles across verbs, we next exclude *A*0, *A*1, and *AM*∗ from evaluation (Figure 4). The semi-supervised extension again substantially outperforms the supervised model when fewer than about 700 annotated examples are available.

Finally, Purity / Collocation breakdown for our semi-supervised extension (*SemiSup*) evaluated

an all roles and all roles except *A*0, *A*1, and *AM*∗ is shown on Figure 5 and Figure 6, respectively. Labeled data mostly provides evidence for combining clusters, so more labeled data implies collocation improvements albeit with some drop in purity.

Our semi-supervised method outperforms the state-of-the-art supervised model when the number of labeled sentences is relatively small, but falls behind when the amount of annotated data grows. This is likely due to the simplistic and overly coarse representation and modeling of the linking between syntax and semantics which places an upper bound on how well the original unsupervised model and the semi-supervised extension can do. However, our results strongly suggest that approaching semi-supervised SRL by exploiting labeled data in unsupervised methods is a promising research direction. Existing state-of-the-art methods can already be used for languages and domains for which little or no annotated data is available.

5 Additional Related Work

Additionally to the semi-supervised approaches to SRL discussed in the introduction, semi-supervised and weakly-supervised techniques have also been explored for other types of semantic representations but these studies have mostly focused on restricted domains (Kate and Mooney, 2007; Liang et al., 2009; Titov and Kozhevnikov, 2010; Goldwasser et al., 2011; Liang et al., 2011). Similarly, unsupervised induction for other shallow semantic formalisms include Poon and Domingos (2009, 2010) and Titov and Klementiev (2011).

A related problem of inducing script knowledge, or narrative event chains, has recently received a considerable attention (Chambers and Jurafsky, 2008; Manshadi et al., 2008; Chambers and Jurafsky, 2009; Regneri et al., 2010, 2011) with approaches mostly considering unsupervised or weakly-supervised setting due to scarcity of labeled data. Though in this paper we focus on the labeling of arguments the complementary task of unsupervised argument identification was considered in Abend et al. (2009).

Unsupervised learning has been one of the central paradigms for the closely-related area of relation extraction, where several techniques have been proposed to cluster semantically similar verbalizations of relations (Lin and Pantel, 2001; Banko et al., 2007). Similarly to SRL, semi-supervised approaches in this area are also typically based on bootstrapping techniques (e.g., (Agichtein and Gravano, 2000; Rosenfeld and Feldman, 2007)) and often achieve impressive results. However, their set-up is arguably different from ours as relation extractors are generally more precision-oriented, focus primarily on binary relations and can partially sidestep the complexity of language.

6 Conclusions

In this work, we demonstrated that unsupervised techniques can be improved by exploiting small amounts of labeled data yielding SRL parsers competitive with supervised approaches in a low resource setting. We also uncovered some of the deficiencies of the existing unsupervised approaches; namely, overly coarse modeling of syntax-semantics interface resulting in a lower asymptotic performance in semi-supervised settings. These results motivate further research into design of generative models appropriate for semi-supervised learning of shallow semantics.

ABSTRACT
Given the growing amount of resources developed in the NLP community, it is crucial to exploit as much as possible annotated data and tools across different research domains. Past works on discourse analysis have been conducted in parallel with research on semantic inference and, although the two fields of study are intertwined, there have been only few initiatives to put them into relation. Our work addresses the issue of interoperability by investigating the connection between implicit *Restatement* relations in the Penn Discourse Treebank (PDTB) and Textual Entailment. We compare the performance of two TE systems on the *Restatement* pairs and we argue that TE is a subclass of *Restatement* through a manual validation of the pairs. Furthermore, we observe that entailing pairs extracted from the PDTB add interesting and additional levels of complexity to TE, since inference relation relies less on lexical-syntactic variations, and more on reasoning.

TITLE AND ABSTRACT IN ITALIAN

A caccia di inferenze semantiche nel Penn Discourse Tree Bank

Data l'ingente quantità di risorse sviluppate in trattamento automatico del linguaggio, l'importanza di sfruttare anche in altri campi di ricerca i dati annotati e gli strumenti implementati è diventata fondamentale. In passato, lavori sull'analisi del discorso sono stati condotti parallelamente alla ricerca sulle inferenze semantiche, ma sebbene i due campi di studio presentino numerosi punti in comune, non ci sono state iniziative per avvicinarli. Questo lavoro affronta la questione dell'interoperabilità investigando le connessioni tra la relazione implicita di *Restatement* nel Penn Discourse Treebank (PDTB) e Textual Entailment (TE) (implicazione semantica). Comparando i risultati ottenuti da due sistemi che riconoscono automaticamente la relazione di implicazione, e dall'annotazione manuale di un sottoinsieme di coppie, mostriamo come il TE sia riconducibile ad una sottocategoria di *Restatement*. Inoltre, osserviamo che le coppie in relazione di implicazione estratte dal PDTB mostrano un livello di complessità superiore rispetto a quelle considerate dai sistemi attuali, in quanto la relazione di inferenza si basa meno su variazioni lessico-sintattiche, e più sul ragionamento.

1 Introduction

Given the growing amount of resources and automatic systems developed in the NLP community, it is crucial to guarantee the highest possible compatibility among them, and to exploit as much as possible annotated data and tools across different research domains.[1] Past works on discourse analysis have been conducted in parallel with research on semantic inference (in particular, on textual entailment phenomena, see Sammons et al. (2010), Bentivogli et al. (2010)) and, although the two fields of study seem to be intertwined, no effort has been made into the reuse of annotated data and processing tools across both domains.

With this work, we address the issue of interoperability by investigating the connection between implicit *Restatement* relations in the Penn Discourse Treebank (PDTB) (Prasad et al., 2008) and the Textual Entailment (TE) relation as defined by Dagan et al. (2009). Consider for instance the following sentences extracted from the PDTB and annotated as being in a *Restatement* relation:

(1) *Because hurricanes can change course rapidly, the company sends employees home and shuts down operations in stages.*
The company doesn't wait until the final hours to get ready for hurricanes.

(2) *He's not a reformer – he wants to have the image of a reformer.*
He doesn't want to have the image of the gun man.

Both in Example (1) and (2), a person reading the first sentence would infer that the following is most likely true, which is literally the definition of the textual entailment relation, i.e. a directional relation between a coherent textual fragment (T) and a language expression, which is considered as a hypothesis (H). Entailment holds, i.e. T $\Rightarrow$ H, if the meaning of H can be inferred from the meaning of T, as interpreted by a typical language user (Dagan et al., 2009). In the examples above, *'The company doesn't wait until the final hours[...]'* and *'He doesn't want to have the image of the gun man'* may be both inferred from the previous sentence by a typical language user, without the need of specific background knowledge.

Since in the PDTB more than 3,000 pairs have been labeled as having an implicit *Restatement* relation, it would be important to assess if they can be used also as training instances for TE systems, and if they represent categories of textual entailment pairs that up to now have not been part of the research agenda of the Recognizing Textual Entailment (RTE) evaluation campaigns[2] due to reasons of convenience for the task definition.

For such challenges, the creation of RTE data sets is a costly and time-consuming activity, requiring a lot of manual work for the creation of the T-H pairs and their annotation (about 1000 training and test instances have been usually provided by the organizers of RTE-1 to RTE-5 challenges). Furthermore, textual pairs extracted from the PDTB would represent real data in a discourse context as opposed to RTE pairs, where T is typically an excerpt extracted from a document (generally newspapers) and H is manually created. On the other hand, if *Restatement* and TE are proved to be equal, RTE technologies could be reused to identify and label this type of implicit relations, which are difficult to detect with existing discourse parsers.

[1] This issue has been recently debated during the Collaboratively Constructed Semantic Resources Workshop's panel at ACL2012, where the importance of the development of functional resources strongly connected with NLP systems was underlined, to allow for resources reusability in different tasks.

[2] `http://aclweb.org/aclwiki/index.php?title=Recognizing_Textual_Entailment`

While the importance of discourse information in TE has already been discussed in relation to anaphora and bridging phenomena (in particular starting from RTE-5, where the T was composed by longer paragraphs, requiring coreference resolution (Mirkin et al., 2010b) (Mirkin et al., 2010a)), little attention has been paid to discourse relations holding between sentences, although this is strictly connected to the problem of coreference (for further discussion on this topic, see Section 3).

In this work, we address the following research questions:

- What are the main differences between *Restatement* and TE relations, given that they are very similar from a theoretical point of view?
- Is it possible to use RTE systems to identify implicit *Restatement* relations, since current approaches have proved to have some limitations and achieve poor performance?
- From a TE perspective, is it possible to use entailing pairs extracted from the PDTB to train or evaluate TE systems?

We believe that addressing these issues is important both from a computational and a theoretical point of view: the findings of this study would be beneficial to system developers as well as to computational linguists interested in discourse and inference phenomena.

The paper is structured as follows: in Section 2 past work related to the identification of implicit relations in the Penn Discourse Treebank is presented and the task of Recognizing Textual Entailment is introduced. In Section 3 the PDTB is described, with a focus on implicit and *Restatement* relations. In Section 4 we present the experimental setting, introducing the TE systems we used, and then we detail both the first and the second experiment we carried out. Finally, we draw some conclusions and discuss future work in Section 5.

2 Related work

A number of approaches have been proposed for annotating *explicit* discourse relations following the PDTB paradigm. While the first attempts were limited to retrieving the heads (usually the main verb) of discourse arguments (Elwell and Baldridge, 2008; Wellner and Pustejovsky, 2007), or to extracting only the sentences containing the arguments (Prasad et al., 2010), more recent works have focused on the identification of the exact arguments spans and on the development of end-to-end discourse parsers (Lin et al., 2010; Ghosh et al., 2011b,a). These works rely on the information conveyed by explicit connectives, which proved quite easy to classify using syntactic information (Pitler et al., 2008; Pitler and Nenkova, 2009).

If the connective is not overtly expressed, however, the task is more challenging and requires different features compared to explicit relations. Experiments by Lin et al. (2009), Pitler et al. (2009) and Lin et al. (2010) showed that, despite the promising results and the progress with respect to their baselines, there is still room for improvement.

As introduced before (Section 1), the notion of textual entailment has been proposed as an applied framework to capture major semantic inference needs across applications in NLP (Dagan and Glickman, 2004), (Dagan et al., 2009). Given a pair of textual fragments, it considers if a competent speaker with basic knowledge of the world would typically infer the second from the first one. To promote the development of general TE recognition engines, designed to provide generic modules across applications, since 2005 the Recognizing Textual Entailment

evaluation campaigns[3] have asked participants to develop a system able to detect an inference relation between T-H pairs. In this applied framework, inferences are performed directly over lexical-syntactic representations of the texts. Current systems mainly rely on Machine Learning techniques (typically SVM), logical inference, cross-pair similarity measures between T and H, and word alignment. The definition of TE captures quite broadly the reasoning about language variability needed by different applications for natural language understanding and processing, e.g. information extraction (Romano et al., 2006), text summarization (Barzilay and McKeown, 2005), and reading comprehension systems (Nielsen et al., 2009). Following this rationale, the data sets provided by the challenge organizers are composed of T-H pairs collected from several applicative scenarios (e.g. Question Answering, Information Extraction, Information Retrieval, Summarization), reflecting the way by which the corresponding application could take advantage of automated entailment judgement.[4]

3 *Restatement* relations in the Penn Discourse Treebank

The Penn Discourse Treebank (PDTB) is a resource built on top of the Wall Street Journal (WSJ), in which discourse relations have been manually identified and classified. A *discourse relation* holds between two and only two text spans called *arguments*, that correspond to propositions, events and states.[5]

In the PDTB, relations can be explicitly signaled by a set of lexically defined connectives (e.g. "because", "however", "therefore", etc.). In these cases, the relation is overtly marked, which makes it relatively easy to detect using NLP techniques (Pitler et al., 2008). A relation between two discourse arguments, however, does not necessarily require an explicit connective, because it can be inferred also if a connective expression is missing. These cases are referred to as *implicit relations*, and in the PDTB they are annotated only between adjacent sentences within parahraphs. In case the connective is not overt, PDTB annotators were asked to insert a connective to express the inferred relation.

Examples (3) and (4) represent sentences connected, respectively, by an explicit and an implicit relation. The abstract objects involved in a discourse relation are called `Arg1` and `Arg2` according to syntactic criteria and are reported in italics and in bold respectively.[6]

(3) Explicit: *Use of dispersants was approved* when **a test on the third day showed some positive results.**

(4) Implicit: *The projects already under construction will increase Las Vegas's supply of hotel rooms by 11,795, or nearly 20%, to 75,500*. **By a rule of thumb of 1.5 new jobs for each new hotel room, Clark County will have nearly 18,000 new jobs**.

While in Example (3) the connective "when" explicitly signals a relation holding between `Arg1` and `Arg2`, in (4) no connective was originally expressed. A consequence relation is inferred

[3] `http://aclweb.org/aclwiki/index.php?title=Textual_Entailment_Resource_Pool`

[4] Trying to face more real scenarios, in recent editions of the challenge, i.e. RTE-6 and 7, more complexity was added to the traditional main task, asking TE systems to find all the sentences that entail a given H in a set of documents about a topic.

[5] In order to study entailment phenomena between arguments, we make the assumption that arguments correspond to full clauses or sentences. However, in some cases arguments are just textual fragments shorter than clauses.

[6] This notation convention will be applied to all examples reported in this paper, extracted from the PDTB.

between '*the increase in the number of rooms*' and '*the increase in the number of jobs*', though no *explicit* connective expresses this relation.

Each implicit and explicit relation is assigned a sense label based on a three-layered hierarchy of senses. The top-level, or *class level*, includes four major semantic classes, namely TEMPORAL, CONTINGENCY, COMPARISON and EXPANSION. For each class, a more fine-grained classification has been specified at *type* level. For instance, the relation in Example (1) belongs to the CONTINGENCY class and the *Cause* type. A further *subtype* level has been introduced to specify the semantic contribution of each discourse argument.

In this work, we focus on sentence pairs connected by an *implicit* relation and belonging to the EXPANSION class. In particular, we are interested in the relations in the EXPANSION class marked as *Restatement*, because the way in which such relation is defined shows high similarity with the textual entailment relation.

A *Restatement* relation is annotated between two arguments when the semantics of `Arg2` restates the semantics of `Arg1` and it is inferred that the situations described in `Arg1` and `Arg2` hold true at the same time. *Restatement* relations are further specified into three subtypes, namely "specification", "generalization" and "equivalence". The subtype label depends on the ways in which `Arg2` restates `Arg1`: ||Arg1|| $\rightarrow$ ||Arg2|| in the case of generalization, ||Arg1|| $\leftarrow$ ||Arg2|| in the case of specification, and ||Arg1|| $\leftrightarrow$ ||Arg2|| in the case of equivalence, with $\rightarrow$ indicating logical implication. If more than one subtype interpretation is possible, annotators were allowed to provide a *type* instead of a subtype label, therefore some relations are just classified as *Restatement*.

While intuitively the equivalence relation shares more commonalities with the definition of paraphrase since they both represent bidirectional relations, the specification and generalization types seem to fit well into the definition of textual entailment provided in Section 1 (where the relation of specification has to be considered as a reverse entailment, i.e. the second textual fragment entails the first one).

Let's consider three PDTB sentences annotated as *Restatement*, specifically as implicit specification (5), generalization (6) and equivalence (7):

(5) *She was the child of relative privilege*. **Her mother was a translator; her father was the eternal vice director**.

(6) *Chinese and foreign economists now predict prolonged stagflation: low growth and high inflation.* **The economy is crashing hard**.

(7) *It was like someone had turned a knife in me*. **I was dumbfounded**.

We can represent them in the format of TE pairs, setting as T the first textual fragment and as H the second one (reversing the order for the specification type, as explained before):

(5') T: **Her mother was a translator; her father was the eternal vice director**.
H: *She was the child of relative privilege*.

(6') T: *Chinese and foreign economists now predict prolonged stagflation: low growth and high inflation.*
H: **The economy is crashing hard**.

(7') T: *It was like someone had turned a knife in me*.
H: **I was dumbfounded**.

For all the three pairs, a human reading T would infer that H is most likely true (i.e. they are positive TE pairs).

Leaning on these observations, our intuition is that such pairs automatically extracted from the PDTB could therefore be used to train TE systems, integrating the data sets provided by the RTE challenges organizers (in Section 4 experiments are carried out to prove our intuition). Similarly to RTE pairs, also these sentences are extracted from newspapers. But, while the creation of new T-H pairs requires quite a lot of manual work (for the creation of the H and subsequent annotation), the PDTB is an already available resource. Moreover, in line with the direction of RTE challenges that are now moving toward more real scenarios providing entire documents as T (see RTE-5 to 7), PDTB sentences represent good examples of real data.

Partially guided by reasons of convenience for the task definition, some assumptions have been defined by the organizers of RTE challenges, as for instance the a priori truth of the texts, and the same meaning of entities mentioned in T and H. From a human perspective, the inference required are in general fairly superficial, since generally no long chains of reasoning are involved. Pairs extracted from the PDTB would therefore add interesting and additional levels of complexity to the task, since the relation of inference between T and H relies less on lexical-syntactic variations, and more on reasoning. For instance, Examples (8) and (9) (labeled as *Restatement.equivalence* in the PDTB) can still be considered as positive TE examples, even if they require a lot of background knowledge (e.g. knowledge of idioms and metaphors) for their resolution.

(8) T: **Yet for all his cynicism, he's at heart a closet idealist, a softy with a secret crush on truth, justice and the American Way**.
H: *He's the kind of guy who rescues trampled flags*.

(9) T: *It was like flying without a pilot in the front of the plane*.
H: **It was crazy**.

Even if such level of complexity is still not afforded by current TE systems, the study of these types of arguments could bring new light into textual inference, encouraging the exploration of cases that up to now have not been part of the research agenda.

In the next section we carry out an experimental study *i)* to evaluate the performances of current TE systems on the pairs extracted from the PDTB, and *ii)* to better understand if the theoretical similarity in the definitions of the *Restatement* and the TE relation is actually proved on real data.

4 Experimental setting

In this section, we first introduce the TE systems we used (Section 4.1), and then we present the two sets of experiments we carried out. The first was performed to verify if implicit *Restatement* relations can be detected using current TE systems (Section 4.2). The second was run on a subset of manually re-annotated sentences (Section 4.3), to further verify the relationship between entailment and *Restatement* relations on a controlled data set.

4.1 TE systems description

In order to analyze the correspondence between the *Restatement* and the textual entailment relation, we run different experiments using two off-the-shelf TE systems: VENSES (Delmonte et al., 2009) and EDITS (Kouylekov and Negri, 2010). We choose these two systems because: *i)* they are freely available, *ii)* they obtained similar performances at the last RTE campaigns, and *iii)* they rely on different NLP approaches: VENSES is a rule-based system incorporating and combining different levels of linguistic information, from lexical to semantic knowledge. EDITS, instead, is a supervised TE system implementing a distance-based framework, whose modular architecture combines distance and similarity algorithms.

4.1.1 The VENSES system

VENSES is a rule-based system for recognizing textual entailment based on a linguistic analyzer and an evaluation module.

The first relies on a number of submodules common in Information Extraction systems, i.e. a tokenizer, a multiword and NE recognition module, a PoS tagger based on finite state automata, an in-built syntactic and semantic parser and a pronominal binding module. It also marks and interprets negation, modals and progressive mood.

The evaluation system uses a cost model with rewards/penalties for T-H pairs, where textual entailment is interpreted in terms of semantic similarity: the closest the T-H pairs are in semantic terms, the more probable is their entailment. Rewards in terms of scores are assigned for each 'similar' semantic element.

The system release used in our experiments, which we downloaded at `http://project.cgm.unive.it/venses.html`, is available in two versions: one assigns higher similarity to sentence pairs according to 'shallow' criteria, while the other accounts for 'deep' semantics.

4.1.2 The EDITS system

The EDITS system (Edit Distance Textual Entailment Suite) is an open-source software package for recognizing TE[7] (Kouylekov and Negri, 2010) implementing a distance-based framework which assumes that the probability of an entailment relation between a given T-H pair is inversely proportional to the distance between T and H (i.e. the higher the distance, the lower is the probability of entailment). Within this framework, the system implements different approaches to distance computation, i.e. both edit distance algorithms (that calculate the T-H distance as the cost of insertions, deletions and substitutions that are necessary to transform T into H), and similarity algorithms (e.g. Word Overlap, cosine similarity). Each algorithm returns a normalized distance score between 0 and 1. At a training stage, distance scores calculated over annotated T-H pairs are used to estimate a threshold that best separates positive from negative examples. Such threshold is then used at a test stage to assign a judgment and a confidence score to each test pair.

4.2 Experiment 1: complete data set

Our first experiment is aimed at checking if implicit *Restatement* relations can be detected using existing textual entailment systems. Given that this relation type in the PDTB is defined in

[7] `http://edits.fbk.eu/`

a similar way to textual entailment, we expect TE systems to label sentence pairs having a *Restatement* relation as 'entailing', while sentence pairs connected through another relation type (*Comparison*, *Contingency* or *Temporal*) are likely to be classified as 'not entailing'.

4.2.1 Data set description

We extract all sentence pairs having an implicit *Restatement* relation in the PDTB and we include them in our data set as positive examples. Then, we extract the same number of pairs from the PDTB having an implicit *Comparison*, *Contingency* or *Temporal* relation (the proportion of the three classes reflects their proportion in the PDTB). These pairs are included in the data set as negative examples. The other pairs labeled as *Expansion* but not belonging to the *Restatement* subtype have not been considered in the experiment.

In order to create sentence pairs resembling Text-Hypothesis pairs from RTE challenges, it was necessary in some cases to change the order of the arguments in the positive examples:

- Sentence pairs connected through a *Generalization* label were kept in their original format. Since ||Arg1|| → ||Arg2||, then the sentence corresponding to `Arg1` was considered the Text and `Arg2` the Hypothesis.
- Sentence pairs connected through a *Specification* label were reversed, with `Arg2` being the Text and `Arg1` the Hypothesis. For instance, given the sentences reported in (10) and connected through an implicit *Specification* relation, we build the T-H pair reported in (11).

  (10) *This is an old story.* (`Arg1`). **We're talking about years ago before anyone heard of asbestos having any questionable properties.** (`Arg2`).

  (11) T: We're talking about years ago before anyone heard of asbestos having any questionable properties.
  H: This is an old story.

- In case of sentence pairs connected through an *Equivalence* relation, the longer sentence in the pair was considered as the Text and the shorter one the Hypothesis. This was done in order to resemble as much as possible the T-H pairs in RTE data sets, where the hypothesis is usually shorter than the text. According to the definition of equivalence as ||Arg1|| ⟷ ||Arg2||, however, the entailment relation should hold in both directions.
- For sentence pairs connected through a generic *Restatement* label, we applied the same rule as for the *Equivalence* cases.

Our data set was built to include as positive examples all implicit *Restatement* relations (of any subtype) extracted from the PDTB. In case a relation was annotated with multiple labels, we selected it only if the first option was *Restatement*, otherwise the sentence pair was not included in the data set, neither as positive nor as negative example. Then, the same number of negative examples was collected, having the same proportion of implicit COMPARISON, CONTINGENCY and TEMPORAL relations as in the PDTB. In the end, the data set comprises *6,244 sentence pairs*, equally divided into positive and negative examples.

Since EDITS needs a training set to learn the threshold that best separates positive from negative pairs, the data set was split into a training and a test set, each being 50% of the complete

data set with an equal distribution of the sense labels. VENSES does not require supervision, therefore only the test set was used with this system.

4.2.2 Results and discussion

We run VENSES (both deep and shallow versions) and EDITS on the test set. The training set was used by EDITS to learn the threshold, as explained in Section 4.1.2. We apply two basic configurations of EDITS, i.e. Word Overlap and Cosine similarity algorithms on lemmatized texts (stopwords removed).

We compute a simple baseline based on word overlap between the two arguments: we first calculate for each training pair a similarity score using the Text::Similarity::Overlaps library[8] (we use the F1 value, which is a weighted average between the percentage of overlapping words in the text and the percentage of overlapping words in the hypothesis). Then, we train a simple NaiveBayes classifier using only this value as feature (an SVM classifier was trained as well but achieved poorer performance). The model was further used to classify the pairs in the test set.

We report the results in Table 1.

	Baseline	**VENSES** (d.)	**VENSES** (s.)	**EDITS** (wo)	**EDITS** (cos.)
Positive Pairs	*67.53*	33.33	36.14	55.48	51.48
Negative Pairs	*32.07*	62.46	60.16	48.5	49.94
Overall	*49.88*	**47.89**	**48.15**	**49.33**	**50.06**

Table 1: Systems performances on test set (% correctly classified pairs)

VENSES shows a different performance on negative and positive examples both with the shallow and the deep settings. The system has a conservative approach towards entailment, in that it underestimates the positive examples and overestimates the negative ones. Therefore, its performance is better on non-entailing pairs. EDITS strategy, instead, seems to be better balanced. Nevertheless, the systems do not significantly outperform the baseline, which tends to label as 'entailing' also negative pairs.

Given that the performances we obtained on the PDTB data set are below the average system performances in standard RTE tasks (the accuracy of most of the systems ranges between 55% to 65% for the two-way judgement task), these results may depend on two reasons: *i)* either the entailment phenomena underlying the positive examples are more difficult to detect than those in RTE data sets, due to the fact that PDTB pairs are extracted from a real corpus, or *ii)* our hypothesis that the pairs in a *Restatement* relation express also entailment does not hold.

Manually analyzing a set of pairs from the data set for error analysis, we realized that both reasons we hypothesized are (partially) true. As introduced before, TE definition is based on (and assumes) common human understanding of language, as well as common background knowledge. However, the entailment relation is said to hold only if the statement in the text licenses the statement in the hypothesis, meaning that the content of T and common knowledge together should entail H, and not background knowledge alone. For instance, let's consider Example (12).

(12) T: The earlier generation of our crowd bankers had stressed above all probity, tradition,

[8] http://search.cpan.org/tpederse/Text-Similarity-0.08/lib/Text/Similarity/Overlaps.pm

continuity and reputation.
H: They were old-fashioned elegant gentlemen.

Even assuming that in H "They" co-refers with the "bankers" in T, according to the definition of TE this is not a positive example, since the amount of background knowledge to be assumed to judge this pair asides from information provided by T. Quite a lot of the pairs tagged as *Restatement* in the PDTB and present in our data set fall into that category, and cannot therefore be considered as positive textual entailment pairs. At the same time, what the literature assumes as background knowledge to be introduced in the inference process is not completely clear (see the debate among Dagan et al. (2006), Manning (2006) and Zaenen et al. (2005)), making the assignment of the entailment judgment to such pairs particularly difficult.

In order to understand and prove if the low performances obtained by the TE systems in our first experiment are due to the presence of *Restatement* sentences that are negative entailment pairs, we conduct a second experiment on a reduced data set.

4.3 Experiment 2: reduced data set

To verify the correctness of our initial hypothesis, i.e. that the sentences annotated as being into a *Restatement* relation express entailment, we run a second experiment focusing on a manually-annotated subset of pairs, as described in the following sections.

4.3.1 Data set description

To investigate to what extent the *Restatement* type is related to entailment, we manually annotated a subset of sentences randomly extracted from the positive examples of Experiment 1 as being *Entailing*, *Non Entailing* or *Entailing with Coreference*. The first two labels were assigned following the RTE annotation guidelines, while the third one was introduced because we observed that in many cases the content of T and H could be put into relation only assuming that coreference was resolved.

We assign a *Coreference* label and not an *Anaphoric* one because we do not limit this analysis to sentences in which some entities are identical, but we also cover pairs in which some information is implicit, and a coreference relation different from identity holds between the two (e.g. bridging). Since the pairs were extracted from adjacent sentences in real documents, this phenomenon is very frequent, because coreference is frequently used as a device to improve textual cohesion. Note that the antecedent is not always in T, as in the following example showing a *Restatement.generalization* relation, in which "She" in T may be resolved through "Marie-Louise (called Marie Latour in the film)" in H:

(13) T: She was untrained and, in one botched job killed a client. Her remorse was shallow and brief. Although she was kind and playful to her children, she was dreadful to her war-damaged husband; she openly brought her lover into their home.
H: Marie-Louise (called Marie Latour in the film) was not a nice person.

In some cases, one of the two sentences is a direct speech restating what was described in the other sentence. Also for these cases, we adopted the *Coreference* label. As a clarification, we report the sentence pair (14): the pronouns "He" and "me" in H should be resolved by "Mr. Sorrell" and "Mr. Roman" in T.

(14) T: But Mr. Roman flatly denied the speculation, saying Mr. Sorrell had tried several times to persuade him to stay, offering various incentives and in one instance sending a note with a case of wine.
H: He asked me not to resign.

We are aware that this kind of sentences would not be considered entailing in standard RTE data sets, but we decided to mark them as *Entailing with Coreference* because direct speech is very frequent in newswire documents, on which the PDTB is based, and we wanted to account also for these cases.

We annotated 160 sentence pairs for each of the four Restatement subtypes (*Restatement.specification*, *Restatement.generalization*, *Restatement.equivalence* and generic *Restatement*), thus collecting 640 annotated pairs. Two annotators were involved in the task. Each annotated independently 240 pairs, while 160 additional pairs were annotated by both, so as to compute inter-annotator agreement.

While the percentage of agreement between the two annotators is 84%, weighted kappa is 0.59. As a rule of thumb, this is a satisfactory agreement, although it reflects the fact that the great majority of assignments are "not entailing", making the probability of chance agreement very high. It is interesting to note that only in one case annotators disagree on whether an entailing relation is also coreferential, meaning that this distinction is well founded and linguistically motivated. In RTE tasks, agreement (Fleiss' Kappa) is usually around 0.98 after reconciliation. Although it is not directly comparable to our agreement (we apply weighted kappa and we do not perform reconciliation), this may reflect the fact that our hypotheses are not manually defined, thus their level of complexity is higher than in standard RTE tasks. As an example, we report in (15) a *Restatement.equivalence* relation on which the annotators disagree. The sentence in H is a sort of lesson that can be drawn from T:

(15) T: The problem is, if people get down in the dumps, they stop selling.
H: Discouragement feeds on itself.

In order to build the final data set, we removed the pairs on which the annotators disagreed (26 in total) and then merged the other annotations. The data set we obtain includes 614 pairs connected through some type of *Restatement* relation and annotated as *Entailing*, *Not Entailing* or *Entailing with Coreference*. Some statistics on the data are reported in Table 2.

Relation Type	**YES**	**YES-COREFERENCE**	**NO**
Specification	7	7	144
Generalization	26	7	123
Equivalence	39	11	93
Restatement	17	16	124
Overall	89	41	484

Table 2: Statistics on manually annotated data in the reduced data set

We observe that most of the pairs are not entailing, and this is generally due to: *i)* the presence of additional information in H not present in T (so the truth of H cannot be verified), as in Example (16), or to *ii)* the presence of not relevant information in H, as in Example 17.

(16) T: Each right entitles the shareholder to buy $100 face amount of 13.5% bonds due 1993 and warrants to buy 23.5 common shares at 30 cents a share.
H: Under the offer, shareholders will receive one right for each 105 common shares owned.

(17) T: It responds to it.
H: Arbitrage doesn't cause volatility.

These results provide a first answer to the research questions posed in Section 1: despite the definition of the *Restatement* relation in the PDTB, it does not exactly match with the textual entailment relation. Nevertheless, there is an overlap between the two: the annotation suggests that entailing pairs may be a subclass of *Restatement*. As regards the different *Restatement* types, *Specification* is the least related to entailment, with 91% of the pairs annotated as not entailing. This depends on the fact that T and H appear in the original documents in a reversed order, with H typically containing additional information which is not in T. Surprisingly, the relation type showing highest proportion of entailing pairs is *Equivalence* (35% of the examples), and not *Generalization* (21%). In fact, the latter includes many cases in which H is a sort of motto that cannot be inferred directly from T. *Equivalence*, instead, implies less abstraction and is often a reformulation of T at lexical level. Intuitively, pairs into an Equivalence relation are expected to be paraphrases (bidirectional entailment relation), but it is not always the case. For instance, Example (8) can be considered as a positive example of entailment (T⇒ H) once coreference is resolved (both T and H are talking about the same event), but the opposite does not hold, i.e. H does not entail T.

The pairs manually annotated as entailing (130 in total) were used to build a second data set. To balance this new data set with respect to positive and negative pairs in order to run our experiments, we randomly extracted 130 pairs from the negative examples of Experiment 1 (Section 4.2). In the end, we created a data set including 260 pairs, equally divided into positive and negative examples. Compared to the extended data set, all positive pairs in this reduced version have been manually checked, so that they are certain examples of Restatement *and* entailing relation.

4.3.2 Results and discussion

We re-run EDITS and VENSES on the reduced data set to see whether the systems perform better on correct manually annotated entailing pairs. We prepared two versions of the data set: one includes the pairs as they are, while in the other the entailing pairs marked as coreferring were manually resolved, e.g. pronouns were replaced by their extended form, bridging relations were made explicit, and so on.

Since EDITS requires supervision, we split the data set randomly selecting 160 pairs (balanced with respect to positive and negative pairs) to be used for training and 100 for testing. Again, VENSES was run only on the test set, in both the shallow and the deep configuration. We also computed a word-overlap baseline, as in Experiment 1. Results on both versions of the data set (*with* and *without* coreference resolution) are reported in Table 3.

We observe that when running our experiments on the new data set without coreference resolution, both VENSES and EDITS strongly outperform the baseline, while in Experiment 1 there was no significant difference between the three systems. With VENSES, the deep

	Baseline	**VENSES** (d.)	**VENSES** (s.)	**EDITS** (wo)	**EDITS** (cos)
Without coref. res.					
Positive Pairs	*38.00*	40.00	54.00	60.78	38.81
Negative Pairs	*66.00*	82.00	84.00	59.18	69.17
Overall	*52.00*	**61.00**	**69.00**	**60.00**	**59.00**
With coref. res.					
Positive Pairs	*36.00*	56.00	46.00	48.48	41.1
Negative Pairs	*80.00*	82.00	84.00	49.5	66.14
Overall	*58.00*	**69.00**	**65.00**	**49.00**	**57.00**

Table 3: Systems performances on test set (% correctly classified pairs)

version performs better after coreference resolution, but the shallow one achieves a better performance on the original data. Even if EDITS performances are better then the baseline on the original data set, they drop on the reduced data set (in particular, the configuration based on the word overlap algorithm). One of the reasons for that can be seen in the complexity of the pairs extracted from the PDTB, where lexical overlap between T and H is close to 0, and therefore word overlap algorithms fail to correctly detect the positive entailment pairs. VENSES performances show in fact that a linguistically-motivated system including some semantics in the process performs better on such pairs. Moreover, EDITS is negatively influenced by the small size of the data set, since only 160 pairs are used for system training, while for the RTE challenges about 1000 pairs are used for this goal. As short term future goal, we plan to re-run those experiments exploring more customized configurations of EDITS (combining different edit distance algorithms), and including entailment rules to provide it with semantics. In any case, all approaches (including the baseline) improve significantly compared to Experiment 1. On the manually annotated data set the systems performance is comparable to the performance achieved in RTE tasks.

The results of Experiments 1 and 2 allow us to provide some answers and observations concerning the second and the third research questions posed in Section 1. The second question was asking whether it is possible to use RTE systems to identify implicit *Restatement* relations. Current approaches have proved to have some limitations and achieve poor performance, obtaining on average 0.35 F1 on the detection of implicit *Restatement* relations (Lin et al., 2009). Experiment 2 shows that currently available RTE systems outperform such results, and could therefore represent an interesting direction to explore to accomplish the task of identifying implicit *Restatement* relations on a subset of PDTB sentences (i.e. sentences tagged as *Restatement*, where the first argument entails the second one).

The third research question was asking - from a TE perspective - whether it is possible to use entailing pairs extracted from the PDTB to train or evaluate TE systems. As showed in the error analysis following Experiment 1 (Section 4.3.1), less than 1/4 of the *Restatement* pairs are also entailment pairs. At the same time, this subset of *Restatement* and entailment pairs contain interesting and particularly complex pairs, since the relation of inference between T and H relies less on lexical-syntactic variations and more on background knowledge and reasoning. Moreover, such pairs contain entailment phenomena that up to now have not been part of the research proposed by the RTE evaluation campaigns organizers. For instance, in a set of sentences from the PDTB the second argument (i.e. the fragment we consider as H) is a motto, or a metaphor (see Examples (8) and (9)). The presence of such types of arguments,

that are easy to understand and solve for humans thanks to their knowledge of the world but almost impossible for machines, could bring new light into textual inference. Indeed, it would encourage the exploration of categories of entailment phenomena that up to now TE systems are not able to face, but that, due to their frequency in real data, cannot be disregarded.

5 Conclusion and future perspectives

In this paper, we provide an analysis of the relation between *Restatement* and textual entailment in the PDTB. Starting from their (similar) theoretical definition, we empirically verified if systems developed for textual entailment recognition can be successfully used to detect implicit *Restatement* relations. Although this first experiment proved that RTE systems are not effective in the task, a manual annotation of the experimental data set showed that part of the *Restatement* examples are also entailing, suggesting that the relation of textual entailment may be a subset of *Restatement* relation. Therefore, RTE techniques could be explored to solve the task on this subset of sentences. Data annotation allowed us to observe also that the *Specification* subtype is the least correlated to entailment cases and that coreference resolution is crucial in identifying entailing sentences in real texts, in line with past research on this topic (Mirkin et al., 2010a,b).

We further showed that the entailing pairs being in a *Restatement* relation represent interesting and particularly complex pairs, because they contain entailment phenomena that are not yet considered in the data provided for RTE evaluation campaigns. Taking into consideration also these cases extracted from real data would bring new light into research on textual inferences, in line with the most recent editions of RTE challenges that are now moving toward more real scenarios. In order to foster this new interesting research direction, the manually tagged pairs used for Experiment 2 will be made available at `http://hlt.fbk.eu/en/people/tonelli/Resources`.

Several research lines have to be considered as future research. As a first step, we plan to improve our experimental evaluation with different respects: *i)* augmenting the size of the reduced data set, in particular annotating more pairs of the PDTB to obtain more TE pairs for RTE systems training and evaluation; *ii)* customizing the EDITS system configuration to increase its performances; *iii)* experimenting with different available RTE systems to compare several approaches to RTE (e.g. logic-based, Machine Learning) on these particularly complex data and *iv)* including other pairs belonging to the EXPANSION class (but not labeled as *Restatement*) in our data set.

Moreover, we would like to verify if the relation between *Restatement* and textual entailment holds also in the other direction, i.e. if positive pairs in RTE data sets would actually be labeled as cases of *Restatement*, and if one of the *Restatement* subtypes can be more frequently associated with positive pairs. Nevertheless, such an annotation could be problematic because *Restatement* is usually defined in the discourse context and taking two sentences in isolation without the surrounding discourse is not likely to lead to meaningful annotations.

Acknowledgments

Abstract
The annotations of explicit and implicit discourse connectives in the Penn Discourse Treebank make it possible to investigate on a large scale how different types of discourse relations are expressed. Assuming an account of the Uniform Information Density hypothesis, we expect that discourse relations should be expressed explicitly with a discourse connector when they are unexpected, but may be implicit when the discourse relation can be anticipated. We investigate whether discourse relations which have been argued to be expected by the comprehender exhibit a higher ratio of implicit connectors. We find support for two hypotheses put forth in previous research which suggest that continuous and causal relations are presupposed by language users when processing consecutive sentences in a text. We then proceed to analyze the effect of Implicit Causality (IC) verbs (which have been argued to raise an expectation for an explanation) as a local cue for an upcoming causal relation.

Keywords: Causality, Continuity, Discourse relations, Discourse cues, Implicit discourse relations, Corpus study, Uniform Information Density.

1 Introduction

David Hume, in his prominent work "An enquiry concerning human understanding" proposed that ideas in the human mind were associated according to at least three types of relations: resemblance, contiguity in time or place, and causality (Hume, 1784). Since then, many language scientists have tried to adapt this idea about human general reasoning to the world of language (Simon, 1952; Hobbs, 1990; Kehler, 2000). A *discourse relation* as defined by linguists is an inference intended by the writer or made by a reader to establish local coherence among individual sentences. For example, a binary *causal* relation refers to a logical cause-consequence inference whose elements are directly accessible in the text: two propositional arguments plus an operator that could be an explicit connective such as "because" (1-a). The operator might sometimes not be explicit in the text, but in most cases a suitable connective could be inserted to specify the coherence relation between the involved propositions (1-b).

(1) a. Bill took his daughter to the hospital, because she looked pale and sick in the morning.
    b. I was very tired last night. [Therefore] I went to sleep earlier than usual.

According to some cognitive theories on discourse processing, people have expectations about inter-sentential relations when reading a text, which bias their inferential decisions during comprehension (Segal et al., 1991; Murray, 1997; Levinson, 2000; Sanders, 2005). Two important characteristics that are expected to exist between consecutive events in a text are continuity and causality. Segal et al. (1991) and Murray (1997) argue that readers expect a sentence to be causally congruent and continuous with respect to its preceding context. Continuity in the sense of Segal et al. means that the same frame of reference is maintained, for example by subsequent sentences talking about the same event, without shift in perspective. Continuous discourse relations are claimed to be easier to process and more expected than other types. On the other hand, relations that are discontinuous (for example adversatives) would be less expected and more difficult to process. This notion also includes temporal continuity, implying that a non-linearity in presenting a consequence before its effect or any two situations in a reverse temporal order (1-a) is less expected than a relation keeping the forward temporal transition between events (1-b). A second hypothesis about what kind of discourse relations are typically assumed by comprehenders was proposed by Sanders (2005) in his "causality-by-default" hypothesis, which states that language users prefer causal relations to other types (such as mere expansion or temporal relations) when establishing discourse coherence.

To investigate the validity of these hypotheses in the experimental paradigm, researchers have studied participants' sentence completion preferences, coherence judgments, and reading patterns during reading of the sentence pairs implying different types of discourse relations (Irwin, 1980; Trabasso et al., 1984; Caron et al., 1988; Millis et al., 1995; Murray, 1997; Kuperberg et al., 2011). We are, however, not aware of a large-scale study of these hypotheses in naturally occurring texts. To address this, we analyzed the use of causal/temporal relations and their markers in the Penn Discourse Tree Bank (PDTB; Prasad et al., 2008), a large corpus of newspaper texts which is annotated with discourse relations.

Our methodology relies strongly on the assumption of *implicitness of the discourse connector as a sign of expectation of the discourse relation*: if readers have a default preference to infer a specific relation in the text, this type of relation should tend to appear without explicit markers. The assumption is drawn on a usage-based approach to the study of language preferences that links comprehension phenomena with typicalities in production (Langacker, 2000). It also can be thought of in terms of the Uniform Information Density (UID) hypothesis (Frank and Jaeger, 2008) which suggests that humans tend to spread information evenly across a text or utterance, thereby reducing or omitting redundant optional markers (e.g., Levy and Jaeger, 2007; Florian Jaeger, 2010). At the level of inter-sentential relations, this would mean that the presence of explicit connectives is necessary when the relation is unexpected, but that a connective may be implicit if the relation is predictable. Hence, we investigate the validity of the following predictions in the corpus:

1. continuous discourse relations should be implicit more often than discontinuous ones
2. causal relationships should be implicit more often than other discourse relationships
3. relations which keep the forward temporality should be implicit more often than their backward counterparts.

These predictions refer to general tendencies of comprehenders to expect that phrases and sentences are linked causally, and that the sentences in e.g. a narrative are interpreted in a continuous manner. Beside these general expectations regarding the upcoming discourse relation, expectations can also be influenced by local factors: (Pitler et al., 2008) found that discourse relations in the PDTB are not independently distributed. For example, explicit comparisons are significantly more often followed by implicit contingencies than would be expected under the independence assumption. Furthermore, Sanders (1997) and (Sagi, 2006) showed that the genre of a text, or more specifically, the distribution of different types of relations in a particular text can shape the expectation of a reader about what relations will appear more frequently later in the text.

The discourse relation between two sentences can also become clear by other means such as shared entities, adverbial phrases and even the type of verbs used in the arguments. An interesting case are so-called implicit causality (IC) verbs (as the verb "scolded" in (2-a); see Section 5.6 for more details), which have recently been argued to trigger the expectation for a reason (see (2-b)) to be communicated in the following sentence (Rohde and Horton, 2010), such that the discourse relation between the sentences is a backward causal relation.

(2) a. Arthur scolded Patricia.
    b. She had put thumbtacks on the teacher's chair.

According to the UID hypothesis, we would expect that causal relations which contain an IC verb in their first argument (Arg1) would be expressed without an explicit connective more often, as the reason relation is predictable. In other words, as our third hypothesis, we investigate whether:

4. backward causal relations that contain an IC verb (which already marks causality) in their first argument are implicit more often than those that contain a non-IC verb.

This work strives to get a better understanding of when discourse relations are expressed implicitly, and when they should be explicitly stated. Furthermore, it can possibly inform work on automatic identification of discourse relations, especially in the absence of explicit discourse markers (Sporleder, 2008; Lin et al., 2009; Zhou et al., 2010). The rest of the paper is structured as follows. Section 2 includes a review of the causality-by-default and the continuity hypotheses and the related experimental studies. In Section 3, we introduce the PDTB corpus and the relevant relations we extract to obtain evidence for the aforementioned hypotheses. Section 4 will describe our method of analysing implicitness and Section 5 includes the results. Finally, conclusions are presented in Section 6.

2 Background on the Continuity and Causality Hypotheses

In this section we explain the *continuity* hypothesis (Segal et al., 1991; Murray, 1997) and the *causality-by-default* hypothesis (Sanders, 2005). Taken together, these hypotheses suggest that language users first try to establish causal relatedness and temporal linearity between phrases when processing a text.

2.1 The Continuity Hypothesis

Levinson (2000) notes in his discussion on presumptive meanings that *"when events are conjoined they tend to be read as temporally successive and if at all plausible, as causally linked."*. An early notion of the continuity hypothesis proposed by Segal et al. (1991) suggests that discourse connectives are used to mark the deictic continuity or discontinuity in texts (their study was limited to narratives). As Murray (1997) states, the hypothesis is that comprehension difficulty ensues when a text event is discontinuous without this discontinuity having been explicitly marked. Segal et al. (1991) found that comprehenders expect subsequent sentences to be causally congruent and temporally continuous. Support for the continuity hypothesis comes also from a series of experiments by Murray (1997). In an initial sentence completion experiment, subjects had to write a continuation to the preceding discourse starting with a connective that was either additive, causal, or adversative. Murray confirmed that sentences generated in response to an additive or causal connective generally depicted continuous events with respect to the preceding discourse, while completions following adversative connectives depicted discontinuous events. In a subsequent experiment, he asked people to read sentence pairs with inappropriately placed connectives, and found that the disruptive effect was largest for inappropriately placed adversative connectives. Sentences with inappropriately placed adversative connectives were also judged as less coherent than ones with inappropriately placed causal or additive connectives. In particular, there was no difference in processing disruption or coherency judgment between inappropriately used additive and causal connectives, which is why Murray attributes the difference between these connectors and adversative ones to the underlying continuity or discontinuity of the described event. Murray interprets his findings in terms of readers generally expecting a continuous event and their processing being more disrupted by a connective that signals an upcoming discontinuity, than by one that would signal continuity. Taken together with an earlier experiment (Murray, 1995), which showed that correctly placed adversative connectors also have a greater beneficiary effect than correctly placed causal or additive connectors, Murray concludes that adversative connectives are more *salient* than connectives that signal continuity.

While he generally classifies causal relations as continuous ones, Murray also notes that a

connective like "because" which signals a temporally non-linear causal relation (*backward* transition from the effect to the cause) should have stronger contextual effects than connectives such as "so" or "therefore". In the literature, some types of adversative relations are interpreted as *negative causal* relations, e.g., a pair of sentences connected with *although* implies a causal relation in which an unexpected consequence has happened (König, 1991). According to Segal et al. (1991) and Murray (1997), such relations — usually referred to as *concession* — are not expected to the same degree as positive causal relations, which benefit from a higher degree of continuity. The continuity hypothesis also predicts that temporal relations between sentences which cue a non-linear relationship between the arguments would be more difficult to process, and that cues for temporal non-linearity (such as "after", as opposed to "before", which indicates the expected temporal order) should be more salient.

2.2 The Causality-by-default Hypothesis

The main motivation behind our study of causal relations comes from Sanders's cognitive theory of discourse representation. Specifically, the causality-by-default hypothesis states:

"because experienced readers aim at building the most informative representation, they start out assuming the relation between two consecutive sentences is a causal relation" – Sanders (2005) .

Experimental evidence for this claim comes from a range of studies on understanding causal relations in narratives (Trabasso et al., 1984), the effect of connectives on recall of inter-sentential relations (Irwin, 1980; Caron et al., 1988) and preferences in sentence completion tasks (Murray, 1997). A recent study of online sentence processing furthermore reveals that causal relations between sentences facilitate processing even in the absence of discourse connectors: Kuperberg et al. (2011) finds that a small discourse consisting of three sentences was easier to process when the sentences were causally related. Specifically, a larger N400 (an EEG signal which typically indicates semantic anomalies) was found when sentences were irrelevant. All of these findings suggest that readers have a prior expectation that consecutive sentences in a text should be causally related and congruent, unless an explicit cue such as adversative connectives (e.g., *but*) provides marking for another type of relation. The most relevant experiment specific to the tendency towards causal inference is again the one by Murray (1997) in which subjects were asked to continue individual sentences that ended with either a period or a connective of the aforementioned types (additive, causal or adversative). The majority of the answers for the no-connective condition conveyed a causal relation, meaning that subjects often chose a type of continuation that provided a cause or a consequence for the given sentence instead of a simple additive continuation or an adversative one.

However, arguments against the causality-by-default hypothesis can also be found in the literature. Millis et al. (1995) performed an experiment where two consecutive sentences (that did not stand in an obviously causal relationship) were connected with a full stop, or one of the three discourse connectors "because", "and" or "after", as the indicators of causal, additive and temporal relations, respectively. The sentence pairs inherently could be interpreted as expressing any of the mentioned relation types. Millis at al. found that causal inferences (as measured by asking participants a "Why?" question after pair of sentences) were only reliably made in the "because" condition, but not in the conditions where the sentences were connected by a period or one of the other connectors. They concluded that

the discourse marker "because" played a very important role in people's forming of an inference, and that this inference was not formed automatically in these contexts.

The studies we reviewed are all small scale and use carefully designed experimental materials; it is, however, an open question whether the hypotheses generated based on the experimental studies also hold for naturally occurring texts. An additional difficulty is that results from previous studies are often not easily comparable, as they use a slightly different taxonomy of discourse relation types (e.g., *adversative* relations in Murray (1997) includes both negative causal and negative additive relations, while in other related studies such as König (1991),Couper-Kuhlen and Kortmann (2000), and Köhne and Demberg (2011) the former is referred to as a *concession* relation). In this paper, we use the discourse relation categorization of the Penn Discourse Treebank and see how different sentence connectives are being used in naturally occurring text with respect to the extent they reflect causality and continuity.

3 An Overview of the PDTB Corpus

Penn Discourse Tree Bank (PDTB; Prasad et al., 2008) is a large corpus of texts from the Wall Street Journal, which is annotated with discourse relations between every pair of adjacent clauses, sentences or larger text spans[1]. The PDTB covers all 25 sections of the Penn Treebank, which has been annotated with various other linguistic information such as syntactic structures and semantic frames.

Discourse relations can either be marked explicitly with a discourse connector (such as "because", "nevertheless", "and"), or be implicit[2]. Both explicit and implicit discourse relations are annotated in the corpus, and each discourse relation is marked with a discourse connector and two propositional arguments. In the case of implicit relations, a suitable discourse connector was identified (and inserted) by the annotators. Each argument is an independent text segment whose boundaries are also determined by the annotators. Labeling of the relations has been done according to a hierarchy of discourse relation senses (see Figure 1), including four top-level classes: `CONTINGENCY`, `COMPARISON`, `TEMPORAL` and `EXPANSION`.

Temporal Relations `TEMPORAL` relations include `Synchronous` and `Asynchronous` types. `Asynchronous` relations have two subtypes `precedence` and `succession`, which mark forward (3-a) and backward (3-b) temporal transitions respectively.

(3) a. He believes [that $55 a share is the most you can pay for Georgia Gulf], before [it becomes a bad acquisition].
b. [The fields were developed], after [the Australian government decided in 1987 to make the first 30 million barrels from new fields free of excise tax].

We classify `Asynchronous` temporal relations as markers of *discontinuity*, following (Segal et al., 1991). Among the `Asynchronous` temporal relations, the ones where events are in the correct temporal order should be easier to process than the ones where temporal order is

[1]For details on the choice of text spans and adjacency we refer the reader to Prasad et al. (2008).

[2]Other than explicit and implicit relations, the corpus contains two other categories of relations, namely EntRel, indicating the relation between sentences only according to the common entities, as well as AltLex, in which the relation between the two arguments is not lexicalized via the defined set of connectives. We do not include AltLex category in our analysis as it only contains one percent of all the tagged relations.

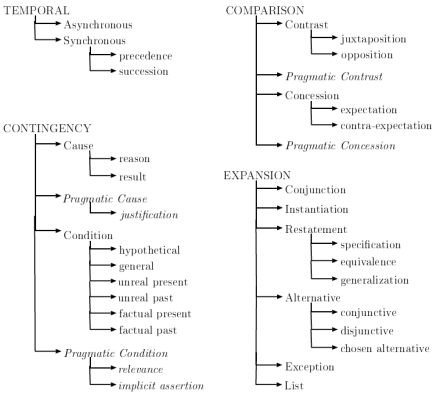

Figure 1: Hierarchy of senses in PDTB (Prasad et al., 2008)

reversed. `Synchronous` temporal relations are harder to classify: they sometimes introduce new events and should thus be classified as discontinuous.

Contingency Relations Causal relations in the PDTB hierarchy are categorized as members of the `CONTINGENCY` family. `Cause` itself is divided into two subtypes, namely `reason` and `result`. These two subtypes, respectively, indicate forward and backward cause-consequence relations between their arguments as shown in (4-b) (`reason`) and (4-a) (`result`).

(4) a. [The governor couldn't come]$_{cause}$, so [the lieutenant governor welcomed the special guests]$_{consequence}$.
b. [There was some profit-taking]$_{consequence}$, because [prices for all precious metals had risen to levels at which there was resistance to further advance]$_{cause}$, he said.
c. [Mrs Yeargin is lying], because [they found students in an advanced class a year earlier who said she gave them similar help].

In addition to the `Cause` type in the `CONTINGENCY` class, there is a type called `Pragmatic Cause` which is much less frequent but still relevant to our study. It includes only one subtype, namely `justification`, indicating an epistemic causal relation in which the second argument provides a justification for a claim expressed in the first argument, see (4-c). In the literature, this has also been referred to as *diagnostic* relation (Traxler et al., 1997). In PDTB hierarchy conditional discourse relations are also categorized as `CONTINGENCY` relations, see Figure 1. They typically include "if" sentences but are not in the domain of our study, as we cannot classify them as either continuous / discontinuous or causal.

Comparisons All types of `COMPARISON` relations can be classified as discontinuous. As mentioned at the end of Section 2.1, König (1991) proposed that concessive relations are the dual of causal discourse relations in the sense that they involve a negative cause-consequence inference. In the PDTB, `Concession` relations are divided into two subtypes: `expectation` and `contra-expectation`, which represent as the duals of `reason` and `result`

respectively. In `expectation` relations (5-b) the second argument of the connective is a cause for something that is in contrast with the first argument, and in `contra-expectation` (5-a) the first argument of the connective is a cause for something in contrast to what the second argument asserts.

(5) a. [The demonstrators have been non-violent]$_{cause}$, but [the result of their trespasses has been to seriously impair the rights of others unconnected with their dispute]$_{neg-consequence}$.
b. [Third, oil prices haven't declined]$_{neg-consequence}$, although [supply has been increasing]$_{cause}$.

Other relation types of the comparison class, namely `contrast` and `pragmatic contrast` cover some of the adversative relations that have been compared with causal relations in studies such as Murray (1997).

Expansions Among the `EXPANSION` relations we classify as continuous the types `Instantiation`, `Restatement` and `List`. `Alternative` and `Exception` senses are obviously types of discontinuity. The remaining type, namely `Conjunction` relations are used in cases where "Arg2 provides additional, discourse new, information that is not related to Arg1 in any of the ways described for other types of `EXPANSION`." (The PDTB Research Group, 2008, p. 37). It is difficult to make one classification for the whole class - during manual inspection we found that these relations should sometimes be classified as *discontinuous* because they indicate a deictic shift in entity.

4 Methods

Given the continuity hypothesis, we would expect continuous relations to be very frequent in the corpus, and in particular more frequent than discontinuous relations. Similarly, we expect to see a relatively high frequency of causal discourse relations. An analysis of simple frequencies of total occurrences would however be rather limited, as there are a number of possible confounds. In particular, we would like to be able to test whether there is any evidence for people generating expectations of upcoming discourse relations, as argued by the continuity and causality literature.

To test whether comprehenders in fact do generate expectations about upcoming discourse relations, we draw on the uniform information density (UID) hypothesis (Frank and Jaeger, 2008). The UID hypothesis suggests that humans tend to spread information evenly across a text or utterance, and thereby use linguistic means in order to reduce or omit highly predictable linguistic material (which, because it is predictable, carries only a small amount of information and therefore would lead to a dip in information density if not reduced or omitted). Florian Jaeger (2010) show this effect for the optional "that" in English complement clauses, which they find is omitted more often if the complement clause is predictable from the verb than when it is not. It has been suggested that the function of such a constant rate of information density would be to facilitate information transfer (Genzel and Charniak, 2002). In analyzing the rate of implicit discourse connectors in function of the predictability of the discourse relation according to the continuity and causality-by-default hypotheses, we hypothesize that speakers are also able to dynamically choose to use an explicit discourse connector or drop it in order to achieve UID. In order to measure the ratio of implicit discourse connectors in a discourse relation, we define the

implicitness measure as follows:

$$Implicitness(relation) = \frac{\#\text{ of implicit } relation}{\#relation}$$

A large value of implicitness (in particular, larger than average implicitness among all relations, which is 0.46) for a particular discourse relation in the corpus would thus indicate that the relation is expressed without the use of a specific discourse connector more often than average. We interpret high values of implicitness as the producer not needing to explicitly specify the relation for the comprehender because it is predictable (or otherwise easily inferable from local cues[3]). It would also suggest that the annotators of the corpus tended to mark that relation even in the absence of direct textual signals. On the other hand, a small value of implicitness means that the discourse relation is expressed with an explicit discourse cue more often than average, and we would interpret that as the relation being not easily predictable or difficult to process, such that an explicit marker is needed to avoid a peak in information density.

5 Results

This section will first discuss evidence for general patterns of the use of discourse markers, and then proceed to analyze a specific case of IC verbs, which are a local cue of causality.

5.1 Analysis of Global Expectations

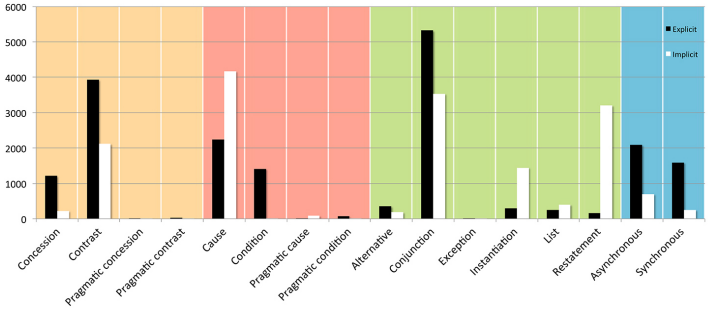

Figure 2: Frequency distribution of different types of relations in PDTB corpus: relation types are arranged across the horizontal axis according to their comprising classes: comparison, contingency, expansion and temporal.

Figure 2 depicts the distribution of different relation types over 19,009 explicit and 16,327 implicit considered relations[4]. There are 16 relation types in the hierarchy, some of which

[3]This notion of *no need for marking* of specific discourse relations such as causal ones reminds us also of Kehler's coherence theory, which indicates that arguments on syntactic decisions should be revisited with respect to the inferences underlying the establishment of discourse relations. For example, Kehler (2000) asserts that in elliptic structures, requirement of parallelism between the two involved discourse segments is important when a *resemblance* relation is targeted. In contrast, when a causal relation is being expressed via an elliptic construction, people understand it with no need of exact structural parallelism to help them with argument identification and alignment.

[4]Not all relations in the PDTB are annotated down to the third level of the hierarchy (this happened

are more frequent than others. The most frequent labels used to annotate the explicit relations (those associated with a textual discourse marker present in the original text) are `Conjunction`, `Contrast`, `Cause` and `Asynchrony`. It is obvious from the chart that the distribution of explicitly marked discourse relations is different from the distribution of implicit occurrence. The most frequent types among implicit relations are in order `Cause`, `Conjunction`, `Restatement`, and `Contrast`. In terms of total frequencies of the different discourse relationships (see Figure 2), `Conjunction`, `Cause` and `Contrast` are the most common relations, and hence could be claimed to be most expected on a pure frequency-based account. However, the relations `Conjunction` and `Contrast` have rather low rates of implicitness (see Figure 3).

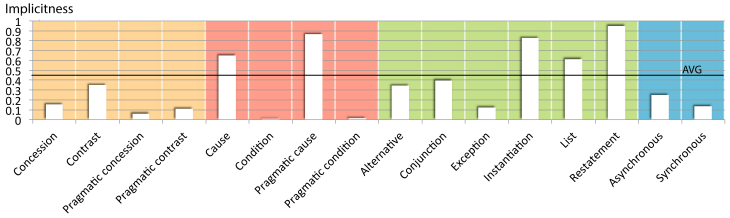

Figure 3: Implicitness of different types of relations in PDTB corpus: relation types are arranged across the horizontal axis according to their comprising classes: comparison, contingency, expansion and temporal.

5.2 Evidence for the Continuity Hypothesis

In Section 3 we classified the PDTB discourse relations with respect to continuity or discontinuity of an event in the sense of Segal et al. (1991). In particular, we argued that all of the discourse relations in the `COMPARISON` and `TEMPORAL`[5] family describe discontinuous events, while `Cause` and `Pragmatic Cause` are continuous. Within the `EXPANSION` family, we argued that `Instantiation`, `Restatement` and `List` are continuous, while `Exception` and possibly `Conjunction` can be viewed as denoting discontinuous events. Figure 3 depicts the implicitness of different level-2 types of discourse relations in the PDTB. We find that the relations that denote continuous events are exactly the ones that have implicitness values larger than average implicitness, while the ones that can be classified as discontinuous are exactly the ones with lower values of implicitness. The PDTB data thus provides strong supporting evidence for the continuity hypothesis. We will get back to more detailed analyzes concerning the concept of temporal continuity in Sections 5.4 and 5.5.

5.3 Evidence for the Causality-by-default Hypothesis

The causality-by-default hypothesis (Sanders, 2005) proposes that people preferentially interpret consecutive sentences as standing in a causal relationship. The data from the

when no consensus on the more detailed classification could been reached among the annotators). In our study, we only included those relations that were annotated down to at least the second level of the hierarchy. Also, some relations are tagged with more than one type. Hence, the sum over occurrences of all types does not necessarily match the total number of argument pairs in the corpus.

[5]Note: `Synchronous` is not straightforward to classify.

PDTB corpus shows that causal relations are not the only ones that are often expressed without an explicit connective, and hence with view on the UID hypothesis are not the only predictable relation (e.g., `Restatement` is a more implicit relation). Nevertheless, causal relations are the most frequent type of implicit discourse relations in the PDTB, see Figure 2. The implicitness of causal discourse relations is significantly higher (at 0.65) than the implicitness of the other frequent discourse relations, in particular `Conjunction` (0.39), `Concession` (0.15), `Asynchronous` (0.25), as well as the average overall relation types (0.46), – all comparisons significant at $p < 0.001$, according to a binomial test. This result supports the hypothesis we constructed on top of the causality-by-default and the UID hypotheses: in the absence of explicit connectives, a causal relation is expected between neighboring sentences.

5.4 Temporal Continuity

Now it is time to compare the subtypes of causal and temporal relations to investigate whether continuity in the temporal ordering of events is implicit or marked explicitly most often. Table 1 includes frequencies of the forward vs. backward causal, concessive and temporal relations in the corpus. As predicted, for each pair of the same type, the forward relation is associated with a higher degree of implicitness. We performed a binomial significance test and obtained $p < 0.001$ for all pairwise comparisons. This result supports the continuity hypothesis in the sense that discourse markers tend to be dropped when the relation between the arguments conform to linearity in time (Murray, 1997).

Type:subtype	Explicit	Implicit	Implicitness	Signif.
Cause:result	752	1704	**0.69**	***
Cause:reason	1488	2467	0.62	
Concession:contra-expectation	804	186	**0.19**	***
Concession:expectation	392	31	0.08	
Asynchrony:precedence	986	536	**0.35**	***
Asynchrony:succession	1101	161	0.12	

***: significant at $p < 0.001$ according to a binomial test

Table 1: Forward and backward occurrences of causal, concessive and temporal relations.

5.5 Textual Order of Arguments

It should be kept in mind that forward/backwardness of the relation (or the connective) in some cases does not correspond with the order in which the arguments of the relation appear in the text. Connectives such as "because" and "although" can take their subordinate clause (Arg2 according to PDTB) to the beginning of a composite sentence, see for example (6).

(6) Because the drought reduced U.S. stockpiles, they have more than enough storage space for their new crop, and that permits them to wait for prices to rise.

Since all of the occurrences of a particular relation type (e.g., *reason*) in the PDTB are tagged with the same label regardless of the textual order of the arguments, we performed a second analysis. Table 2 presents separate statistics for the Arg1-connective-Arg2 (ordered)

versus the connective-Arg2-Arg1 (reversed) occurrences for the relations `Cause`, `Concession` and `Asynchrony`, which we also focused on in our analysis of temporal continuity. PDTB annotators always put connectives between the arguments of the implicit relations. That is why we only present numbers for the explicit occurrences. Interestingly, there are always more ordinal modifications (the reversed presentation) when a backward relation of any type is being expressed. This implies that even in the presence of the cues, people have a tendency to keep the textual order of the arguments the same as the temporal order in which the associated events happened. In order to conduct a more accurate analysis of the temporal transition, given the information about argument organization we gathered all implicit and explicit occurrences of temporally linear vs. non-linear instances from all the 6 relation subtypes and performed a correlation analysis. In this analysis reversed occurrences of backward relations count as temporally linear and reversed occurrences of forward relations are taken as temporally non-linear (e.g., a reason relation in which Arg2 appears first in the text is taken as linear, just like a result relation). The chi-square test of the temporal linearity and the implicitness of the relation shows a significant correlation between these two factors ($\chi^2 = 67.31$, $df = 1$, $p < 0.001$). This is a more accurate result (compared with our analysis of continuity merely according to the relation types in 5.4) which indeed supports our hypothesis based on the UID and the continuity hypotheses: temporal forwardness is implicit in relations between consecutive sentences and its explicit cues are typically dropped.

Type:subtype (explicit only)	Ordered	Reversed	Signif.
Cause:result	746	6	***
Cause:reason	1324	**164**	
Concession:contra-expectation	791	13	***
Concession:expectation	183	**209**	
Asynchrony:precedence	931	55	***
Asynchrony:succession	867	**234**	

***: significant at p < 0.001 according to a binomial test

5.6 A potential local predictor: Implicit Causality Verbs

Implicit Causality verbs (such as *adore*, *inspire*, *humiliate*) have been studied for many years, mostly in the context of coreference (whether the subject of the clause explaining the reason is the subject or object of the IC verb). Recently, IC verbs have however also been argued to make comprehenders anticipate an upcoming causal discourse relation, i.e. comprehenders expect to learn about the reason if they hear a sentence with an IC verb, like "Peter adored his older brother.": In a visual world experiment, Rohde and Horton (2010) compared sentences with IC verbs to sentences with transfer-of-possesion (TOP) verbs, and found that participants are much more likely to expect a reason following an IC verb sentence than when they have heard a sentence with a TOP verb. This indicates that people are able to take into account local cues like IC verbs and anticipate upcoming discourse relations.

To test on the corpus data the validity of the hypothesis that IC verbs lead people to anticipate causal relationships, we extracted all sentences from the PDTB which contained

an IC verb in the Arg1 of a discourse relation. In order to identify the IC verbs, we used a list of 300 IC verbs provided by Ferstl et al. (2011). In order to avoid noise in the data, we extracted only those instances where the IC verb was the main verb of an Arg1 which contained only a single sentence. Therefore, we simultaneously queried the PDTB annotation and the syntactic annotation of the Penn Treebank. To make sure that the IC verb worked as a cue in the sentence, we only considered relations with ordered arguments, namely the Arg1-connective-Arg2 occurrences. We found that the discourse relation was labeled as `reason` significantly more often if Arg1 contained an IC verb than when it did not ($p < 0.01$), however, the size of the effect was small: likelihood of `reason` given an IC verb in Arg1 was 14.0%, and 11.7% for other verbs. This is support (though relatively weak) for IC verbs actually affecting the upcoming discourse relation.

The more interesting question in the context of the UID hypothesis, however, is whether markers for causal relations following IC verbs are more likely to be absent, due to the added predictability of the `reason` relationship. We compared the implicitness of reason relations where the Arg1 contains an IC verb to the implicitness of reason relations with non-IC verbs as the head of Arg1. Counterintuitively, we found that the implicitness of reason relations with an IC verb in the Arg1 was smaller than for non-IC Arg1s. To make sure that this effect was not due to noise, we also checked all occurrences of IC verbs manually and only included the correct verbs and not homonyms (such as for *lie*) or other unintended semantic sense (e.g. "leave it up to somebody" instead of "leave somebody"). We found that such incorrectly tagged verbs were evenly distributed among implicit and explicit relations, such that the implicitness value was not affected by the noise (implicitness was 61% for IC verb reason relations and 65% for non-IC verb reason relations). Table 3 shows the manually checked numbers within reason relations (for all relations, only automatically extracted numbers are available due to the large number of occurrences, and absence of effect from manually checking the IC verbs in reason relations[6]).

	Total	IC verb in Arg1	
Implicit: reason relations	2462	153	(manually checked)
Explicit: reason relations	1324	96	(manually checked)
Implicit: all relations	15682	910	(automatically extracted)
Explicit: all relations	16147	1034	(automatically extracted)

Table 3: Total frequency of relations and the frequency of IC verbs appearing as the head of a single-sentence Arg1. All selected relations are also filtered to have ordered arguments.

The result goes against our predictions and merits further investigation in further work: all verbs need to be classified into their IC semantic class according to the previous research, and finer-grained verb sense disambiguation should also be considered[7], and further factors such as whether the verb occurs in passive voice could be taken into account. Also, the list

[6]The number of automatically extracted reason relations including IC verbs were 164 and 108 for the implicit and explicit occurrences, respectively.

[7]Ferstl et al. (2011) categorize IC verb usages into 4 classes: AgentPatient, AgentEvocator, Experiencer-Stimulus, and StimulusExperiencer. For example, the AgentPatient class covers *activity* transitive verbs such as *"carry"* which associate Agent and Patient roles to the involved entities. The 300 IC verb list that we employed also did not contain information about which fine-grained verb sense should be treated as an IC verb.

of 300 IC verbs from (Ferstl et al., 2011) are only annotated for their subject or object bias. In future work, these verbs should all be tested for the strength of predicting an upcoming reason relationship; and the result could be taken into account to see whether the prediction of higher implicitness of discourse cues signaling a reason relationship following IC verbs possibly holds for those IC verbs which strongly predict a reason relationship.

6 Conclusions

We conducted an empirical study of discourse relations in newspaper text, specifically the PDTB treebank, with respect to the causality-by-default and continuity hypotheses. We found supporting evidence for both hypotheses: As the *continuity hypothesis* (Murray, 1997; Segal et al., 1991) predicts, discourse relations which are discontinuous or temporally non-linear are much more likely to be expressed with an explicit discourse marker than those which are continuous. The statistics on the forward vs. backward temporal transition between arguments of discourse relations furthermore show a higher degree of implicitness for the forward directionality of all causal, concessive and temporal relations than for the backward versions of them.

Causal relations constitute the largest proportion of the implicit discourse relations in the corpus, which suggests that they are more expected when no discourse marker is present, compared to many other relation types such as temporals, adversatives and additives. From a usage-based perspective, this provides partial support for the *causality-by-default* hypothesis put forth by Sanders (2005) in the sense that causal relations are identified even if no textual element explicitly marks them. However, in the absence of explicit sentence connectives other types of discourse relations could also be inferred, such as restatement or instantiation, which also account for a large proportion of unmarked relations in the PDTB corpus.

We also investigated implicit causality verbs which have been argued to act as local cues for an upcoming causal relationship. However, we found that their presence in the first sentence of a reason relationship does not increase the probability of the explicit connective to be dropped. This finding stands in contrast to what we predicted via an account of the UID hypothesis, which suggests that optional markers might be dropped if they contribute less information. Nevertheless, we observed that presence of an IC verb in the first argument of a sentence pair could generally signal a reason relation in the corpus, in line with the experimental finding of (Rohde and Horton, 2010) on discourse-level predictions. Taken together, our findings raise an interesting question for the future work: to what extent can global patterns vs. local cues account for the discourse relations being left implicit?

While the patterns we observed in the production data are compatible with the mentioned hypotheses about causality and continuity, they do not give us insight about the source of the tendency. Our results along with the related experimental findings can be considered from a frequency-based perspective, meaning that typical patterns in language production lead to expectations during comprehension about causality and continuity. Alternatively, it could be that people have an intrinsic tendency towards congruent and temporally ordered relations both in production and interpretation.

ABSTRACT
Cross-language information retrieval today is dominated by techniques that rely principally on context-independent token-to-token mappings despite the fact that state-of-the-art statistical machine translation systems now have far richer translation models available in their internal representations. This paper explores combination-of-evidence techniques using three types of statistical translation models: context-independent token translation, token translation using phrase-dependent contexts, and token translation using sentence-dependent contexts. Context-independent translation is performed using statistically-aligned tokens in parallel text, phrase-dependent translation is performed using aligned statistical phrases, and sentence-dependent translation is performed using those same aligned phrases together with an *n*-gram language model. Experiments on retrieval of Arabic, Chinese, and French documents using English queries show that no one technique is optimal for all queries, but that statistically significant improvements in mean average precision over strong baselines can be achieved by combining translation evidence from all three techniques. The optimal combination is, however, found to be resource-dependent, indicating a need for future work on robust tuning to the characteristics of individual collections.

1 Introduction

Cross-Language Information Retrieval (CLIR) is the problem of retrieving documents relevant to a query written in a different language. There are two main approaches to tackle this problem: translating the query into the document language, or translating documents into the query language. Query translation has become the more popular approach for experimental work due to the computational feasibility of trying different system variants without repeatedly translating the entire document collection (Oard, 1998; McCarley, 1999).

Query translation approaches for CLIR can be pursued either by applying a Machine Translation (MT) system or by using a token-to-token bilingual mapping, with or without translation probabilities. These approaches have complementary strengths: MT makes good use of context but at the cost of typically producing only one-best results, while token-to-token mappings can produce *n*-best token translations but without leveraging available contextual clues. This has led to a small cottage industry of what we might refer to as "context recovery" in which postprocessing techniques are used to select or reweight translation alternatives, usually based on evidence from term co-occurrence.

We argue that this false choice between MT and *n*-best token-by-token translation results from thinking of MT systems as black boxes. A modern statistical MT system has internally a series of increasingly rich representations that are exploited during the training and decoding processes. First, token alignments are generated for each training sentence pair, a process that also creates context-independent token-to-token translation probabilities. Second, these alignments are generalized to learn a Synchronous Context-Free Grammar (SCFG), in which probabilistic rules describe the translation of larger units of text. Finally, the translation grammar is combined with a language model to produce translations of entire sentences. As the whole process is statistically generated, it is at any point able to produce a ranked list of the highest scoring translations rather than only the one best choice. Although it is desirable to exploit these internal representations when performing retrieval, one possible disadvantage of using such a complex translation model is efficiency. However, modern decoders, e.g., `cdec` (Dyer et al., 2010), use pruning methods to efficiently search for the most likely translations of a given text.

In this paper, we describe two ways to exploit these internal representations and construct context-sensitive term translation probabilities. One method is to extract a context-aware portion of the SCFG by selecting only the grammar rules that apply to a given query. Using token alignments within each rule, a probability distribution can be constructed to represent the translation candidates for each query token, an approach that we refer to as "phrase-based." Another solution is to perform translation in context using the full MT system on the entire query and then to reconstruct context-sensitive token translation probabilities by accumulating translation likelihood evidence from each of the top *n* query translations.

These context-sensitive token translation probabilities can then be used in the same way as context-independent probabilities. In this work we use a technique based on mapping term statistics before computing term weights (Pirkola, 1998; Darwish and Oard, 2003), leading to a representation known as Probabilistic Structured Queries (PSQ). By doing this, we establish a strong context-independent "token-based" baseline that we can then compare directly with our proposed context-sensitive approaches.

Experiments on TREC 2002, NTCIR-8, and CLEF 2006 CLIR tasks, with topics in English and documents in Arabic, Chinese, and French, respectively, show that our approach consistently yields significant improvements over this baseline. The best results are achieved when we

perform a linear interpolation of all three approaches (query-based, phrase-based, and token-based). The remainder of this paper is organized as follows: Related work is described in Section 2, followed by our proposed approaches in Section 3, evaluation on the three collections in Section 4, and conclusions in Section 5. All of our code and test data are available as part of the open-source Ivory retrieval engine, available at `http://ivory.cc/`.

2 Background and Related work

Drawing inspiration from MT, Ponte and Croft (1998) introduced a monolingual information retrieval approach based on language models. This approach, which models the retrieval problem as if some noisy channel had corrupted some document into the query, was later extended by Berger and Lafferty (1999) and others. Combining language models with translation models to perform CLIR was a natural next step, and that approach yielded substantial improvements over earlier dictionary-based baselines, reporting Mean Average Precision (MAP) scores in the range of 90% of monolingual comparison conditions (Xu and Weischedel, 2005; Kraaij et al., 2003; Federico and Bertoldi, 2002). Nie (2010) summarizes this line of work well.

One limitation of applying language and translation models in CLIR is that they have mostly focused on isolated tokens (i.e., unigram models). To address this, there has been a substantial amount of work on exploiting query context in CLIR, dominated by approaches that use term co-occurrence statistics to select the most appropriate set of translation terms, based on some cohesion measure (Gao et al., 2006; Liu et al., 2005; Adriani and Rijsbergen, 2000; Seo et al., 2005). Expressing term dependency relations explicitly has been shown to produce good results in monolingual retrieval (Gao et al., 2004; Metzler and Croft, 2005), but extending that idea to CLIR has proven not to be as straightforward as one might expect. The closest approximation to be widely explored has been translation of multi-word expressions (so-called "phrase translation," although the "phrases" are often statistical rather than linguistic phenomena) in order to limit polysemy effects (Adriani and Rijsbergen, 2000; Arampatzis et al., 1998; Ballesteros and Croft, 1997; Chen et al., 2000; Meng et al., 2004; Zhang et al., 2007). Gao et al. (2012) recently introduced a query expansion approach also inspired by MT, modeling how query tokens are transformed into document tokens based on query context.

Inside an MT system we find a rich representation of alternative translations of the source "sentence" (which in our case is a query). MT-based CLIR approaches typically use one-best results since it has proven to be convenient to treat MT systems as black boxes (Magdy and Jones, 2011). One early CLIR system did try augmenting MT output using a bilingual dictionary (Kwok, 1999) in order to include alternative translations. More recently, Nikoulina et al. (2012) described techniques to maximize MAP when tuning an MT system and rerank the top n translations. Our approach focuses on combining different sources of evidence within an MT system, and can be considered complementary to these techniques. Combining the n-best derivations is also routinely used in speech retrieval (Olsson and Oard, 2009).

2.1 Context-independent Query Translation

As a baseline, we consider the technique presented by Darwish and Oard (2003). Given a source-language query $s = s_1, s_2, ...$, we represent s in the target language as a Probabilistic Structured Query (PSQ), where each token s_j is represented by its translations in the target language, weighted by the bilingual translation probability. These token-to-token translation probabilities are learned independently from a separate parallel bilingual text using automatic word alignment techniques, and we call this probability distribution Pr_{token}. In this approach,

the score of document d, given source-language query s, is computed by the following equations:

$$\text{Score}(d|s) = \sum_{j=1}^{\#\text{ terms}} \text{BM25}(\text{tf}(s_j, d), \text{df}(s_j)) \quad (1)$$

$$\text{tf}(s_j, d) = \sum_{\{t_i | Pr_{\text{token}}(t_i|s_j) > L\}} \text{tf}(t_i, d) Pr_{\text{token}}(t_i|s_j) \quad (2)$$

$$\text{df}(s_j) = \sum_{\{t_i | Pr_{\text{token}}(t_i|s_j) > L\}} \text{df}(t_i) Pr_{\text{token}}(t_i|s_j) \quad (3)$$

where L is a lower bound on translation probability. We also impose a cumulative probability threshold, C, so that translation alternatives of s_j are added (starting from the most probable ones) until the cumulative probability has reached C. As shown above, we use the Okapi BM25 term weighting function (with parameters $k_1 = 1.2$, $b = 0.75$), although in principle any other weighting function can be substituted.

Let us demonstrate this "token-based" representation model by an example. Following an Indri-like (Metzler and Croft, 2004) notation for query representations, the English query *Maternal leave in Europe* yields the following PSQ under this model for target language French:

```
#comb(#weight(0.74 matern, 0.26 maternel)
      #weight(0.49 laiss, 0.17 quitt, 0.09 cong, ...)
      #weight(0.91 europ, 0.09 européen))
```

Some of the translations are omitted due to space constraints. The `#comb` operator corresponds to the sum operator in equation (1), whereas the `#weight` operator is implemented as the weighted sum in equations (2) and (3). Within the `#weight` structure, terms follow their probabilities, which correspond to the Pr_{token} values in these equations. Notice that the translation distribution for the source token *leave* is uninformed by the context *maternity leave*, therefore the candidates *laisser* (Eng. let go, allow) and *quitter* (Eng. quit) have higher probabilities than *congé* (Eng. vacation, day off) in this model.

2.2 Machine Translation for Cross-Language IR

State-of-the-art statistical MT systems typically use hierarchical phrase-based translation models based on a Synchronous Context-Free Grammar (SCFG) (Chiang, 2005). In an SCFG, the rule `[X] || α || β || 𝒜 || ℓ(α → β)` indicates that the context free expansion $X \rightarrow \alpha$ in the source language occurs synchronously with $X \rightarrow \beta$ in the target language, with a likelihood of $\ell(\alpha \rightarrow \beta)$.[1] In this case, we call α the Left-Hand Side (LHS) of the rule, and β the Right-Hand Side (RHS) of the rule. We use indexed nonterminals (e.g., [X,1]) since in principle more than one nonterminal can appear on the right side. A sequence of token alignments $\mathcal{A}$ indicates which token in α is aligned to which target token in β.

Consider the following four rules from an SCFG:

R_1. `[S] || [S,1] || [S,1]`
R_2. `[S] || [X,1] || [X,1]`
R_3. `[X] || [X,1] leav in europ || cong de [X,1] en europ || 1-0 2-3 3-4 || 1`
R_4. `[X] || matern || matern || 0-0 || 0.69`

In the above notation, S refers to the sentence; therefore, the first two rules are special rules,

[1] The likelihood function ℓ is not a probability density function because it is not normalized.

describing that there is one sentential form, consisting of a single variable. In the third and fourth rules, we see the structure of the English phrase and how it is translated into French.

In contrast to the baseline model, this approach can handle both token and phrase translations. It can consider dependencies between query terms and therefore provide a more context-sensitive and appropriate translation of a given query. On the other hand, it is more dependent on training data and thus may not be as useful when the training set size is limited.

3 Context-Sensitive Query Translation

In this paper, we explore ways to improve the baseline token-translation model discussed above by exploiting the internal representations of the MT system. We describe two ways to construct a context-sensitive probability distribution for each query term, which can then be used directly by a similarly structured PSQ to retrieve ranked documents using equation (1). The first of these techniques (Section 3.1) was described in our previous paper and evaluated on a single collection (Ture et al., 2012); the second approach is new.

3.1 Probabilities from n-best Derivations

In MT, decoding is the process that finds the most probable translation with respect to an SCFG trained on a bilingual parallel corpus and a language model trained on monolingual target-language text. To control computational complexity, most decoders search for the most probable derivations by using pruning strategies.[2] The efficiency of our approaches is discussed in detail in Section 4.

When using one-best query translation, equations (1), (2) and (3) simplify to:

$$\text{Score}(d|s) = \sum_{i=1}^{m} \text{BM25}(\text{tf}(t_i^{(1)}, d), \text{df}(t_i^{(1)})) \tag{4}$$

where $t^{(1)}$ is the most probable translation of s, computed by:

$$\begin{aligned} t^{(1)} &= \arg\max_t [\max_{D \in \mathscr{D}(s,t)} \ell(t, D|s)] = \arg\max_t [\max_{D \in \mathscr{D}(s,t)} \text{TM}(t, D|s)\text{LM}(t)] \\ &= \arg\max_t \left[\text{LM}(t) \max_{D \in \mathscr{D}(s,t)} \prod_{r \in D} \ell(r)\right] \end{aligned} \tag{5}$$

where TM and LM correspond to the translation and language model scores, and $\mathscr{D}(s,t)$ is the set of possible derivations that generates the pair of sentences (s,t) (e.g., the sequence of four rules that translate the example query in Section 2.2 is one such derivation). The likelihood of each grammar rule r, $\ell(r)$, is learned as part of the training process of the translation model, by generalizing from token alignments on the training data (Chiang, 2007).

Decoders produce a set of candidate sentence translations in the process of computing equation (5), so we can generalize our model to consider the n candidates with the highest likelihoods, for some $n > 1$. We start by preprocessing the source query s and each candidate translation $t^{(k)}$. For each source token s_j, we use the derivation output to determine which grammar rules were used to produce $t^{(k)}$, and the token alignments in these rules to determine which target tokens are associated with s_j in the derivation. By doing this for each translation candidate $t^{(k)}$, we construct a probability distribution of possible translations of s_j based on the n query

[2] We use *derivation* to make it clear that what results is a rule sequence, not just a translated string.

translations. Specifically, if source token s_j is aligned to (i.e., translated as) t_i in the k^{th} best translation, the value $\ell(t^{(k)}|s)$ is added to its probability mass, producing the formula for Pr_{nbest}:

$$Pr_{\text{nbest}}(t_i|s_j) = \frac{1}{\varphi} \sum_{\substack{k=1 \\ s_j \text{ aligned to } t_i \text{ in } t^{(k)}}}^{n} \ell(t^{(k)}|s) \quad (6)$$

where φ is the normalization factor.[3] We should emphasize that Pr_{nbest} is a well-defined probability distribution for each s_j, so if a source token is translated consistently into the same target token in all n translations, then it will have a single translation with a probability of 1.0. Mapping *tf* and *df* statistics from source to target vocabulary is achieved by replacing Pr_{token} with Pr_{nbest} in equations (2) and (3).

Pr_{token} and Pr_{nbest} are similar in describing the probability of a target-language token given a source-language token, but differ by how the probability values are learned. For both approaches, we start from a large, potentially out-of-domain, sentence-aligned bilingual corpus. This corpus is first token-aligned using a word aligner. From these token alignments, one can directly deduce token translation probabilities, which correspond to Pr_{token}. In order to learn Pr_{nbest}, we add the MT system as an intermediate component, which creates a translation model from the token alignments, and then applies it (along with a language model) to the query text, using a decoder. Therefore, the distribution is informed by the query context and its derivation.

The advantage of Pr_{token} is the ability to model all of the translational varieties existent in the bilingual corpus, although these may be too noisy to properly translate a given query. For Pr_{nbest}, on the other hand, we would expect the distribution to be biased in favor of appropriate translations, but perhaps at the cost of some reduction in variety due to overfitting to the query context. For comparison, below are the translation probabilities for the same example query:

```
#comb(#weight(0.91 matern, 0.09 maternel, ...)
      #weight(1.0 cong) #weight(1.0 europ))
```

The overfitting issue is partially mitigated by using the n-best translation derivations, as opposed to the "1-best translation" approach, which treats the MT system as a black box. However, the lack of textual variety in the n most probable derivations is a known issue, caused by the fact that statistical MT systems identify the most probable derivations (not the most probable strings), many of which can correspond to the same surface form. This phenomenon is called "spurious ambiguity" in the MT literature, and it occurs in both phrase-based (Koehn et al., 2003) and hierarchical phrase-based MT systems (Chiang, 2007). For instance, according to Li et al. (2009), a string has an average of 115 distinct derivations in Chiang's `Hiero` system. Researchers have proposed several ways to cope with this situation, and we plan to integrate some of these in our future work. However, an alternative approach is to exploit grammar rules directly: this allows us to increase variety without introducing noisy translations, and we discuss this approach next.

3.2 Probabilities from the Translation Grammar

An alternative approach to exploit the MT system is to learn context-sensitive translation probabilities directly from the translation grammar. Hierarchical phrase-based MT systems use suffix arrays to extract all rules in an SCFG which apply to a given source text, requiring a

[3] Since a source token may be aligned to multiple target tokens in the same query translation, we still need to normalize the final likelihood values.

smaller memory footprint in the decoding phase (Lopez, 2007). We can use this feature to learn a token translation probability mapping that is a middle point between Pr_{token} and Pr_{nbest} in terms of context-aware choices and providing a varied set of translation alternatives.

We propose the following method to construct a probability distribution from a set of SCFG rules: For each grammar rule, we use the token alignments to determine which source token translates to which target token(s) in the phrase pair. Going over all grammar rules that apply to a given query, we construct a probability distribution for each token that appears on the LHS.

More specifically, given a translation grammar $\mathcal{G}$ and query s, we first use a suffix array extractor (Lopez, 2007) to obtain the subset of rules $\mathcal{G}(s)$ for which the source side pattern matches s. For each rule r in $\mathcal{G}(s)$, we identify each source token s_j on the LHS of r, ignoring any non-terminal symbols. From the token alignment information included in the rule structure, we can find all target tokens that s_j is aligned to. For each such target token t_i, the likelihood value of s_j being translated as t_i is increased by the likelihood score of r. If there are multiple target tokens, we increase the likelihood of each one equally. After repeating this process for all rules in the subset, we have constructed a list of possible translations and associated likelihood values for each source token that has appeared in any of the rules. We can then convert each list into a probability distribution, Pr_{phrase}, by normalizing the likelihood scores:

$$Pr_{\text{phrase}}(t_i|s_j) = \frac{1}{\psi} \sum_{\substack{r \in \mathcal{G}(s) \\ s_j \leftrightarrow t_i \text{ in } r}} \ell(r) \tag{7}$$

where ψ is the normalization factor and $s_j \leftrightarrow t_i$ represents an alignment between tokens s_j and t_i. Pr_{phrase} is different than Pr_{token} because it takes query context into account. Basically, we only look at the part of the grammar that applies to phrases in the source query, therefore create a bias in the probability distribution based on this context. It is also different than Pr_{nbest} because we do not perform any search, and there is no use of a language model. Thinking in terms of the MT pipeline, the representation we are exploiting in this approach is the extracted grammar, right before decoding has taken place, after token alignments have been generated. In order to illustrate the intuition behind this approach, the same example query is represented as follows using Pr_{phrase}:

```
#comb(#weight(0.68 matern, 0.06 maternel, ...)
      #weight(0.35 cong, 0.24 laiss, 0.13 quitt, ...)
      #weight(0.90 europ, 0.07 européen, ...))
```

When compared to Pr_{token}, notice that the translation distribution of *leave* shifts towards the more appropriate translation *congé* as a result of this approach.

3.3 Combining Sources of Evidence

All three approaches for query translation (i.e., token-based, phrase-based, and query-based) have complementary strengths, so we introduce a unified CLIR model by performing a linear interpolation of the three probability distributions:

$$Pr_{\text{c}}(t_i|s_j;\lambda_1,\lambda_2) = \lambda_1 Pr_{\text{nbest}}(t_i|s_j) + \lambda_2 Pr_{\text{phrase}}(t_i|s_j) + (1-\lambda_1-\lambda_2) Pr_{\text{token}}(t_i|s_j) \tag{8}$$

Replacing Pr_{token} with Pr_{c} in equation (1) gives us the document scoring formula for the combined model (call Score_{c}).

Until now, we focused on the translation of single-token terms, but we can also use the n-best derivation list to identify how multi-token "phrases" are translated in context. The right hand side of the rules in the n most probable derivations provides us with statistically meaningful target-language phrases, along with their associated probabilities (described by Pr_{multi} below). With this addition, we score each document by a weighted average of the single-token approach (i.e., Score_c) and the sum of document scores for the multi-token terms:

$$\text{Score}(d|s;\gamma) = \gamma \text{Score}_{\text{c}}(d|s;\lambda_1,\lambda_2) + (1-\gamma) \sum_{\text{phrase } p} \text{BM25}(\text{tf}(p,d), \text{df}(p)) Pr_{\text{multi}}(p) \quad (9)$$

$$Pr_{\text{multi}}(p) = \frac{1}{\psi} \sum_{k=1}^{n} \sum_{\substack{\text{rule } r \in D^{(k)} \\ p \in RHS(r)}} \ell(r) \quad (10)$$

where ψ is the normalization factor and $D^{(k)}$ is the derivation of the k^{th} best translation. Below is the representation of the example query under this model, with γ set to 0.8:

```
#combweight(0.8 #comb(#weight(0.81 matern, 0.12 maternel, ...)
                      #weight(0.45 cong, 0.25 laiss, 0.10 quitt, ...)
                      #weight(0.95 europ, 0.04 européen, ...))
            0.1 ''en europ'', 0.08 ''cong de'', 0.01 ''cong matern'', ...)
```

The `#comb` structure represents Pr_{c} and the remaining multi-token terms represent Pr_{multi}, all extracted from the top n derivations. The `#combweight` operator corresponds to equation (9).

4 Evaluation

We evaluated our system on the latest available CLIR test collections for three languages: TREC 2002 English-Arabic CLIR, NTCIR-8 English-Chinese Advanced Cross-Lingual Information Access (ACLIA), and CLEF 2006 English-French CLIR. For the Arabic and French collections, we used title queries because they are most representative of the short queries that searchers frequently pose to web search engines. Chinese queries in the NTCIR-8 ACLIA test collection are in the form of complete syntactically correct questions, but for consistency we treated them as bag-of-words queries in our experiments with no special processing. The collections contain 383,872, 388,589 and 177,452 documents, and 50, 50, and 73 topics, respectively.

We learned our English-to-Arabic translation model using 3.4 million aligned sentence pairs from the GALE 2010 evaluation. Our English-to-Chinese translation model was trained on 302,996 aligned sentence pairs from the FBIS parallel text collection. We trained an English-to-French translation model using 2.2 million aligned sentence pairs from the latest Europarl corpus (version 7) that was built from the European parliament proceedings.[4]

Token alignments were learned with GIZA++ (Och and Ney, 2003), using 5 Model 1 and 5 HMM iterations. An SCFG serves as the basis for the translation model (Chiang, 2007), which was extracted from these token alignments using a suffix array (Lopez, 2007). We used `cdec` for decoding, due to its support for SCFG-based models and its efficient C-based implementation, making it faster than most of the other state-of-the-art systems (Dyer et al., 2010). A 3-gram language model was trained from the target side of the training data for Chinese and Arabic, using the SRILM toolkit (Stolcke, 2002). For French, we trained a 5-gram LM from the monolingual dataset provided for WMT-12. The Chinese collection was segmented using the Stanford segmenter (Tseng et al., 2005), English topics and the French collection

[4] http://www.statmt.org/europarl

were tokenized using the OpenNLP tokenizer,[5] and Arabic was tokenized and stemmed using the Lucene package.[6] For English and French, we also lowercased text, stemmed using the Snowball stemmer, and removed stopwords.

4.1 Effectiveness

We used Mean Average Precision (MAP) as the evaluation metric. The baseline token-based model yields a MAP of 0.2712 for Arabic, 0.1507 for Chinese, and 0.2617 for French. Direct comparisons to results reported at TREC, NTCIR, and CLEF (respectively) are hard to make because of differences in experimental conditions, but the comparisons we are able to make suggest that these baseline MAP values are reasonable.[7] For Arabic, the best reported results from TREC-2002 were close to 0.40 MAP (Fraser et al., 2002), but those results were achieved by performing query expansion and learning stem-to-stem mappings; our experiment design requires token-to-token mappings (which result in sparser alignments). For Chinese, the NTCIR-8 topics are in the form of questions, and systems that applied question rewriting performed better than those that did not. Also, 15 of the questions are about people, for which our vocabulary coverage was not tuned. If we disregard these 15 topics, our baseline system achieves 0.1778, close to the best reported results with comparable settings, with a MAP of 0.181 (Zhou and Wade, 2010). For French, our baseline achieves close to the same score as the one reported result at CLEF-2006 that did not incorporate blind relevance feedback (0.2606 MAP) (Savoy and Abdou, 2006).

As discussed in Section 3, we implemented three techniques to construct a term translation probability distribution: Pr_{nbest}, Pr_{phrase} and Pr_{token}, described by equations (6), (7) and (1) above.[8] We assessed these three approaches by (i) comparing them against each other, and (ii) measuring the benefit of a linear combination, i.e., Pr_{c}, described by equation (8).

Experiment results are summarized in Table 1 and illustrated in Figure 1. In that figure, we provide three connected scatterplots of MAP scores within a range of values for λ_1 and λ_2. In order to see the effectiveness of the interpolated model with respect to parameters λ_1 and λ_2, we performed a grid search by applying values in increments of 0.1 (ranging from 0 to 1) to the interpolated model Pr_{c}. For readability, figures only include a representative subset of λ_2 settings, where different lines represent different values for λ_2. To distinguish the extreme settings of $\lambda_2 = 0$ and $\lambda_2 = 1$, we use a filled circle or square, respectively.

The left edge represents $\lambda_1 = 0$, meaning that we do not use probabilities learned from the n-best derivations (i.e., Pr_{nbest}) in our interpolation. Along the y-axis on the left edge, we see results for various settings of λ_2, which controls how much weight is put on Pr_{phrase} and Pr_{token}. Within these settings, a particularly interesting one is when λ_2 is set to 0. In this case, the approach is solely based on context-independent translation probabilities (i.e., Pr_{token}), which is the baseline model (call this condition A). When λ_2 is set to 1, we rely on phrase-based term translation probabilities (i.e., Pr_{phrase}, call this condition B). By contrast, at the right edge, $\lambda_1 = 1$, so we rely only on Pr_{nbest} when translating query terms (call this condition C). For

[5] http://opennlp.apache.org

[6] http://lucene.apache.org

[7] The best results often employ blind relevance feedback, multiple lexical resources and/or very long queries. While these techniques can be useful in deployed applications, we have chosen not to run such conditions in order to avoid masking the effects that we wish to study.

[8] We fixed $C = 0.95, L = 0.005, n = 10$ for all models after manually trying a range of values.

Figure 1: Effectiveness results.

reference, the dotted horizontal line represents simply taking the one-best translation from the MT system (i.e., described by equation (4), call this condition D).

In the case of the Arabic collection, we observe a strictly decreasing trend for the MAP scores as λ_2 decreases, and the best results are obtained when λ_1 is 0 and λ_2 is 1.0 (call the condition with the best MAP score E). In other words, the interpolation yields a maximum 0.3058 MAP when it was based entirely on Pr_{phrase}, ignoring distributions Pr_{token} and Pr_{nbest}. For the Chinese collection, λ_1=0.2 and λ_2=0.7 yields the best result (MAP=0.1916), whereas effectiveness peaks at λ_1=0.3 and λ_2=0.4 for the French collection, with a MAP score of 0.3084.

Based on the randomized significance test proposed by Smucker et al. (2007), the combined approach (E) outperforms all models (except for the phrase-based approach) in the Arabic collection with 95% confidence. When we ran the same test on the other two collections, we found that the combined approach is significantly better than the baseline (A) and 1-best (D) approaches for Chinese, whereas MAP is significantly higher than baseline A for French. These results confirm that the complementary advantages of each model can be combined into a single superior model using our approach.

We also experimented with the multi-token term representation in equation (9), by varying the γ parameter. With γ set empirically to 0.8, the MAP increased by 0.005 for French, and remained about the same for Arabic and Chinese.

When the three individual models (conditions A, B and C) are compared (i.e., ignoring the

Condition	MAP		
	Arabic	Chinese	French
A: λ_1=0, λ_2=0 (Pr_{token})	0.2712	0.1507	0.2617
B: λ_1=0, λ_2=1 (Pr_{phrase})	0.3058	0.1867	0.2868
C: λ_1=1, λ_2=0 (Pr_{nbest})	0.2431	0.1709	0.2979
D: 1-best	0.2473	0.1535	0.2829
E: best $\{\lambda_1, \lambda_2\}$	$0.3058^{a,c,d}$	$0.1916^{a,d}$	0.3084^{a}

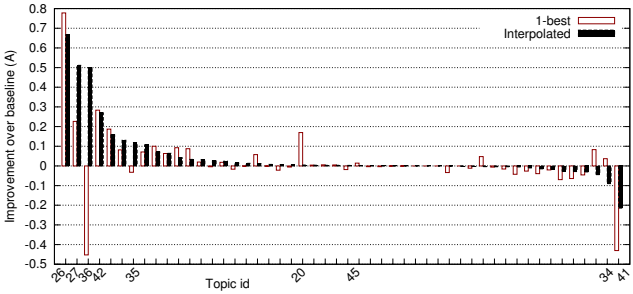
Table 1: A summary of experimental results under different conditions, for all three CLIR tasks. Superscripts indicate if the best result is significantly better than conditions A, B, C, and D.

interpolated results), the phrase-based model (B) is significantly better than the token-based baseline (A) for Arabic and Chinese, but statistically indistinguishable from the same baseline model in the case of French. For French, the best retrieval effectiveness results from the *n*-best full query translation model (C), significantly better than the baseline model (A). This shows that there is no individual model that outperforms the rest in all three collections. The real strength of our approach is therefore to introduce a unified probabilistic model that can combine all of these different approaches in a principled manner.

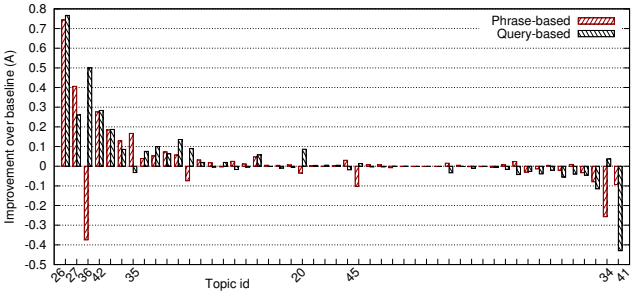
For topic-specific analysis, we looked at the distribution of the average precision (AP) differences between the various models. We observe that our best interpolated model (E) yields better AP than the token-based baseline model (A) for 36 of the 43 Arabic topics in which there was a noticeable difference (7 of the 50 Arabic topics exhibited differences of 0.001 or less). For the Chinese collection, the same was true for 41 of 57 topics (with 16 exhibiting a negligible difference), whereas the comparable statistic is 29 of 44 for French.

For space reasons, we illustrate these differences only for French. Figure 2(a) plots the AP improvement of the best interpolated model (E) and the one-best MT approach (D) over (or the average degradation below) the token-based baseline (A), sorted left to right by decreasing AP improvement for the interpolated model (E); Figure 2(b) similarly plots the same AP differences for the phrase-based (B) and *n*-best full query translation approaches (C), again with reference to the token-based baseline (A), with topics sorted in the same order to facilitate comparison. These plots make it quite clear that the three approaches vary in their per-topic effectiveness. Rather than slight variations in all of the topics, we see several cases in which one of the models is superior to the others. For instance, the *n*-best full query translation approach is a clear winner for topics 26, 36 and 42, whereas the phrase-based approach outperforms for topics 27 and 35. Despite its drawbacks, there are topics in which the token-based model is superior to our more sophisticated approaches, notably topics 34 and 41. Once again, this analysis supports our argument that combining these three probabilistic models into one unified approach can capture some of the best of each. In general, we expect the interpolated model to be more robust, since it has access to more evidence than the individual models.

In practice, we would like to select model parameters without observing all the test topics. Therefore, we ran 10-fold cross-validation experiments on each collection, selecting parameters that maximize MAP on nine folds and evaluating on the remaining one. This method yields a MAP of 0.2979 for Arabic, 0.1733 for Chinese, and 0.2872 for French, all significantly better than the token-based baseline (A). We also explored if we could use two of the collections to tune parameters for the third. For this, we first ranked each (λ_1, λ_2) pair by MAP on each collection. In order to select the parameters for a particular collection, we added the ranks



(a) Interpolated and 1-best models vs. the token-based baseline approach.



(b) Phrase- and query-based (i.e., n-best) models vs. the token-based baseline approach.

Figure 2: Per-topic AP improvement over token-based baseline (condition A) for French.

from the other two collections and picked the one with the lowest sum. Using this method, the selected parameters were $(0.1, 0.1)$ for Arabic, $(0.3, 0.5)$ for Chinese, and $(0.1, 0.1)$ for French. When compared to the token-based baseline (A), this approach showed significant improvements only for Chinese. We conclude from this analysis that the optimal combination of models depends on the collection, language, and resources. Once these are fixed, we can use a subset of the topics to appropriately tune parameters for the rest. However, better tuning methods need to be devised for a truly robust approach to combining these CLIR models.

4.2 Efficiency

We compared the various CLIR approaches in terms of efficiency (query evaluation time), performing experiments on a machine running Red Hat Linux on a 2.4 GHz processor. We processed the Arabic topics using each model and measured running time per query in milliseconds. Averages over three repeated runs are reported in Table 2 (with 95% confidence intervals).

As described before, there are three processes in the MT pipeline: token alignment, grammar extraction, and decoding. Token alignment is query-independent and required for all three approaches, so we did not include it in our running time comparison of running times. For the construction of Pr_{phrase}, we only need to extract grammar rules that apply to each given query,

	Process	Pr_{token}	Pr_{phrase}	Pr_{nbest}			Pr_{c}
				1-best	**5-best**	**10-best**	
MT	Grammar extraction	-	7.57				
	Decoding	-	-	134.94			134.94
IR	Initialization	negligible	64.38	negligible			64.38
	Generation	48.12	negligible	5.80	59.47	62.25	49.11
	Ranking	545.64	514.17	97.64	158.81	179.07	601.95
Total time (in *ms*)		594±22	586±13	246±15	361±28	383±22	858±20

Table 2: Average running times for processes in the CLIR pipeline (in *ms*).

whereas Pr_{nbest} also requires decoding.[9]

The remaining processes that we need to consider are part of the IR pipeline: initialization of the CLIR model, generation of query representations in the target language, and ranking of the most relevant documents in the collection. We only count query-dependent initialization costs, since other costs such as loading the bilingual dictionary need to be done only once, even with many queries. The input of the generation step is the source-language query, and the output is a PSQ that represents that query in the target language. In the phrase-based method, this step takes a negligible amount of time, because the probability distribution is already in memory at the beginning of this step, and it is very small (i.e., probabilities for a few query terms only). For Pr_{nbest}, generation time rises linearly as n is increased.

Ranking time depends on the complexity of the query representation. With more complex representations, it is possible to increase effectiveness, but at the cost of efficiency. Therefore, a desirable CLIR approach would express all the relevant information and nothing more. The distributions Pr_{token} and Pr_{phrase} tend to include more translation alternatives per query term, resulting in a more complex representation and longer ranking time. As a result, interpolating all three distributions generates a complex representation as well.

When we look at the total running times in Table 2, we observe that the n-best approach is significantly more efficient than the token-based baseline, even though it requires additional MT processes to fully translate the queries. When $n = 1$, the reduction in total running time is nearly 60%. The savings become more modest as n increases, approximately 39% and 35% for 5-best and 10-best MT approaches. Increasing n also improves effectiveness, thus there is a tradeoff to consider when deciding on the value for n. There is a similar tradeoff for the token-based approach: the representation can be simplified if more aggressive thresholding is used, e.g., if C increased in equation (1); however, this may result in a less effective model.

We do not see the same efficiency improvements from reduction in query complexity with the phrase-based model; the query complexity is similar to the baseline approach. As a result, the phrase-based approach runs in about the same total time. However, the MAP score improves considerably for all of the collections, so we can say that Pr_{phrase} is superior to Pr_{token}.

The combined model Pr_{c} yields the highest MAP scores but also takes the longest time to complete. When compared to the baseline model, running time increases by 44%, which seems acceptable given the consistently significant improvements. We should note that our implementation is not fully optimized, and is open to further improvements in the future.

As a summary of our evaluation, we believe that the best choice depends on user expectations. For a faster and possibly more effective model, Pr_{nbest} and Pr_{phrase} seem to be good alternatives

[9] It is reasonable to assume that the decoder time to find top n translations is the same as finding the one-best result.

to Pr_{token}. For best effectiveness, the interpolation of the three probability distributions is a good choice, providing significantly better results at the cost of additional complexity.

5 Conclusions and Future Work

In this paper, we introduced a theoretical framework that uses a statistical translation model for cross-language information retrieval. Our approach combines the representational advantage of probabilistic structured queries with the richness of the intermediate information produced by translation models. We proposed two ways of exploiting the internal representation of translation models to learn context-sensitive term translation probabilities: (1) aggregate information from the *n*-best translation outputs by an MT decoder, or (2) extract the subset of the translation grammar that applies to a given query, and use the token alignments in each rule to construct a probability distribution. Although using translation models for CLIR is not a novel approach, we have introduced novel ideas on *how* one can utilize the rich internal representation of MT systems for this task.

We evaluated our models on an English-Arabic task from TREC 2002, an English-Chinese task from NTCIR-8, and an English-French task from CLEF 2006, finding in all three cases that an optimal linear combination of the three approaches can significantly improve MAP, but that the optimal parameters vary by collection. We also compared approaches in terms of efficiency and showed that our framework provides a set of choices, allowing a beneficial tradeoff between improving efficiency and effectiveness. Because we used only one collection per language, experiments with multiple collections for the same language will be needed before we can begin to speculate on whether these differences are language-dependent, collection-dependent, or some combination of the two. Additionally, we would like to try this approach on more languages to further study the consistency in improvements, and also with different parallel corpora and monolingual language modeling collections, in order to tease out whether the differences we are seeing in the optimal combination weights are resource dependent (varying principally with different parallel corpora and/or language models).

In terms of modeling, we plan to revisit the rather ad hoc way we have incorporated multi-word expressions, exploring ways of leveraging them in each model separately rather than at the final evidence combination stage. Also, since the benefit of performing full machine translation would be expected to increase as available context increases, we would like to explore the potential for translating documents in addition to queries. Following the same methods described in this paper, we could learn a new set of probability distributions from the document translations, which could be combined with the current three approaches to construct an even richer and possibly more accurate CLIR model. We also plan to explore the effect of using a phrase-based MT system as an alternative to the SCFG-based model in our experiments.

In conclusion, we have introduced ways of using statistical translation models for CLIR that take greater advantage of the capabilities of current statistical MT systems, and we hope that the promising results we have reported will spur the community to further explore this space.

ABSTRACT

This paper introduces a novel method for joint unsupervised aquisition of verb subcategorization frame (SCF) and selectional preference (SP) information. Treating SCF and SP induction as a multi-way co-occurrence problem, we use multi-way tensor factorization to cluster frequent verbs from a large corpus according to their syntactic and semantic behaviour. The method extends previous tensor factorization approaches by predicting whether a syntactic argument is likely to occur with a verb lemma (SCF) as well as which lexical items are likely to occur in the argument slot (SP), and integrates a variety of lexical and syntactic features, including co-occurrence information on grammatical relations not explicitly represented in the SCFS. The SCF lexicon that emerges from the clusters achieves an F-score of 68.7 against a gold standard, while the SP model achieves an accuracy of 77.8 in a novel evaluation that considers all of a verb's arguments simultaneously.

TITLE AND ABSTRACT IN FRENCH

Factorisation de tenseurs à plusieurs dimensions pour l'acquisition lexicale non supervisée

Cet article présente une méthode originale pour l'acquisition simultanée de cadres de sous-catégorisation (*subcategorization frames*) et de restrictions de sélection (*selectional preferences*) appliquée au lexique verbal. L'induction simultanée de ces deux types d'information est vue comme un problème de cooccurrence à plusieurs dimensions. On introduit donc une méthode de factorisation de tenseurs, afin de classer les verbes fréquents d'un grand corpus suivant leur comportement syntaxique. L'approche est fondée sur un ensemble de traits de nature syntaxique et lexicale, y compris des informations de cooccurrence au sein des relations grammaticales qui ne sont pas explicitement représentées dans les schémas de sous-catégorisation. Le dictionnaire de sous-catégorisation produit par la méthode de classification obtient une F-mesure de 68,7 lors de l'évaluation face à un dictionnaire de référence tandis que les restrictions de sélection ont une exactitude (*accuracy*) de 77,8 en tenant compte de tous les arguments simultanément.

KEYWORDS: subcategorization frames, selectional preferences, lexical acquisition, tensor factorization, unsupervised machine learning.

KEYWORDS IN FRENCH: cadre de sous-catégorisation, restriction de sélection, acquisition lexicale, factorisation de tenseurs, apprentissage non supervisé.

1 Introduction

Verb subcategorization lexicons and selectional preference models capture two related aspects of verbal predicate-argument structure, with subcategorization describing the syntactic arguments taken by a verb, and selectional preferences describing the semantic preferences verbs have for their arguments. Each type of information can support NLP tasks requiring information about predicate-argument structure. For example, subcategorization has proved useful for parsing (Carroll and Fang, 2004; Arun and Keller, 2005; Cholakov and van Noord, 2010), semantic role labeling (Bharati et al., 2005; Moschitti and Basili, 2005), verb clustering, (Schulte im Walde, 2006; Sun and Korhonen, 2011) and machine translation (Han et al., 2000; Hajič et al., 2002), while selectional preferences have benefited parsing (Zhou et al., 2011), semantic role labeling (Gildea and Jurafsky, 2002; Zapirain et al., 2009), and word sense disambiguation (Resnik, 1997; Thater et al., 2010; Seaghdha and Korhonen, 2011).

Verb subcategorization frame (SCF) induction involves identifying the arguments of a verb lemma in a corpus, and generalizing about the *frames* taken by the verb, where each frame includes a number of arguments and their syntactic types. Consider e.g. sentence (1), where the verb *show* takes the frame SUBJ-DOBJ-CCOMP (subject, direct object, and clausal complement).

(1) $[\text{Our October review}]_{\text{SUBJ}}$ comprehensively $[\text{shows}]_{\text{VERB}}$ $[\text{you}]_{\text{DOBJ}}$ $[\text{what's in store in next month's magazine}]_{\text{CCOMP}}$.

Predicting the set of SCFs for a verb can be viewed as a multi-way co-occurrence problem of a verb and its different arguments. One of the main challenges is distinguishing arguments from adjuncts (e.g. temporal, locative, or manner modifiers). Most SCF induction work to date considers only the co-occurrences of verb lemmas with different grammatical relation types (subject, object, prepositional phrase, etc.). Taking SCF acquisition to the next level requires consideration of the lexical fillers of potential argument slots for more accurate argument-adjunct discrimination.

Selectional preference (SP) induction involves predicting the likelihood of a given lexical item occurring in an argument slot, and generalizing about the lexical classes which occur in the slot, which may be dependent on the SCF. In sentence (2), for example, the verb *show* takes the frame SUBJ-DOBJ, and the direct object of *show* in this frame is likely to be inanimate.

(2) $[\text{Stalin}]_{\text{SUBJ}}$, who must have been well informed through his network of spies, $[\text{showed}]_{\text{VERB}}$ $[\text{no emotion}]_{\text{DOBJ}}$.

Most SP induction work to date has focused on discovering lexical preferences within the direct object slot alone, or at most three-way co-occurrences between verb, subject, and direct object, and has not considered the full range of potential argument slots for which verbs subcategorize, thus losing some of the contextual information which may be helpful in learning SPs. Moreover, the ability of SP acquisition methods to model the full range of verbal arguments, including e.g. clausal complements, has not been tested.

As the two types of lexical information – SCFs and SPs – are closely interlinked and can complement each other, it would make sense to acquire them jointly. However, to the best of our knowledge, no previous work has developed a model for their joint acquisition.

Unsupervised machine learning is attractive for lexical acquisition because it works where little labeled data is available, and ports easily between tasks and languages. Increasingly sophisticated techniques have been applied to SP induction (Rooth et al., 1999; Van de Cruys, 2009; Ó Séaghdha, 2010; Ritter and Etzioni, 2010; Reisinger and Mooney, 2011) while work

on unsupervised SCF acquisition has been limited (Carroll and Rooth, 1996). In this paper we present a largely unsupervised method for the joint acquisition of SCFs and SPs, adapting a method that has been successfully used for SP induction (Van de Cruys, 2009) so that it learns *whether* a verb subcategorizes for a particular argument slot together with *which* lexical items occur in the slot.

Our method uses a co-occurrence model augmented with a factorization algorithm to cluster verbs from a large corpus. Specifically, we use non-negative tensor factorization (NTF) (Shashua and Hazan, 2005), a generalization of matrix factorization that enables us to capture latent structure from multi-way co-occurrence frequencies. The factors that emerge represent clusters of verbs that share similar syntactic and semantic behaviour. To evaluate the performance on SCF acquisition, we identify the syntactic behaviour of each cluster. The SCF lexicon that emerges from the clusters achieves a promising F-score of 68.7 against a gold standard. We further introduce a novel SP evaluation in which we investigate the model's ability to induce preferences for the co-occurrence of a particular verb lemma and all of its arguments *at the same time*. The model achieves a high accuracy of 77.8 on this new evaluation. We also perform a qualitative evaluation which shows that the joint model is capable of learning rich lexical information about both syntactic and semantic aspects of verb behaviour in data.

2 Related Work

Recent SCF acquisition approaches use the output of an unlexicalized parser to generate SCF hypotheses, followed by statistical filtering and/or smoothing to remove noise. Briscoe and Carroll (1997); Korhonen (2002); Preiss et al. (2007) use handcrafted rules to match parser output to a pre-defined set of SCFs, achieving an F-measure of about 70 against a manually annotated gold standard, while O'Donovan et al. (2005); Chesley and Salmon-Alt (2006); Ienco et al. (2008); Messiant (2008); Lenci et al. (2008); Altamirano and Alonso i Alemany (2010); Kawahara and Kurohashi (2010) induce the inventory of SCFs from parsed corpus data. Candidate frames are identified by grammatical relation (GR) co-occurrences, often aided by language-specific heuristics. Statistical filtering or empirically-tuned thresholds are used to select frames for the final lexicon. These 'inductive' approaches have achieved respectable accuracy (60-70 F-measure against a dictionary) and are more portable than earlier methods. However, their ability to improve in accuracy is limited by their inability to incorporate information beyond the GR co-occurrences and heuristics that identify candidate SCFs on a per-sentence basis. Such cues provide no capacity for learning further from the data, e.g. from the lexical content of verbal arguments or from other GRs which are not part of the SCF.

Unsupervised machine learning has been applied to tasks where portability is equally important (Blei et al., 2003; Dinu and Lapata, 2010) but its application to SCF acquisition remains limited. Carroll and Rooth (1996) combined a head-lexicalized context-free grammar with an expectation-maximization (EM) algorithm to acquire an SCF lexicon. Dębowski (2009) used a filtering method based on the point-wise co-occurrence of arguments in parsed data to acquire a Polish SCF lexicon, but this method does not take the semantics of the verb's arguments into account. Lippincott et al. (2012) developed a graphical model for inducing verb frames in corpus data. The model identifies argument types of verbs but not *sets* of SCFs taken by a verb, as full scale SCF systems do.

Recent SP acquisition approaches use latent semantic information to model SPs, making use of probabilistic models, such as latent Dirichlet allocation (LDA) (Ó Séaghdha, 2010; Ritter and Etzioni, 2010; Reisinger and Mooney, 2011), or non-negative tensor factorization (NTF)

(Van de Cruys, 2009). Other approaches solely make use of distributional similarity methods (Bhagat et al., 2007; Basili et al., 2007; Erk, 2007). All approaches model two-way verb-argument co-occurrences, with the exception of Van de Cruys (2009) which models three-way verb-subject-object co-occurrences.

To our knowledge, no previous method has learned SCFs and SPs jointly. Scheible (2010) used SCFs as features in a Predicate-Argument Clustering (Schulte im Walde et al., 2008) approach to SP acquisition, but did not evaluate the resulting clusters for SCFs and found that the SP method did not outperform previous methods. Abend et al. (2009) used co-occurrence measures to perform unsupervised argument-adjunct discrimination for PPs, but not full SCFs.

Our method makes use of non-negative tensor factorization (NTF) (Shashua and Hazan, 2005). Tensor factorization is the multilinear generalization of matrix factorization. It has been extensively studied in the field of statistics (Kolda and Bader, 2009), and has yielded promising results on SP acquisition (Van de Cruys, 2009). We introduce a novel way of considering SCFs with an arbitrary number of arguments, and SPs as multi-way co-occurrences in the context of these larger SCFs. The resulting model provides an ideal framework for joint acquisition of SCF and SP information. The only form of supervision in the model is parameter estimation and choice of the best feature set via cross-validation.

3 Subcategorization Frame Inventory

To facilitate thorough qualitative evaluation (Section 5.6), we defined our SCFs in terms of syntactic slots, and in the form of common GRs. Finer-grained inventories including lexicalized elements and semantic interpretation were left for future work (see Section 7).

We use the GR types produced by the RASP parser (Briscoe and Carroll, 2002). Altogether we experimented with combinations of nine GR types out of the 13[1] which can be headed by verbs, selected on the basis of their frequency in the parsed BNC corpus and relevance for subcategorization. For this initial experiment, we focused on higher-frequency arguments since they will have the greatest impact on downstream applications.

Our first eight basic GR types are as follows. In subject position we included non-clausal subjects (SUBJ)[2], ignoring sentences with clausal subjects, which are much less frequent. Since objects are key arguments for subcategorization, we included all three object types – direct objects (DOBJ), second objects of ditransitive constructions (OBJ2), and prepositional arguments (IOBJ). Although OBJ2 is less frequent than other objects, it is important for identifying ditransitive frames. We included both types of clausal complements – XCOMP (infinitival/unsaturated) and CCOMP (finite/saturated) – and also PCOMP, which often signifies a *wh*-object of a preposition. We also included particles (PRT). Together, these eight GR types account for 62% of the GRs in the parsed BNC corpus. Using these GRs, there are 23 SCFs in our gold standard (see Section 5.1), of which the 15 with the highest type frequency are shown in Table 1.

Although modifiers are generally not included in SCFs (and are also excluded from our gold standard) we experimented with using them as features, to determine whether their distribution could help reach a better generalization. We focused on non-clausal modifiers (NCMOD). Counting them, the nine GR types account for 95% of the GRs in the BNC corpus.

[1] We count particles (here PRT) as a separate type, though RASP classifies them as a subtype of non-clausal modifiers.

Frame	Example sentence	Frame	Example sentence
SUBJ-DOBJ	Susan *found* the book.	SUBJ-XCOMP	Susan *wanted* to find the book.
SUBJ-DOBJ-IOBJ	Susan *put* the book on the table.	SUBJ-DOBJ-XCOMP	Susan *asked* Peter to attend.
SUBJ	Susan *knocked*.	SUBJ-DOBJ-IOBJ-PRT	Susan *filled* Peter in on the class.
SUBJ-IOBJ	Susan *appealed* to Peter.	SUBJ-CCOMP	Susan *believed* that Peter had found the book.
SUBJ-PRT	Susan *gave* up.	SUBJ-DOBJ-CCOMP	Susan *told* Betty that Peter had found the book.
SUBJ-DOBJ-PRT	Susan *picked* up the book.	SUBJ-DOBJ-OBJ2	Susan *gave* Betty a book.
SUBJ-PCOMP	Susan *thought* about whether she wanted to go.	SUBJ-IOBJ-XCOMP	Susan *appeared* to Peter to be worried.
SUBJ-IOBJ-PRT	Susan *gave* up on the project.		

Table 1: Fifteen SCFs with highest type frequency in our gold standard, with example sentences.

4 Methodology

4.1 Non-negative tensor factorization

Distributional co-occurrence data is usually represented in the form of a *matrix*. Matrices are perfectly suited for the representation of two-way co-occurrence data, but are unable to cope with multi-way co-occurrence data. We therefore make use of the generalization of a matrix, which is called a *tensor*. Tensor objects are able to encode co-occurrence data beyond two modes. Figure 1 shows a graphical comparison of a matrix and a tensor with three modes. Note that a tensor need not be restricted to three modes; in fact, our model requires tensors of up to 12 modes. Such tensors are difficult to represent visually, but the mathematical machinery remains unchanged.

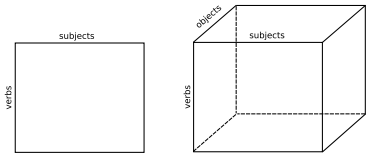

Figure 1: Matrix representation vs. tensor representation.

In order to create a succinct and generalized model of the extracted data, a statistical factorization technique called non-negative tensor factorization (NTF) is applied to the data. The NTF model is similar to parallel factor (PARAFAC) analysis – popular in areas such as psychology and bio-chemistry – with the constraint that all data needs to be non-negative (i.e. ≥ 0). PARAFAC is a multilinear analogue of the singular value decomposition (SVD), used e.g. in latent semantic analysis (Landauer and Dumais, 1997). The key idea is to minimize the sum of squares between the original tensor and the factorized model of the tensor. For an N-mode tensor $T \in \mathbb{R}^{D_1 \times D_2 \times \ldots \times D_N}$ this gives objective function (1), where k is the number of dimensions in the factorized model and $\circ$ denotes the outer product.

$$\min_{x_i \in \mathbb{R}^{D_1}, y_i \in \mathbb{R}^{D_2}, \ldots, z_i \in \mathbb{R}^{D_N}} \| T - \sum_{i=1}^{k} x_i \circ y_i \circ \ldots \circ z_i \|_F^2 \quad (1)$$

With non-negative tensor factorization, the non-negativity constraint is enforced, which yields a model with objective function (2).

$$\min_{x_i \in \mathbb{R}^{D_1}_{\geq 0}, y_i \in \mathbb{R}^{D_2}_{\geq 0}, \ldots, z_i \in \mathbb{R}^{D_N}_{\geq 0}} \| T - \sum_{i=1}^{k} x_i \circ y_i \circ \ldots \circ z_i \|_F^2 \quad (2)$$

The algorithm results in N matrices, indicating the loadings of each mode on the factorized dimensions. The model for the three-mode case is represented graphically in figure 2, visualizing the fact that the NTF decomposition consists of the summation over the outer products of N (in this case three) vectors.

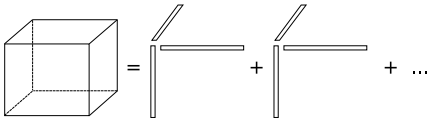

Figure 2: Graphical representation of the NTF as the sum of outer products.

Computationally, the NTF model is fitted by applying an alternating least-squares algorithm. In each iteration, two of the modes are fixed and the third one is fitted in a least squares sense. This process is repeated until convergence.[3]

4.2 Construction of verb-argument tensors

In order to discover SCFs and SPs, we construct a tensor that contains the multi-way co-occurrences of a verb and its different arguments.

4.2.1 Corpus data

We used a subset of the corpus of Korhonen et al. (2006), which consists of up to 10,000 sentences for each of approximately 6400 verbs, with data taken from five large British and American cross-domain corpora. To ensure sufficient data for each verb, we included verbs with at least 500 occurrences, yielding a total of 1993 verbs. The corpus data was tokenized, POS-tagged, lemmatized, and parsed with the RASP system (Briscoe and Carroll, 2002). RASP uses a tag-sequence grammar, and is unlexicalized, so that the parser's lexicon does not interfere with SCF acquisition. RASP produces output in the form of GRs. Passive sentences and those with clausal subjects were ignored.

4.2.2 Tensor construction

The corpus data is used to construct an N-mode tensor, where N represents the number of GRs. Each mode contains a different GR to the verb. Given the eight GRs from Section 3 plus the verb itself, this yields a 9-mode tensor (up to 12-mode when modifiers and split clausal modifiers are included; see Section 4.2.3).

For any particular verb instance (i.e. sentence), not every GR type will be instantiated. However, to model the multi-way co-occurrences in a tensor framework, each instance must have a feature for every mode to be incorporated into the tensor. Previous applications of non-negative tensor

[3]The algorithm has been implemented in MATLAB, using the Tensor Toolbox for sparse tensor calculations (Bader and Kolda, 2007).

factorization in NLP have not needed a representation for the non-instantiation of a mode. We introduce an empty, *void* (–) feature when a particular mode is not instantiated. For example, sentence (1) from Section 1 would be encoded as the tuple in (3):

(3) $\langle show_V, review_N, you_P, –, –, –, be_V, –, –\rangle$

indicating that the VERB, NCSUBJ, DOBJ, and CCOMP slots are filled with respectively $show_V$, $review_N$, you_P, *and* be_V, and that the remaining slots (IOBJ, OBJ2, PCOMP, XCOMP, PRT) are empty. (See Section 4.2.3 for alternative feature sets for each mode.)

Our final tensor then records how many times the tuple is attested in the corpus (i.e. how many times these particular features for the various grammatical relations occur together with the verb in question). The constructed tensor is then factorized to a limited number of latent dimensions, minimizing objective function (2). We normalize the factorization matrices to 1, to ensure a proper probability distribution.

Initially, we experimented with the number of latent dimensions of the factorization model (in the range 50–200). In further experiments, we retained the number of 150 dimensions, as this gave us the best results, and the model did not improve beyond 150 dimensions.

4.2.3 Feature sets

We constructed the feature sets for each mode in a number of different ways. Our base model uses the POS tag of the argument and no other features. We then experimented with a variety of additional features, based on linguistic intuitions about SCFS and SPS, as follows.

head The lexical head of the argument as well as the POS tag is used;

extpp PPS are extended to include the head of the PP's object, e.g. to_London_N (for the head models) or *to_N* (for the POS models) instead of simply *to*;

split both XCOMP and CCOMP are split up into two different modes to differentiate between null and lexicalized complementizers (e.g. for CCOMP, whether the complementizer is null or *that*);

mod modifiers (NCMOD) are included as an extra mode in the tensor.

Only the models with head features are relevant for SP acquisition. The head features also test how sensitive the learning of SCFS is to lexical-semantic as opposed to purely syntactic generalizations. The extended PP features provide additional lexical-semantic information. The clausal complement subtypes are available in the RASP output and offer a finer-grained syntactic analysis of these GRS. Finally, we used modifiers to test whether modifier co-occurrences, although (by definition) not part of the SCFS, might still be helpful in generalizing about subcategorization (i.e., maybe verbs taking similar frames also take similar modifiers). For each mode, we included the features that occurred with frequency ≥ 500 in the corpus, to maintain tractability.

For example, sentence (1) from Section 1 would be encoded as the tuple in (4) in the base POS-only model, and the tuple in (5) in the model with head and modifier features.

(4) $\langle show_V, N, P, –, –, –, V, –, –\rangle$

(5) $\langle show_V, review_N, you_P, –, –, –, be_V, –, –, comprehensively_R\rangle$

5 Experiment 1: SCF Induction

5.1 Evaluation method

SCF lexicons are traditionally evaluated against gold standards. We took the gold standard of Korhonen et al. (2006), which is a superset of SCFs in large dictionaries, and created a version using our eight basic GR types to define the SCFs. The resulting gold standard contains 183 general language verbs, with an average of 7.4 SCFs per verb. No attempt is made to distinguish between multiple senses of polysemous verbs; SCFs belonging to all senses are included for each lemma in the gold standard.

We evaluated the acquired SCF lexicons using type precision (percentage of SCF types that the system proposes which are correct), type recall (percentage of SCF types in the gold standard that the system proposes), and F-measure (the harmonic mean of type precision and recall).

We have two baselines. For baseline 1, we adopt the baseline of O'Donovan et al. (2005) which uniformly assigns to all verbs the two SCFs known to be most frequent in general language, transitive (SUBJ-DOBJ) and intransitive (SUBJ). This is a challenging baseline for SCF acquisition because of the Zipfian nature of SCF distributions: a small number of frequent SCFs are taken by the majority of verbs. For baseline 2, as described in Section 4.2.3, we use the base model with only POS features and none of the additional lexical or modifier features.

5.2 Mapping latent dimensions to SCFs

In order to evaluate this technique for SCF acquisition, we need to characterize each latent dimension according to its syntactic behaviour, i.e. map each dimension to a characteristic SCF.

Each latent dimension $\mathbf{z}$ is represented by a set of N vectors, indicating the loadings of each mode on $\mathbf{z}$. Because the loadings were normalized, each vector contains a probability distribution, over verbs or features. For a dimension $\mathbf{z}$ and a given mode (i.e. GR slot) we use the probability $p(\text{–}|\mathbf{z})$ of a void appearing in that slot to decide whether that slot is characteristically empty or filled for that dimension. For the verb mode, we use the probability $p(\mathbf{v}|\mathbf{z})$ to decide whether a verb $\mathbf{v}$ takes that dimension's characteristic SCF.

The mapping thus has two parameters. The first, θ_{verb}, represents the minimum $p(\mathbf{v}|\mathbf{z})$ for $\mathbf{v}$ to be assigned the characteristic SCF of $\mathbf{z}$. Based on early experiments, we chose to test three values for θ_{verb}, 0.001, 0.002, and 0.003.

The second parameter, θ_{void}, represents the maximum value of $p(\text{–}|\mathbf{z})$ at which the argument slot will be considered part of the SCF of $\mathbf{z}$. For example, if $p(\text{–}|\mathbf{z}) > \theta_{void}$ in the vector representing the DOBJ mode for $\mathbf{z}$, then the characteristic SCF of $\mathbf{z}$ does not include a direct object. We did not apply the θ_{void} threshold to subjects, but rather assumed that all characteristic SCFs include subjects; early experiments showed that subjects were otherwise sometimes erroneously excluded from the SCFs because the data contained high numbers of subjectless embedded clauses. For all other modes, we tested θ_{void} values from 0.1 to 0.8 in increments of 0.1.

The mapping process can be thought of as labeling the clusters produced by the tensor factorization. E.g. for a latent dimension $\mathbf{z}$ with a void value below θ_{void} for the DOBJ and IOBJ modes, its label is simply SUBJ-DOBJ-IOBJ. This label is assigned as an SCF to all the verbs with probabilities over θ_{verb} in $\mathbf{z}$.

If a dimension's characteristic SCF does not correspond to an SCF in the gold standard, that

Frame	# dims	Frame	# dims
SUBJ-DOBJ	29	SUBJ-XCOMP	17
SUBJ-DOBJ-IOBJ	9	SUBJ-DOBJ XCOMP	5
SUBJ	24	SUBJ-DOBJ-IOBJ-PRT	0
SUBJ-IOBJ	12	SUBJ-CCOMP	26
SUBJ-PRT	7	SUBJ-DOBJ-CCOMP	0
SUBJ-DOBJ-PRT	5	SUBJ-DOBJ-OBJ2	5
SUBJ-PCOMP	3	SUBJ-IOBJ-XCOMP	0
SUBJ-IOBJ-PRT	3		

Table 2: SCFs in order of type frequency in gold standard, with number of latent dimensions mapped to them (model features: POS, modifiers).

cluster is excluded from the evaluation. This typically happens with high values of θ_{void} because too many argument slots are simultaneously included in the SCF.

Note that multiple dimensions may be mapped to each SCF, because we chose the number of latent dimensions to be greater than the number of SCFs in the inventory. This decision allows the system to detect semantic structure in the data at a finer-grained level, which we hypothesized would improve overall accuracy on subcategorization acquisition, and to discover multiple lexical classes within a single argument slot. The relationship between number of dimensions mapping to an SCF and the frequency of the SCF is somewhat complex. To the extent that different verbs appear in different clusters, we expect that a larger number of dimensions mapping to an SCF roughly corresponds to higher type frequency of the SCF. However, some clusters contain more verbs than others; also, more clusters may indicate more semantic variability in argument slot fillers, without corresponding to higher frequency. A general relationship between type frequency and number of dimensions can be seen in Table 2, although note the high number of clusters mapped to the clausal complement frames SUBJ-XCOMP and SUBJ-CCOMP, possibly because these relations are semantically variable and used for adjuncts as well as arguments.

5.3 Tuning parameters

We used ten-fold cross-validation to tune the parameters θ_{verb} and θ_{void}, as well as to select the best feature combination (see Section 4.2.3). We randomly divided our test verbs into ten sets, each containing either 18 or 19 verbs. For each fold, we selected the parameters that gave the highest accuracy on the remaining nine-tenths of the verbs agaist the gold standard, and used those settings to acquire the lexicon for the 18 or 19 verbs in the fold.

For all ten folds, the best result was achieved with $\theta_{verb} = 0.001$ and $\theta_{void} = 0.4$, and with modifier features, but without extended PPs or split clause types. For seven of the folds, the best result was achieved with POS features, and for the other three with head features.

5.4 Results

Table 3 shows the results for our system after tuning with cross-validation. The parameters are: $\theta_{verb} = 0.001$, $\theta_{void} = 0.4$, POS and modifier features. Precision and recall are averaged over the ten folds. The standard deviation for precision was 4.3 and for recall 5.9. The final system achieves an F-measure of 68.7, well above the baseline 1 F-measure of 36.9, and nearly four

	P	R	F
Baseline 1	86.3	23.5	36.9
Baseline 2 (POS features)	53.1	83.3	64.8
Final system	61.0	78.5	68.7

Table 3: Results of cross-validation experiment. Precision and recall averaged over ten folds. F-score calculated as harmonic mean of the average P and R.

points better than the baseline 2 F-measure of 64.8. All of the improvement over baseline 2 is in precision, which shows that adding features beyond simple GR co-occurrences is beneficial to accurate SCF acquisition. Because of the Zipfian nature of SCF distributions, the system does not match the precision of baseline 1.

Direct comparison against previous unsupervised SCF acquisition methods on English was not possible because of the use of different data and frame inventories. However, best current methods involving handcrafted rules have reached a ceiling at an F-measure of about 70 (Korhonen et al., 2006; Preiss et al., 2007). Our results are promising considering the challenges of less supervised lexical acquisition.

5.5 Investigation of features

We also investigated the contribution of the different feature sets on the entire gold standard, using the values for θ_{verb} and θ_{void} which emerged from the cross-validation. The results of the different models are shown in Table 4 (note that the best result is slightly different from that in Table 3 because it is on the entire gold standard, not averaged over folds).

Table 4: Results for each feature set, with 150 dimensions, $\theta_{verb} = 0.001$, $\theta_{void} = 0.4$. ** significant difference from next row with $p < 0.01$, * with $p < 0.05$. †† significant difference from baseline (row 14) with $p < 0.01$, † with $p < 0.05$.

The differences in F-measure between the top few models are rather small, but the models show wide variance in precision and recall. Using the head words of the arguments as features seems to favor precision (rows 2, 3, 9, 15, 16), while using POS tags favors recall. This is probably because evidence for different arguments is less sparse using POS tags, making less frequent frames easier to identify, but finer-grained distinctions more difficult. The highest F-scores are achieved with modifier features (rows 1, 2); however, these models strongly favor recall over precision, suggesting that the general applicability of modifiers to many verb classes interferes with accurate identification of SCFs. More balanced models have head features and split clausal complement types (row 3), or head features, extended PPs, and split clausal types (row 9), without losing out on F-score. This suggests that lexical-semantic features are valuable for SCF acquisition. Another trend is towards more accurate models with fewer additional features; individual features and pairs of features seem to provide the most improvement (rows 1-7) over the base model (row 14), but the model with all additional features (row 16) has markedly worse performance, which may indicate a data sparsity problem.

We carried out significance tests for the mentioned model differences using stratified shuffling (Yeh, 2000). These tests indicate that most of the models (rows 1-11) have significantly higher F-score than the baseline, and most show significant pairwise differences in precision and recall.

Parameter tuning with cross-validation resulted in a θ_{void} of 0.4 (though exploration of the models in Table 4 showed that some models performed better with even lower values). This means that the model only needs to assign a relatively low confidence score to the void feature to infer that a slot is not part of an SCF. This is probably because adjuncts and other noise in the data means that these slots are filled some of the time. We observed many cases of void probabilities nearly equal to 1 in various dimensions – most verbs never occur with an OBJ2, for example. However, void probabilities tend to be fairly low for CCOMP and XCOMP.

5.6 Qualitative evaluation

Table 5 shows the accuracy by SCF for the fifteen most frequent frames, using the final model that resulted from cross-validation. The system performs very well on a number of SCFs, especially the most frequent ones such as SUBJ-DOBJ, SUBJ-DOBJ-IOBJ, and SUBJ, but also on some SCFs involving the semantically important particle verbs, such as SUBJ-DOBJ-PRT and SUBJ-IOBJ-PRT. Precision is lower on frames involving clausal complements (XCOMP and CCOMP), possibly because these GRs are used frequently for adjuncts. Accuracy is also poor on SUBJ-PCOMP and SUBJ-DOBJ-OBJ2. These GRs are rarer and may be subject to parser errors (e.g. OBJ2).

6 Experiment 2: SP Induction

6.1 Introduction

Our second experiment looks at the model's ability to induce SPs. We investigate the model's ability to induce *multi-way* SPs, i.e. the preference of the model for the co-occurrence of a particular verb and all of its particular arguments *at the same time*.

The calculation of a SP value according to our NTF model is fairly straightforward. Recall that our model yields probabilities $p(\mathbf{v}|\mathbf{z})$, i.e. the probability of a verb given a latent dimension, and, for each argument to the verb, $p(\mathbf{g}|\mathbf{z})$, i.e. the probability of an argument given a latent dimension. The final SP value $SP(v, GR)$ for a particular verb v and a list of arguments GR then amounts to calculating the product of the probabilities of the verb and the various GRs given a particular latent dimension, and summing over all dimensions (equation 3).

Frame	P	R	F	Frame	P	R	F
SUBJ-DOBJ	95.4	98.8	97.0	SUBJ-XCOMP	44.0	98.6	60.9
SUBJ-DOBJ-IOBJ	89.6	88.5	89.0	SUBJ-DOBJ-XCOMP	45.9	79.4	58.1
SUBJ	82.7	98.7	90.0	SUBJ-DOBJ-IOBJ-PRT	0.0	0.0	0.0
SUBJ-IOBJ	80.6	91.5	85.7	SUBJ-CCOMP	35.9	100.0	52.8
SUBJ-PRT	75.2	87.1	80.7	SUBJ-DOBJ-CCOMP	33.3	71.1	45.4
SUBJ-DOBJ-PRT	72.8	83.0	77.6	SUBJ-DOBJ-OBJ2	20.0	90.3	32.8
SUBJ-PCOMP	56.9	45.7	50.7	SUBJ-IOBJ-XCOMP	0.0	0.0	0.0
SUBJ-IOBJ-PRT	71.9	83.1	77.1				

Table 5: Results by SCF for fifteen most frequent frames in gold standard with best-performing model.

$$SP(v, GR) = \sum_{i=1}^{k} p(v|z_i) \prod_{g \in GR} p(g|z_i) \quad (3)$$

We evaluate our method's ability to induce SPs using the lexicalized (HEAD) model that achieves the best score in our first experiment, i.e. model 2 in Table 4.

6.2 Evaluation method

To evaluate the results of the NTF model with regard to SPs, we make use of a pseudo-disambiguation task (similar to the one used by Rooth et al. (1999)). The task allows us to evaluate the generalization capabilities of the model. For a particular tuple (viz. a verb and its various arguments) that appears in a held-out test corpus, we generate random instances in which one or several arguments are substituted by random instantiations. We exhaustively substitute every individual argument, as well as the various random combinations.[4] For the sentence in (1), this yields instances like:

(6) $\langle show_V, rabbit_N, you_P, –, –, –, be_V, –, –\rangle$

(7) $\langle show_V, consumption_N, tunnel_N, –, –, –, dream_V, –, –\rangle$

We then calculate SP values according to our model, both for the corpus instance and the random instances. A tuple is considered correct if our model prefers the corpus instance over all random instances. Accuracy is then calculated by averaging over all instances that are part of the test corpus.

We compare our NTF model to a simple non-negative matrix factorization (NMF) model, comparable to the unsupervised model presented by Rooth et al. (1999). For this model, a matrix was constructed that contains the pairwise co-occurrence frequencies of verbs and their various arguments. As noted before, a matrix is only able to represent two modes; hence, the first mode consists of the verbs, while the second mode contains the concatenated list of the different argument features. We used the same number of features as with the NTF model, and also factorized to 150 dimensions. According to the NMF model, a tuple is considered correct if, for each argument to the verb, the model prefers the verb-argument pair containing the attested argument over the verb-argument pair containing the random substitute. As a baseline, we

[4] We do not substitute empty argument slots with lexical arguments; neither do we substitute filled arguments slots with *void* values. This experiment solely focuses on the induction of selectional preferences; the induction of SCFs is evaluated in experiment 1.

include an uninformed random model, which makes a random choice among the various possibilities.[5]

The models are evaluated using ten-fold cross-validation: the corpus is divided into 10 equal parts; in each fold, models are trained on nine tenths of the corpus, and tested on the remaining tenth.

6.3 Results

The results of the ten-fold cross-validation are shown in table 6. The NTF model clearly outperforms the matrix factorization model with regard to the reconstruction of SPS, with the NTF model reaching a score about 10% higher than its NMF counterpart. These results indicate that the use of multi-way data leads to a richer and more accurate representation of SPS. For comparison, (Van de Cruys, 2009) achieved accuracy of 90.89 on a three-way pseudo-disambiguation task, which is less complex than our eight-way task.

	accuracy (%)
baseline	29.21 ± .08
NMF	69.71 ± .28
NTF	**77.78** ± .17

Table 6: Selectional preference accuracy using ten-fold cross-validation (mean accuracy and standard deviation)

6.4 Qualitative evaluation

Additionally, we performed a qualitative evaluation of the 150 latent dimensions yielded by our NTF model. This evaluation shows that our model is indeed able to capture semantic information from the data. Recall from Section 5.2 that multiple dimensions map to a single SCF. Our cluster analysis shows that such dimensions reflect semantic information. Below are three example dimensions (denoted by the top 10 verbs with highest value on each dimension) that all map to a simple transitive SCF.

dim 29 buy, sell, use, collect, produce, handle, remove, purchase, obtain, eat

dim 38 kill, love, see, like, marry, know, meet, visit, help, say

dim 44 examine, identify, see, consider, assess, investigate, discuss, study, determine, explore

The three different transitive SCFS clearly exhibit different semantic properties. Dimension 29 seems to represent a general 'trading' dimension, in which the DOBJ argument contains inanimate objects, largely goods. The DOBJ argument has nouns such as *thing*, *material*, *food*,... as its top features. Dimension 38, on the other hand, is a transitive frame where the DOBJ argument takes animate objects. The last dimension 44 represents a transitive frame in which the DOBJ argument takes abstract objects.

Among the dimensions that map to the SUBJ-IO SCF, i.e. a single PP argument, there are also some interesting semantic and syntactic distinctions. Dimension 91 clearly represents a 'travel' cluster with a location complement; the IO slot for this dimension is mostly PPs lexicalized with *to*. Dimension 122 is a 'communication' cluster, and again most of the prepositions in the IO slot are *to*. Dimension 123 consists of verbs that occur with *at*, largely vision and non-verbal

[5] Note that the number of possibilities for both tensor and matrix model is exactly the same.

communication verbs. Finally, dimension 134 is interesting, because there is no clear semantic cohesion, but it represents cluster of verbs that take PP *for*. This indicates that the model is learning both semantic and syntactic regularities.

dim 91 go, come, return, move, walk, get, run, rush, travel, fly

dim 122 talk, speak, listen, write, belong, happen, appeal, come, say, lie

dim 123 look, stare, smile, laugh, shout, gaze, glance, glare, grin, scream

dim 134 wait, pay, look, care, work, ask, vote, call, prepare, apply

The results presented here indicate that our model is able to capture syntactic as well as semantic properties. On a coarse-grained level, our model is able to induce a verb's different SCF frames. When we zoom in to the level of individual clusters, we notice that these clusters are often semantically cohesive, expressing the selectional preferences of the verb's argument slots. The ability to capture both syntax and semantics is an important advantage of our method.

7 Conclusion

We have presented a novel method for joint unsupervised SCF and SP acquisition which allows the incorporation of a range of features (syntactic, lexical and semantic) in the acquisition process. Although SCFs and SPs are closely related and can complement each other, to the best of our knowledge, no previous work has proposed a joint model for them.

Applying NTF to the multi-way co-occurrence tensor of verbs and their arguments, we are able to cluster verbs from a large corpus according to their syntactic and semantic behaviour. The SCF lexicon that emerges from the clusters yields an F-score of 68.7 against a gold standard, outperforming lexicons produced by our baseline methods. This performance is promising for a largely unsupervised method. The model yields an accuracy of 77.8 on a new pseudo-disambiguation evaluation for SPs, in which all arguments of the verb are considered at once, clearly outperforming a matrix factorization model. Our qualitative evaluation reveals that the method is indeed capable of learning rich lexical information about both syntactic and semantic aspects of verb behaviour in corpus data.

In the future, we plan to improve our approach in several directions. In addition to improving the detection of low accuracy SCFs through the use of lexical features that may help to distinguish arguments from adjuncts in clausal complements, we plan to improve precision by using e.g. statistical filtering. We also plan to extend the model to acquire finer-grained SCFs for English. This will involve e.g. refining SCFs with lexicalized elements and including semantically-based SCFs in the inventory, making use of the factorization method's ability to induce latent structure, as demonstrated by the SP evaluation. Finally, we intend to improve our SP acquisition through the use of a more extensive feature set.

A key advantage of this approach is that it is able to combine syntactic SCF and semantic SP acquisition. In the future, we plan to explore the joint induction of verb syntax and semantics in greater depth and look into modelling additional information about semantic verb classes which tend to capture similar SCF and SP behaviour. This could facilitate inducing a more comprehensive lexical resource that supplements the SCFs and SPs with a verb classification – in the style of VerbNet (Kipper-Schuler, 2005) – providing generalizations that can be useful for a wider range of NLP tasks.

ABSTRACT
We propose a novel associative approach for bilingual word lexicon extraction (BLE) from parallel corpora that relies on the paradigm of data reduction instead of data augmentation. The key insight of the approach is the effective usage of sub-corpora sampling and properties of low-frequency words in the task of lexicon induction, particularly in a setting where only limited parallel data are available. Word translation pairs are extracted from many smaller sub-corpora (sampled from the original corpus) according to several frequency-based criteria of similarity. We prove the validity of our data sampling approach, and show that this method outperforms IBM Model 1 and associative methods based on similarity scores and hypothesis testing in terms of precision and F-measure in the task of lexicon extraction. Additionally, we show that our sampling-based method can learn correct word translations from fewer data.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (CROATIAN)

Uzorkovanje Potkorpusa uz Primjenu u Ekstrakciji Dvojezičnih Rječnika

U radu se predlaže nov asocijativan pristup ekstrakciji dvojezičnih rječnika iz usporednih korpusa koji se oslanja na paradigmu smanjivanja količine podataka umjesto njezinog povećavanja. Ključna je ideja pristupa učinkovita uporaba uzorkovanja potkorpusa te svojstava niskofrekventnih riječi u zadatku indukcije rječnika, posebice u situacijama kada je na raspolaganju ograničen skup usporednih podataka. Prijevodni parovi riječi ekstrahirani su iz većeg broja manjih potkorpusa (uzorkovanih iz izvornog korpusa) temeljem nekoliko frekvencijski utemeljenih kriterija sličnosti. U radu je pokazana ispravnost našeg pristupa temeljenog na uzorkovanju potkorpusa. Pokazano je da ovaj postupak u smislu F-mjere na zadatku ekstrakcije leksikona nadmašuje IBM-ov Model 1 te asocijativne postupke temeljene na ocjenama sličnosti i testiranju hipoteze. Također je pokazano da naš postupak temeljen na uzorkovanju može naučiti ispravne prijevode riječi iz manjih količina podataka.

KEYWORDS: bilingual lexicon extraction, empirical word translation, sub-corpora sampling, data reduction, low-frequency words.

KEYWORDS IN CROATIAN: ekstrakcija dvojezičnih rječnika, empirijsko prevođenje riječi, uzorkovanje potkorpusa, smanjivanje količine podataka, niskofrekventne riječi.

COLING 2012, Mumbai, December 2012.

1 Introduction

Bilingual word lexicons serve as an invaluable and indispensable source of knowledge for both end users (as an aid for translators or other language specialists) and many natural language processing tasks, such as dictionary-based cross-language information retrieval (Carbonell et al., 1997; Levow et al., 2005) and statistical machine translation (Och and Ney, 2003).

In order to construct high quality bilingual lexicons for various domains, it is necessary to build such lexicons manually by hand or extract them automatically from parallel corpora. Compiling such lexicons manually is often a labor-intensive and time-consuming task, whereas parallel corpora either do not exist or are of limited size for most language pairs. Therefore the focus of the researchers has turned towards bilingual lexicon extraction (BLE) from comparable corpora (Rapp, 1995; Fung and Yee, 1998; Rapp, 1999; Diab and Finch, 2000; Fung and Cheung, 2004; Morin et al., 2007; Haghighi et al., 2008; Laroche and Langlais, 2010; Andrade et al., 2010; Shezaf and Rappoport, 2010; Vulić et al., 2011; Prochasson and Fung, 2011; Vulić and Moens, 2012; Tamura et al., 2012). However, such lexicons contain a great deal of noise and, moreover, the methods for BLE from comparable corpora typically rely on seed lexicons which are again hand-built or extracted from parallel corpora.

With respect to that observation, numerous systems for various applications trained on parallel or comparable data almost exclusively rely on knowledge from bilingual lexicons extracted from parallel texts. These lexicons are usually acquired from word translation probabilities of the IBM alignment models (Brown et al., 1993; Och and Ney, 2003) or obtained by associative methods such as the log-likelihood score or the Dice coefficient. They are then used in systems for extracting parallel sentences from non-parallel corpora (Fung and Cheung, 2004; Munteanu and Marcu, 2005), bilingual sentence alignment (Moore, 2002), estimating phrase translation probabilities (Venugopal et al., 2003), extracting parallel sub-sentential fragments from non-parallel corpora (Munteanu and Marcu, 2006), word-level confidence estimation (Ueffing and Ney, 2007), sub-sentential alignment for terminology extraction (Lefever et al., 2009), cross-lingual text classification and plagiarism detection (Pinto et al., 2009) and others.

High accuracy of automatically constructed bilingual word lexicons is the top priority for these systems. Church and Mercer (1993) advocate a simple solution of collecting more data in order to utilize statistical and stochastic methods in a more effective way. However, these systems are typically faced with only limited parallel data for many language pairs and domains (Resnik and Smith, 2003).

In order to tackle these issues, we propose a novel approach built upon the idea of *data reduction* instead of *data augmentation*. The method is directed towards extraction of only *highly reliable translation pairs* from *parallel data of limited size*. It is based on the idea of *sub-corpora sampling* from the original corpus. For instance, given an initial corpus $\mathscr{C}$ of 4 data items $\{I_1, I_2, I_3, I_4\}$, the construction of, say, a sub-corpus $SC = \{I_2, I_4\}$ may be observed as: (1) sampling items $I_2, I_4 \in \mathscr{C}$ for SC (hence the term sub-corpora sampling) or (2) removing data items I_1, I_3 from the original corpus $\mathscr{C}$, so that $SC = \mathscr{C} - \{I_1, I_3\}$ (hence the term data reduction). By reducing the size of the initial corpus, we typically decrease frequencies of the words in a newly formed sub-corpus. This simplifies the establishment of potential translation candidates, since that is now reduced to a problem of establishing reliable translational equivalence between low-frequency words. We explain the method for establishing translational equivalence based on the absolute frequency distributions of words in a sub-corpus. We exploit it in the construction of the algorithm for BLE. Moreover, each word exhibits a different distribution over items in each

newly built sub-corpus, and it is different from the fixed distribution in the original corpus. It allows us to identify different potential translation candidates in different sub-corpora and then form word translation tables by combining these evidences acquired from different sub-corpora. The key strength of the proposed algorithm is that it takes the entire initial corpus into account, regardless of its size, and at the same time it also benefits from the sampling of a vast number of different subsets/sub-corpora sampled from that initial corpus, and the evidences of potential word translation pairs coming from these sub-corpora.

In the remainder of the paper, we show that: (1) Bilingual lexicon extraction benefits from the concept of data reduction and sub-corpora sampling - the key intuitions, assumptions and the construction of the algorithm are provided in Section 2; (2) The proposed algorithm for BLE removes a lot of noise from the bilingual word lexicons by harvesting only the most accurate translation candidates, and it outscores other standard models for BLE from parallel data; (3) Due to the concept of data reduction, the proposed algorithm does not suffer from a problem of indirect associations; (4) Most importantly, the proposed algorithm outperforms other models for BLE when dealing with parallel data of limited size. The results are presented in Section 4. Finally, Section 5 lists conclusions and possible paths of future work.

2 Learning Translation Pairs Using Sub-Corpora Sampling

Section 1 has already provided a general intuition behind our method for mining translational candidates from aligned corpora. Now, we provide an in-depth description and analysis of our algorithm for bilingual word lexicon extraction. First, we explain the key reasoning that led us to our approach that relies on *data sampling*. Second, we provide the criteria for extracting translation candidates that purely rely on their distributional features, but do not employ any similarity-based measure or hypothesis testing for word association, and finally, we present our algorithm for BLE that processes words of all frequencies in an uniform way.

2.1 Why Sampling Sub-corpora?

The foundation of this work is built upon the so-called *Zipfian phenomenon* which states that, regardless of the size of a corpus, most of the distinct words occur only a small number of times. For instance, Moore (2004b) measures that in the first 500,000 English sentences taken from the Canadian Hansards data (Mihalcea and Pedersen, 2003), one finds 52,921 distinct word types, of which 60.5% occur five or fewer times, and, moreover, 32.8% occur only once. A general solution to mitigate the problem of low-frequency words is by augmenting the amount of input training data. However, that approach leads to a *chicken and egg problem* - adding more data will increase frequencies of the words already present in the corpus, and, accordingly, solve the issue of the low-frequency words, but at the same time, it will introduce many extra words, where some of them were previously out-of-vocabulary. Most of these new words will now be low-frequency words - again we observe the very same Zipfian phenomenon, and the problem of low-frequency words is still present. Therefore, we have decided to take an opposite path, where "removing" data from the initial corpus (that actually means sampling a sub-corpus with less data items from the original large corpus) and properties of low-frequency words (Moore, 2004b; Prochasson and Fung, 2011) should actually help us detect correct cross-lingual word associations. By reducing the corpus size, we also decrease frequencies of the words in the corpus. In an extreme case, when the reduced corpus consists of only one sentence, almost all words in that "corpus" will occur only once or twice. Intuitively, for words with higher frequencies, one needs to remove more data, i.e., to sample a sub-corpus of smaller size, to

bring the words down to only a few occurrences in the sub-corpus. We will show that it is easier to establish translational equivalence for low-frequency words.

2.2 Criteria for Extraction of Translation Pairs

Given is a source language S, a target language T, and a corpus $\mathscr{C}$ of N aligned item pairs $\mathscr{C} = \{(I_1^S, I_1^T), (I_2^S, I_2^T), \ldots, (I_N^S, I_N^T)\}$, where, depending on the corpus type, item pairs may be sentences, paragraphs, chunks, documents, etc. For parallel corpora, the item pairs are pairs of sentences. The goal is to extract potential translation candidates from the item-aligned set using only *internal distributional evidences*. Internal evidences, according to Kay and Röscheisen (1993), represent information derived only from the given corpora themselves. Our criteria for establishing translational equivalence between words are derived from this trivial case:

Imagine the scenario where a source word w_1^S occurs only once on the source side of the corpus $\mathscr{C}$, in a source item I_j^S. There is a target word w_2^T occurring in a target item I_j^T (which is aligned to I_j^S) and the word w_2^T also occurs only once on the target side of the corpus $\mathscr{C}$. Additionally, there does not exist another source word w_a^S such that it occurs only once on the source side of the corpus and, at the same time, exactly in the item I_j^S, and there does not exist another target word w_b^T that occurs only once on the target side of the corpus and exactly in the item I_j^T. Our key assumption is that the words w_1^S and w_2^T should then be listed as translation candidates. We can further generalize the intuition, that is, two words are extracted as translation candidates if they both satisfy the entire set of features $\mathscr{F}$, and there are no other words that satisfy this set of features.[1]

The set $\mathscr{F}$ may include various clues as features, but in our work we opt only for the internal, language-independent features that are related to the distributions of words over corpora. A source word w_1^S and a target word w_2^T are listed as potential translation candidates if they fulfil the following criteria:

1. The overall frequency of w_1^S on the source side of the corpus is equal to the overall frequency of w_2^T on the target side of the corpus.
2. The overall frequency of both words is above some minimum frequency threshold M_f.
3. w_1^S and w_2^T occur only in aligned item pairs, and with exactly the same frequency.
4. The number of aligned item pairs in which the words occur is above some minimum M_i.
5. There is no source word w_a^S such that the pair (w_a^S, w_2^T) satisfies all the previous conditions, and there is no target word w_b^T such that the pair (w_1^S, w_b^T) satisfies all the previous conditions.[1]

For instance, if the French word *pluie* occurs 4 times in the whole corpus, 2 times in item I_j^S, 1 time in item I_k^S, and 1 time in item I_l^S, and there is the English word *rain* that also occurs 4 times in total, 2 times in item I_j^T, 1 time in item I_k^T, and 1 time in item I_l^T, and there are no other words with the same frequency distribution in the corpus, we claim *(pluie, rain)* to be a pair of translation candidates.

In our work, we have opted for the listed criteria/constraints, but we are free to adjust or add more criteria if we want to boost a certain behavior of the model, that is, if we want to focus

[1] This specifies one-to-one alignment constraint, but more relaxed criteria are also possible. For instance, we could allow 2 or more target words to have the same features as a source word and then distribute partial link counts over all target candidates.

more on accuracy or on coverage of the lexicon. By imposing, for instance, stricter thresholds for M_f or M_i (e.g., accepting only candidates that occur in at least two items), we can direct the algorithm for lexicon extraction towards higher accuracy, and, vice versa, by relaxing the thresholds, we boost the coverage of the lexicon.

In summary, the proposed criteria for extraction of translation candidates are not biased towards high-frequency or low-frequency words, as they treat all words the same, trying to find potential candidates according to the defined set of features. However, in practice, the majority of the matched candidates will be low-frequency words.

2.3 The Algorithm for Lexicon Extraction

By employing the aforementioned criteria for extraction of translation candidates on the initial corpus $\mathscr{C}$, we are able to extract only a limited number of translation pairs, since distributional evidences for the large corpus $\mathscr{C}$ are fixed and unchangeable. But by sampling data from $\mathscr{C}$, we actually build a new corpus, a sub-corpus $SC \subset \mathscr{C}$ of size $K < N$, which now has a changed set of distributional evidences, which may lead to extracting additional translation candidates. The process of data reduction may be observed as a process of *sampling*, i.e., we randomly pick a subset of item pairs from $\mathscr{C}$, and build a new sub-corpus SC. We can then repeat the process, sample another sub-corpus and try to detect more translation candidate pairs.

Having the large corpus $\mathscr{C}$ of a finite size N, the number of different sub-corpora is huge, but finite. The exact number of different sub-corpora that can be sampled from $\mathscr{C}$ is $M_{\mathscr{C}} = \sum_{K=1}^{N} \binom{N}{K}$. Since we are clearly unable to process all the possible sub-corpora, we need to design a smart strategy to: (1) cover the entire initial corpus and (2) detect translation pairs for both high-frequency and low-frequency words.

2.3.1 One Sampling Round with Fixed Sub-Corpora Size

Let us fix the size of sub-corpora to some value K. We want to assure that every item pair from $\mathscr{C}$ is taken into account in at least one sub-corpus of size K. Additionally, we want to be able to repeat the procedure and obtain more different sub-corpora of the same size. The procedure is as follows:

1. Initialize: Detect the number of sub-corpora for this round: $\lfloor \frac{N}{K} \rfloor$.
2. Randomly shuffle the item pairs in $\mathscr{C}$ to obtain a permutation of the item pairs in $\mathscr{C}$.
3. Split $\mathscr{C}$ into sub-corpora of equal size K as follows:
   - For $i = 1, \ldots, \lfloor \frac{N}{K} \rfloor - 1$, assign the item pairs from position $(i-1) \cdot K + 1$ until position $i \cdot K$ to the sub-corpus SC_i.
   - Assign the remaining item pairs from position $(\lfloor \frac{N}{K} \rfloor - 1) \cdot K + 1$ until the end (position N) to the sub-corpus $SC_{\lfloor \frac{N}{K} \rfloor}$.

We build a set of $\lfloor \frac{N}{K} \rfloor - 1$ sub-corpora of size K and one sub-corpus of size $K + N \bmod K$, while, at the same time, we ensure that the complete original corpus $\mathscr{C}$ is covered. We will call the described procedure the *sampling round*. If we want to repeat the procedure and acquire another set of sub-corpora of the same size, we simply go back to Step 2 of the procedure and perform another sampling round.

2.3.2 The Final Algorithm: SampLEX

Now, we have everything set for the construction of the algorithm. In order to capture words with different frequencies, we need to vary the sub-corpora size K. With respect to the Zipf's law (Prochasson and Fung, 2011), we have decided to vary the values of K from N down to 1, where K is divided by 2 in each step of the loop (see the final algorithm). In that way, we ensure that all the words occur as low-frequency words in at least some sub-corpora of various sizes. Again, if we want to reduce frequencies of high-frequency words, we need samples of smaller sizes, so such words will typically learn its translation candidates from sampled sub-corpora consisting of only a few sentences. One pass of the algorithm from the values N to 1 is called an *iteration*.

We can detect potential translation candidates in many different sub-corpora (of various sizes). Additionally, we should assign more weight to translation pairs that fulfil the strict criteria in sub-corpora of larger size K. For instance, if we detect that two words have identical frequency distributions and have fulfilled all the criteria from Subsection 2.2 in a sub-corpus consisting of a few millions items, that evidence should be more important than detecting that the two words could be extracted from a sub-corpus comprising only a few sentences. Thus, for each potential translation pair t_{ij} we assign a corresponding overall score $c_{t_{ij}}$. If we detect that the two words that form the translation pair t_{ij} could be extracted from a sub-corpus of size K, we update the score $c_{t_{ij}} := c_{t_{ij}} + 1 \cdot weight_K$, where $weight_K = \lfloor \frac{N}{K} \rfloor$. This way we assign more importance when the pairs are extracted from larger sub-corpora. For instance, if we detect that two words from the potential translation pair t_{ij} are extracted as translation candidates from the original corpus $\mathscr{C}$, then $K = N$ and $c_{t_{ij}} := c_{t_{ij}} + 1$.

The final algorithm is as follows:

1. **Input:** The initial large corpus $\mathscr{C}$ of size N.
2. **Initialize:** (1) Define the criteria for extraction of translation candidates; (2) Initialize an empty lexicon L. Each entry in the lexicon L will have the following form: $(t_{ij}, c_{t_{ij}})$, where t_{ij} denotes the extracted translation pair consisting of a source word w_i^S and a target word w_j^T, while $c_{t_{ij}}$ is a variable that denotes the score for the translation pair t_{ij}.
3. **Set** initial sub-corpora size: $K := N$.
4. **Perform** one *sampling round* with the current sub-corpora size set to K (Subsection 2.3.1). We obtain $\lfloor \frac{N}{K} \rfloor$ different sub-corpora: $SC_1, \ldots, SC_{\lfloor \frac{N}{K} \rfloor}$, all of size K except the last one (its size is always $K + N \bmod K$).
5. **Extract** translation pairs from all sub-corpora obtained in Step 4. If a translation pair t_{ij} is already present in the lexicon L, update the score $c_{t_{ij}} := c_{t_{ij}} + 1 \cdot weight_K$ for that pair. Otherwise, add the translation t_{ij} to L and set its current score $c_{t_{ij}} := 1 \cdot weight_K$.
6. **Set** new sub-corpora size: $K := \lfloor K/2 \rfloor$.
7. **If** $K > 0$, **go** to Step 4. Otherwise, we have reached the end of one *iteration* and we need to **check** the stopping criteria (**go** to Step 8).
8. **Check** the stopping criteria: **if** no new translation pairs were extracted after the end of one whole iteration **or** we have reached the maximum or the predefined number of iterations **or** timeout, **go** to Step 9. Otherwise, **go** to Step 3.
9. **Output:** The lexicon L.

We will call this procedure the **SampLEX** algorithm. The proposed algorithm exhibits only one possible strategy for mining translation pairs from sub-corpora. For instance, we could

opt for another strategy when deciding how to change the size of sub-corpora, skip already processed sub-corpora, remodel the criteria for extraction from Section 2.2, change stopping criteria, or employ a procedure for the sub-corpora sampling different from the one presented in Subsection 2.3.1. However, our main goal is to propose a general framework for lexicon extraction when the data sampling approach is employed, where other researchers could design their own algorithms built upon the same idea.

2.3.3 Properties of the Algorithm

Reducing corpora size provides several benefits. First, establishing associations between translation candidates is much easier when we deal with low-frequency words - we reduce our problem to a *binary decision problem*. According to the specified criteria for extraction, two words are simply considered to be a translation pair, or they are not. By employing the criteria that rely on raw frequency counts as distributional evidences, we remove the need of an association measure based on hypothesis testing such as the G^2 statistic (Dunning, 1993; Agresti, 2002) or a similarity-based measure such as the Dice coefficient (Dice, 1945), which are often unreliable when dealing with low-frequency words (Manning and Schütze, 1999).

The *SampLEX* algorithm is *symmetric* and *non-directional*. The final output of the algorithm provides translation pairs along with their counts obtained after training. We can easily transform them into word translation probabilities to build word translation tables similar to those of IBM Model 1. Since the algorithm is symmetric, we can obtain both source-to-target and target-to-source word translation probabilities after the algorithm run is completed:

$$P(w_2^T|w_1^S) = \frac{c_{t_{12}}}{\sum_j c_{t_{1j}}} \qquad P(w_1^S|w_2^T) = \frac{c_{t_{12}}}{\sum_j c_{t_{j2}}} \tag{1}$$

Surprisingly, another modeling advantage lies in *randomness* when selecting sub-corpora. Namely, if we detect that two words constantly co-occur in aligned items randomly sampled from the large corpus, regardless of the surrounding context, it actually strengthens the confidence that those two words really constitute a translation pair. During the sampling procedure, sentences are moved from their "natural" surrounding of other sentences (the context in this case) and the new sub-corpus is built by randomly taking sentences from the entire corpus. If the same translational equivalence between the two words is encountered in more different sub-corpora, it also raises the *significance* of that equivalence. Also, by building sub-corpora of smaller sizes from the original large corpus, we perform an implicit *disambiguation* - a word occurring only once or twice in a small sub-corpus cannot bear more meanings in that sub-corpus, although it might have more meanings in the large superset corpus.

3 Experimental Setup

In this section, we present datasets used for training, training setup of the SampLEX method and state-of-the-art models for bilingual lexicon extraction from parallel data often used in real-life applications.

3.1 Training

3.1.1 Training Collections

We work with Europarl data (Koehn, 2005) for Dutch-English and Italian-English language pairs, retrieved from the website[2] of the OPUS project (Tiedemann, 2009). We use subsets of the corpora, comprising the first 300,000 sentence pairs. For Dutch-English, there are 76,762 unique Dutch words, and 37,138 unique English words. For Italian-English, there are 68,710 unique Italian words and 37,391 unique English words. The unbalance between the number of unique vocabulary words is mostly due to a richer morphological system in Italian and the noun compounding phenomenon in Dutch.

Since we also want to test and evaluate the behavior of our system in a setting where only limited parallel data are present, we construct additional subsets of Europarl data consisting of the first 2,000, 10,000 and 50,000 sentence pairs from the corpora.

3.1.2 Training Setup of the SampLEX Method

Parameter values are set to the same values for all training datasets. We set $M_f = M_i = 0$, which means that all words that occur in a sub-corpus at least once may be extracted. By setting some higher thresholds M_f and M_i, we could move the algorithm towards extracting lexicons of higher accuracy, but lower coverage. We stop our training procedure for *SampLEX* after 1000 iterations for all corpora. The SampLEX algorithm converges quickly - many translations are found in the first few iterations. However, having more iterations implies obtaining more different evidences from different sub-corpora and assigning more significance for the extracted candidates (see Subsection 2.3.3). Therefore, we have decided to use 1000 iterations for safety. Other stopping criteria are also possible (see Step 8 in Subsection 2.3.2).

3.2 State-of-the-Art Models for BLE

In order to evaluate the performance of our *SampLEX* algorithm for bilingual lexicon extraction, we compare it with other models that constitute state-of-the-art for BLE, and are often used in real-life applications (see Section 1).

3.2.1 IBM Model 1

Our first baseline is IBM Model 1 (Brown et al., 1993) for word alignment, which is a purely lexical model, i.e, the only set of parameters employed by the model are word translation probabilities. We omit the exact generative story for IBM Model 1, but the curious reader may find all the details in (Brown et al., 1993) or (Och and Ney, 2003). Word translation probability $P(w_2^T|w_1^S)$ denotes a probability that a source word w_1^S generates a target word w_2^T. These probabilities can then be used to decide upon translational equivalence between words and to build bilingual lexicons from parallel texts.[3] That makes it comparable to our *SampLEX* model, which can also output word translation probabilities (Equation 1). IBM Model 1 is used in many systems as a primary tool for bilingual lexicon extraction from parallel data (e.g., Venugopal et al. (2003), Munteanu and Marcu (2005), Munteanu and Marcu (2006), Lefever et al. (2009)). We use standard GIZA++ settings and train IBM Model 1 with 5 iterations

[2] http://opus.lingfil.uu.se/Europarl3.php

[3] We have also tried to use word translation probabilities from the higher order IBM Models, but we have not detected any major difference in results on the task of bilingual word lexicon extraction.

(**IBM1-i5**) and 20 iterations (**IBM1-i20**) of the EM algorithm, as often found in the literature (Och and Ney, 2003; Moore, 2004a).

3.2.2 The Dice Coefficient

Another baseline model is a similarity-based model relying on the Dice coefficient (**DICE**):

$$DICE(w_1^S, w_2^T) = \frac{2 \cdot C(w_1^S, w_2^T)}{C(w_1^S) + C(w_2^T)} \tag{2}$$

where $C(w_1^S, w_2^T)$ denotes the co-occurrence count of words w_1^S and w_2^T in the aligned items from the corpus. $C(w_1^S)$ and $C(w_2^T)$ denote the count of w_1^S on the source side of the corpus, and the count of w_2^T on the target side of the corpus, respectively. The Dice coefficient was used as an associative method for word alignment by Och and Ney (2003), Tiedemann (2003) used it as one associative clue for his clue-based word alignment, and Melamed (2000) used it to measure the strength of translational equivalence.

3.2.3 Log-Likelihood Ratio

Another associative model that we use is based on the log-likelihood-ratio (**LLR**), that is derived from the G^2 statistic (Dunning, 1993). LLR is a more appropriate hypothesis testing method for detecting word associations from limited data than the χ^2 test (Manning and Schütze, 1999) and was previously used as an effective tool for automatically constructing bilingual lexicons (Melamed, 2000; Moore, 2001; Munteanu and Marcu, 2006). Its definition is easily explained on the basis of a contigency table (Kilgarriff, 2001; Padó and Lapata, 2007), which is a four-cell matrix for each pair of words (w_1^S, w_2^T) (see Table 1).

	w_1^S	$\neg w_1^S$
w_2^T	k	l
$\neg w_2^T$	m	n

Table 1: The contigency table for a pair of words (w_1^S, w_2^T).

The contingency table records that source word w_1^S and target word w_2^T co-occur in k aligned item/sentences pairs, and w_1^S occurs in m aligned pairs in which w_2^T is not present. Similarly, w_2^T occurs in l aligned pairs in which w_1^S is not present, and n is the number of aligned pairs that involve neither w_1^S nor w_2^T. The final formula for the log-likelihood ratio is then defined as:

$$\begin{aligned} LLR(w_1^S, w_2^T) = G^2(k,l,m,n) = 2(&k\log k + l\log l + m\log m + n\log n \\ &-(k+l)\log(k+l) - (k+m)\log(k+m) \\ &-(l+n)\log(l+n) - (m+n)\log(m+n) \\ &+(k+l+m+n)\log(k+l+m+n)) \end{aligned} \tag{3}$$

High LLR scores can indicate either a positive association or a negative one (Moore, 2004b). Since we expect translation pairs to be positively associated, we impose an additional constraint: $P(w_1^S, w_2^T) > P(w_1^S) \cdot P(w_2^T)$, where $P(w_1^S, w_2^T) = \frac{k}{k+l+m+n}$, $P(w_1^S) = \frac{k+m}{k+l+m+n}$ and $P(w_2^T) = \frac{k+l}{k+l+m+n}$. This constraint keeps only positively associated words in the lists of potential translation candidates.

3.3 Evaluation Methodology

3.3.1 Lists of Ground Truth Translation Pairs

In order to evaluate the BLE models, we have designed a set of ground truth translations - we have randomly sampled a set of Dutch content words that occur in the full corpus comprising 300, 000 sentences. Following that, we have used the *Google Translate* tool plus an additional annotator to translate those words to English. The annotator has manually revised the lists and has kept only words that have their corresponding translation in the English vocabulary. In order to build a one-to-one ground truth dataset of translations, only one possible translation has been annotated as correct. In case when more than 1 translation is possible, the annotator has marked as correct the translation that occurs more frequently in the English Europarl data. Finally, we have come up with a set of 1001 ground truth one-to-one translation pairs. We have followed the same procedure for Italian-English and have also constructed a set of 1001 ground truth translation pairs.[4]

3.3.2 Evaluation Metrics

All the methods under consideration actually retrieve ranked lists of translation candidates. Let us keep only the first translation candidate from each ranked list, and build a non-probabilistic lexicon of one-to-one word translations: L_e. Assuming that we now have a set G of ground truth one-to-one word translation pairs, we can evaluate the quality of our lexicon with respect to the ground truth set G. We use standard precision, recall and F-Measure ($\beta = 1$) scores as our evaluation metrics:

$$Prec_{L_e,G} = \frac{|L_e \cap G|}{|L_e|} \qquad Rec_{L_e,G} = \frac{|L_e \cap G|}{|G|} \qquad F_{L_e,G} = (1+\beta^2)\frac{Prec_{L_e,G} \cdot Rec_{L_e,G}}{\beta^2 \cdot Prec_{L_e,G} + Rec_{L_e,G}}$$

Since sometimes a word has more than one correct translation (e.g., Dutch word *verklaring* can be translated as both *statement* and *declaration*), and the current evaluation setting cannot capture that phenomenon, we also evaluate the quality of the lexicon in a more lenient setting, where, instead of performing the hard cut-off, i.e., instead of keeping only the top candidate from the ranked list, we keep the ranked list of all the candidates from the list and calculate the *mean reciprocal rank* (MRR) (Voorhees, 1999). For a source word w_i^S, $rank(w_i^S)$ denotes the rank of its correct translation (as provided by the set of ground truth translation pairs) within the retrieved list of potential translation candidates. MRR of the lexicon is then defined by the following formula:

$$MRR_{L_e,G} = \frac{1}{|L_e|} \sum_{w_i^S \in L_e} \frac{1}{rank(w_i^S)} \tag{4}$$

4 Results and Discussion

We conduct several experiments to measure the quality of the lexicon constructed using the *SampLEX* algorithm: (1) we evaluate the lexicon obtained by SampLEX using the full corpus of 300, 000 sentences, and compare its accuracy with the accuracy of baseline systems from Section 3.2 trained on the same corpus, (2) after performing the error analysis, we carry out another set of experiments that prove that the *SampLEX* algorithm, due to its modeling

[4] We will make the datasets publicly available.

properties, alleviates the problem of *indirect associations* and, finally, (3) we test our lexicon in a setting where only limited parallel data are available and show that the *SampLEX*-based lexicon outperforms other bilingual word lexicons in that setting in terms of quality provided by the F-measure and precision scores.

4.1 Experiment I: Testing the Quality of the Lexicon in Terms of Precision

Unlike our baseline state-of-the-art systems for BLE, the *SampLEX* algorithm does not assure the full coverage of the source vocabulary, as it does not necessarily build ranked lists of translation candidates for all the words observed during training. However, our claim is that translation pairs obtained by *SampLEX* are of higher quality than those obtained by the baseline systems. Therefore, with this experiment we want to answer the following question: "Are translation pairs obtained by the SampLEX algorithm really more accurate than translation pairs obtained by other methods?". In order to answer that question, we calculate the precision and MRR scores on our ground truth datasets for Italian-English and Dutch-English, where all the BLE methods have been trained on the full 300,000 datasets. The obtained scores are presented in Tables 2 and 3.

	Dutch-English				
	IBM1-i5	**IBM1-i20**	**DICE**	**LLR**	**SampLEX**
Prec(300k)	0.7113	0.7023	0.6963	0.7662	**0.8221**
MRR(300k)	0.8196	0.8045	0.7767	0.8542	**0.9069**

Table 2: Precision and MRR scores for all models trained on the first 300,000 sentences of Dutch-English Europarl data, and evaluated on the sets of 1001 ground truth translation pairs for Dutch-English.

Prec(300k)	0.7912	0.7752	0.7932	0.8361	**0.8771**
MRR(300k)	0.8781	0.8588	0.8494	0.8945	**0.9250**

Table 3: Precision and MRR scores for all models trained on the first 300,000 sentences of Italian-English Europarl data, and evaluated on the sets of 1001 ground truth translation pairs for Italian-English.

As previously shown by Moore (2004a), LLR serves as a better associative method than the Dice coefficient for the word alignment task. We obtain the same finding for bilingual lexicon extraction. Additionally, the model based on LLR is also better than IBM Model 1 when applied for BLE. Munteanu and Marcu (2006) drew the same conclusion, and they used the LLR-based lexicon in their system when a higher precision of the lexicon was paramount. However, the results reveal that the quality of the lexicon obtained by the *SampLEX* algorithm is superior to the LLR-lexicon *in terms of precision* and, consequently, to all other evaluated lexicons.

4.2 Experiment II: Investigating Indirect Associations

When examining the results, we have detected that one advantage of our SampLEX algorithm is due to its mitigating the phenomenon of the so-called indirect associations. Indirect associations,

as defined by Melamed (2000), are associations between words that have a tendency to co-occur much more often than expected by chance, but are not mutual translations. Lexicon extraction models unaware of the indirect associations tend to give translational preference to higher-frequency words. Considering the fact that one key assumption of our model is sub-corpora sampling that causes decreasing frequencies of words in the obtained sub-corpora from which translation pairs are learned, our model should successfully mitigate the problem of indirect associations. Indeed, during the error analysis, we have detected that both IBM Model 1 and LLR provide a wrong translation of the Dutch word *beschouwen (consider)*, since both models retrieve the English word *as* as the first translation candidate (due to a very high frequency of the collocation *consider as*). Other examples of the same type include the Dutch word *integreren (integrate)* which is translated as *into*, *betwijfelen (doubt)* which is translated as *whether*, or an Italian example of the verb *entrare (enter)* which is translated as *into*. Our BLE model, on the other hand, provides correct translations for all these examples. Dagan et al. (1993) noted that collocates often tend to cause confusion among algorithms for bilingual lexicon extraction. More examples include the Dutch word *opinie (opinion)*, translated as *public* by IBM Model 1 and LLR (due to a high frequency of the collocation *public opinion*), the Dutch word *cirkels (circles)*, translated as *concentric*, or the Italian word *pensionabile (pensionable)*, translated as *age*. All these examples are again correctly translated by our model for lexicon extraction.

In order to test the hypothesis that our lexicon extraction model does not suffer from the problem of learning indirect associations, we have conducted a small experiment. For the purpose of the evaluation, we have constructed a small dataset of 219 Italian verbs in first person plural of the present tense. We have also constructed the set of ground truth translations in the same way as in Subsection 3.3.1. These verbs are easy to extract because they all have the same suffix *-iamo* (e.g., the verb *respiriamo*, meaning *(we) breathe*). If the problem of indirect associations for a lexicon extraction method is prominent, the English word *we* will appear as the first translation for many of these verbs, instead of the word that really bears the content of the verb (e.g., *breathe*). Table 4 shows precision and MRR scores for the lexicon extraction models evaluated on this toy dataset. As expected, due to its modeling property related to the

	IBM1-i5	**DICE**	**LLR**	**SampLEX**
Prec(300k)	0.4475	0.4201	0.6119	**0.8584**
MRR(300k)	0.5575	0.5108	0.7300	**0.9140**

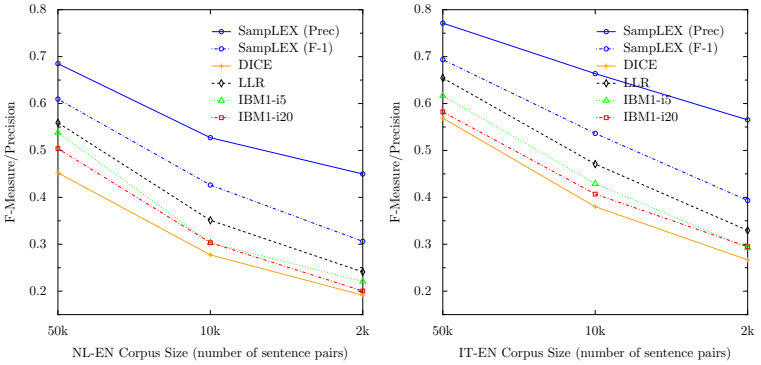
Table 4: Precision and MRR scores on our evaluation set consisting of Italian *-iamo* verbs (present tense, first person plural).

reduction of word frequencies, our BLE model does not suffer from the problem of indirect associations like other models. That property eventually has a positive impact on precision and MRR scores and the overall quality of the lexicons obtained by our SampLEX algorithm.

4.3 Experiment III: Experiments with a Limited Amount of Parallel Data

In a real-life situation, one often possesses only limited parallel data (e.g., terminology texts from special, very narrow domains and sub-domains). With this final set of experiments we test the performance of all the models for lexicon extraction in such a setting with limited parallel data. To simulate the shortage of data, we have extracted three additional corpora of smaller sizes by selecting the first 2,000, 10,000 and 50,000 sentence pairs from our Dutch-English and Italian-English Europarl data. From our initial ground truth set (Subsection 3.3.1), we

have only kept the words that occur at least once in the respective corpora as ground truth for evaluations (e.g., there are 444 words in the ground truth dataset for the corpus consisting of the first Dutch-English 2,000 sentence pairs, and 931 words for the corpus consisting of the first 50,000 Dutch-English sentence pairs). Our question is now: "Are lexicons extracted by SampLEX really of better quality than lexicons obtained by other methods when dealing with parallel corpora of limited size?" As mentioned before, the *SampLEX* algorithm does not have a property to provide results in a form of ranked lists for the entire source vocabulary, but we claim that *SampLEX* is directed towards extracting only highly reliable and precise candidates which, consequently, leads to lexicons of a higher quality. That claim is again supported by the findings presented in Figure 1(a) for Dutch-English, and in Figure 1(b) for Italian-English.



(a) Dutch to English (b) Italian to English

Figure 1: Precision and F-Measure scores over parallel corpora of different size (2k, 10k and 50k aligned sentence pairs). Since *SampLEX* does not necessarily obtain the lists of translations for all words in a vocabulary, its precision scores are different than its F-measure scores. For all other models within this evaluation setting, it is valid: *Precision=Recall=F-measure*.

We have also performed an additional experiment to test whether the translation candidates for Dutch and Italian words that happen to be retrieved by the *SampLEX* algorithm still display better overall precision and MRR scores than the translation candidates for the same Dutch and Italian words obtained by the other methods. If that is not true, we could use *SampLEX* only to extract source words for which a translation might be found, but the particular translation for each extracted word could then be obtained by some other method. However, it is not the case, as the results in Tables 5 and 6 reveal. As noted in the literature (Manning and Schütze, 1999), we observe that, of all the baseline models for BLE, LLR suffers the least from data sparsity, but still performs worse than our method.

Since *SampLEX* is built on the concept of data sampling, the criteria for extracting translation candidates and the whole training process inherently remain the same when working with parallel corpora of limited size. However, it is natural that the results decrease when the size of the large corpus $\mathscr{C}$ decreases. The more data we possess, the more sub-corpora we can sample, which finally provides better chances to extract correct translation pairs. We could say

that *SampLEX* takes the best of both worlds - it benefits from the idea of data reduction, yet it provides better scores when more input data are available.

5 Conclusions and Future Work

In this paper, we have proposed a statistical framework for the construction of a bilingual word lexicon built upon the idea of sampling many smaller sub-corpora from an initial larger item-aligned corpus.

The *SampLEX* algorithm for bilingual lexicon extraction presented in the paper is directed towards extraction of only highly reliable word translation pairs. After comparisons with other models for BLE from parallel data, we have proved that *SampLEX* builds word lexicons of higher accuracy and overall quality as revealed by the F-measure and precision scores, which is especially important in a setting where only a limited amount of parallel data is available. The proposed framework allows for many further experimentations and possible applications. The description of the framework provided in the paper is generic - it is language-independent and applicable to any corpus that provides some sort of alignment (at the sentence, paragraph or document level). In future work, we plan to design algorithms for mining word translations from comparable corpora based on the similar idea of sub-corpora sampling.

Acknowledgments

The research has been carried out in the framework of the TermWise Knowledge Platform (IOF-KP/09/001) funded by the Industrial Research Fund, KU Leuven, Belgium.

ABSTRACT
Online discussion forums are a valuable means for users to resolve specific information needs, both interactively for the participants and statically for users who search/browse over historical thread data. However, the complex structure of forum threads can make it difficult for users to extract relevant information. Automatically identifying whether the problem in a thread has been solved or not can help direct users to threads where the original problem has been solved, hence enhancing their prospects of solving their particular problem. In this paper, we investigate the task of Solvedness classification by exploiting the discourse structure of forum threads. Experimental results show that simple features derived from thread discourse structure can greatly boost the accuracy of Solvedness classification, which has been shown to be very difficult in previous research.

KEYWORDS: Discourse Structure, Web User Forum, Social Media, Dialogue Act.

Proceedings of COLING 2012: Technical Papers, pages 2739–2756,
COLING 2012, Mumbai, December 2012.

1 Introduction

Web user forums (or simply "forums") are online platforms for people to discuss information and obtain information via a text-based threaded discourse, generally in a pre-determined domain (e.g. IT support or DSLR cameras). With the advent of Web 2.0, there has been an explosion of web authorship in this area, and forums are now widely used in various areas such as customer support, community development, interactive reporting and online eduction. In addition to providing the means to interactively participate in discussions or obtain/provide answers to questions, the vast volumes of data contained in forums make them a valuable resource for "support sharing", i.e. looking over records of past user interactions to potentially find an immediately applicable solution to a current problem. On the one hand, more and more answers to questions over a wide range of domains are becoming available on forums; on the other hand, it is becoming harder and harder to extract and access relevant information due to the sheer scale and diversity of the data.

In the domain of troubleshooting-oriented forums, one potential way to enhance information access and support sharing is to automatically identify threads where the original information need has been resolved. By filtering out threads which do not contain a valid answer, we can focus the attention of users on threads which have a greater chance of containing the required solution. Baldwin et al. (2007) explore this task of Solvedness classification, and find that it is an extremely difficult problem. Figure 1 shows an example thread, made up of 5 posts from 3 distinct participants, from the ILIAD (Improved Linux Information Access by Data Mining) dataset of Baldwin et al. (2007). In this thread, Post1 and Post3 are both from the thread's initiator UserA. Post1 asks a question, and Post3 asks for more information about an answer provided by UserB in Post2. In response to Post3, UserB adds more information to his/her original answer, and Post5 provides another independent answer. In threads like this, it is important to identify whether the problem is solved or not, and also where solution(s) are likely to be found.

This research proposes to use information derived from thread discourse structure (Kim et al., 2010b; Wang et al., 2011) to help predict Solvedness of threads, without validating the answers provided in the threads. The discourse structure of the thread is modelled as a rooted Directed Acyclic Graph (DAG), and each post in the thread is represented as a node in this DAG. The reply-to relations between posts are then denoted as direct edges (Links) between nodes in the DAG, and the type of a reply-to relation is defined as Dialogue Act (DA). The Link between two connected posts (i.e. having a reply-to relation) is represented as the distance between the two posts in their chronological ordering. In the annotated version of the example ILIAD thread, as is shown in Figure 1, UserA initiates the thread with a question (Dialogue Act = Question-question: (Kim et al., 2010b)) in the first post, by asking a question. In response, UserB provides an answer (Dialogue Act = Answer-answer). Then, UserA confirms more details about the answer provided (Dialogue Act = Answer-confirmation). UserB responds to UserA to add more information about his/her previous answer (Dialogue Act = Answer-add). Finally, UserC proposes an independent answer again to the original question (Dialogue Act = Answer-answer).

Specifically, we explore features extracted from the thread discourse structure which can be used to help classify the Solvedness of threads. We experiment with both gold-standard and automatically predicted discourse structure, and find that thread discourse structure (which in no way evaluates the correctness of each post) can, indeed, boost thread classification accuracy,

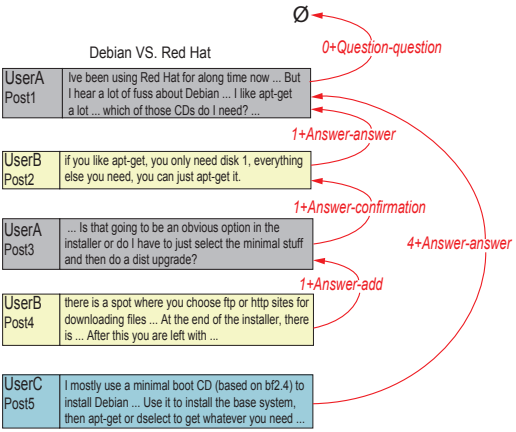

Figure 1: A snippeted ILIAD thread with annotated discourse structure.

achieving state-of-the-art results over the task. We also investigate the correlation between thread discourse structure prediction F-score and thread Solvedness classification accuracy, and demonstrate a positive correlation. Finally, we show that focusing on improving the F-score over certain dialogue acts is able to boost Solvedness classification.

2 Related Work

As far as we are aware, there is very little NLP work that is specifically targeted at the thread-level analysis of web user forum data. The most closely-related work is that performed by Baldwin et al. (2007), on which this work is directly based. Baldwin et al. (2007) focused on three specific characteristics detected from forum threads, namely *Task orientation* (i.e. whether a thread focuses on solving a problem), *Completeness* (i.e. whether the initial post provides enough information of the problem) and *Solvedness* (i.e. whether the problem is solved). Three classification tasks were identified base on these three characteristics, and experiments were carried out using a range of classification and regression methods. Baldwin et al. (2007) explored not only bag-of-words features, but also another 18 lexical and contextual features from distinct partitions of the thread, namely *initial posts*, *first response post*, *all responses posts* and *final post from the initiator*. 250 threads with various topics from a Linux-related forum and mailing list were annotated for use in the experiments in the paper. While the experimental results illustrated the difficulties in performing the three tasks automatically, the experiments also implied that their approach could be employed to rank threads based on their characteristics.

Research on thread discourse structure analysis and classification over user forums has gained in momentum in recent years. Fortuna et al. (2007) defined 5 post-level dialogue acts to describe the levels of agreement (i.e. agreement, disagreement, insult) and identify questions and answers (i.e. question and answer) in forum posts. Xi et al. (2004) defined 5 prevalent types of post-level dialogue acts in forum threads. This set of dialogue acts was then adapted

and extended by Kim et al. (2010b) to describe possible types of posts in troubleshooting-oriented online forums. Specifically, Kim et al. (2010b) devised a post-level dialogue act set and annotated a set of threads taken from CNET.[1] In this work, they proposed a set of novel features, which they applied to the separate tasks of post link classification and dialogue act classification. They later applied the same basic methodology to dialogue act classification over one-on-one live chat data with provided message dependencies (Kim et al., 2010a), demonstrating the generalisability of the original method. In both cases, however, they tackled only a single task, either link classification (optionally given dialogue act tags) or dialogue act classification, but never the two together.

Wang et al. (2011) delved into the task of thread discourse structure parsing further. They used the same features as Kim et al. (2010b), but different parsing approaches. Specifically, Wang et al. (2011) approached thread discourse structure parsing as a joint link and dialogue act classification task, by using CRFSGD (Bottou, 2011) and MaltParser (Nivre et al., 2007). They also demonstrated that the methods they use for thread discourse structure parsing are able to perform equally well over partial threads as complete threads, by experimenting with "in situ" classification of evolving threads.

There is also research focusing on particular types of dialogue acts, such as question–answer pairs in emails (Shrestha and McKeown, 2004) and forum threads (Cong et al., 2008), question–context–answer in forum threads (Cong et al., 2008; Ding et al., 2008; Cao et al., 2009), initiation–response pairs (e.g. question–answer, assessment–agreement, and blame–denial) in forum threads (Wang and Rosé, 2010), as well as request and commitment in emails (Lampert et al., 2007, 2008a,b, 2010).

Thread discourse structure can be used to facilitate different tasks in web user forums. For example, threading information has been shown to enhance retrieval effectiveness for post-level retrieval (Xi et al., 2004; Seo et al., 2009), thread-level retrieval (Seo et al., 2009; Elsas and Carbonell, 2009), sentence-level shallow information extraction (Sondhi et al., 2010), and near-duplicate thread detection (Muthmann et al., 2009). Moreover Wang and Rosé (2010) demonstrated that initiation–response pairs (e.g. question–answer, assessment–agreement, and blame–denial) from online forums have the potential to enhance thread summarisation and automatically generate knowledge bases for Community Question Answering (cQA) services such as Yahoo! Answers. Furthermore, Kim et al. (2006) showed that dialogue acts can be used to classify student online discussions in web-enhanced courses. Specifically, they use dialogue acts to identify discussion threads that may have unanswered questions and need the attention of an instructor.

These previous research efforts suggest that the thread structural representation used in Wang et al. (2011), which includes both linking structure and the dialogue act associated with each link, could potentially provide even greater leverage in these tasks. We specifically target the thread-level task of Solvedness classification as it is conceptually the most difficult of the three classification tasks proposed by Baldwin et al. (2007), and intuitively, it is the task which stands to gain the most from discourse parsing.

3 Data Description

We use ILIAD (Improved Linux Information Access by Data Mining) data set created by Baldwin et al. (2007), which contains threads crawled from Linuxquestions[2] and Debian mailing lists.[3] The ILIAD dataset is made up of 250 threads, which are annotated with three Boolean thread-level labels, namely *Task Orientation*, *Completeness* and *Solvedness*. This paper only explores the classification task of Solvedness, which addresses the question of "is there a documented solution to the original problem described by the thread initiator in the thread (including the possibility of URLs pointing off to solutions elsewhere on that same forum or generally on the web)?" A detailed description of the other tasks and the dataset is presented in Baldwin et al. (2007).

To explore the task of using discourse structure to predict the Solvedness of a thread, we annotated the ILIAD threads for discourse structure based on the dialogue act set proposed by Kim et al. (2010b). The dialogue act set is made up of 5 super-categories: Question, Answer, Resolution, Reproduction and Other. The Question category contains 4 sub-classes: question, add, confirmation and correction. Similarly, the Answer category contains 5 sub-classes: answer, add, confirmation, correction and objection. For example, the label Question-add signifies the Question superclass and add subclass, i.e. addition of extra information to a question. For full details of the original dialogue act tagset, see Kim et al. (2010b).

The original dialogue act set was developed primarily over troubleshooting-oriented threads (i.e. the CNET dataset described in Section 2), however there are non-troubleshooting threads present in the ILIAD dataset (hence the *Task Orientation* thread classification task is addressed in Baldwin et al. (2007)). After manual analysis of the ILIAD data, we identified that the dialogue act tagset was largely transferable in its original state, but needed the addition of the information sub-class to the Question super-category (i.e. Question-information). Question-information is used on posts in threads which are not troubleshooting-oriented and only provide information (e.g. on developer mailing lists to report on a bug fix). We also relaxed the definition of Resolution slightly to accommodate non-troubleshooting threads. For example, in one thread the initiator requests an update to a wiki page, and this update is confirmed later by a non-initiator. In this case, this non-initiator's post is labelled as Resolution. In the original definition, Resolution can only be used on posts from the initiator of the thread.

The modified dialogue acts (DAs) used to annotate the ILIAD dataset for discourse structure are described in Table 1. The annotation was performed by two annotators. The main annotator annotated all 250 threads (containing 1158 posts), and the secondary annotator independently annotated 26 randomly-selected threads (containing 113 posts) for quality assurance purposes. During annotation, annotators first annotate the Links between posts in a thread, and then identify the type of each link (DA). The κ values for agreement between the two annotators are 0.64 for combined Link and DA tagging, 0.79 for just the Links and 0.68 for just the DAs.

While both the ILIAD and CNET datasets are mainly troubleshooting-oriented and technical, they come from different domains. Therefore, we expect the DA and Link distributions of them to be different. However, to our surprise, the distributions of both DAs and Links in the two datasets are remarkably similar, supporting the suggestion that the DA label set has cross-domain applicability.

[2] http://www.linuxquestions.org
[3] http://lists.debian.org/completeindex.html

Super-category	Sub-class	Description
Question	question	the post contains a new and independent question.
	add	the post provides additional information or asks a follow-up question, regarding a previous question.
	confirmation	the post confirms details or errors in a question.
	correction	the post corrects errors in a question.
	information*	the post is in a non-troubleshooting thread, and only provides information.
Answer	answer	the post proposes an answer to a question.
	add	the post provides additional information to an answer.
	confirmation	the post confirms details or errors in an answer.
	correction	the post corrects errors in an answer.
	objection	the post objects to an answer.
Resolution	—	a user confirms that an answer works.*
Reproduction	—	a non-initiator asks a similar question, or confirms that an answer should work.
Other	—	the post does not belong to any of the above classes.

Table 1: The Dialogue Act (DA) set used for annotating ILIAD dataset. ("*" signifies a difference over the original DA proposed by Kim et al. (2010b))

Regarding the Solvedness label for ILIAD dataset, the original thread-level annotations were done by three annotators are on a five-point scale, with 1 indicating high confidence in Solvedness for a given thread and 5 indicating low confidence (Baldwin et al., 2007). These annotations were aggregated by taking the simple mean across the three annotators and discretising into binary classes, with 2.5 as the breakpoint. Out of the 250 threads in the ILIAD dataset, 28 threads had a score of 2.5 and were discarded in the original paper. In the interests of comparability with the original research, we experiment over this reduced dataset (denoted ILIAD_{222}), but question the theoretical soundness of removing these threads from the dataset, so additionally experiment with the full dataset (denoted ILIAD).

4 Discourse Structure Parsing for Thread Solvedness Classification

Baldwin et al. (2007) showed that the task of automatic Solvedness classification on ILIAD_{222} is extremely hard. This is because the annotation was often based on expert knowledge of Linux, and a great deal of information not explicitly mentioned in the thread. Take the thread in Figure 1 for example: although two independent answers are provided in Post2 and Post5, it is almost impossible to identify whether there is a correct solution unless the whole thread is understood at a technical level.

Although predicting Solvedness is challenging, we believe that the use of thread discourse structure should assist in the task. As a first step, we need to do thread discourse structure parsing, which includes predicting both the linkings (Links) between posts and the type (DA) of each link.
