Discourse structure parsing, as discussed in Wang et al. (2011), can be addressed in several ways. If a structured classification approach, such as Conditional Random Fields (CRFs: Lafferty et al. (2001)), is used, we can either classify the Link and DA separately and compose them afterwards (denoted as Composition), or we can classify the combined Link and DA (e.g. treat 0+Question-question as a single label) directly (denoted as Combine). Another approach is

Feature Category	Feature Name	Description
DA-only	LastPostDA	The DA of the last post in the thread.
	LastNonInitDA	The DA of the last post from a non-initiator in the thread.
	HasResolution	Whether the thread contains a Resolution post.
LinkDA-based	LastPairDA	The DA pair for the deepest post pair in the thread tree. In the case of ties, the pair containing the latest post is chosen.
	LastSubthreadDA	The sequence of DAs in the longest subthread in the thread tree. In case of ties, the sequence containing the latest post is chosen.

Table 2: Thread discourse structure features used for Solvedness classification.

to treat discourse structure parsing as a dependency parsing problem. Dependency parsing (Kübler et al., 2009) is the task of automatically predicting the dependency structure of a token sequence, in the form of binary asymmetric dependency relations with dependency types. The joint classification task of Link and DA is a natural fit for dependency parsing, in that the task is intrinsically one of inferring labelled dependencies between posts.

For discourse structure parsing, all experiments were carried out based on 10-fold cross-validation, stratifying at the thread level to ensure that all posts from a given thread occur in a single fold. The results are evaluated using post-level micro-averaged F-score ($\beta = 1$). All three discourse structure parsing methods were tested in our experiments, by using CRFSGD (Bottou, 2011) and MaltParser (Nivre et al., 2007). As for features, we experimented with all the features proposed by Wang et al. (2011), including Initiator, Position, TitSim, PostSim, Punct and UserProf, as well as many of our own features. We found that using CRFSGD with a simple Initiator (i.e. whether a post's author is the initiator of the thread) feature and the Combine approach achieves the highest Link and DA joint (LinkDA) classification F-score of 0.626. This is significantly better[4] than a strong heuristic baseline which classifies all first posts as 0+Question-question and all subsequent posts as 1+Answer-answer, which achieves a joint classification F-score of 0.420.

We also explored the possibility of domain adaptation, by using threads from the CNET dataset of Kim et al. (2010b) to augment the ILIAD thread discourse structure parsing. However, we were unable to achieve any significant improvements.

When using the thread discourse structure (i.e. Link and DA) for Solvedness prediction, one natural question is "could we simply use Resolution to identify solved thread?" While Resolution is a clear identifier of solved threads with 100% precision, only 8% of the threads contain Resolution posts, and yet 80.4% of the threads are labelled as solved. Therefore, by only using Resolution, a classifier could not do better than a majority class baseline. Instead, we propose to use a combination of discourse structure features to address the Solvedness classification problem. Table 2 displays all the discourse structure features[5] used in this paper, which can be grouped into two categories: (1) those based on only the DAs (DA-only); and (2) those based

[4]All statistical significance results in the paper are based on randomised estimation (Yeh, 2000), at a significance level of $p < 0.05$.

[5]We have experimented with many "discourse structure" features and non-"discourse structure" features, and these are particularly useful and interesting.

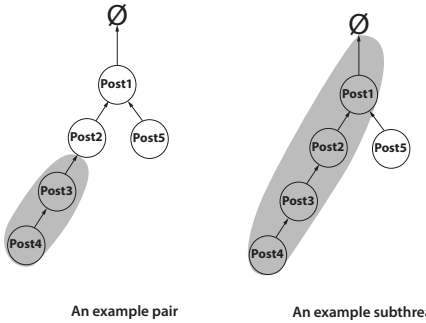

Figure 2: Examples of a pair and a subthread in a thread.

on Link and DA (LinkDA-based). When using the Link information, we rely on the notions of "pairing" and "subthreading". A pair is defined to be the combination of a post with the parent post it links to (noting that a given post can participate as child in multiple "pairs" as it can link to multiple posts), and a subthread contains all posts in a given path from a leaf node to the root node following the link structure. Figure 2 shows an example of each, based on the sample thread from Figure 1. As the `LastPostDA` is Answer-answer from Post5 (the final post), the `LastNonInitDA` for the thread is Answer-answer, `HasResolution` is 0 (as there are no Resolution posts), `LastPairDA` is Answer-add/Answer-confirmation from the pairing of Post4 and Post3, and `LastSubthreadDA` is Answer-add/Answer-confirmation/Answer-answer/Question-question from the subthread Post4/Post3/Post2/Post1.

5 Solvedness Classification

Baldwin et al. (2007) experimented with various learners from three machine learning software packages, namely LIBSVM (Chang and Lin, 2011), TiMBL (Daelemans et al., 2010) and Weka (Hall et al., 2009), and found that LIBSVM performs superiorly on the Solvedness classification task. Therefore, LIBSVM is used for Solvedness classification in this research.

In our initial experiments, we experimented with different kernel functions for LIBSVM, including linear, polynomial, radial basis function (RBF) and sigmoid kernels, and found the linear kernel to outperform other kernels. Therefore, LIBSVM with linear kernel is used throughout our experiments. We approach the Solvedness classification task by firstly following the procedure of Baldwin et al. (2007), where ILIAD_{222} is used. Subsequently, we carry out experiments over the full 250-thread ILIAD dataset. In both cases, various combinations of the features introduced in Section 4 are used. To generate these features, both the gold-standard LinkDAs and the automatically predicted ones are used.

All our Solvedness classification experiments were carried out based on stratified 10-fold cross-validation. The results are evaluated using classification accuracy (ACC). As our baselines, we use a majority classifier (ZeroR), as well as the best Solvedness classifier provided by Baldwin et al. (2007) (ADCS). As mentioned earlier, randomised estimation (Yeh, 2000) (at a significance level of $p < 0.05$) is used throughout the paper for statistical significance testing.

Feature Category	System/feature(s)	ACC_{gold}	ACC_{auto}
Baseline	ZeroR	.779	
	ADCS	.788	
DA-only	`LastPostDA`	.833*	.775
	`LastNonInitDA`	.766	**.792**
	`HasResolution`	.779	.779
	`LastPostDA` +`LastNonInitDA`	.834*	.779
	`LastPostDA` +`HasResolution`	**.883***	.775
	`LastNonInitDA` +`HasResolution`	.874*	**.792**
	`AllDAFeat`	**.883***	.779
LinkDA-based	`LastPairDA`	.851*	**.792**
	`LastSubthreadDA`	.833*	.779
	`AllLinkDAFeat`	.833*	**.792**
	`AllDAFeat` +`AllLinkDAFeat`	.865*	**.792**

Table 3: Results over ILIAD$_{222}$, using discourse structure features from the gold-standard and also the discourse parsing model ("*" signifies a significantly better result than both baselines; the best result in each column is indicated in **boldface**).

5.1 Experiments over ILIAD$_{222}$

Table 3 presents the results from experiments over ILIAD$_{222}$, using the thread discourse structure features generated from both the gold-standard (ACC_{gold}) LinkDAs, and automatically predicted ones (ACC_{auto}). The automatically predicted discourse structure of the whole ILIAD$_{222}$ dataset is obtained by aggregating the discourse structure predictions from each fold of the 10-fold cross-validation experiments described in Section 4. The combination of all DA-only features (i.e. `LastPostDA`, `LastNonInitDA` and `HasResolution`) is denoted `AllDAFeat`, and the combination of all LinkDA-based features (i.e. `LastPairDA` and `LastSubthreadDA`) is denoted `AllLinkDAFeat`. Results which are significantly better than both baseline results are signified by "*", and the best result(s) in each column are presented in **boldface**.

Looking first at the ACC_{gold} results in Table 3 we can see that, not surprisingly, `HasResolution` by itself does not have any effect on the prediction (see our comments in Section 4). Moreover, while `LastPostDA` leads to a significant improvement, `LastNonInitDA` does not have a significant effect. More interestingly, the combination of `LastPostDA` or `LastNonInitDA` with `HasResolution` leads to further improvements. This is because the classifiers trained on `LastPostDA` or `LastNonInitDA` are aggressive and misclassify many solved threads as unsolved, which `HasResolution` can correct.

The ACC_{gold} column also shows both the potential and shortcomings of LinkDA-based features — i.e. while both `LastPairDA` and `LastSubthreadDA` lead to significantly better results in isolation, combining them does not lead to further improvements. Moreover, combining all the features (i.e. `AllDAFeat` +`AllLinkDAFeat`) leads to a drop in results compared to just using `AllDAFeat`. We hypothesise that there are a number of reasons for this. Firstly, the `LastPairDA`, `LastSubthreadDA` and DA-based features have dependencies between each other, in that they all draw on the same set of DAs. While they are closely related, the classifiers do not have any access into the internals of the features to leverage them, causing the learner to overfit the training data. Secondly, while `LastPairDA` and `LastSubthreadDA` lead to low results in isolation, this is almost certainly because of the sparse nature (`LastPairDA` and

Feature Category	System/feature(s)	ACC_{gold}	ACC_{auto}
Baseline	ZeroR	.804	
	ADCS	.804	
DA-only	LastPostDA	.784	.780
	LastNonInitDA	.792	.788
	HasResolution	.804	.804
	LastPostDA +LastNonInitDA	.848*	.776
	LastPostDA +HasResolution	.864*	.780
	LastNonInitDA +HasResolution	.872*	.788
	AllDAFeat	**.884***	.776
LinkDA-based	LastPairDA	.832	**.816**
	LastSubthreadDA	.832	.792
	AllLinkDAFeat	.824	.792
	AllDAFeat +AllLinkDAFeat	.852*	.792

Table 4: Results over ILIAD, using discourse structure features from the gold-standard and also the discourse parsing model ("*" signifies a significantly better result than both baselines; the best result in each column is indicated in **boldface**).

LastSubthreadDA have 72 and 135 distinct values, respectively), much moreso than the DA-based features. When combined with the other features, however, some of these features are found to have utility.

Looking next to the ACC_{auto} results in Table 3, we can see that we surpass the two baselines, delivering on the promise of discourse parsing aiding in Solvedness classification. The results drop appreciably relative to those achieved with the gold-standard labels, and in fact the improvements over the baselines aren't statistically significant. This is perhaps not surprising, however, given than the F-score for discourse parsing was a modest 0.626, meaning that errors will propagate through to the thread-level classification.

While these results are certainly encouraging, and were worthwhile in terms of establishing the superiority of our method when discourse parsing features are used, we always had reservations about the ILIAD_{222} dataset, due to the most contentious instances having been removed from the dataset. In introducing these instances back into the dataset and labelling them as solved, the task becomes both more realistic and more challenging, including the ZeroR baseline rising up further. In the next section, we reapply our methods to the ILIAD dataset.

5.2 Experiments over ILIAD

We carry out the same experiments done in Section 5.1 over the whole ILIAD dataset, and present the results in Table 4. Again, the results which are significantly better than both baseline results are signified by "*", and the best result in each column is presented in **boldface**.

From Table 4 we can see a similar trend to that in Section 5.1, with our method improving over both baselines when we use either gold-standard or automatically-predicted features. However, there are some notable differences. Looking first at the ACC_{gold} column, firstly, none of LastPostDA, LastNonInitDA and HasResolution led to any improvement in isolation. However, the combination of these three features led to results that are significantly better than the baselines, with AllDAFeat achieving the best result of 0.883. Secondly, neither LastPairDA nor LastSubthreadDA has a significant impact on results, and their combination

DA	LastPostDA	LastNonInitDA	HasResolution	AllDAFeat
Question-add	0.999	0.811	—	0.999
Question-confirmation	0.881	0.991	—	0.961
Question-information	0.918	—	—	0.918
Answer-answer	0.500	0.513	—	0.498
Answer-add	0.461	0.550	—	0.489
Answer-confirmation	0.918	—	—	0.918
Answer-objection	0.918	1.000	—	0.954
Reproduction	1.000	1.000	—	1.000
Resolution	0.332	0.918	0.229	0.237
Other	0.971	0.934	—	0.952

Table 5: Entropy of each DA against the Solvedness class distribution for every DA-only feature and AllDAFeat features.

(i.e. AllLinkDAFeat) also does not outperform the baselines significantly. Looking next to ACC_{auto}, we achieve the best results with LastPairDA once again, surpassing the baselines but not at a level of statistical significance. Overall, while it is clear that the Solvedness classification task becomes harder when we experiment with the full ILIAD dataset, we were able to reproduce the overall results from Section 5.1.

6 Results Analysis and Simulation

Examining the differences between the results for ACC_{gold} and ACC_{auto} in Section 5.1 and Section 5.2 leads us to suspect that if the F-score of the thread discourse parsing could be boosted, we would be able to achieve better Solvedness classification accuracy. Furthermore, because the most effective discourse structure features, i.e. LastPostDA, LastNonInitDA and HasResolution, only make use of a subset of the DAs, we anticipate that if we can improve the F-score over certain DAs, we will be able to significantly boost our Solvedness classification accuracy.

To test these hypotheses, firstly, we examine the entropy (presented in Table 5) of every DA against the Solvedness class distribution for each DA-only feature (i.e. LastPostDA, LastNonInitDA and HasResolution) and the combination of all DA-only features (i.e. AllDAFeat). From Table 5, we can see that Answer-answer, Answer-add and Resolution have relatively low entropy compared to the rest of the DAs. Therefore, it seems that these three DAs can contribute more in Solvedness classification.[6]

Secondly, we conducted simulation experiments to examine the potential relation between DA classification and Solvedness classification. The simulation starts with a seed DA classification result (SeedResults), based on CRFSGD and the Initiator feature. This seed DA classification achieves a F-score of 0.651, significantly better than a strong heuristic baseline (i.e. 0.515) which classifies all first posts as Question-question and all subsequent posts as Answer-answer. Then, an arbitrary higher goal (e.g. 0.8) is set and an artificial classification result (ArtificialResults) is created by randomly correcting errors in the output of the discourse parsing model. The corrections are made evenly across all DA labels, relative to the original error rates for each DA. Next, a simulator is used to predict the labels of each instance, by randomly selecting from the

[6]Note that this entropy analysis can only capture the association between a single DA and the Solvedness class, and we are not able to capture more subtle feature interactions.

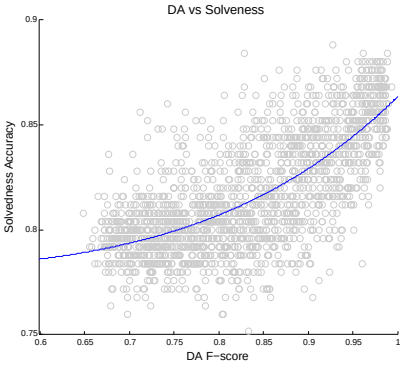

Figure 3: Simulation over all DAs (AllDA).

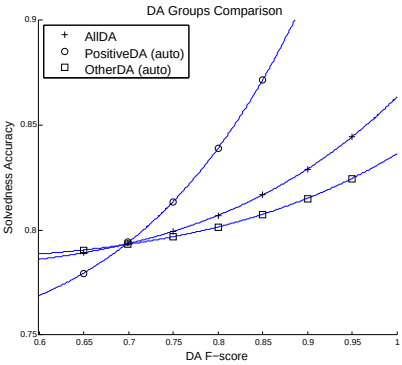

Figure 4: Simulation over automatically-generated DA groups (PositiveDA$_{auto}$ and OtherDA$_{auto}$).

labels returned by SeedResults and ArtificialResults with equal chance. In order to generate enough simulated results, we pick 20 goal F-score figures between 0.651 and 1.0, and run the simulator 100 times for each of these figures. Finally, we use these 2000 simulated discourse structure predictions to classify Solvedness using `AllDAFeat` features, and plot each pair of discourse structure F-score and Solvedness accuracy in a scatter plot. We also try to fit a series of simple polynomial models of the form $y = ax^n + b$ ($n \in \{1, 2, 3, 4, 5\}$)[7] to the plot. We find that the model for $y = ax^5 + b$ provides the best fit with the data, although the differences in the range $n \in \{2, 3, 4, 5\}$ are negligible. Figure 3 shows the graph, along with the curve of best fit for the function $y = ax^5 + b$.

From Figure 3 we can see that there is a clear correlation between the F-score of DA classification and the accuracy of Solvedness classification, and that the impact of DA classification on Solvedness classification is, in fact, accentuated for higher F-scores. Theoretically, therefore, by improving the DA classification F-score, the Solvedness classification accuracy will increase accordingly.

The entropy analysis showed that not all DAs have the same utility for the task of Solvedness classification — i.e. some DAs are more important (lower entropy) than others. We select the three DAs (i.e. Answer-answer, Answer-add and Resolution) with lowest entropy values from Table 5, because these DAs seem to be the most effective across the three feature types (i.e. `LastPostDA`, `LastNonInitDA` and `HasResolution`). Then, we carry out an analogous simulation over this set of automatically-selected DAs (PositiveDA$_{auto}$). Additionally, we conducted a simulation over the 8 non-selected DAs (OtherDA$_{auto}$).[8] Once again, a line of best fit for $y = ax^5 + b$ is generated for the resulting simulations. The curves of best fit are shown in Figure 4, along with the original curve of best fit for all DAs (AllDA) from Figure 3.

[7] Choosing $n > 5$ does not result in better fit with the data.

[8] Question-correction and Answer-correction are never used in annotating the discourse structure of ILIAD dataset.

DA Group	DA	F-score
PositiveDA$_{auto}$	Answer-answer	0.782
	Answer-add	0.641
	Resolution	0.514
OtherDA$_{auto}$	Question-question	0.992
	Question-add	0.678
	Question-confirmation	0
	Question-information	0
	Answer-confirmation	0
	Answer-objection	0
	Reproduction	0
	Other	0

Table 6: Micro-averaged DA classification F-scores per DA over ILIAD

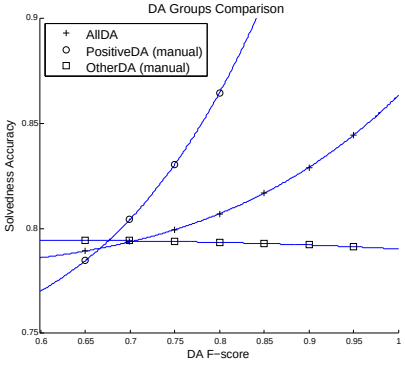

Figure 5: Simulation over manually-created DA groups (PositiveDA$_{manual}$ and OtherDA$_{manual}$).

From Figure 4 we can see that, as suspected, the PositiveDA$_{auto}$ group is much more important than the OtherDA$_{auto}$ group for Solvedness classification. Therefore, to improve Solvedness classification, we should focus our attention on improving the DA classification F-score for DAs such as Answer-answer, Answer-add and Resolution. Table 6 shows the micro-averaged F-scores of DA classification, calculated per DA. When we do a breakdown of the results for the discourse parsing model, we can see that there is definitely room for improvement with Answer-answer, Answer-add and Resolution. Moreover, Answer-answer and Answer-add are the most-frequent and third most-frequent DAs in the ILIAD dataset, respectively, appearing 354 and 147 times. Therefore, there appears to be considerable scope for improvement.

While the identification of the more important DAs can be done automatically as shown above, we also attempted to select them in a more ad hoc way, based on our understanding and analysis of the data set. Intuitively, if a thread's last post or the last post from a non-initiator is Question-confirmation, Question-information, Answer-confirmation or Answer-objection, this thread is more likely to be unresolved. At the same time, we can observe that the micro-

average F-scores for all these DAs are 0, that is the model never predicts a post to be one of these DA types correctly. To explore the utility of these additional DAs, we conducted an additional simulation experiment including Question-confirmation, Question-information, Answer-confirmation, Answer-objection and Resolution in PositiveDA$_{manual}$, and relegating the other 6 DAs to OtherDA$_{manual}$. The results for these manually-created groupings are shown in Figure 5.

From Figure 5 we can see that the improvements in discourse parsing over the manually-chosen PositiveDA$_{manual}$ will lead to even greater improvements over Solvedness prediction than before, if only we can get the models to make predictions using them. Perhaps even more surprising is that our simulations predict that improvements over OtherDA$_{manual}$ stand to *degrade* Solvedness classification. These findings set the direction for future work on improving the F-score of the discourse parser.

7 Conclusions and Future Work

In this research, we explore the task of Solvedness classification, that is the automatic prediction of whether the information need on the part of the initiator of a thread has been resolved or not, by parsing thread discourse structure in the form of a rooted directed acyclic graph over posts, with edges labelled with dialogue acts. While Solvedness classification has been shown to be very difficult in previous research (Baldwin et al., 2007), we achieve significantly better results using gold-standard discourse structure. We are also able to attain improvements in Solvedness classification accuracy using automatically-predicted thread discourse structure, although not at a level of statistical significance. However, simulations suggest that as we improve the F-score of thread discourse structure parsing, the Solvedness classification accuracy will increase disproportionately. Additionally, we showed that a particular subset of DAs is crucial to Solvedness classification accuracy, and that if we can improve the F-score of our discourse structure predictions over these DAs, we stand to make large gains in Solvedness classification accuracy.

In future work, we plan to firstly investigate ways to improve the discourse parser F-score over the PositiveDA$_{auto}$ and PositiveDA$_{manual}$ sets of DAs. Moreover, we plan to delve further into feature engineering, looking at other means of capturing thread discourse structure. Additionally, although our preliminary experiments on using CNET annotated threads to help ILIAD discourse structure parsing were not positive, it would be interesting to investigate the effect of using CNET threads in predicting specific DAs for the ILIAD dataset.

ABSTRACT

Implicit discourse relation recognition is a challenging task in the natural language processing field, but important to many applications such as question answering, summarization and so on. Previous research used either artificially created implicit discourse relations with connectives removed from explicit relations or annotated implicit relations as training data to detect the possible implicit relations, and do not further discern which examples are fit to be training data. This paper is the first time to apply a different typical/atypical perspective to select the most suitable discourse relation examples as training data. To differentiate typical and atypical examples for each discourse relation, a novel single centroid clustering algorithm is proposed. With this typical/atypical distinction, we aim to recognize those easily identified discourse relations more precisely so as to promote the performance of the implicit relation recognition. The experimental results verify that the proposed new method outperforms the state-of-the-art methods.

KEYWORDS: Discourse relation recognition, single centroid clustering, implicit discourse relation.

1 Introduction

It is widely agreed that sentences/clauses are usually not understood in isolation, but in relation to their neighbouring sentences/clauses. The task of discourse relation recognition is to identify and label the relations between sentences/clauses, which is fundamental to many natural language processing applications such as question answering, automatic summarization and so on.

Discourse relations, such as comparison and causal relations, can be divided into explicit and implicit relations by the presence or absence of discourse connectives (e.g., *but*, *because* et. al.). Previous study indicates that the presence of discourse markers can greatly help relation recognition and the most general senses (i.e., comparison, contingency, temporal and expansion) can be disambiguated with 93% accuracy based solely on the discourse connectives (Pitler et al., 2008). On the other hand, the absence of explicit textual cues makes it very difficult to identify the implicit discourse relations. Thus, recently discourse relation recognition research puts more efforts to meet the challenges in implicit discourse relation recognition.

Existing work mainly focused on exploiting various linguistic features to learn the implicit discourse relation classifiers based on the training data collected (Wellner, Pustejovsky and Havasi, 2006; Pitler, Louis and Nenkova, 2009; Lin, Kan and Ng 2009; Wang, Su and Tan, 2010). Most useful linguistic features (such as word pairs) are extracted from the local context, which is usually determined as **Argument 1 (Arg1,** the first sentence/clause**)** plus **Argument 2** (**Arg2**, the second sentence/clause). Like the other related work in the literature, in this paper, we focus on the recognition of local implicit discourse relations, i.e. only the two arguments are examined.

To collect training data, the state-of-the-art methods normally start from the artificial/real perspective and simply make use of the implicit relations either derived from explicit or manual annotations. Marcu and Echihabi (2002); Sporleder and Lascarides (2008) created artificial implicit relations as training data by removing discourse connectives from the explicit relation examples. The advantage of these methods is that a large number of (artificial) implicit relation examples could be used as training data, saving the labor extensive and time-consuming annotation work. However, the experimental results in Sporleder and Lascarides (2008) showed that training on a large artificial data set is not necessarily a good strategy. Lin, Kan and Ng (2009) also pointed out that an artificially implicit relation corpus may exhibit marked differences from a natively implicit one. Also surprising is the fact that the results were not as good as expected when the classifiers are trained by using the manually annotated real implicit relations, though better than the results based on the artificial implicit relations.

Then the following questions come to our minds. Do all the real natively implicit relation examples provide useful hints for training the classifiers? Is it a reasonable choice if the training data is over-restricted to the annotated implicit relation examples even when the quantity of these data is limited and their annotation demands a high cost? Can a part of, if not all of, the artificial implicit relations created from the explicit relations be picked out to train an implicit relation classifier? In short, can we obtain more effective training examples at less cost?

With the above consideration, we argue that an effective training set is composed of typical examples, which have distinct characteristics to signify their discourse relations. These typical examples, however, can be either the natively implicit relations or the created implicit relations with connectives removed from the explicit relations. Using the typical examples as training data,

an implicit relation classifier with higher discrimination power can be built according to the linguistic features in the two arguments.

We provide three *Comparison* relation examples from the Penn Discourse TreeBank (PDTB) v2.0 (Prasad et al., 2008) which is widely used in the research of relation recognition as follows to illustrate what the possible typical examples are like.

(1) **Arg 1**: 44 North Koreans oppose the plan,
Arg 2: (while) South Koreans, Japanese and Taiwanese accept it or are neutral.
(2) **Arg 1**: In such situations, you cannot write rules in advance.
Arg 2: you can only make sure the President takes the responsibility.
(3) **Arg 1**: Columbia Savings is a major holder of so-called junk bonds.
Arg 2: New federal legislation requires that all thrifts divest themselves of such speculative securities over a period of years.

Here, the first one is an artificial implicit relation with the connective (i.e. "*while*") deleted while the second and third examples are natively implicit. The first and second ones are possibly typical because they have distinguishable linguistic features (such as: oppose/accept, cannot /can) to verify their relations. In contrast, it is hard to find significant characteristics in the third one to determine its discourse relation. The trained implicit relation classifier would possibly suffer a decline in performance if a lot of examples like the third one are included in the training set.

Based on the analysis above, we for the first time propose to select training data for implicit discourse relation recognition from a new typical/atypical perspective other than from an artificial/real perspective. Identifying the typical examples from both artificially created and real implicit discourse relations is the focus of this work. Assuming that the typical examples of a discourse relation are usually connected through the similar features, Yarowsky's algorithm (1995), as one of the first bootstrapping algorithms, gives us the following inspiration: given a small set of *seed* typical discourse relation examples, more typical examples are added iteratively by identifying the significant features of the seed set. In this paper, a training data selection approach named single centroid clustering (SCC) is proposed to acquire the typical examples for each relation. With the typical examples in the training set, the task of implicit relation recognition is cast to a classification problem. The experimental results show that the training set selected in such a way can improve the performance of an implicit relation classifier.

The rest of this paper is organized as follows. Section 2 introduces the related work. Section 3 describes our framework of implicit relation recognition, and introduces the types of features involved. Section 4 proposes the single centroid clustering algorithm that selects the typical examples iteratively. Section 5 presents the experimental results. Section 6 concludes our work.

2 Related Work

2.1 Implicit discourse relation recognition

So far, the existing research which used statistical models to recognize implicit discourse relations mainly falls into two categories according to whether the data annotation is required.

One research line tried to use the large quantity of unannotated explicit relations as a training set, which are roughly identified by discourse connectives and then converted to artificial implicit relations through removing the discourse connectives. Among the pioneer work was the one

presented by Marcu and Echihabi (2002) who applied massive amounts of unannotated explicit relations and lexical features to train the Naïve Bayes classifier for both explicit and implicit discourse relation recognition. Following the same idea, Saito, Yamamoto and Sekine (2006) conducted the experiments with the combination of cross-argument word pairs and phrasal patterns as features on Japanese sentences. Blair-Goldensohn（2007）further extended the work of Marcu and Echihabi (2002) by involving syntactic filtering and topic segmentation. Another interesting work is that of Zhou et al. (2010), which predicted discourse connectives between arguments via a language model. Then the generated connectives plus other linguistic features were combined in a supervised framework to determine the implicit discourse relation.

However, Sporleder and Lascarides (2008) discovered that the models of Marcu and Echihabi (2002) did not perform well on implicit relations recognition with artificially created relations as training data and concluded that removing discourse markers may lead to a meaning shift in the examples. Sporleder and Lascarides (2008) promoted the other research line that used the human-annotated training data. The development of various discourse banks also made the use of human-annotated data feasible. Based on Rhetorical Structure Theory Discourse Treebank (RST-DT) (Carlson et al. 2001), Soricut and Marcu (2003) developed two probabilistic models to identify elementary discourse units and generate discourse trees at the sentence level. Further Hernault et al. (2010); Feng and Hirst (2012) explore various features for discourse tree building on RST-DT. With the Discourse Graphbank (Wolf and Gibson, 2005), Wellner et al.(2006) integrated multiple knowledge sources to produce syntactic and lexical semantic features, which were then used to automatically identify and classify explicit and implicit discourse relations. Especially after the release of the second version of the PDTB v2.0 (Prasad et al., 2008), more research began to take the advantage of the annotated implicit relations for training purpose and were dedicated to exploiting various linguistic features in the supervised framework (Pitler, Louis and Nenkova, 2009; Lin, Kan and Ng, 2009; Wang, Su and Tan, 2010). Lin, Kan and Ng (2009) conducted a thorough performance analysis for four classes of features including contextual relations, constituent parse features, dependency parse features and cross-argument lexical pairs, while Pitler et al. (2009) applied several linguistically informed features, such as word polarity, verb classes, and word pairs. Wang, Su and Tan (2010) adopted the tree kernel approach to mine more structure information and got better results. These efforts of feature selection have achieved better performance though not that satisfying. The quality of training data are partly responsible for the difficulty of improving the performance of implicit relation recognition.

To better recognize the implicit discourse relations, we propose to review the annotated discourse corpora available at hand, identify and choose typical relation examples as training data for supervised learning. To the best of our knowledge, this paper is the first time to re-think the training data and implicit relation recognition from a novel perspective.

2.2 Rhetoric Discourse Treebank and Penn Discourse Treebank

As for the available discourse corpora, due to the space limitation we mainly introduce the two widely used discourse corpora - the Penn Discourse TreeBank (PDTB) and Rhetorical Structure Theory Discourse Treebank (RST-DT), which provide a common platform for researchers to develop discourse-centric systems.

The PDTB focuses on encoding discourse relations with the discourse connectives, adopting a lexically grounded approach for the annotation. For each pair of adjacent sentences within the same paragraph, annotators selected the explicit or implicit discourse connective which best

expressed the relation between the sentences. Then, the annotations can be seen as being of a predicate-argument structure, where a discourse connective is treated as a predicate taking a pair of adjacent sentences as its arguments. Thus, this discourse connective grounded approach exposes a clearly defined level of discourse structure. In PDTB, a hierarchy of relation tags is provided for the relation annotation. In our experiments, we only use the top level of the annotations, which is composed of four major relation classes: *Temporal*, *Contingency*, *Comparison* and *Expansion*. These four core relations allow us to be theory-neutral, since they are almost included in all discourse theories, sometimes under different names.

RST-DT is manually annotated under the Rhetoric Structure Theory framework (Mann and Thompson, 1988). In this corpus the rhetoric relations are labelled hierarchically between non-overlapping adjacent text spans which range from elementary discourse units (EDU, the minimal building blocks of a discourse tree) to paragraph. A total of 110 different relations were used for the tagging of the RST corpus (RST-DT, 2002). The final inventory of the relations is data driven and can be partitioned into 18 classes, from which we still select four classes including *Temporal*, *Contrast*, *Cause*, and *Background* to verify our method. These four relations spanning over individual sentences are collected to keep consistent with the discourse relations from PDTB.

So far, most of the previous works experimented on one corpus only. With the aim to verify the portability of our methods, we examine two corpora in this paper.

3 The Learning Framework for Implicit Discourse Relation Recognition

In this paper, the problem of implicit relation recognition is approached in the supervised learning framework. Figure 1 illustrates the architecture of our system.

The first and most important step is to collect the training data. As stated in Section 1, on the one hand, not all the annotated implicit relations contain significant features to distinguish themselves from the other relation types. On the other hand, we expect to pick out the suitable examples of the artificial implicit relations and strengthen their influence on the training process. We argue that the examples suitable to be training data are generally the typical ones having distinct linguistic features to signify their discourse relations, yet they can be of real implicit relations (denoted as *IM* data) or artificially implicit relations with connectives removed from explicit relations (denoted as *EX* data).

To select typical examples, for each discourse relation type the original artificial/real partition (denoted as EX_i/IM_i) is converted to a novel typical/atypical partition (denoted as A_i/B_i), which is obtained automatically by the proposed *single centroid clustering* (SCC) algorithm. Starting from an initial seed set, SCC iteratively refines typical examples and removes atypical examples if necessary. This algorithm is detailed in Section 4.

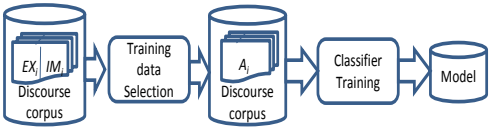

FIGURE 1 – System architecture for implicit discourse relation recognition

Assume there are n discourse relations. Let $Y=\{R_0, R_1, \ldots, R_n\}$ where R_i represents the ith typical relation type and R_0 denotes the atypical case. After the conversion from artificial/real partition to

typical/atypical partition, we get the $A_i/B_i(1 \le i \le n)$ and assign the relation label $R_i(1 \le i \le n)$ to each typical example in the set A_i. Each example in the union $A_0 = \cup B_i(1 \le i \le n)$ is labelled as R_0. Then the set of ordered pairs $<A_i, R_i>$ $(0 \le i \le n)$ can be used to train an implicit relation classifier for labelling $R_i(1 \le i \le n)$. Both clustering and classification require representing the annotated argument pairs with feature vectors. We introduce the feature selection in subsection 3.1.

3.1 Feature Selection

Various linguistic features have been experimented for recognizing implicit discourse relations in previous studies (Marcu and Echihabi, 2002; Pitler, Louis and Nenkova, 2009; Lin et al., 2009). Learning from them, we consider the following 7 types of features.

Polarity: The polarity of each sentiment word is tagged as positive, negative or neutral according to Multi-perspective Question Answering Opinion Corpus (Wilson et al., 2005). Note that the sentiment words preceded by negated words would be assigned an opposite tag. For example, "good" would be assigned as positive while “not good” is negative. Negated neutral is ignored. The occurrence of negative, positive and neutral polarities in each argument and their cross product are used as features.

Inquirer tags: General Inquirer lexicon (Stone et al., 1966) divides each word into fine-grained semantic categories described by the inquirer tags. From all the categories, we select 21 pairs of complementary categories, such as: *Rise* versus *Fall*, or *Pleasure* versus *Pain*, etc. The occurrence of each complementary category pair in the two arguments are used as features.

Modality: The presence of modal words including their various tenses and abbreviations in both arguments and their cross product are used as features.

SameWord: This type of feature represents whether a noun or a verb simultaneously occurs in both arguments. The intuition of using this feature is similar to that of the ***Verbs*** feature in (Pitler et al., 2009), for indicating the semantic association of the two arguments.

FirstLastFirst3: The first word, the last word, the first three words of each argument, the pair of the two first words and the pair of the two last words in the two arguments are used as features.

CrossWordPairs: The words in each argument compose one set. This type of features indicates the word pairs from the cross product of the two sets.

IntraWordPairs: The word pairs that occur in the same argument.

Since the length of the two arguments is relatively short, it is quite common that a feature is observed only once if it is present. Hence each feature is assigned a binary value to indicate whether it is present or absent. Assuming d features are extracted, each example is represented with a d-dimension binary feature vector.

4 Single Centroid Clustering for Training Example Selection

4.1 Overview

A good training set usually exhibits the property that most of its items have distinct features to differentiate the instances in the different classes. To precisely classify implicit discourse relations, the typical examples which have significant linguistic features except discourse connectives for identifying their relations are fit to be included in the training set. In this section,

we introduce the Single Centroid Clustering (SCC) algorithm which picks out the typical examples for each discourse relation from both *EX* and *IM* data.

Algorithm 1: Single-Centroid Clustering algorithm

Input: For relation i, artificial implicit relation set EX_i, real implicit relation set IM_i,
Output: Typical relation example set A_i, Atypical relation example set B_i

1. Initialize A_i: A_i= seed set of typical examples;
2. $B_i = EX_i \cup IM_i - A_i$
3. Compute the centroid CA_i for A_i
4. While stopping criterion has not been met
5. For each example e_j in A_i:
6. If dist $(e_j, CA_i) > T_{dis}^{(i)}$:
7. $A_i = A_i - \{e_j\}$; $B_i = B_i \cup \{e_j\}$
8. For each example e_j in B_i:
9. If dist$(e_j, CA_i) <= T_{dis}^{(i)}$:
10. $A_i = A_i \cup \{e_j\}$; $B_i = B_i - \{e_j\}$
11. Compute the centroid CA_i for A_i
12. End While

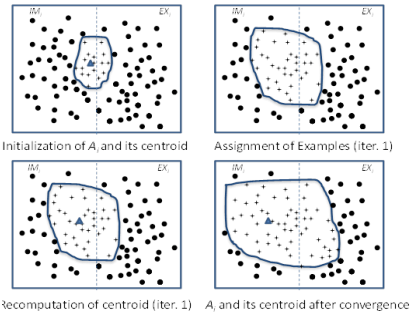

FIGURE 2 – Illustration of the Single Centroid Clustering algorithm

The principle underlying SCC is similar to that of the Yarowsky algorithm (1995), which has been successfully applied to the Word Sense Disambiguation (WSD). Yarowsky augmented the seed sets of each sense based on two powerful constraints, namely one-sense-per-collocation and one-sense-per-discourse. In our SCC algorithm, the features introduced in Section 3.1 are used to obtain the constraints of augmenting the seed sets and pick out those typical examples for each discourse relation. The SCC algorithm, as shown in Algorithm 1, consists of two loops. The "outer loop" can be regarded as a supervised learning process. In particular, based on the current available typical examples, SCC computes for each relation the centroid that judges which features are significant. The "inner loop" uses the current centroid of a relation to re-assign all the examples of the relation as either typical or atypical.

Figure 2 illustrates a snapshot of SCC on relation R_i, with dots and crosses representing the data in the A_i and B_i sets respectively. The closed curve in the left-top graph represents the seed set of typical examples. The closed curves in the other three graphs represent the intermediate and final results of the typical examples sets. The solid triangles in the middle of the closed curves denote the centroids computed based on typical examples. When SCC reaches its stable state, the final typical example set is passed to the classification models as training data. Take the three sentence pairs in Section 1 for example, the ideal output from SCC should include the first and the second examples in the typical set of the Comparison relation.

4.2 Implementation Details

4.2.1 Seed Set Construction

For each relation $R_i(1 \le i \le n)$, we can identify a relatively small number of typical examples as the seed set either manually or automatically. Similar to the Yarowsky algorithm (1995), to avoid the laborious procedure, through observation we manually lay down some simple rules to identify the distinct features for each relation from the 7 feature types and then select those containing the distinct features from the corresponding relation examples to compose of the seed set. The rules for identifying distinct features are illustrated in Table 1. Taking the *Comparison* relation for example, rule (1) identify the features of "Arg 1 is positive and Arg 2 is negative" and "Arg 1 is negative and Arg 2 is positive" which are from the **Polarity** feature type. Rule (2) can identify the features which are related to the words *seldom*, *back*, etc. according to the feature types of **FirstLastFirst3**, **CrossWordPairs**, and **IntraWordPairs**. Other strategies of selecting typical example seed set and the experimental comparisons are provided in Subsection 5.3.

Class	Description of Rules
Comparison	(1) A pair of opposite polarity tags is identified respectively in Arg 1 and Arg 2. (2) Arg 1 or Arg 2 contains the words including *seldom, back, yet, only.*
Contingency	(1) Opposite polarity tags are identified respectively in Arg 1 and Arg 2. (2) Arg 1 or Arg 2 contains the words including *draw, as, result.*
Temporal	Arg 1 or Arg 2 contains the words including *following, last, first, second.*
Expansion	Arg 1 and Arg 2 contain the same noun words or verb words.

TABLE 1 – Rules for selecting the seed set of typical examples.

4.2.2 Centroid Computation

A_i can be seen as the iteratively refined typical set. Suppose A_i is composed of $|A_i|$ examples $\{e_1^{(i)}, e_2^{(i)}, \ldots, e_{|A_i|}^{(i)}\}$, each example $e_j^{(i)}$ $(1 \le j \le |A_i|)$ is represented by a d-dimension feature vector $(e_{j1}^{(i)}, e_{j2}^{(i)}, \ldots e_{jd}^{(i)})$. In the d-dimensional Boolean space, the centroid CA_i is also represented by a d-dimension binary feature vector $(c_1^{(i)}, c_2^{(i)}, \ldots, c_d^{(i)})$, where $c_k^{(i)}$ is the value in the k^{th} dimension. We define $c_k^{(i)}$ as:

$$c_k^{(i)} = \begin{cases} 1, & \frac{\sum_j e_{jk}^{(i)}}{|A_i|} > T_c^{(i)} \\ 0, & otherwise \end{cases} \quad (1)$$

where $T_c^{(i)}$ is the percentage threshold corresponding to R_i. $c_k^{(i)}$ is assigned to 1 if the k^{th} feature occurs more than a certain percentage (i.e. $T_c^{(i)}$) of the examples that belong to the typical set A_i.

In this way, the centroid values actually reflect which features are significant to the corresponding discourse relation. Normally, centroid is used to compute the "average" of all objects in a certain space, and it should be noted that the computation of *centroid* in a Boolean space here does not strictly observe the "average" form.

4.2.3 Distance Metric

For each relation R_i, we exclude atypical examples from A_i or select typical ones into A_i by computing the distance between discourse relation examples and the centroid of CA_i. Assuming the example e is represented by the feature vector $(e_1, e_2, \ldots, e_d)$, the distance between e and CA_i is defined as follows.

$$dist(e, CA_i) = \sum_k w_k \cdot |c_k^{(i)} - e_k| \quad (2)$$

$$w_k = \begin{cases} \frac{|A_i| \cdot T_c - \sum_k e_{jk}^{(i)}}{|A_i|}, c_k^{(i)} - e_k = -1 \\ \frac{\sum_k e_{jk}^{(i)}}{|A_i|}, \ otherwise \end{cases} \quad (3)$$

where $|c_k^{(i)} - e_k|$ reflects whether the example e has a different value from CA_i in the k-th dimension and $w_k (1 \leq k \leq d)$ is used to measure the influence of the difference in the k-th dimension on the distance between e and CA_i. Here, w_k is determined according to the frequency of the k-th feature occurring in all examples of a discourse relation. The distance between an example e and the centroid CA_i denotes the representativeness or to say the typicality of the example e to the relation R_i. The smaller the distance value of an example, the more typical the example is.

A distance threshold $T_{dis}^{(i)}$ is set to control which examples should be selected into the typical set of R_i. The examples with distance less than $T_{dis}^{(i)}$ are possibly re-assigned to the typical set A_i. $T_{dis}^{(i)}$ is defined depending on the maximum distance and the minimum distance between the examples and the centroid CA_i, i.e.,

$$T_{dis}^{(i)} = min_e dist(e, CA_i) + p^{(i)} (\max_e dist(e, CA_i) - \min_e dist(e, CA_i)) \quad (4)$$

where $p^{(i)}$ is a control parameter within the interval (0,1) for R_i. If $p^{(i)}$ is set 0, $T_{dis}^{(i)}$ equals to the minimum distance, meaning that no examples can be included into the typical set. On the other extreme, if $p^{(i)}$ is 1, $T_{dis}^{(i)}$ equals to the maximum distance, it allows all the examples to be selected. The value of $p^{(i)}$ is also tuned to assure that typical examples can be well selected in each iteration.

5 Experiments and Evaluation

5.1 Experiment Set-up

The experiments and evaluations are conducted on the PDTB and RST-DT corpus, which contains 2519 and 385 Wall Street Journal articles respectively. PDTB is mainly used to evaluate and analyse recognition performance of our methods. RST-DT is used to verify the portability.

Following the work of Pitler, Louis and Nenkova (2009), the sections 2-20 of PDTB are used for training, the sections 0-1 for development and the sections 21-22 for test. As for the discourse relations, we adopt the top level of PDTB's annotations, which is composed of four major relation classes: *Temporal*, *Contingency*, *Comparison* and *Expansion*. Though PDTB allows each

sentence pair to be annotated with more than one relation, we only extract the first relation labelled for each sentence pair here. Table 2 shows the number of each relations in PDTB.

Class	Training		Test	Develop.
	EX	*IM*	Implicit	Implicit
Comparison	4209	1894	146	191
Contingency	2505	3281	277	287
Temporal	2633	665	67	54
Expansion	4770	6792	556	651
Total	14117	12632	1046	1183

TABLE 2 – Discourse relation distribution in PDTB.

According to the 7 types of features introduced in Section 3.1, in total 4022 features are extracted. Then each sentence pair is represented as a 4022-dimension binary feature vector. The two classifiers, i.e., the Naïve Bayes and Decision Tree classifiers are implemented with MALLET[1]. Two metrics, i.e., accuracy and F_1 measure, are used to evaluate the performance:

$$\text{Acc} = \frac{TruePositive + TrueNegative}{All} \quad \text{and} \quad F_1(R_i) = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall}$$

where *precision* and *recall* are two most common criteria to evaluate information retrieval and information extraction systems.

Four sets of experiments are designed (1) to tune the two thresholds $T_c^{(i)}$ and $T_{dis}^{(i)}$ in SCC; (2) to compare different strategies of selecting seed sets for SCC; (3) to compare the performance of various training sets on different classifiers; (4) to verify the portability of our methods.

5.2 Threshold Tuning in SCC

SCC aims at selecting typical examples for training discourse classifiers. Since it is difficult to directly evaluate the quality of a training set, we evaluate the training set outputted by SCC via the classification performance of a Decision Tree classifier. For each discourse relation R_i, SCC involves two main thresholds. $T_c^{(i)}$ determines which features are significant to the relation R_i, and $T_{dis}^{(i)}$ defines the borderline between the typical examples and the atypical ones. It is hard to find a global optimized solution for the combination of these two factors. So we apply a gradient search strategy. As in formula (4), $p^{(i)}$ is the only determining factor of $T_{dis}^{(i)}$. At first we set $p^{(i)}$ the value of 0.5, and different values of $T_c^{(i)}$ ranging from 0.05 to 0.35 are examined. Then, given that $T_c^{(i)}$ is set to the value with the best performance, we conduct experiments to find an appropriate value for $p^{(i)}$.

We ran four binary classifiers to distinguish each discourse relation (*Comp.*, *Cont.*, *Temp.*, and *Expa.* for short) from the others. For each relation, we include equal number of positive and negative examples in the training data. The positive examples are selected from the typical set of the relation while the negative examples are randomly chosen from the atypical set of the same relation or the other discourse relations. We use all the 1183 implicit relations in the development set, which is representative of the natural distribution of implicit discourse relations. Table 3 lists the F_1 and accuracy (within parentheses) of the implicit relation classifiers.

[1] www.mallet.cs.umass.edu.

T_c	*Comp*. vs. other	*Cont*. vs. other	*Temp*. vs. other	*Expa*. vs. other
0.05	23.2 (54.2)	39.0 (24.3)	12.8 (54.5)	0 (45.0)
0.10	23.9 (40.4)	41.9 (26.5)	12.8 (46.4)	64.4 (53.6)
0.15	**27.9 (39.4)**	38.6 (24.6)	12.5 (43.6)	66.2 (54.6)
0.20	27.6 (24.1)	39.9 (37.4)	12.4 (47.1)	68.3 (55.4)
0.25	17.4 (75.1)	42.1 (29.1)	**13.4 (45.5)**	**71.0 (55.0)**
0.30	18.4 (73.0)	**42.3 (28.3)**	11.7 (45.2)	55.2 (50.0)
0.35	17.0 (74.9)	39.1 (24.8)	12.6 (43.0)	55.2 (50.0)

TABLE 3 – F_1 (Acc) with varying $T_c^{(i)}$ values (p=0.5).

Table 3 shows that the value of $T_c^{(i)}$ directly influences the quality of the generated training set. When $T_c^{(i)}$ is assigned a smaller value, more features will satisfy the percentage requirement. That means more features will be reflected in the centroid and it will cause the distance between an example and the centroid is closer to one another. Then when $T_{dis}^{(i)}$ is fixed, more examples will enter into the typical set. Oppositely, when $T_c^{(i)}$ is assigned a larger value, it is more difficult for a feature to satisfy the percentage requirement. Then less number of features is reflected in the centroid. Notice that in general cases when the value of $T_c^{(i)}$ is larger than 0.35, the generated centroid closely approaches to the zero vector and thus does not work in the typical example selection. According to the best F_1 of each relation, we set the $T_c^{(i)}$ values to **0.15**, **0.3**, **0.25** and **0.25** for *Comp*., *Cont*., *Temp*., and *Expa*. respectively.

$p^{(i)}$	*Comp*. vs. other ($T_c^{(i)}$=0.15)	Cont. vs. other ($T_c^{(i)}$=0.3)	Temp. vs. other ($T_c^{(i)}$=0.25)	Expa. vs. other ($T_c^{(i)}$=0.25)
0.1	23.1(42.0)	0(75.7)	6.0(37.2)	0(45.0)
0.2	25.6(45.5)	0(75.7)	8.8(38.1)	0(45.0)
0.3	24.3(66.4)	29.8(58.7)	9.6(52.0)	0(45.0)

TABLE 4 – F_1 (Acc) with varying $p^{(i)}$ values ($T_c^{(i)}$ is fixed).

Next, with the tuned $T_c^{(i)}$ values, we inspect the performance of SCC with different $T_{dis}^{(i)}$ by tuning the value of $p^{(i)}$. Table 4 illustrates that almost all the classification reach their best performance at around $p^{(i)}$=0.5 where the threshold is the average of the minimum and maximum distances of the examples to the corresponding centroid. Then, in the following experiments, we set the $T_c^{(i)}$ values to **0.15**, **0.3**, **0.25** and **0.25** for *Comp*., *Cont*., *Temp*., and *Expa*., and all values of $p^{(i)}$ to 0.5.

At the same time, we observe the constituents of the best training data set generated by SCC for each relation. Table 5 illustrates the distributions of the final training set. From this table we can see that both the *IM* examples and *EX* examples contribute to the final typical example sets which is composed of 6753 artificial examples and 7816 real ones , According to Table 2 and Table 5, about 61.8 percent (7816/12632) of the *IM* examples and 47.8 percent (6753/14117) of the *EX* examples are typical. In the cases where the explicit discourse markers are absent, normally

richer linguistic features are involved to indicate the implicit discourse relations. For this reason, the real implicit examples tend to be typical.

	From EX_i	From IM_i	Total
$A_{Comp.}$	1293	852	2145
$A_{Cont.}$	1717	1418	3135
A_{Temp}	2090	404	2494
$A_{Expa.}$	1653	5142	6795
Total	6753	7816	14569

TABLE 5 – Constituents of the final typical sets.

5.3 Influence of Initial Seed Sets

The SCC algorithm begins with a seed set of typical examples that are picked out from the training data according to the manually summarized rules (denoted as the manual strategy) in section 4.2.1. The seed sets are generally composed of 1-5% of the corresponding relations.

stragegy	*Comp.* vs. other	*Cont.* vs. other	*Temp.* vs. other	*Expa.* vs. other
Manual	**27.9(39.4)**	**42.3(28.3)**	**13.7(44.9)**	**71.0(55.0)**
IM_seed	22.5(57.6)	39.8(47.4)	9.5(48.5)	50.9(47.4)
*EX*_seed	20.2(62.6)	39.0(24.3)	7.9(45.0)	55.2(50.0)
Random	19.1(75.7)	37.8(29.8)	8.0(27.9)	53.6(45.2)

TABLE 6 – F_1 (Acc) with different seed sets on Dev. Data.

stragegy	*Comp.* vs. other	*Cont.* vs. other	*Temp.* vs. other	*Expa.* vs. other
Manual	**28.5(62.0)**	**48.5(49.4)**	**14.7(69.0)**	**71.1(57.3)**
IM_seed	26.4(60.7)	41.9(26.5)	12.0(35.8)	52.6(49.2)
*EX*_seed	21.2(63.0)	41.9(35.4)	11.7(52.4)	54.6(50.1)
Random	22.2(47.1)	36.3(48.8)	11.1(40.2)	52.6(49.2)

TABLE 7 – F_1 (Acc) with different seed sets on Test Data.

For comparison purpose, we also examine the other three automatic seed set selection strategies on both development and test data. The results are shown in Table 6 and Table 7. We select the *IM* and *EX* data as seed set separately, denoted as *IM_seed* and *EX_seed* strategy respectively. With the Random strategy, we randomly select 10% of examples from the *EX* and *IM* data as the seed set for each relation. Both Table 6 and Table 7 show the superiority of the manual strategy over the other three. SCC to some extent is sensitive to the initialization of the typical set and could achieve a better performance with a better seed set of typical examples.

5.4 Evaluation of Implicit Relation Classifiers

We build four binary classifiers (*Comp.* vs Other, *Cont.* vs Other, *Temp.* vs Other, and *Expa.* vs Other) for relation labelling, and implement a 4-way classifier directly using the typical examples. All the 1046 implicit relations in the test data are used to compare our algorithm with the others.

Table 8 summarizes the performance implemented by Decision Tree (DT) and Naïve Bayes (NB) classifiers trained on different training sets in comparison with the state-of-the-art performance presented in Pitler et al. (2009), which solely uses the *IM* data to examine the influence of several linguistic features on implicit relation prediction. The second and third rows respectively show

Pitler's best results using single feature (Pitler-1) and combined features (Pitler-2), which are evaluated by a Naïve Bayes classifier. The IM_i, EX_i, EX_i+IM_i rows refer to our results of directly taking the *IM* data, the *EX* data, and both the *EX* and *IM* data as the training set respectively. Notice that all implementation of the IM_i method but feature selection is the same as Pitler's, though the performance of the IM_i method is far below Pitler's best results. This means feature selection is a key to promoting the performance.

		Comp. vs. Other	*Cont.* vs. Other	*Temp.* vs. Other	*Expa.* vs. Other	4-way
NB	Pitler-1	21.0(52.6)	36.7(62.4)	15.9(61.2)	71.3(59.2)	(65.4)
	Pitler-2	22.0(56.6)	47.1(67.3)	16.8(63.5)	76.4(63.6)	--
	IM_i	6.7(81.4)	41.9(28.0)	13.4(30.7)	44.4(51.9)	(51.3)
	EX_i	18.7(74.3)	40.1(27.6)	12.4(48.6)	8.2(46.6)	(34.1)
	EX_i+IM_i	14.0(76.5)	41.9(27.0)	12.7(44.8)	27.5(47.5)	(42.3)
	SCC	**24.3(58.3)**	**43.1(65.2)**	**18.0(92.2)**	**68.6(52.4)**	**(68.3)**
DT	IM_i	11.6(41.5)	38.7(40.5)	14.3(76.1)	38.8(44.7)	(53.5)
	EX_i	18.9(70.5)	41.9(26.5)	12.1(8.2)	0(46.8)	(42.6)
	EX_i+IM_i	14.0(76.5)	41.9(26.5)	9.0(67.3)	0(46.8)	(51.4)
	SCC	**28.5(62.0)**	**48.5(49.4)**	**14.7(69.0)**	**71.1(57.3)**	**(72.2)**

TABLE 8 – Performance comparison on PDTB.

SCC means using the training set which is composed of typical examples. Since the typical examples are picked out by SCC due to their distinct features, it is more suitable for the DT classifier to acquire the classifying rules according to the distinct features. That is why the performance of the DT classifier is better than that of the NB classifier in Table 8. The performance of both the DT and NB classifiers trained by typical examples are comparable to Pitler-1 and Pitler-2, though feature selection is not concerned in our systems. This table also shows that using typical examples as training data is more effective than using either IM_i, EX_i, or both IM_i and EX_i data as training set. For detecting the comparison relation with the DT classifier, the training set output by SCC significantly outperforms IM_i, by as much as about 17% absolute improvement in F_1-scores (i.e., 28.5 vs. 11.6). It is also observed that the performance of using IM_i as training set is comparable to that of using EX_i. This conforms to our assumption that typical examples contributes to the classification performance, while the final typical example set is composed of almost the same percent of the *IM* data and *EX* data according to Table 5.

According to the typical/atypical distribution in the training data, the test data should be composed of about 61.8% of typical ones and 38.2% of atypical ones. Since we do not preprocess the test data, the typical examples and the atypical ones in the test data are identified for their relations simultaneously. We observe the 4-way classification results with the DT classifier and find that most examples correctly identified are typical while the wrongly identified examples are usually atypical. For example, the third example in Section 1 is identified as *Expansion*.

5.5 Evaluation of Portability

To verify the portability of our method on RST-DT, we divide the whole RST-DT data into 347 training articles and 38 test articles. Different from PDTB, RST-DT includes about 18 relation types (RST-DT, 2002). To avoid data sparseness, we choose 4 relations that include a sufficient amount of examples. They are *Temporal*, *Contrast*, *Cause* and *Background*, and to some extent they are consistent with the 4 discourse relation types of PDTB. At the same time, we collect all

the 4 discourse relations spanning over individual sentences. Table 9 illustrates the relation distribution. For the 4 relations, we set $T_c^{(i)} = 0.25$ and $p^{(i)}=0.5$, SCC outputs the typical and atypical sets and their sizes are also given in the table.

Class	Training		Test	SCC	
	EXi	***IMi***	Implicit	A_i	B_i
Contrast	972	578	311	610	940
Background	701	677	330	660	718
Cause	304	785	535	846	243
Temporal	466	462	244	590	338

TABLE 9 – Relation distribution on RST.

Here, we evaluate the performance of SCC with the Decision Tree classifier. We compare it with the three baselines: real implicit examples (IM_i), artificial implicit examples (EX_i) or all the examples as training data (IM_i+EX_i). Table 10 shows that SCC can promote the performance with statistical significance (i.e., p-value[2]<0.1) on F_1. In addition, F_1 of *Contrast vs Other* (31.6) outperforms that of *Comparison vs Other* (28.5) on PDTB. It is the same for *Temporal*. According to our analysis, the reason is that the relations of RST-DT are fine-grained and it is relatively easy for SCC to obtain typical examples.

	Contrast vs. Other	*Background* vs. Other	*Cause* vs. Other	*Temporal* vs. Other
SCC	**31.6 (43.3)**	**38.3 (31.1)**	**54.8 (37.7)**	**31.2 (38.2)**
IM_i	27.6 (56.1)	34.8 (30.4)	35.6 (54.4)	29.2 (17.1)
EX_i	24.0 (64.9)	34.0 (41.5)	30.6 (57.1)	17.6 (67.0)
IM_i+EX_i	20.8(62.4)	34.9 (30.5)	32.2 (56.6)	27.2 (43.8)

TABLE 10 – F_1 (Acc) comparison on RST-DT.

Conclusions

In this paper, we for the first time present the typical/atypical perspective to select the most suitable training examples for implicit discourse relation recognition. A novel single centroid clustering algorithm is proposed to differentiate typical and atypical examples for each discourse relation. The experimental results show that the performance of the implicit relation classifiers with the typical examples selected as the training set are comparable to the best state-of-the-art methods on PDTB v2.0. In addition, the experiments on RST-DT show statistically significant improvements over the baselines and demonstrate the portability of our method. We will further explore more linguistic features and employ our approach on finer grained relation types. In SCC, we want to further investigate other distance formula. We also hope to explore the effective way to make use of the unlabelled discourse data.

Abstract

Together with the ever-growing amount of Chinese web data, the number of opinions voiced by Chinese users is rapidly increasing, and analyzing them is an important task. This paper introduces a Chinese Evaluative Information Analyzer (CEIA) and proposes a method to improve its performance. We use *evaluative information* as a unifying term for the information about attitudes, opinions, sentiments and so on. This paper makes three contributions: (i) CEIA can identify and analyze a more diverse and richer set of evaluative information than previous studies for Chinese; (ii) to implement the system, we constructed an original annotated corpus for Chinese evaluative information and built a large sentiment dictionary; (iii) we introduce syntactic dependency, semantic class and distance features to improve the evaluative information extraction. The performance of the system and the effectiveness of the newly introduced features are evaluated in a series of experiments on our Chinese evaluative information corpus.

Title and Abstract in Chinese

中文评价信息分析

随着网络的不断普及，中文用户在网络平台上发表的评价性文本的数量也在迅速增长，因而分析这些日益膨胀的评价性信息则成为一项重要的课题。本论文介绍了一个中文评价信息分析系统（CEIA）并提出新的方法来提高系统的性能。在这里我们用评价信息来统一表达关于态度，观点和情感等的评价性相关信息。本文的贡献主要体现在以下三个方面：（i）与以往研究相比，CEIA可以识别和分析更加多种多样，更加丰富的评价信息；（ii）为了实现CEIA，我们标注了一个中文评价信息语料并且构筑了一个大规模的情感词典；（iii）我们引入了句法依存特征，语义聚类特征和距离特征来提高评价信息抽取的性能。通过在中文评价信息语料库上一系列实验，给出了系统的整体性能，并验证了新方法的有效性。

1 Introduction

To automatically find or track the attitudes, feelings and evaluations in texts, opinion mining and sentiment analysis have been extensively studied from different perspectives (Pang and Lee, 2008). With the ever-growing number of Chinese users (over half a billion users only in mainland China), the amount of web opinions in Chinese is rapidly increasing, and analyzing them is an important task. However, research and resources about the Chinese opinion analysis lag behind those for extensively studied languages, such as English. Therefore, opinion analyzers, which can deal with Chinese web data of a great variety of topics and styles, are especially in great need.

To meet this requirement, we introduce a Chinese Evaluative Information Analyzer (CEIA) that can mine a wide variety of evaluative information from Chinese web documents. We use *evaluative information* as a unifying term for the information concerning attitudes, opinions and sentiments, and so on, which is useful to provide a view of evaluation.

The system automatically analyzes Chinese evaluative information through the following processes: (1) *extracts evaluative expressions*; (2) *identifies evaluation holders*; (3) *extracts evaluation targets*; (4) *determinates evaluation types*; (5) *determinates the sentiment polarities of the evaluative expressions*.

CEIA has the following two characteristics:

Firstly, CEIA can analyze a more diverse and richer set of evaluative information than the previous studies for Chinese. The previous research on Chinese opinion analysis focuses on subjective expressions (*opinionated sentences*) (Liu, 2010), as in the Multilingual Opinion Analysis Task (MOAT) of NTCIR (Seki et al., 2010). However, some objective expressions that describe positive or negative facts are also informative in that they express some kinds of evaluations. Also, requests are some kinds of representations of opinions or attitudes. Consider the following sentences,

1. *Many people are using mobile phone A.*
2. *The users hope company A will offer them a security lock function.*

The sentence 1 suggests that "mobile phone A" is popular and has been chosen by many people. The sentence 2 claims that the company A does not offer a security lock function now and the user request the company to offer it. In some sense, this sentence also includes the evaluation or unsatisfied feelings of the users. We want to consider such cases as "implicit" evaluations for "mobile phone A" and "company A", in addition to subjective expressions such as "I love mobile phone A".

To the best of our knowledge, this is the first paper that treats the above implicit evaluations in Chinese evaluative information analysis. Implicit evaluations have been considered by Nakagawa et al. (2008) for Japanese. They presented the study about extracting subjective and objective Japanese evaluative expressions from the web and their work was used in WISDOM system (Akamine et al., 2010) [1] , and shown to be useful to support users' judgement of information credibility. Inspired by their work, we adopt the task definition and expand the research scope of Chinese evaluation information analysis.

Secondly, CEIA can deal with the data in diverse topics and writing styles. The existing studies about Chinese opinion analysis are domain-limited. For example, Chinese Opinion Analysis Evaluation (COAE) (Zhao et al., 2008) mainly deals with opinion analysis of reviews. MOAT (Seki et al.,

[1] http://wisdom-nict.jp/

2010) deals with the analysis of news articles, which are written in a formal writing style. To make our system more robust to the web data of a great variety of topics and styles, we constructed an original annotated Chinese evaluative information corpus whose sentences are extracted from web pages of wide range of topics and styles. CEIA consists of many machine learning modules such as CRFs and SVMs and the corpus was used to train these modules, resulting in a robust evaluative information analyzer.

To achieve high system performance is also a primal goal of evaluative information analysis. In this work, we introduce new features to improve the performance. Specifically, syntactic dependency features, semantic class features and distance features are added to the baseline models. To demonstrate the performance of our system and the effectiveness of our new features, we conducted a series of experiments on the Chinese evaluative information corpus.

2 CEIA

In this section, we describe the entire picture of CEIA and the resources for the system. We first introduce the specifications of the evaluative information on which this study is focused, and then we explain how an evaluative information corpus is constructed. Finally, we explain each process of CEIA in detail.

2.1 Evaluative Information

There is a wide variety of evaluative information on the web, such as reviews of products and criticisms of policies. The information reflects various perspectives of individuals or organizations. Research on evaluative information analysis are conducted from different points of views and at different levels of granularity (Kobayashi et al., 2004; Kaji and Kitsuregawa, 2006; Liu, 2010; Pang and Lee, 2008; Akamine et al., 2010). In this section, we describe the specifications of evaluative information on which this study is focused.

We analyze the evaluative information at a fine-grained level. We use a 5-tuple that consists of (1) an evaluative expression, (2) an evaluation holder, (3) an evaluation target, (4) an evaluation type, and (5) sentiment polarity as the basic unit of evaluative information and call it an *evaluative information set*. Each item is defined as follows.

Evaluative expression is a span of text that describes the evaluation. It can be a single word, a multi-word expression, or a sentence.

Evaluation holder is a person, a group or an organization that expresses the evaluation.

Evaluation target is a thing, a matter, or an entity about which the evaluation was expressed.

Evaluation type is the category to which the evaluative expression belongs. It will be explained in detail in the following subsection.

Sentiment polarity indicates whether the evaluation expression for the evaluation target is positive or negative from the viewpoint of the evaluation holder. For some cases, it may differ from the polarity of the whole sentence. For examples, *Mike strongly objected to the war.* Although the entire sentence is not negative, the sentiment polarity of evaluative expression "*strongly objected to*"is negative. That is to say, the evaluation holder "*Mike*" has a negative opinion on the evaluation target "*war*". From this point of view, we consider the sentiment polarity in the connection with specific evaluation holders and evaluation targets at fine-grained levels.

2.1.1 Evaluation Type and Sentiment Polarity

There are various kinds of evaluative expressions such as approving or opposing attitudes, description of merits or desirable events, and so on. To clarify the scope of evaluations that we address in this study,we classify evaluative expressions into several categories. Such categorization is also helpful for further use of evaluative information.

Following the work of Akamine et al. (2010), we use the following evaluation types. Each type, except for "Request", has sentiment polarities: positive (+) or negative (−). We use underline to show evaluation targets, boldface for evaluative expressions, and italics for the evaluation holders.

- Emotion+/−: an expression that expresses human feelings or emotions.
  e.g., *XiaoLi* **is not interested in** product A. (Emotion−)
- Comment+/−: an expression that expresses approval/disapproval or praise/criticism.
  e.g., *Mike* said that movie A **is one of the best he has ever seen**. (Comment+)
- Merit+/−: an expression that cites good points/shortcomings or merits/demerits.
  e.g., Drug A **starves and kills cancer cells**. (Merit+)
- Event+/−: an expression that describes good/bad events, desirable/undesirable experience.
  e.g., Camera X **broke just three days after I bought it**. (Event−)
- Adoption+/−: an expression that shows adoption, promotion or rejection.
  e.g., **Nobody bought** Mike's ebook. (Adoption−)
- Request: an expression that expresses proposals, obligations, advices, hopes or requests.
  e.g., *The users* **hope Company A can offer them a security lock function**. (Request)

2.2 Chinese Evaluative Information Corpus

To train our system and analyze a wide variety of evaluative information, we constructed an evaluative information corpus which consists of Chinese sentences extracted from web pages of wide range of topics and styles. We chose 66 topics which relate to things we use in daily life, controversial policies, movie reviews and so on. The followings are the steps for the corpus construction:

(1) Use the topic as the keyword and search documents using a Web search engine.

(2) Collect HTML files of 900 web pages from the retrieval results for each topic. Specifically, the first 300 pages in the retrieval results from forum sites, the first 300 pages from blogs and the first 300 pages from general sites.[2] In this way, the corpus can cover different writing styles and reflect more diverse perspectives.

(3) Randomly choose candidate sentences that include topic keywords from the above files. For each topic, we randomly collected 200 sentences, and for each sentence, we provided context information (the previous two sentences and subsequent two sentences) for annotation reference.

(4) Trained annotators judged whether a sentence contained any evaluative expressions or not. If the sentence contained evaluative expressions, the annotator annotated the evaluation holders, the text spans of the evaluative expressions, the text spans of the evaluation targets, the evaluation types and the sentiment polarities. That is to say, an evaluative information set was annotated for each evaluation expression. For evaluation holder annotation, if the writer is the evaluation holder, [*author*] is annotated as the holder. If the holder is neither explicitly written in the sentence

[2]We suppose the URL including "forum", as the web pages from forum sites, the URL including "blog", as the web pages from blog sites, and the rest are general sites, although it may include some noise.

Giga-word	1,977	770	2,747
Total	8,247	20,164	28,411

Table 1: The statistics of sentiment dictionary

nor is the writer, [*undefined*] is annotated. When annotating the current sentences, the annotator could refer to its context information. In some cases, one sentence may contain multiple evaluative targets or multiple evaluation expressions, and then multiple evaluative information sets must be annotated. For example, *Mike said that Movie A is great but it is not better than Movie B which is the best movie he has seen.* Two evaluative information sets should be annotated: (1) (is great, Mike, Movie A, Comment+) and (2) (is the best movie he has seen, Mike, Movie B, Comment+). Note that *it (Movie A) is not better than Movie B* is a comparative expression. we do not deal with the comparative sentences that do not show clear sentiment polarities at present.

The total number of sentences in the corpus was 6,680. There were 5,111 evaluative information sets in the corpus. It took 380 man-hours to construct the entire corpus.

2.3 Sentiment Dictionary

A sentiment dictionary is a set of words and their polarities (for example, [break a record, +], [break the law, −]). Such a dictionary is a fundamental resource for evaluative information analysis. We built a Chinese sentiment dictionary in the following way.

(1) Since it is time-consuming to built a dictionary without any reference, we semi-automatically translated an existing Japanese sentiment dictionary (JSD)[3] to Chinese. We mapped the entries of JSD with a Japanese-Chinese bilingual dictionary, and obtained Chinese translations and their polarities transferred from Japanese entries. Unmapped entries were translated by human. The resulting Chinese entries and polarities were finally manually checked. There were 36,981 entries in JSD (9,030 positives and 27,951 negatives) , and we obtained 25,664 entries for Chinese.

(2) So that the dictionary covers the frequently used polarity-bearing words, we also auto-segmented and tagged the XIN_CMN portion of Chinese Gigaword Version 2.0 (LDC2009T14), which has approximately 311 million words, and collected adjectives (with POS tags "VA" and "JJ") and idiom candidates with high frequency. We removed the overlap between the words collected from JSD, and manually checked the rest of the candidates, and tagged them with polarity.

Finally, we build a Chinese sentiment dictionary with 28,411 entries. Its detailed statistics are shown in Table 1. It is used in evaluative expression extraction and polarity classification models.

2.4 CEIA System

CEIA flow is shown in Figure 1. First, the user inputs raw sentences; second, the system (1) extracts the evaluative expression from the input sentences, (2) identifies the evaluation holder, (3) extracts the evaluation target, (4) categorizes the evaluation type and (5) determinates the sentiment polarity. Finally the results from these processes are summarized and displayed as output to user. The rest of this section describes the above processes in detail.

[3]The dictionary is distrubuted only to the member of the ALAGIN forum (http://alaginrc.nict.go.jp). It is for the freely available package of opinion extraction tool, which can be obtained from http://alaginrc.nict.go.jp/opinion/index_e.html

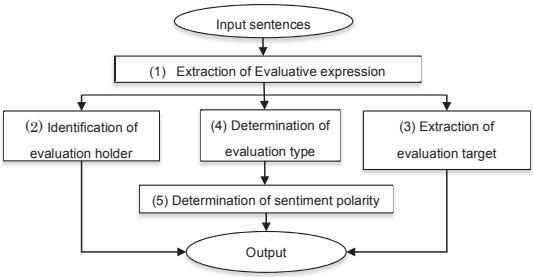

Figure 1: CEIA flow

Type	Feature	Description
Word feature	$w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}$, $w_{i-1}\&w_i, w_i\&w_{i+1}$	Word surfaces of the previous but one, previous, next, and next but one words; word surface bigram of the previous (next) word and the current word.
POS tag feature	$t_{i-2}, t_{i-1}, t_i, t_{i+1}, t_{i+2}$, $t_{i-1}\&t_i, t_i\&t_{i+1}$	POS tags of the previous but one, previous, next, and next but one words; POS tag bigram of the previous (next) word and the current word.
Polarity feature	$p_{i-2}, p_{i-1}, p_i, p_{i+1}, p_{i+2}$, $p_{i-1}\&p_i, p_i\&p_{i+1}$	The word polarities of the previous but one, previous, next, and next but one words; word polarity bigram of the previous (next) word and the current word.

Table 2: Feature templates for evaluative expression extraction

2.4.1 Extraction of Evaluative Expressions

The goal of this process is to identify the words, phrases or sentences that express the evaluations in the text. We use the sequence tagging method with the BIO tag-set, which was initially used for opinion extraction by Breck et al. (2007). In the method, each word is tagged with one of three types of labels based on its position in the evaluative expressions: (B) beginning of an evaluation expression, (I) inside of an evaluation expression or (O) outside of an evaluation expression. For example, for the sentence, "*The chief editor* **really loves** book A." , the BIO tags are encoded in the following way:

The/O chief/O editor/O **really/B loves/I** book/O A/O ./O

We employ the linear chain CRFs (Lafferty et al., 2001) as our learning model for BIO tagging. Specifically, we use CRF++ (version 0.54) implementation by Taku Kudo. [4]

The features shown in Table 2 are used in the CRF for the i-th word in a sentence. Here, w_i, t_i, and p_i denote the current word surface, the part-of-speech tag and the polarity of the i-th word in the input sentence, respectively. A word's polarity is obtained from the sentiment dictionary. To search the word in the dictionary, we use forward maximum matching. We generate the above features with the unigram template of CRF++ (i.e., as the combination with the output tag at the current position, o_i). We also use the tag bigram feature (i.e., $o_{i-1}\&o_i$) .

2.4.2 Extraction of Evaluation Targets

The evaluation target is extracted from a sentence that contains the evaluative expression with a BIO tagging method using a CRF, as in the extraction of evaluative expressions. We use the same word feature and POS tag feature as in evaluative expression extraction and introduce position

[4] http://crfpp.sourceforge.net/

Type	Feature	Description
unigram p	$w_1, t_1, w_2, t_2, ...w_s, t_s,$	For the words previous to the evaluation expressions, the word and POS tag unigrams are added as type-p unigram features
unigram x	$w_{s+1}, t_{s+1}, ...w_{s+n}, t_{s+n},$	For the words in the evaluation expressions, the word and POS tag unigrams are added as type-x unigram features
unigram n	$w_{s+n+1}, t_{s+n+1}, w_{s+n+2}, t_{s+n+2}, ...w_l, t_l,$	For the words next to the evaluation expressions, the word and POS tag unigrams are added as type-n features
bigram	$w_{s+1}\&w_{s+2}, t_{s+1}\&t_{s+2}, ... w_{s+n-1}\&w_{s+n}, t_{s+n-1}\&t_{s+n}$	For the words in the evaluation expressions, the word bigram and POS tag bigram features are added
category	$c_i\&w_{i-1}, c_i\&w_i, c_i\&w_{i+1}, c_j\&w_{j-1}, c_j\&w_j, c_j\&w_{j+1}..$	For the words in the evaluative expressions, the category and word bigram feature are added: the category and the previous word bigram, the category and current word bigram and the category and the next word bigram

Table 3: Feature templates for evaluation type determination

features. The position feature setting is $\{e_{i-2}, e_{i-1}, e_i, e_{i+1}, e_{i+2}, e_{i-1}\&e_i, e_i\&e_{i+1}\}$. Here, e_i is a flag that expresses the position of w_i with respect to the evaluative expression. If w_i is previous to an evaluative expression, then e_i is "p"; if w_i is in an evaluative expression, then e_i is "x"; and if w_i is next to an evaluative expression , then e_i is "n". For example, for the sentence, " *The chief editor* **really loves** book A." , the e_i is encoded in the following way. If no holder was found by the CRF model, [*undefined*] was set as the evaluation target of the current evaluation expression.

The/p chief/p editor/p really/x loves/x book/n A/n ./n

2.4.3 Determination of Evaluation Types

We predicted the evaluation types using one-versus-rest multi-class linear kernel support vector machines (SVMs). We used the features shown in Table 3 for SVMs. Here w_i, t_i and c_i denote the word surface, the part-of-speech tag and the type category of the i-th word, respectively. l, n and s denote the number of words in the input sentence, the number of words in the evaluative expression and the number of words previous to the evaluative expression in the input sentence, respectively.

A word's type category is obtained from a type category dictionary. In the investigation of evaluation types, which has been described in Section 2.1.1, we found that each evaluation type has some characteristic words. Therefore we manually listed such characteristic words for each evaluation type and generated a type category dictionary, which includes 141 entries, for example, [希望(hope), Request], [憎恨(hate), Emotion], [称赞(praise), Comment]. For words in the evaluative expressions, the category feature can be generated only when the word is in the type category dictionary. The category feature can provide some improvement in performance according to our preliminary experiments.

2.4.4 Identification of Evaluation Holders

While the evaluation holders are sometimes stated explicitly in sentences where the evaluative expressions are contained, in more than half of the cases in Chinese, they are not clearly stated in the sentence. When evaluation holders are not expressed in the sentence, the evaluation holder is usually the information sender, i.e., the "author" in other words. Therefore, we consider that the opinion holder identification consists of a classification task and an information extraction task. That is, the evaluation holder is identified in two steps in CEIA: (1) use linear kernel support vector machines (SVMs) to determine whether the evaluation holder is *author* or *not-author*; (2) if the evaluation holder is not the author, then use a CRF tagging

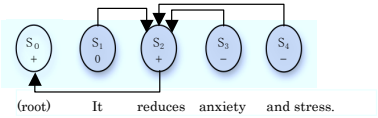

Figure 2: Example of CRFs with hidden variables

model to extract the evaluation holder for each evaluative expression. For the SVM model, in addition to the same features in types of unigram p, unigram x, unigram n and bigram as in Section 2.4.3, we also use the bigram p $\{w_1\&w_2, t_1\&t_2 ... w_{s-1}\&w_s, t_{s-1}\&t_s\}$ and bigram n $\{w_{s+1+1}\&w_{s+n+2}, t_{s+n+1}\&t_{s+n+2} ... w_{l-1}\&w_l, t_{l-1}\&t_l\}$ features to add the bigram information for the words previous to the evaluation expressions and the words next to the evaluative expressions. For CRF model, we use the same features as in Section 2.4.2. If no holder was found by the CRF model, [*undefined*] was set as the evaluation holder of the current evaluation expression.

2.4.5 Determination of Sentiment Polarity

A typical approach for sentiment classification is to use supervised machine learning algorithms with bag-of-words as features (Pang et al., 2002). However, this method cannot consider syntactic structures that seem essential to infer the polarity of a whole sentence. We follow the work of Nakagawa et al. (2010) and use a dependency tree-based method, which was demonstrated to perform better than other methods based on bag-of-words in both English and Japanese sentiment classification tasks. The sentiment polarity is classified using conditional random fields (CRFs) with hidden variables. In the method, the sentiment polarity of each dependency subtree, which is not observable in training data, is represented by a hidden variable. The polarity of the whole sentence is calculated by considering the interactions between the hidden variables. For example in Figure 2, each phrase (indicated by a circle) in the polarity-bearing sentence/expression has a random variables. The random variable represents the polarity of the dependency subtree whose root node is the corresponding phrase. Two random variables are dependent if their corresponding subtrees have head-dependent relations (indicated by an arc). Usually the polarity is labeled in expression/sentence level in the annotated corpus, and subtrees are not labeled, so all the random variables except for the root node are hidden variables (indicated by gray circles). In the model, if a head word tend to reverse the polarity of the dependent word, reversal polarity feature can be used. That is to say, it can deal with the reversal of sentiment polarities caused by polarity shifting words. For example, the "reduce" in the example is polarity shifting word. "Reduce anxiety" is positive, while "anxiety" is negative. In order to deal with the polarity shifting, 179 Chinese polarity shifting words were collected and used in the CEIA. As for the features, we used the same features as those in Nakagawa et al. (2010).

3 New Features

In this section, we describe our approach that effectively employs the dependency information, semantic class and distance information into the above evaluative information extraction (specifically evaluative expression extraction and evaluation target extraction).

3.1 Dependency Features

The use of syntactic or deep linguistic features has been tried in opinion analysis in the literature. Johansson and Moschitti (2010) demonstrated that the features derived from grammatical and

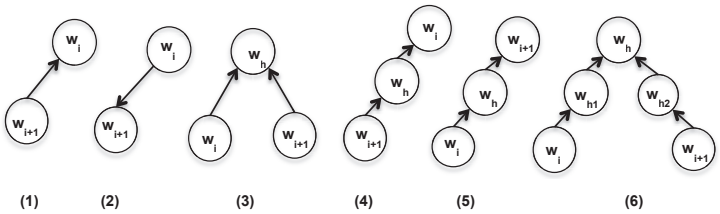

Figure 3: Different dependencies between w_i and w_{i+1} that can be linked by one or two arcs

semantic role structure can be used to improve the detection of opinionated expressions in subjectivity analysis. However, based on their evaluation, the precision decreases while the F-measure is increased. In addition, they claimed that a sequence tagging model cannot be used when using syntactic features, and they used reranking method, which will slowdown the processing. We introduce a simple dependency features for our tagging model that can be generated with the help of a Chinese dependency parser for evaluative information extraction.

Using a dependency parser, two kinds of dependency information can be obtained:

(i) *head* : the head of the current word, which is either a value of word ID, or zero ('0') if the word is the root node of the sentence.
(ii) *dependency relation*: the dependency relation of the current word to the head. The dependency relation is presented by the dependency labels: SBJ, OBJ, PRD, NMOD, VMOD, etc. The labels show function categories, such as the subject, object, predicate and so on.

We introduce the following two kinds of dependency features:

(i) *dependency head feature*: this feature is generated from the head information. The head-dependent relations between neighboring words w_i and w_{i+1} that can be linked by one or two arcs or can be linked to the same head by the same number (one or two) of arcs are summarized in Figure 3. We encoded the head-dependent relation into a new type of feature. We tried several feature representations and found that the features derived from the following method were most effective. We categorized the head-dependent relation between w_i and w_{i+1} into four groups:

- Near head-dependent relation (NH): the cases of (1), (2) and (3) in Figure 3.
- Medium head-dependent relation (MH): the cases of (4), (5) and (6) in Figure 3.
- Last word (LW): if w_i is the last word of the sentence/expression.
- Far head-dependent relation (FH): all the possible dependencies except for the above three groups.

The new features of $deph_i$ and $w_i\&deph_i$ are added for the i-th word in a sentence. Here $deph_i$ is head-dependent relation group of w_i and w_{i+1} , labeled with NH, MH, LW or FH. We suppose that such labels encode the syntactic distance information. For example, although w_i and w_{i+1} is the neighborhood in a sentence, they are distant syntactically, if the head-dependent relation group is labeled with FH.

(ii) *dependency relation feature*: this feature is generated with the information of the dependency relation. The dependency relation feature setting for evaluative expression extraction is

$\{depr_i, t_i\&depr_i\}$. Here, $depr_i$ is the dependency label of the relation between w_i and w_i's head in a sentence. Since the grammatical information is very important for evaluation target extraction, new features of { $depr_{i-2}$, $depr_{i-1}$, $depr_i$, $depr_{i+1}$, $depr_{i+2}$, $depr_{i-1}\&depr_i$, $depr_i\&depr_{i+1}$} are added for evaluation target extraction. With these features, the grammatical function information can be encoded in both the evaluative expression and evaluation target extraction tasks.

3.2 Semantic Class Features

The idea of combining semantic classes of words with discriminative learning has been previously reported in the context of named entity recognition (Miller et al., 2004; Kazama and Torisawa, 2008), dependency parsing (Koo et al., 2008) and Chinese word segmentation and POS tagging (Wang et al., 2011). We adopt and extend these techniques to evaluative information analysis and demonstrate their effectiveness in this task.

We produced the semantic classes of various levels of granularity, by using the Brown cluster hierarchy (Brown et al., 1992) at various lengths. Note that a semantic class is represented by a bit string that reflects the branching of the semantic class hierarchy.

We designed two kinds of semantic class features:
(i) full string feature: full string of the semantic class for w_i;
(ii) 6-bit prefix feature: 6-bit prefix of the semantic class for w_i.

3.3 Distance Feature

The target extraction task is to extract a target for a given evaluative expression. In most cases, the evaluation target and the evaluative expression are near to each other. Therefore, we add the distance label between w_i and the evaluative expression as a new feature for evaluation target extraction. The distance labels are defined in the following way: we first compute the distance d between w_i and the evaluative expression in word count; then when d is larger than 10, the distance label is "L"; otherwise if w_i is on the lefthand side of the evaluative expression, the distance label is d; and if w_i is on the righthand side of the evaluative expression, the distance label is $-d$. The feature setting of distance feature is $\{dis_{i-2}, dis_{i-1}, dis_i, dis_{i+1}, dis_{i+2}, dis_{i-1}\&dis_i, dis_i\&dis_{i+1}\}$. Here, dis_i is the distance label of w_i . With these feature, the position information with regard to the evaluative expression can be encoded.

4 Experiments

We evaluated the performance of the CEIA system and the effect of the new features.

4.1 Experimental Setting

We used the Chinese evaluative information corpus described in Section 2.2 as the training and test sets and performed 10-fold cross validation experiments on the corpus.

To conduct the experiments, we used the Chinese morphological analyzer described in Wang et al. (2011) and a Chinese dependency parser (CNP) [5] to obtain the Chinese word segmentation, part-of-speech tags and dependency information.

To generate the semantic classes of words, we used the XIN_CMN portion of Chinese Gigaword Version 2.0 (LDC2009T14), which has approximately 311 million words, as a large raw data and set the number of classes to 1000.

[5] http://alaginrc.nict.go.jp/cnp/index.html

We use the following measures to evaluate the performance of the system:

Recall (R) : ratio of correctly extracted evaluative expressions/targets/holders to the number of expressions/targets/holders in the gold standard corpus.
Precision (P): ratio of correctly extracted evaluative expressions/targets/holders to the number of expressions/targets/holders in system's output.
F-measure (F): harmonic mean of recall and precision.
Accuracy (Acc): ratio of the number of correct system output to the number in the gold standard. The accuracy of each tasks is defined as follows:

Accuracy of evaluation type determination: ratio of correctly identified evaluation types to the number of evaluative expressions in the gold standard corpus.
Accuracy of evaluation polarity determination: ratio of correctly classified sentiment polarities to the number of evaluative expressions of polarity-bearing evaluation types in the gold standard corpus.

To calculate the recalls, precisions and F-measures of the evaluative expressions and the evaluation targets, we use the following three criteria:

Exact match: extracted expression/target/holder is regarded as correct if it exactly matches the gold standard.

Partial match: extracted expression/target/holder is regarded as correct if it overlaps the gold standard's one. Our partial match is different from the overlap-based precision and recall measures in Breck et al. (2007). A potential issue with their overlap-based precision and recall is that the measures may drastically overestimate the system's performance as follows: a system predicting the whole sentence as an extracted expression would achieve 100% overlap-based recall and precision, if the gold standard contains any evaluative expression. In order to avoid this problem, we deal with the duplicate matches as follows: an extracted expression is only counted as overlapping with the first gold standard one, even if it can overlap with more than one gold standard's ones. From this point of view, our metric is stricter than in Breck et al. (2007).

Span partial match: this evaluation metric takes the span coverage of extracted expression/target/holder with respect to the span of the gold standard's one into consideration. We define this metric by refining the soft precision and recall described in Johansson and Moschitti (2010). First the span coverage c of a span s with respect to another span s', which measures how well s' is covered by s , was defined: $c(s,s') = \frac{|s \cap s'|}{|s'|}$. In this formula, the operator $|*|$ counts tokens (Chinese characters), and the intersection $\cap$ represents the overlap of the two spans. Then, if two spans overlapped, instead of adding "1" to the number of correctly extracted expression as in partial match, we add the span coverage to the number of correctly extracted expression. For example, if the gold standard evaluative expression had 8 tokens and 6 tokens of extracted expression overlapped with the gold standard, then we consider $3/4$ of the expression is correctly extracted. We deal with the duplicated matches in the same way as in partial match to avoid the overestimation. Although Johansson and Moschitti (2010) tried to alleviate the overestimation problem with their soft precision and recall, their measure still tend to reward long spans in recall [6] and overestimate the precision in some cases. Our metrics solved both the overestimation in recall and precision. Our metric is bounded below the exact match and above the partial match.

[6] a system predicting the whole sentence as an extracted expression would achieve 100% soft recall in Johansson and Moschitti (2010)

Task	Exact match	Partial match	Span partial match
Evaluative expression extraction	R=0.1730 P=0.2933 F=0.2176	R=0.4560 P=0.7728 F=0.5734	R=0.3934 P=0.6264 F=0.4832
Evaluation target extraction	R=0.4171 P=0.6530 F=0.5089	R=0.5442 P=0.8521 F=0.6640	R=0.5226 P=0.7934 F=0.6300
Evaluation holder identification	R=0.7455 P=0.9630 F=0.8401	R=0.7518 P=0.9714 F=0.8474	R=0.7509 P=0.8672 F=0.8047
Evaluation type determination	Acc = 0.5787	-	-
Evaluation polarity determination	Acc = 0.8146	-	-

Table 4: The performance of CEIA

4.2 Performance of CEIA

The performance of the entire CEIA system is shown in Table 4. The figures are for the best combination of the features, which will be described later. The performance of each task was evaluated independently. For example, for sentiment polarity determination task that determine the polarity of the evaluative expressions, the input evaluative expressions are the gold standard ones rather than the system output of the evaluative expression extraction task. For the evaluative expression, the performance of the exact match seems to be low. This is because it is difficult to detect the exact span of an evaluative expression. The evaluative expression detection in English also came to such situation and most work use partial match measures (Johansson and Moschitti, 2010). The performance of our system for partial match is reasonably good. Although the recall was not high, to extract information from a large amount of raw data, such as billions of web documents, we believe that the precision is a very important metric. The precision of the evaluative information extraction is 0.77. With such a relatively high precision, we suppose the evaluative expression extraction can play an active role in the actual application.

We also compared our system with the other works or systems reported in the literature, which are in the close task definition, although it is not fair to compare directly, because we deal with different languages and use different test sets. We just use their work as a reference to show that our system provided a reasonable result, when dealing with the same task in different language contexts.

As for sentiment polarity determination, we follow the work of Nakagawa et al. (2010). Their method was shown to perform better than other methods based on bag-of-words and provided accuracies ranging from 0.861 to 0.773 for a series of Japanese and English test sets. Because our test sets include various topics, this complicates the polarity classification task. Since our classification accuracy was 0.8146, we can say that Nakagawa et al. (2010)'s model also works well for Chinese.

As for the evaluative expression extraction, as we mentioned in the Section 1, Nakagawa et al. (2008) extracted subjective and objective Japanese evaluative expressions from the web. The result of their system with exact match is shown in Table5 . The performance scores are directly taken from their paper. The result indicates the difficulty of this task. The performance of our system is better than their work.

As for evaluation target extraction and evaluation holder identification, Multilingual Opinion Analysis Task (MOAT) of NTCIR-8 (Seki et al., 2010) included these tasks. Table 5 shows the best results with lenient match in opinion holder and opinion target identification tasks of simplified

work	Nakagawa et al. (2008)	MOAT of NTCIR-8	
Task	Evaluative Expression Extraction	Target Identification	Holder Identification
Recall	0.12	0.564	0.792
Precision	0.22	0.735	0.877

Table 6: Performance of new features in evaluative expression extraction

Chinese in MOAT. The results are directly taken from Seki et al. (2010). Although we use different test set and cannot compare the results directly, we can conclude that our system's F-measure is competitive with the systems that deal with a similar task.

4.3 Effect of New Features

We added the new features described in Section 3 to the evaluative expression extraction and target extraction models and performed 10-fold cross validation experiments to evaluate their effectiveness. We also tested the new features for evaluation holder extraction. However we omit the results here because the improvement by the new features was slight.

Table 6 shows the performance of the new feature in the evaluative expression extraction. Here, "all features" is the result of the combination of all the features. As mentioned in Section 4.2, to exactly identify the span of the evaluation is very difficult. Thus, we mainly refer to the results measured by partial match and span partial match here. Dependency features achieved an improvement in both recall and precision. The dependency features that introduced by Johansson and Moschitti (2010) only showed positive effect on recall with their soft partial match measure and partial match. Our span partial match and partial match are stricter measures than theirs. Note that we also evaluated our dependency head and dependency relation features use their soft precision and recall. There was no decrease in both soft precision and recall. In this point, our dependency features was comparably effective. Furthermore, our method uses the dependency features in sequence tagging model and is simpler than their method. The results also show that the full string semantic class features were the most effective ones and that a combination of four types of features achieves the best performance in F-measure. This suggests that these features are relatively independent in feature characteristics.

Table 7 shows the performance of the new features in the evaluation target extraction. The results show that the semantic class feature shows less effect in target extraction task than in evaluative expression extraction task and distance feature were the most effective one. 6-bit prefix features achieved an improvement in partial match. While the dependency head feature did not show a positive effect on the recall , it achieved best results on precision. Dependency relation features and distance features had positive effect for both recall and precision. The combination of all

5 Related Work

Some previous research extracted evaluative or polarity-bearing expressions from web documents with pre-defined linguistic patterns (Kobayashi et al., 2004; Kaji and Kitsuregawa, 2006). However, it is difficult to prepare a small number of fixed syntactic patterns to extract a wide range of evaluative expressions. Nakagawa et al. (2008) presented the study about extracting Japanese evaluative expressions from the web. Our task definition is based on their work. We applied these tasks to Chinese, made a Chinese corpus and presented our new features to improve the performance of evaluative information extraction.

In recent years, there have been several opinion-related evaluation workshops concerning Chinese opinion mining, such as Chinese Opinion Analysis Evaluation (COAE) (Zhao et al., 2008) and the Multilingual Opinion Analysis Task (MOAT) of NTCIR (Seki et al., 2010). Several subtasks are conducted in both COAE and MOAT, including the opinion-bearing sentence detection, opinion target extraction and polarity determination. The opinion target extraction task in COAE identifies the product features, which are defined as product components or attributes. Compared with COAE, the evaluation targets extracted by our system can cover a wider scope; they can be nouns, multi-word expressions or nouns modified by clauses. At the same time, we considered evaluation holders in this research. Since opinion expressers influence the credibility, identifying the evaluative holders is very important for analyzing the evaluations. MOAT also includes the opinion target and opinion holder extraction tasks. Compared with MOAT, we introduce evaluation types and extend the coverage of the opinion mining targets. Explicit and implicit opinions, and subjective and objective evaluations are considered in our research, while MOAT only considers the opinionated sentences, not including the general facts, such as positive or negative facts. Furthermore, COAE mainly deals with opinion analysis in reviews, and MOAT deals with the opinion analysis in news, which are written in a more formal writing styles. Since our system was trained with a corpus, which is written in more diverse writing styles and covers wide domains, we believe it is more robust to the web data of a great variety of topics and styles.

Conclusion

In this paper, we presented a Chinese evaluative information analysis system and proposed new simple yet effective features to improve its performance. Through a series of experiments, we demonstrated that our system can achieve reasonably good performance and that our new features provides substantial improvement in evaluative expression extraction and evaluation target extraction tasks.

Harnessing the CRF complexity with domain-specific constraints. The case of morphosyntactic tagging of a highly inflected language.

Jakub Waszczuk
Institute of Computer Science, Polish Academy of Sciences
Jakub.Waszczuk@ipipan.waw.pl

ABSTRACT
We describe a domain-specific method of adapting conditional random fields (CRFs) to morphosyntactic tagging of highly-inflectional languages. The solution involves extending CRFs with additional, position-wise restrictions on the output domain, which are used to impose consistency between the modeled label sequences and morphosyntactic analysis results both at the level of decoding and, more importantly, in parameters estimation process. We decompose the problem of morphosyntactic disambiguation into two consecutive stages of the context-sensitive morphosyntactic guessing and the disambiguation proper. The division helps in designing well-adjusted, CRF-based methods for both tasks, which in combination constitute Concraft, a highly accurate tagging system for the Polish language available under the 2-clause BSD license. Evaluation on the National Corpus of Polish shows that our solution significantly outperforms other state-of-the-art taggers for Polish – Pantera, WMBT and WCRFT – especially in terms of the accuracy measured with respect to unknown words.

KEYWORDS: morphosyntactic tagging, conditional random fields, Polish.

Proceedings of COLING 2012: Technical Papers, pages 2789–2804,
COLING 2012, Mumbai, December 2012.

1 Introduction

Morphosyntactic tagging is one of the basic problems in Natural Language Processing (NLP), which can be described as choosing most appropriate morphosyntactic descriptions for each word in the particular sentence. We ignore the problem of lemma-ambiguity in our work, since it doesn't occur often within the context of highly-inflectional languages like Polish or Czech (Smith et al., 2005), and concentrate on the problem of choosing correct values of grammatical attributes. Numerous methods have been proposed as a solution to the tagging problem, ranging from rule-based with hand-crafted rules, through transformation-based with rules automatically extracted from a dataset, to stochastic methods like hidden Markov models (Jurafsky and Martin, 2008) or linear-chain conditional random fields (Lafferty et al., 2001; Sutton and Mccallum, 2006). We focus on stochastic methods in this work.

Best solutions for the English language yield tagging accuracy exceeding 97%, but methods designed for one language do not necessarily solve problems inherent to another one. In case of highly-inflectional languages the first (and rather technical) obstacle is the complexity of the morphosyntactic tagset. Polish tags carry information about a number of grammatical attributes – part of speech (POS), case, number, gender etc. – with 13 grammatical categories in total. The Polish tagset used within the 1-million-word National Corpus of Polish (NCP) (Przepiórkowski et al., 2010) is a positional one: first position of the tag represents the grammatical class and subsequent positions contain category values. In the NCP tagset the first position determines the set of grammatical categories (some obligatory, some optional) used in conjunction with the class. For example, the **subst:sg:nom:m1** tag describes a singular (**sg**) human masculine (**m1**) noun (**subst** – substantive) in the nominative case (**nom**).

There are more than 1000 morphosyntactic tags which can be directly extracted from the NCP corpus. It makes the application of methods, which do not scale with the number of tags very well, hard in practice. One of such methods is the conditional random fields (CRFs) formalism, with tagging complexity which is quadratic in the number of tags[1] and with expensive global training process[2]. After the introduction of CRFs within the field of NLP (Lafferty et al., 2001) many methods have been developed in order to exploit their benefits (conditional, feature-rich modeling) while not being restrained by the expensive, global training process of CRFs at the same time. Collins (2002) has shown that by using discriminative methods hidden Markov models (HMMs) can be trained to achieve comparable performance. Toutanova et al. (2003) have proposed tagging with cyclic dependency network, an alternative to CRFs with similar advantages and, additionally, a much less expensive training procedure. In case of CRFs, Sokolovska et al. (2009) have shown that when the set of bigram features is small, the sparse forward-backward recursions method can be used to significantly speed-up the training process. Other optimization techniques, which make it possible to use CRFs to solve large-scale problems (with large output space, in particular), have been described in (Lavergne et al., 2010). However, all these alternatives either deprive us from the pure context of CRFs, or require some additional assumptions and complicate the implementation. We describe a simple extension of CRFs which makes them better suited to the morphosyntactic tagging and partially solves the problem of high computational cost of the training process. Moreover, it can be used together with more implementation-specific optimizations mentioned above.

[1] In case of the simple first-order model.

[2] Assuming that training is performed with respect to the standard log-likelihood function.

We show that by integrating morphosyntactic analysis results into the internals of CRFs it is easy to obtain a high-quality, efficient solution of the tagging problem, even for a language with rich morphosyntactic structure like Polish. Our method can be used within the context of any language for which a high-quality morphosyntactic analysis tool exists. The analyzer should conform to the principle that, for any given input word, the resulting set of potential morphosyntactic tags is either complete (all theoretically possible interpretations are included) or empty (the tool doesn't recognize the word). Partial results can harm the tagging performance because our method always chooses tags consistent with the analysis output. The current implementation requires that tags are represented in a positional form, but this requirement is of a technical nature and it could be easily relaxed. The only assumption which is actually made by the disambiguation method is that tags can be divided into relatively independent parts which are subsequently modeled in separate CRF layers. In practice, when the size of the tagset is small and only one disambiguation layer is sufficient, there are virtually no requirements about the form or structure of the tagset.

The rest of this document is organized as follows. First we describe the constrained version of CRFs (section 2), which provides a way to restrict sets of possible output labels on individual sentence positions. Restrictions are used to impose consistency between morphological analysis results and CRF output labels. Next we show how the introduced mathematical formalism can be used to perform a context-sensitive morphosyntactic guessing (section 3) and disambiguation (section 4) which together constitute Concraft[3], a state-of-the-art tagging system for the Polish language. Final evaluation on the National Corpus of Polish, carried out in accordance with the guidelines described in (Radziszewski and Acedański, 2012), is described in section 6.

2 Constrained Conditional Random Fields

We now recall the definition of conditional random fields and define their extension which we call constrained conditional random fields (CCRFs) throughout this paper. Similar modification of the CRF formalism can be found in (Smith et al., 2005), while comprehensive introduction to CRFs can be found in (Lafferty et al., 2001; Sutton and Mccallum, 2006). CCRFs is a simple but useful extension which employs constraints over individual labels in the output sequence. We represent each constraint as a set of labels, to which a label on the particular position in the sentence must belong. Those constraints are satisfied both during the inference and parameters estimation algorithms, thus improving their efficiency and allowing the model to be better adapted to a particular problem domain. Within the context of morphosyntactic tagging, constraints can be used to enforce consistency between results of morphosyntactic analysis and the tagging process itself.

For simplicity we consider only a first-order (with features defined over two subsequent labels at maximum) HMM-like (no bigram features) conditional random fields. Without the loss of generality we assume that (i) each word in the input sequence is represented by a descriptive set of observations, with each observation capturing some aspect of the word itself or its context, (ii) features can refer only to observations related to the current word. This design decision makes it easier to separate the notion of conditional knowledge, supplied in form of the input sequence, from the internal workings of the CRF implementation. Definitions and equations given below can be extended to describe models of higher order and models with more complex feature types.

[3]Available at `http://hackage.haskell.org/package/concraft` under the 2-clause BSD license. The acronym stands for *Constrained Conditional Random Fields Tagger*.

The formalism described in this section, as well as its generic extension to the second-order case, have been implemented as separate Haskell programming language modules[4] which can be used with other applications in mind (chunking or named entity recognition, for instance). The Haskell language combines advantages of high-level programming and type safety with excellent performance of generated programs[5], which makes it an ideal candidate for conceptually complex mathematical tasks. Both libraries have been used to perform tests described in this paper, as a statistical core of the Concraft tool.

2.1 Definition

Let O be a set of *observations*, Y a set of *labels* and $X = 2^O$. Let $\mathbf{x} = (x_1 \in X, \ldots, x_n \in X)$ be an input sequence of words, where each word is represented by a descriptive set of observation, and $\mathbf{y} = (y_1 \in Y, \ldots, y_n \in Y)$ an output sequence of labels. We also assume that $x_i = \emptyset$ and $y_i = \delta$ for $i < 1 \vee i > n$, where δ is a dummy label not belonging to the Y set. First-order linear-chain CRF defines a conditional probability of the sequence of labels $\mathbf{y}$ given the sentence $\mathbf{x}$ as a normalized product of position-wise model potentials:

$$p_\theta(\mathbf{y}|\mathbf{x}) = Z_\theta(\mathbf{x})^{-1} \prod_{i=1}^{n} \phi_\theta(x_i, y_i, y_{i-1}) \tag{1}$$

where $\theta = \{\theta_k\}_{k=1}^K$ is a set of *parameters*, with the k-th parameter representing the contribution of the k-th *feature* to the overall probability, $\phi_\theta(x_i, y_i, y_{i-1})$ denotes a *potential* on the i-th position of the sentence and $Z_\theta(\mathbf{x})$ is a normalization factor. Potential ϕ is defined as an exponential of the sum of parameters related to features present within the context of (x_i, y_i, y_{i-1}):

$$\phi_\theta(x_i, y_i, y_{i-1}) = \exp\left(\sum_{k=1}^{K} \theta_k f_k(x_i, y_i, y_{i-1})\right) \tag{2}$$

The implemented CCRF handles two kinds of features. A *unigram feature* $(u \in Y, o \in O)$ takes responsibility for modeling dependency between a word described by the observation o and the label u assigned to that word. A *transition feature* $(v \in Y \cup \{\delta\}, u \in Y)$, on the other hand, serves to model dependency between adjacent labels v (which is equal to δ when considering the first position of the sentence) and u. Therefore, the form of the feature function f_k depends on what kind of feature, a unigram one or a transition one, it represents:

$$f_k(x_i, y_i, y_{i-1}) = \begin{cases} \mathbf{1}(y_i = u, o \in x_i) & \text{if } k \text{ identifies unigram feature } (u, o) \\ \mathbf{1}(y_i = u, y_{i-1} = v) & \text{if } k \text{ identifies transition feature } (v, u) \end{cases} \tag{3}$$

where $\mathbf{1}(cond.)$ is equal to 1 when the given condition holds and to 0 otherwise.

Finally, the normalization factor Z is defined as

$$Z_\theta(\mathbf{x}) = \sum_{\mathbf{y} \in Y^n} \prod_{i=1}^{n} \phi_\theta(x_i, y_i, y_{i-1}). \tag{4}$$

[4]Available at `http://hackage.haskell.org/package/crf-chain1-constrained` and `http://hackage.haskell.org/package/crf-chain2-generic` under the 2-clause BSD license.

[5]We relate to the efficiency of optimized programs compiled with a Glasgow Haskell Compiler.

2.2 Constraints

Let $\mathbf{r} = (r_1 \subseteq Y, \ldots, r_n \subseteq Y)$ be a sequence of non-empty constraints over individual labels within the given sentence $\mathbf{x}$. For convenience we assume that $r_i = \{\delta\}$ for $i < 1 \vee i > n$. Definition 1 can be easily modified to take those constraints into account. In particular, the model assigns probability 0 to all label sequences which are inconsistent with the constraints imposed by $\mathbf{r}$:

$$p_\theta(\mathbf{y}|\mathbf{x},\mathbf{r}) = \begin{cases} Z_\theta(\mathbf{x},\mathbf{r})^{-1} \prod_{i=1}^{n} \phi_\theta(x_i, y_i, y_{i-1}) & \text{if } \mathbf{y} \in \prod_{i=1}^{n} r_i \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

The normalization factor within the constrained context is defined as

$$Z_\theta(\mathbf{x},\mathbf{r}) = \sum_{\mathbf{y} \in \prod_{i=1}^{n} r_i} \prod_{i=1}^{n} \phi_\theta(x_i, y_i, y_{i-1}). \tag{6}$$

2.3 Inference

We describe here two methods of inference using CCRFs: finding the most probable label sequence given the sentence and assigning marginal probabilities to individual labels from restricted sets. The first one is used within the context of morphosyntactic disambiguation (section 4), second one within the context of guessing (section 3). Throughout this section we assume that input sentence $\mathbf{x}$, constraints $\mathbf{r}$ and parameters θ are fixed.

2.3.1 Decoding

Given a sentence $\mathbf{x}$ and constraints $\mathbf{r}$, the CCRF model with parameters θ can be used to find the most probable label sequence $\mathbf{y}^*$. Since the normalization factor $Z_\theta(\mathbf{x},\mathbf{r})$ doesn't depend on the label sequence $\mathbf{y}$, the task is equivalent to finding label sequence which maximizes the potential.

$$\mathbf{y}^* = \operatorname*{arg\,max}_{\mathbf{y} \in \prod_{i=1}^{n} r_i} \left(\prod_{i=1}^{n} \phi_\theta(x_i, y_i, y_{i-1}) \right) \tag{7}$$

The task of finding $\mathbf{y}^*$ is often called *decoding*. It can be solved efficiently using the *max-product* algorithm (Wainwright and Jordan, 2008), which can be also employed within the context of the constrained CRF model. Let $r[i \to u]$ denote a sequence of constraints resulting from substituting the i-th element in the sequence r with the singleton $\{u\}$. For $i \in [0..n+1]$ and $u \in r_i$ we denote by $\omega_i(u)$ the partial, maximum cumulative potential acquired between the beginning of the sentence and the i-th position assuming, that label at position i takes the value of $u \in r_i$.

$$\omega_i(u) = \max_{\mathbf{y} \in \prod_{j=1}^{i} r[i \to u]_j} \left(\prod_{j=1}^{i} \phi_\theta(x_j, y_j, y_{j-1}) \right) \tag{8}$$

It can be also defined in a recursive way:

$$\omega_i(u) = \begin{cases} \max_{v \in r_{i-1}} \omega_{i-1}(v) \cdot \phi_\theta(x_i, u, v) & \text{if } i > 0 \\ 1 & \text{otherwise} \end{cases} \tag{9}$$

The recursive definition, together with dynamic programming or memoization techniques, can be used to find the most probable label sequence $\mathbf{y}^*$ (the sequence corresponding to the value $\omega_{n+1}(\delta)$) in an efficient way.

2.3.2 Marginal Probabilities

The CRF models conditional probability of the entire label sequence, but conditional *marginal* probabilities also can be computed in an efficient way. Marginal probabilities can be used in the output of the CRF instead of (or together with) the decoded sequence $\mathbf{y}^*$. In this work we use marginal probabilities to perform context-sensitive morphosyntactic guessing, which is described in section 3.

Let $i \in [0..n+1]$ and $u \in r_i$. We define a forward potential sum as

$$\alpha_i(u) = \sum_{\mathbf{y} \in \prod_{j=1}^{i} r[i \to u]_j} \left(\prod_{j=1}^{i} \phi_\theta(x_j, y_j, y_{j-1}). \right) \tag{10}$$

The notion of a forward potential sum is similar to that defined by the formula (8), but instead of maximizing the cumulative potential between the first and the i-th position we are summing up all cumulative potentials between positions 1 and i of the input sentence. Backward potential sum $\beta_i(u)$ is a reverse concept corresponding to the sum of cumulative potentials between positions $i+1$ and n given that the value of the i-th label is equal to u.

It should be noted that both forward and backward potential sums can be used to compute the value of the normalization factor, since $Z_\theta(\mathbf{x}, \mathbf{r}) = \alpha_{n+1}(\delta) = \beta_0(\delta)$ for the input sentence $\mathbf{x}$ and constraints $\mathbf{r}$. Furthermore, it can be shown that all three concepts provide the following formula to determine the marginal probability of label u at position i:

$$p_\theta(y_i = u | \mathbf{x}, \mathbf{r}) = \alpha_i(u) \cdot \beta_i(u) \;/\; Z_\theta(\mathbf{x}, \mathbf{r}) \tag{11}$$

Finally, the efficient algorithm for forward potential sum computation is known as a *sum-product* algorithm (Wainwright and Jordan, 2008) and it is based on the following recursive definition of the forward potential sum:

$$\alpha_i(u) = \begin{cases} \sum_{v \in r_{i-1}} \alpha_{i-1}(v) \cdot \phi_\theta(x_i, u, v) & \text{if } i > 0 \\ 1 & \text{otherwise} \end{cases} \tag{12}$$

which has an analogous structure to the definition presented in equation (9). Backward potential sum β can be recursively defined in a similar way.

2.4 Parameters estimation

We note only that we apply a Stochastic Gradient Descent method in order to find parameter values which maximize log-likelihood of a training dataset with a Gaussian prior over the parameter values.

3 Morphosyntactic Guessing

In this section we describe an adaptation and an application of the formalism described in section 2 to the morphosyntactic guessing. A dictionary of known forms can be used in order to find all possible interpretations – tags and base forms – of the given word. This language processing phase is called *morphosyntactic analysis*. Unfortunately, due to incompleteness of data resources or spelling errors some forms may not be recognized. Morphosyntactic tagging of such words, called *unknown* throughout this paper, is severely hampered. The average

number of morphosyntactic tags assigned by the morphosyntactic analysis tool to known words, computed on the basis of the NCP million subcorpus, is approximately equal to 4. In case of unknown words we have to consider every possible morphosyntactic tag present in the tagset. This difficulty is reflected in the evaluation results of taggers designed for Polish (see section 6). Results of the morphosyntactic analysis are especially helpful in selecting correct values of lexeme-specific attributes like gender, since it is often hard to determine their values even on the basis of the occurrence context.

By morphosyntactic guessing we mean a method of determining sets of possible morphosyntactic tags for unknown words in the sentence. Thus, it can be thought of as a complement problem to the morphosyntactic analysis. Conceptually, the division of the tagging process into three separate steps of analysis, guessing and disambiguation, is a superficial one. It can be also pointed out that context-sensitive guessing is – from a theoretical, not practical, point of view – a generalization of the disambiguation process. Disambiguator is just a guesser which always proposes one possible tag in the resulting sequence. Yet, it is easier to reason about those three processing stages and to develop efficient tools designed to solve them separately. For example, if we ignore the problem of unknown words completely, we will be constrained to use methods which manage to handle adjacent words with more than 1000 possible tags at the stage of disambiguation. In particular, the method described in section 4 would not be able to handle such cases in an efficient way.

3.1 Model Adaptation

To use the constrained model described in section 2, every input word has to be linked with a list of possible morphosyntactic tags. Each tag is treated as an atomic entity, that is two tags are considered to be different if they differ on at least one grammatical attribute value. Since the method doesn't adopt any assumptions about the structure of morphosyntactic tags, it is very flexible and can be applied to a broad class of natural languages. In the case of known words the choice of possible labels is simple – morphosyntactic analysis is a source of label restrictions. For each unknown word we should consider all morphosyntactic tags from the tagset as potential interpretations. We use a simple heuristic instead, described in (Radziszewski, 2013), where a special set U – a set of all labels assigned to unknown words in the training corpus – is prepared. Since the U set can be in practice much bigger ($\approx$ 300 tags in NCP experiments) than the average set proposed by the analyzer and it is often the case that two adjacent words are unknown, we use the first-order model for the task of morphosyntactic guessing.

While there are many possible ways of using the CCRF to perform actual guessing, we have tested only the simplest one so far. For each unknown word in the input sequence, with the set of restrictions $\mathbf{r}$ fixed to U, we take k most probable labels according to marginal probabilities determined by the CCRF (see 2.3.2) for some arbitrarily chosen value of k.

To speed-up computations, especially within the context of known words, we implement sparse forward-backward recursions (Sokolovska et al., 2009; Lavergne et al., 2010). To make this optimization effective, a set of model features is constructed with respect to words and chosen labels from the training data T, but not with respect to restrictions in T. It is important to note that we can safely apply this optimization within the context of the sum-product algorithm (used during the training phase), but not with the max-product algorithm (used in decoding). Fortunately, to perform guessing we do not have to use max-product algorithm, since only the sum-product is needed to find marginal probabilities of individual labels.

3.2 Observations

A common solution to the morphosyntactic guessing problem is to propose the set of possible tags on the basis of orthographic features acquired for the particular word (e.g. prefixes and suffixes). By using the CRF sequential model we extend this method to take tags assigned on adjacent positions into account. The advantage of such a solution is that the guesser is able to reject morphosyntactic interpretations on the basis of two factors simultaneously: the context and orthographic features of the word.

Our observation schema contains the following set of observations, which are subsequently used to construct the set of unigram features:

- Lowercase prefixes and suffixes of lengths 1 and 2,
- A Boolean value indicating if the word is known,
- Packed shape of the word, and information whether the word is positioned at the beginning of the sentence, combined into one observation.

where each observation is related to the current word, the shape of a word is a string with all lowercased characters replaced by 'l', uppercased characters replaced by 'u', digits replaced by 'd' and any other character replaced by 'x' („Coling-2012" → „ullllllxdddd"), while a packed shape is a shape with all duplicate code characters removed („ullllxdddd" → „ulxd").

Szef	{ 1.S, 2.Sz, 3.f, 4.ef , 5.True, 6.ul-True }	subst:sg:nom:m1	{ subst:sg:nom:m1 }
administracji	{ 1.a, 2.ad, 3.i, 4.ji , 5.True, 6.l-False }	subst:sg:gen:f	{ subst:sg:gen:f , subst:sg:dat:f , subst:sg:loc:f , subst:pl:gen:f }
Wołodymyr	{ 1.W, 2.Wo, 3.r, 4.yr , 5.False, 6.ul-False }	subst:sg:nom:m1	*U*
Łatwyn	{ 1.Ł, 2.Ła, 3.n, 4.yn , 5.False, 6.ul-False }	subst:sg:nom:m1	*U*

Table 1: Morphosyntactically analyzed sentence *Szef administracji Wołodymyr Łatwyn – Chief administrator Wołodymyr Łatwyn* prepared for the CCRF guessing. The observations column includes observations extracted for individual words according to the guessing observation schema. The choice indicates the morphosyntactic tag correct within the context. In the last column results of morphosyntactic analysis are presented. In case of unknown words the *U* set designates the set of potential interpretations.

Prefix and suffix observations are the basic type of information needed to determine the set of possible morphosyntactic interpretations of the given word. By using only short affixes we can be sure to get highly accurate estimations of corresponding parameters. The model learns dependencies between prefixes/suffixes and morphosyntactic tags mostly on words from the corpus which are known, since they are far more frequent in the training material than the unknown words. After that it is able to use this knowledge to guess interpretations of unknown words. Packed shape might be helpful to distinguish some frequent classes of unknown words –

named entities and numbers, in particular. Information about the fact that the word is known or not is also provided. It allows the guesser to exhibit a slightly different behavior on known and unknown words. We do not employ the standard observation – full orthographic form – on purpose. It would probably make the model more accurate with respect to known words, but our main goal is to obtain accurate estimations of prefix- and suffix-specific parameters.

Table 1 presents a sample sentence prepared for the subsequent processing with the CCRF guessing module. For each word the set of observations is determined on the basis of the observation schema described above. Observations are extended with additional prefixes identifying the kind of the particular observation. Every observation is a string, but from a technical point of view observations can be represented by more complex structures as long as their data type is totally ordered, which is the only assumption about the form of observations made on the level of the CCRFs implementation. The presented structure can be used to perform subsequent CCRF processing in the following way:

- The 'observations' column is translated to the input sequence **x**,
- The 'interpretations' column is converted to the sequence of CCRF constraints **r**,
- The contents of the 'choice' column (if any) can be used as the output sequence **y**.

All three columns can be used as the input to the CCRF training process. To perform the actual guessing only the observations and interpretations columns need to be known, of course.

word	guessing results
Szef	{ subst:sg:nom:m1 }
administracji	{ subst:sg:gen:f , subst:sg:dat:f , subst:sg:loc:f , subst:pl:gen:f }
Wołodymyr	{ subst:sg:nom:m2, subst:sg:nom:n, subst:sg:gen:m3 , subst:pl:nom:m1, subst:sg:nom:m3, subst:sg:nom:m1 , adj:sg:gen:m3:pos, subst:sg:loc:f, qub, brev:npun }
Łatwyn	{ subst:sg:gen:m3, subst:sg:nom:m2, subst:sg:nom:n , subst:sg:gen:m1, subst:sg:gen:f, subst:sg:nom:m3, subst:sg:acc:n , subst:sg:nom:m1, subst:pl:gen:m1, subst:sg:nom:f }

Table 2: Results of guessing interpretations of unknown words.

Table 2 shows the results of the guessing process performed on the phrase presented in table 1 with $k = 10$. We do not show the 'choice' column, since it is not used within the process, and the 'observations' column, which has been relevant only for input. Potential interpretations assigned to known words are not influenced by the guesser. The guessing has been performed using the model trained on the part which has not contained the phrase used as an example.

Since the guesser always proposes multiple morphosyntactic tags[6] for individual unknown words in the input, there must be also a lot of incorrect (w.r.t. the context) or even theoretically impossible (w.r.t. the word in question) interpretations in the output. The 'subst:sg:loc:f' tag is clearly not a possible interpretation of the masculine 'Wołodymyr' lexeme, but this fact is hard to determine without any reference to the word in the external dictionary. Therefore, to estimate the accuracy of the guesser we should only take the presence (or absence) of the correct tag

[6] Assuming that $k > 1$ and $|U| > 1$.

in the output set into account. As long as the correct tag is included in the output, it is of no particular concern to us what other output interpretations are. Looking at the 'guessing results' column in table 2 we can see that the guesser successfully determined that noun (substantive) is the most probable class for both unknown words, 'Wołodymyr' and 'Łatwyn', in the example. It has been also able to determine nominative case with a high confidence. The gender attribute is the biggest source of ambiguity in the output results – since the first-order model is used to perform the guessing, the method is not able to agree gender values of unknown words with the gender of the first word in the sentence, 'Szef', which is known to represent a human masculine (m1). Finally and most importantly, the correct full morphosyntactic tag (subst:sg:nom:m1) is included in the output for both unknown words.

4 Morphosyntactic Disambiguation

The last and the most important step of morphosyntactic tagging is a disambiguation phase. It involves choosing for each word, from the set of possible tags, the most appropriate one in the context of the particular sentence. It can be resolved without the prior morphosyntactic analysis or guessing, but these steps – as long as they demonstrate low false negative error rate – should only accelerate disambiguation (thanks to the reduced search space) and improve its accuracy.

Second-order stochastic methods are often chosen as a solution to the tagging problem, see (Collins, 2002; Smith et al., 2005), and we use the second-order flavor of constrained CRFs for disambiguation as well. The complexity of the task is no longer problematic, because sets of possible interpretations are strongly limited for individual words. If a word is known, the set of potential labels is provided by the morphosyntactic analyzer. Otherwise, potential labels are restricted to the set of the k most probable labels determined at the stage of morphosyntactic guessing described in the previous section, where k is the parameter of the guesser.

4.1 Model Adaptation

In case of the disambiguation problem we are more concerned about the performance of the solution in terms of quality than in terms of speed. We rely on the analysis and guessing tools in the second aspect and, in particular, on their ability to reduce the search space for the disambiguator. Therefore, we have chosen to implement a second-order variant of CCRF which incorporates a dense feature set (constraints from the training set are taken into account during the construction of the feature set) with no sparse forward-backward recursions optimization.

The second-order characteristic means that relations between three subsequent labels are modeled directly within the CRF. The sparse forward-backward recursions optimization has not been implemented in this case because it doesn't bring any improvements when the set of model features is dense. An important difficulty stems from the fact that we use the second-order model within the context of a language with more than 1000 potential morphosyntactic tags. It is easy to deduce that there are more than 10^9 possible transition features and, even with additional constraints taken into consideration, there are more than $1.5 * 10^7$ transition features which can be extracted from the NCP corpus directly. It is not only hard to store the model with so many features, but it can also cause problems related to data sparseness and make the model prone to overfitting.

To alleviate this problem we change our treatment of morphosyntactic tags as atomic labels and regard them as complex structures. We also extend our second-order CCRF to model multiple morphosyntactic layers. Tags are divided into separate label layers according to a configuration

file. The file specifies the number of layers and the destination layers (zero, one or more) for each grammatical attribute (POS or grammatical category). Layers are modeled separately (i.e., features cover label values from exactly one layer), but not independently. Finally, labels in individual layers are treated as atomic entities.

This method is also rather flexible and could be used with respect to a language with other tagset structure than the positional one. The only important assumption which is really adopted here is that it is possible to divide a tag into parts which are relatively independent. For instance, in case of the partitioning which assigns case values to the first layer and number values to the second layer, implicit assumption is being made that – given observations – there is no direct dependency between those values apart from the dependency enforced by constraints. If we ignore constraint-related dependencies we can write it in a more formalized way: the case value of the i-th word is conditionally independent of its number value (and, in fact, all other number values in the sentence) given case values of words in positions $i-2$, $i-1$, $i+1$ and $i+2$ and observation values related to the i-th word.

4.2 Observations

In the case of disambiguation we use a richer set of observation types than within the context of guessing, yet it is still rather a minimalistic one. Let w_i denote the word at the i-th position in the input sentence. The following set of observations is used with respect to the i-th position:

- Lowercase orthographic forms of words w_{i-1}, w_i and w_{i+1},
- If the word w_i is unknown:
  - Lowercase prefixes and suffixes of length 1, 2 and 3 of w_i,
  - Packed shape of w_i and information, whether w_i is positioned at the beginning of the sentence, combined into one observation.

The shape observation type has been mentioned earlier within the context of the guesser's observation schema. We haven't recorded any improvements in the tagging quality when using prefix, suffix or shape features as observations for known words. Therefore, we do not use them in our final model.

4.3 Features

Let L be a number of layers and $y(l)$ denote a part of the morphosyntactic tag y assigned to the l-th layer for $l \in \{1,\ldots,L\}$. The layered model handles unigram (l,u,o) and transition (l,w,v,u) features in a similar way to that specified in equation 3. However, in the layered case features are enriched with value l identifying the layer to which the particular feature should be related. Moreover, the form of the feature function f_k changes due to the second-order character of the model.

$$f_k(x_i,y_i,y_{i-1},y_{i-2}) = \begin{cases} \mathbf{1}(y_i(l)=u, o \in x_i) & k \text{ identifies } (l,u,o) \\ \mathbf{1}(y_i(l)=u, y_{i-1}(l)=v, y_{i-2}(l)=w) & k \text{ identifies } (l,w,v,u) \end{cases} \quad (13)$$

While the implementation is general and follows the specification described above, all tests within this work (most importantly, the evaluation) were performed using the configuration inspired by (Acedański, 2010). Tags are divided into two layers, with POS, case and person in the first layer and all the other grammatical categories in the second layer.

5 Related Work

We compare our method with solutions for morphosyntactic tagging of highly inflectional languages, the Polish language in particular. However, the method described in (Smith et al., 2005) – which bears many similarities with our solution – has been successfully used in tagging not only inflectional but also concatenative and templatic languages and we believe that our system could be also adapted to handle them.

Radziszewski (2013) describes WCRFT, an implementation of a tiered tagging method in which a cascade of independently trained linear-chain first-order CRF models is used to disambiguate input in a multi-pass manner: POS values are resolved at first, then case values, gender values and so on. Our system relies on a more general method of tag partitioning and performs disambiguation on all layers simultaneously, so that the choice made in higher layers can propagate down into lower layers, which is not possible in case of a cascade. Besides, our system uses second-order model for disambiguation which allows to capture dependencies between three subsequent tags in an idiomatic way. WCRFT uses the simple heuristic mentioned in section 3.1 to ascertain potential interpretations of unknown words and, optionally, a morphosyntactic guesser developed within a rule-based TaKIPI tagger (Piasecki, 2007; Piasecki and Radziszewski, 2007). It is an *a tergo* guesser, which uses pseudo-suffixes to infer potential morphosyntactic interpretations of unknown words. While it also proposes base forms in its output, it doesn't make use of context-specific information and often commits false negative errors (does not include correct morphosyntactic tags in its output). Since the disambiguation module in not designed so as to correct errors performed on the level of guessing, those false negative errors propagate to subsequent processing phases.

Pantera (Acedański, 2010) is an implementation of the Brill method (Brill, 1992) adapted for the specifics of highly inflectional languages. Pantera also adopts multi-pass method for morphosyntactic tagging without the possibility of downward propagation of disambiguation choices. Tag partitioning in Pantera is a configurable process and the evaluation of Pantera involved the same tag partitioning as the one used for the evaluation of our system: POS, case and person attributes are placed in the first layer, while the rest of grammatical categories is stored in the second layer (Acedański, 2010).

A variant of CRF, where each label must belong to a restricted set of interpretations recognized by a morphosyntactic analysis tool, has been previously used in tagging Korean, Arabic and Czech language (Smith et al., 2005). While the Czech model exhibits similarities to the model described in this paper, there are also important differences between them. In (Smith et al., 2005) there is no special treatment of unknown words. We, in comparison, introduce the context-sensitive morphosyntactic guessing method designed specifically for them. All grammatical attributes are taken into account in our model for Polish, while the model for Czech includes only the four main grammatical attributes – POS, case, number and gender – thus rendering it incapable of disambiguating between values of the remaining attributes. In order to make the training process feasible, Smith et al. (2005) employ factored training, dividing features into five separate classes and estimating parameters within each class independently. We do not adopt such parameter-level independence assumptions and perform global training using the Stochastic Gradient Descent method, yet we achieve an empirical performance which is several times better in terms of the training time. According to Smith et al. (2005), training the POS-specific part of the model for Czech on 768K words from the Czech PDT corpus takes up to two weeks on the 2GHz Pentium machine. Our system needs less than 8 hours to learn

parameters for guessing (3 hours) and disambiguation (5 hours) on 1M words from the NCP corpus using one core of the 2.40GHz Xeon E5620 machine.

6 Evaluation

Evaluation of Concraft has been performed on the one-million-word, balanced NCP subcorpus (Przepiórkowski et al., 2010). In order to be able to compare the tool with other taggers available for Polish, we have followed guidelines provided by Radziszewski and Acedański (2012). It describes a fair method of taggers evaluation, which involves obligatory resegmentation (sentence splitting and tokenization) and reanalysis of the evaluation corpus part. The advantage of this evaluation method is that it measures tagging quality in an environment as close as possible to the real usage case, given the available resources. No artificial assumptions of perfect segmentation or perfect morphosyntactic analysis are made, which was often the case with earlier evaluations of tagging systems (Acedański, 2010; Radziszewski and Śniatowski, 2011) which reported much higher results than could be expected in the real-world usage.

Our tool does not include any sentence splitting, tokenization or morphosyntactic analysis modules yet. Results presented below have been acquired using the preprocessing functionality provided by the MACA tool (Radziszewski and Śniatowski, 2011). For each cross-validation fold, the guesser is trained on the reanalyzed training part. The resulting model is used to guess potential interpretations of unknown words both in the training and the evaluation part, with k (number of retained labels for each unknown word) set to 10. Next, the disambiguation tool is trained on the training part with tags already guessed. Finally, the model obtained is used to perform disambiguation on the evaluation part (processed beforehand by the guesser).

Tagger	Acc_{lower}	Acc_{upper}	Acc^{K}_{lower}	Acc^{U}_{lower}
Pantera	88.99%	89.28%	91.27%	14.74%
WMBT	89.71%	90.04%	91.20%	41.45%
WCRFT	90.34%	90.67%	91.89%	40.13%
Concraft	91.12%	91.44%	92.10%	59.19%

Table 1: Average accuracy measures obtained by individual taggers on the NCP corpus.

Table 1 presents cross-validation results of our system in comparison to the state-of-the-art taggers for Polish: Pantera (Acedański, 2010), WMBT (Radziszewski and Śniatowski, 2011) and WCRFT (Radziszewski, 2013). Pantera and WCRFT have been described in the 5 section. WMBT (Radziszewski and Śniatowski, 2011) and WCRFT (Radziszewski, 2013) both represent a class of tiered tagging methods (Tufiş, 1999), using a cascade of models to perform disambiguation. WMBT uses a memory-based learning method to model individual tiers, while WCRFT uses CRFs for this task. All tools have been evaluated on the same extract of the NCP corpus, and with respect to exactly the same corpus partitioning. Numbers included in the first three rows have been reported in (Radziszewski and Acedański, 2012) and (Radziszewski, 2013).

We report separate evaluation statistics corresponding to different assumptions about the system's behavior in the situation of tokenization-level errors. Accuracy lower bound Acc_{lower} corresponds to the situation when each tokenization error is penalized and treated as a tagging error. Conversely, accuracy upper bound Acc_{upper} doesn't take tokenization errors into account – the measure is computed as if for each token from the reference corpus associated with the incorrectly tokenized part the tagger made the correct decision. Therefore, assuming perfect tokenization, accuracy of the tagger would be somewhere between Acc_{lower} and Acc_{upper}. Next

two statistics, Acc^{K}_{lower} and Acc^{U}_{lower}, show lower bound accuracy with respect to known and unknown words, respectively. Sentence splitting errors are not taken into account. Detailed description of individual statistics can be found in (Radziszewski and Acedański, 2012).

The results show that our system significantly outperforms other taggers, especially within the context of unknown words. They suggest that feature-rich stochastic methods perform better than transformation-based methods (represented by Pantera in the comparison). We suspect that the main reason of the gap between the WCRFT and Concraft performance is the difference in the choice of guessing methods. Our context-sensitive guessing method has been specifically designed as a preliminary filter, which reduces the number of possible interpretations of unknown words. The TaKIPI guesser used within the WCRFT tool during the evaluation yields too many false negatives, which cannot be corrected on the level of disambiguation.

Conclusion and perspectives

We have shown that a domain-specific modification of the CRFs formalism solves most of the complexity-related issues inherent to CRFs with respect to the morphosyntactic tagging of highly-inflectional languages. Not only is the modification easy to comprehend and implement, but it can be also used in combination with other optimizations designed for CRFs in general. We regard this as a confirmation that adapting the model to a particular problem domain should be the foremost optimization considered when designing a solution of a high quality.

The comparison of Concraft and WCRFT doesn't clearly show which tagging system would perform better if we used both of them in combination with the same guesser and this question should be further investigated. In particular, we plan to evaluate the guessing and the disambiguation components of the Concraft system separately. The current state of the disambiguation module still leaves some room for improvement on the level of tag partitioning and observation schema configuration. The CRF implementation can be further generalized by expanding the set of features with bigrams, trigrams or features capturing dependencies between individual tag layers (between parts of the same morphosyntactic tag for instance).

The guessing model can be used to perform guessing in a few reasonable ways. The first one, used within this work, is to output the k most probable labels from the U set for each unknown word in the sentence. Another option is to choose all labels with marginal probability higher than some arbitrarily chosen threshold. This solution has the advantage of making the size of the label set depend on probabilities of individual labels, so that very improbable labels do not get into the result even if they are in the set of the k most probable ones. Advantages of both solutions could be aggregated in a solution which uses both the marginal probability threshold and limits the size of the output set. The same techniques can be used to trim down not only label sets for unknown words, but also those which are assigned to known words. Advantage given by this solution would be a further speed up of computations on the level of the disambiguation phase, but it could potentially harm the tagging accuracy.

Finally, it would be worthwhile to confirm the usability of the tagger by testing its performance on another Slavic language and, afterwards, on a typologically different language (e.g. English, German or French) for which high-quality morphosyntactic analysis tools exist.

ABSTRACT
Recognizing semantic relations between sentences, such as entailment and contradiction, is a challenging task that requires detailed analysis of the interaction between diverse linguistic phenomena. In this paper, we propose a latent discriminative model that unifies a statistical framework and a theory of Natural Logic to capture complex interactions between linguistic phenomena. The proposed approach jointly models alignments, their local semantic relations, and a sentence-level semantic relation, and has hidden variables including alignment edits between sentences and their semantic relations, only requires sentences pairs annotated with sentence-level semantic relations as training data to learn appropriate alignments. In evaluation on a dataset including diverse linguistic phenomena, our proposed method achieved a competitive results on alignment prediction, and significant improvements on a sentence-level semantic relation recognition task compared to an alignment supervised model. Our analysis did not provide evidence that directly learning alignments and their labels using gold standard alignments contributed to semantic relation recognition performance and instead suggests that they can be detrimental to performance if used in a manner that prevents the learning of globally optimal alignments.

1 Introduction

Recognizing Textual Entailment (RTE) (Dagan et al., 2005) is the task of recognizing entailment relations between a given text pair, *Text T* and *Hypothesis H*. RTE is useful for many information access tasks that depend on natural language processing technologies, and a breakthrough would lead to significant progress in information retrieval, document summarization, and question answering, among other tasks.

The majority of approaches proposed in previous work recognize entailment relations between a pair of texts by capturing lexical or structural correspondences. Methods include simple word overlap-based measures (Jijkoun and de Rijke, 2005) as well as alignment of syntactic and semantic dependencies (Sammons et al., 2009; Wang and Zhang, 2009). However, sentence-level semantic relations are affected by various linguistic phenomena: not only lexical semantic relations (synonyms, antonyms) but also monotonicity (e.g. downward-monotone caused by scope of negation), implicative/factive expressions, quantifiers, etc. Thus similarity measures are insufficient to capture these phenomena and their interactions.

Transformation-based approaches are one way to capture the affects of diverse linguistic phenomena and their interactions, where a set of linguistic phenomena are decomposed into units. By doing so it becomes possible to consider their effects on entailment independently. A number of previous works explores transformation-based entailment relation recognition. The approach of Stern et al. (2011) recognizes a sentence-level semantic relation through a proof which represents a sequence of edits from T to H produced by applying various entailment rules and the operations such as insertion, deletion, moving subtrees, etc. In addition, Heilman and Smith (2010) proposed a tree edit model which selects a sequence of edits using Tree Kernels, and Wang and Manning (2010) proposed a latent variable model which consider possible alignments as hidden structures. However, these model do not sufficiently represent interactions between linguistic phenomena such as factuality reversals caused by negation and flipping of entailment direction under downward-monotone contexts. In order to realize precise entailment relation recognition, we need to appropriately deal with semantic relations resulting from the interaction between linguistic phenomena.

One of the most promising approaches to RTE is Natural Logic-based recognition (MacCartney and Manning, 2008; MacCartney, 2009). This approach represents transformations from T to H with a set of three types of alignment edits (*substitution*, *insertion* and *deletion*), and assigns one of a set-theoretically defined semantic relations to each alignment edit. This approach is based on the principle of compositionality, i.e. the sentence-level semantic relation is derived by combining semantic relations of edits using pre-defined composition rules. By doing so, this approach makes progress toward precise sentence-level entailment relation recognition that considers linguistic phenomena and their interactions when assigning semantic relations.

However, several issues remain unexplored. While it is common for alignment inference methods to require data annotated with alignments, it is a challenge to manually annotate alignments in a consistent manner. Annotation of alignments with semantic relations from Natural Logic is a greater challenge due to the complex nature of the semantic relations. In addition, even alignments can be annotated consistently, there is no guarantee of their *global optimality*; that is to say the alignments identified as correct by annotators may not necessarily contribute to identifying the correct semantic relation between a pair of sentences. Identifying alignments considering the full context of a sentence pair is a much more difficult annotation task. However, even without manual alignment annotations, it may be possible to infer consistent and plausible alignments by learning models that promote alignments which agree with annotations of correct semantic relations between sentences. A unified model of alignment and semantic relation

recognition between sentences is needed that learns the alignments which will generate the correct semantic relation by considering the interaction between diverse linguistic phenomena.

In this paper, we propose a novel latent discriminative model that jointly handles predicting alignment edits, classification of their semantic relations and entailment relation recognition by providing a joint distribution of variables including alignment edits, their local semantic relations and sentence-level semantic relations. Inspired by the Natural Logic-based approach of (MacCartney et al., 2008), we incorporate the set of semantic relations and their composition rules from Natural Logic into our proposed model. In addition, our model can be trained from only sentence-level semantic relations to predict alignments and semantic relations that are consistent with Natural Logic composition. To the best of our knowledge, our study is the first work to propose a latent model for training a Natural Logic-based semantic relation recognition system that does not require alignment annotations and that jointly predicts plausible alignments and semantic relations between sentences, modeling a variety of linguistic phenomena and their interactions in a compositional manner.

2 Natural Logic

The concept of *Natural Logic*, a logic over natural language, is originally proposed by Lakoff (1970), and then van Benthem (1988, 1991) and Valencia (1991) explored monotonicity calculus[1] to explain entailment relations using Natural Logic. While they considered only containment relations, MacCartney and Manning (2008) introduced an *exclusion* relation to deal with entailment relations which involve different objects or concepts (e.g. Stimpy is a cat $\models$ Stimpy is not a poodle). In this section, we describe the theory of Natural Logic proposed by (MacCartney and Manning, 2008; MacCartney, 2009).

The basic idea of MacCartney et al's theory is that the semantic relation between sentences can be derived from the semantic relations of *edits* (substitution, deletion and insertion) from T to H. The fundamental assumption of the theory is *compositionality*: (some of) the entailments of a compound expression are a function of the entailments of its parts. They defined the seven types of semantic relations for edits: equivalence ($a \equiv b$ if $a = b$), forward-entailment ($a \sqsubset b$ if $a \subset b$), backward-entailment ($a \sqsupset b$ if $b \supset a$), negation ($a \,^\wedge\, b$ if $a \cap b = \phi \wedge a \cup b = U$)[2], alternation ($a \mid b$ if $a \cap b = \phi \wedge a \cup b \neq U$), cover ($a \cup b \neq \phi \wedge a \cup b = U$), and independence ($a \# b$ otherwise).

Semantic relations provided by edits are *projected* onto other relations depending on their contexts using *projection rules*. For example, in a scope of negation, forward-entailment is projected onto backward-entailment (e.g *soccer* $\sqsubset$ *sports*, *I didn't play soccer.* $\sqsupset$ *I didn't play sports.*). Other linguistic expressions such as logical connectives and quantifiers also projects semantic relations. A semantic relation between sentences is derived by combining the projected semantic relations of edits using *composition rules*. The rules are defined as tuples of semantic relations. Let the seven types of relations be $\mathscr{R}$, $r_i \in \mathscr{R}$, $r_j \in \mathscr{R}$, then a compositional rule is represented by $r_i \bowtie r_j \Rightarrow \boldsymbol{r} \subseteq \mathscr{R}$. Some compositional rule derive a single relations (e.g. $\equiv \bowtie \sqsubset \Rightarrow \sqsubset$), and others derive more than one semantic relations (e.g. $\mid \bowtie \mid \Rightarrow \bigcup \{\equiv, \sqsubset, \sqsupset, \mid, \#\}$). As semantic relation composition proceeded, semantic relations tend to move toward $\#$ [3].

[1] In an *upward-monotone* context, replacing a linguistic expression with a more general expression preserves truth. On the other hand, in a *downward-monotone* context, replacing a linguistic expression with a more specific expression preserves truth.

[2] U denotes a universe.

[3] Due to spacial limitations, we can not give all of the composition rules. For more details, see (MacCartney, 2009).

3 A Latent Discriminative Model for Compositional Entailment Relation Recognition

Given a text T and a hypothesis H, the task of RTE is to infer the correct semantic relation between T and H. However, we attempt to learn not only the correct semantic relation between T and H but also the characteristics of the alignments most likely to support that relation.

We assume that sentence-level semantic relations can be derived compositionally. Following the framework of Natural Logic proposed by (MacCartney and Manning, 2008; MacCartney, 2009), our proposed model assigns local semantic relations to edits which represent a transformation from T to H. A valid set of edits represents an alignment between T and H. Each edit is categorized as one of three types: *substitution*, *deletion* or *insertion*, and is given one of the seven semantic relations defined in Natural Logic described in §2. A semantic relation between T and H is derived from a set of semantic relations of alignment edits by using the projection rules and the composition rules.

The proposed model learns appropriate alignments which are consistent with compositional rules of Natural Logic from only sentence-level semantic relations, where appropriate alignments, their semantic relations and their projections are represented using hidden variables. We use a log-linear discriminative model with hidden variables to provide conditional joint probabilities of alignments, their associated semantic relations, and their projections and a sentence-level semantic relation.

3.1 Model

Our proposed model provides a conditional joint distribution of alignment edits, their semantic relations, their projected relations and the final semantic relation between T and H as follows.

$$p(\boldsymbol{e}, \boldsymbol{r_e}, \boldsymbol{r_e}^P, \boldsymbol{r}^C | \boldsymbol{x}; \boldsymbol{\lambda}) = \frac{1}{Z(\boldsymbol{x})} \exp\left(\sum_k \Psi_k(\boldsymbol{e}, \boldsymbol{r_e}, \boldsymbol{r_e}^P, \boldsymbol{r}^C, \boldsymbol{x}; \boldsymbol{\lambda}) \right) \quad (1)$$

$\boldsymbol{e} = \{e_i\}$ denotes the variables representing edits, and each edit $e_i = \langle \boldsymbol{t}_i, \boldsymbol{h}_i \rangle$ consists of $\boldsymbol{t}_i$, a subset of indices of units (e.g. words) in T, and $\boldsymbol{h}_i$, a subset of indices of units in H. An edit corresponds to substitution if $\boldsymbol{t}_i \neq \phi$ and $\boldsymbol{h}_i \neq \phi$, deletion if $\boldsymbol{t}_i \neq \phi$ and $\boldsymbol{h}_i = \phi$, and insertion if $\boldsymbol{t}_i = \phi$ and $\boldsymbol{h}_i \neq \phi$. $\boldsymbol{r_e}$ represents the set of semantic relations for $\boldsymbol{e}$, where $r_{e_i} \in \boldsymbol{r_e}$ corresponds to the semantic relation of e_i. Since r_{e_i} is derived without considering its context, r_{e_i} can be seen as the semantic relation between $\boldsymbol{t}_i$ and $\boldsymbol{h}_i$. The variables $\boldsymbol{r_e}^P$ represents a set of projected semantic relations derived from $r_{\boldsymbol{e}}$, taking into account their contexts. If an edit is under the scope of negation, a quantifier or a conditional, then r_{e_i} is mapped to an appropriate semantic relation $r_{e_i}^P$ based on that context. Therefore $r_{e_i}^P$ can be seen as the sentence-level semantic relation between T and the sentence which can be obtained by applying the edit e_i to T. The variables $\boldsymbol{r}^C$ denotes a set of semantic relations derived by combining $\boldsymbol{r_e}^P$, where each $r^C \in \boldsymbol{r}^C$ corresponds to the result of composition of two semantic relations. Hereafter, we use r_T^C as the sentence-level semantic relation. Note that $r_T^C \in \boldsymbol{r}^C$. Each variable r in $\boldsymbol{r_e}$, $\boldsymbol{r_e}^P$ and $\boldsymbol{r}^C$ can have seven types of semantic relations described previously. Ψ_k in equation (1) is a *factor* which scores the plausibility of alignment edits, their semantic relations, etc.

Our proposed model uses the following four types of factors to score the plausible alignment edits, their semantic relations and a sentence-level semantic relation.

Alignment Factor $\Psi_A(e, \boldsymbol{x})$ is used to deal with (unlabeled) phrase alignment for entailment relation recognition and is defined as $\Psi_A(e, \boldsymbol{x}) = \boldsymbol{\lambda} \cdot \boldsymbol{f}_A(e, \boldsymbol{x})$. In order to provide good alignments, it is necessary to capture the lexical similarity between words. The features used in this factor are mainly (i) surface-based similarity between alignment units, (ii) semantic relatedness of alignment units, which can be extracted from diverse lexical knowledge databases, and (iii) the contextual information for an edit.

Alignment Semantic Relation Factor $\Psi_S(e, r_e, \boldsymbol{x})$ is introduced to provide plausibility of a semantic relation $r_e \in \boldsymbol{r_e}$ for an alignment edit $e \in \boldsymbol{e}$ and is defined as $\Psi_S = \boldsymbol{\lambda} \cdot \boldsymbol{f}_S(e, r_e, \boldsymbol{x})$. Each variable r_e has a distribution over the seven types of semantic relations defined in Natural Logic. In order to classify semantic relations, not only surface-based similarities, but also lexical semantic relations play an important role. In the NatLog system developed by (MacCartney, 2009), an implementation of an RTE system of Natural Logic, lexical resource-derived features (e.g. WordNet, NomBank, etc.), string similarity features, and lexical category features are used. For this factor, we exploit diverse lexical resources to provide informative features for classifying semantic relations of edits.

Projection Factor $\Psi_P(r_e, r_e^P, \boldsymbol{x})$ provides an appropriate projection from r_e to r_e^P by considering the context of e, and is defined by $\Psi_P(r_e, r_e^P, \boldsymbol{x}) = \boldsymbol{\lambda} \cdot \boldsymbol{f}_P(r_e, r_e^P, \boldsymbol{x})$. This factor captures the effects of monotonicity (e.g. upward, downward). Given r_e and its contexts, the semantic relation of the projected variable r_e^P is uniquely determined using the monotonicity rules of (MacCartney, 2009).

Composition Factor $\Psi_C(r_{i-1}^C, r_e^P, r_i^C, \boldsymbol{x})$ scores tuples of semantic relations, and is defined by $\Psi_{C_i}(r_{i-1}^C, r_e^P, r_i^C, \boldsymbol{x}) = \boldsymbol{\lambda} \cdot \boldsymbol{f}(r_{i-1}^C, r_e^P, r_i^C, \boldsymbol{x})$. In this factor, we use the composition rules used in (MacCartney, 2009) with some modification. We set the derived semantic relations to independence (#) for the rules which derive more than one semantic relations. Therefore, as with Ψ_P, given two semantic relations r_{i-1}^C and r_e^P, the joined relation of the variable r_i^C is uniquely determined.

An overview of the proposed model is shown in Figure 1. In this figure, we show the factor graph constructed by our proposed model for a pair of sentences in Japanese. Our model is divided by three layers: the *alignment layer*, the *projection layer* and the *composition layer*. First, in the alignment layer, our proposed model scores possible alignments using Ψ_A and Ψ_S. For alignment units, we use *bunsetsu* which is a reasonable unit for Japanese linguistic analysis. A *bunsetsu* is a chunk-like unit that consists of one or more content words and zero or more functional words. A set of possible alignments are obtained using an extended MANLI algorithm (MacCartney et al., 2008).

Next, for each alignment obtained by the alignment algorithm, we construct a factor graph as shown in Figure 1. The factor graph has variables for alignments, projected relations, joined relations, and the factors defined previously. In the projection layer, semantic relations of alignments are projected by Ψ_P, and finally a sentence-level semantic relation is obtained in the composition layer using the projected relations and composition rules encoded in Ψ_C.

In inference, since variables related to Ψ_P and Ψ_C are uniquely determined if $\boldsymbol{r_e}$ is given, the model derives the best alignments, their semantic relations, and a sentence-level semantic relation simultaneously. In training, the parameters of the model are updated so as to derive alignments and their semantic relations which derive the correct sentence-level semantic relation based on the composition rules of Natural Logic.

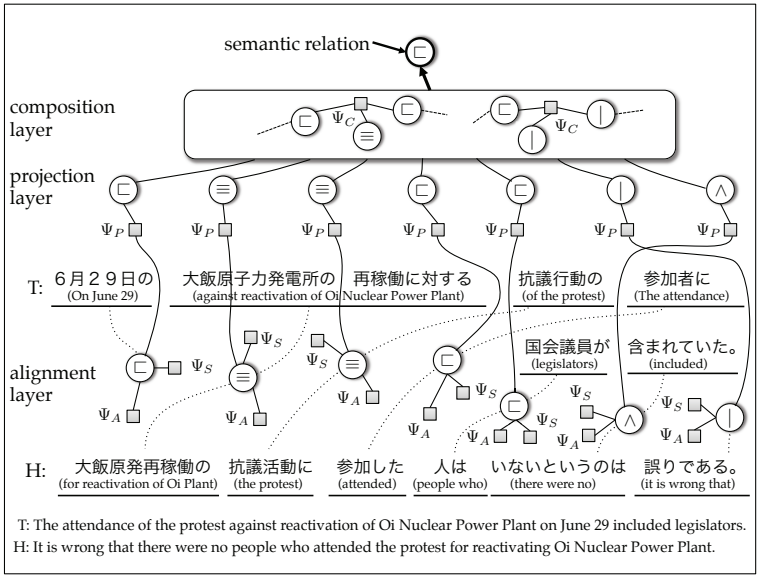

Figure 1: An overview of the proposed model.

3.2 Features

The features used in the proposed model are listed in Table 3.2.

Because RTE datasets are small, it is difficult to incorporate lexical features directly into our model as they may cause overfitting. Instead, we incorporate similarity metrics to model lexicality. On the other hand, because function words are closed class and present in all texts, we can directly use them as features.

While both Ψ_A and Ψ_S score the plausibility of alignments, the features used in their factors are also different. Ψ_A considers not only lexical similarities but also contexts of edits. Let us consider a simple sentence pair *T: USA won the war but Japan lost the war. H: Japan won the war.* In this example, T and H share the same verb *won* but the word *won* in H should be aligned to *lose* in T because they share the same subject (*Japan*). So, we introduce features that capture predicate-argument structure-level contextual information: e.g. how many arguments are shared by the two predicates (NUM_SHARED_ARGS)? On the other hand, Ψ_S pays more attention to inferring the lexical semantic relations of edits. The features used in Ψ_p and Ψ_C work as rules to infer sentence-level semantic relations.

3.3 Learning the Model

The parameters $\boldsymbol{\lambda}$ of the proposed model are trained from sentence-level semantic relations via marginal-likelihood maximization $\mathscr{L}_{\boldsymbol{\lambda}} = \sum_n \log p(r_T^C = l^n | \boldsymbol{x}^n; \boldsymbol{\lambda})$. By applying this objective function, we expect that the proposed model is trained so as to prefer alignment edits and

Factor	Edit	Name	Description
Ψ_A	DEL, INS	TYPE	edit type of e
		SIZE	the number of *bunsetsus* in e
		SAME_NOMINATIVE_IN_{T,H}	1 if e has a nominative argument and the other sentence also contains a nominative argument and its lemmas are the same.
		SAME_CASE_IN_{T,H}	1 if e has an argument of some predicates and the other sentence also contains an argument and its cases are the same.
		{T,H}_CONTAINS_{H,T}_LEMMA	1 if the head word of the *bunsetsu* in e is also contained in the other sentence.
		POS_SEQ	POS sequence in e
		HEADPOS	head POS of e
Ψ_A	SUB	TYPE	edit type of e
		SIZE	the number of *bunsetsus* in e
		NUM_SHARED_ARGS	the number of shared arguments if both t and h in e are predicates
		PARTICLE_SAME	1 if t and t have the same particle
		JAPANESE_WORDNET	Set relation type if e matches an entry in Japanese WordNet (Bond et al., 2009).
		WIKIPEDIA_HYPERNYM-HYPONYM	1 if e matches an entry in (Sumida et al., 2008).
		VERB_ENTAILMENT_REL	1 if an entry in the verb entailment relation dictionary (Hashimoto et al., 2009) matches e
		VERB_RELATION_REL	1 if an entry in the verb relation dictionary (Matsuyoshi et al., 2008) matches e
		PARENT_NUM_SHARED_ARGS	the number of shared arguments of the parent of t and h if t and h are arguments
		BOTH_HAVE_A_ROLE	1 if each *bunsetsu* in e is an argument of a predicate.
		BOTH_HAVE_THE_SAME_ROLE	1 if each *bunsetsu* in e has the same case.
		HEAD_POS_SAME	1 if the POSs of the heads in e are the same
		POS_SEQ_SAME	1 if the POS sequences of chunks in e are the same
		EXACT_MATCH	1 if t and h are the same
		UNIGRAM_COSINE	return unigram cosine value if the cosine similarity of two chunks in e is greater than the pre-defined threshold
Ψ_S	DEL, INS	SIZE	number of *bunsetsus* in e
		HEAD_LEMMA	lemma of the head of *bunsetsu* in e
		HEAD_WORD_CLASS	Word class of the head of *bunsetsu* in e. The word class information is extracted from the dictionary provided by (Kazama et al., 2010)
		NEGATION	1 if the *bunsetsu* contains a negation
Ψ_S	SUB	SIZE	Pair of the number of *bunsetsus* in e
		HEAD_POS_PAIR	POS pair of the heads of *bunsetsus* in e
		HEAD_LEMMA_SAME	1 if the lemmas of the heads in e are the same
		POS_SEQ_SAME	1 if the POS sequences of chunks in e are the same
		JAPANESE_WORDNET	same as in Ψ_A
		WIKIPEDIA_HYPERNYM-HYPONYM	same as in Ψ_A
		VERB_ENTAILMENT_REL	same as in Ψ_A
		VERB_RELATION_REL	same as in Ψ_A
Ψ_P	–	MONOTONE_{UP/DOWN}	the context of e is *upward-monotone* or *downward-monotone*.
Ψ_C	–	COMPOSITION_RULE	1 if the tuple of semantic relations is included in a set of defined compositional rules.

Table 1: Features used for the model.

their semantic relations which infer the correct sentence-level semantic relations based on the composition rules of Natural Logic.

The partial differential of the objective function is

$$\frac{\partial L}{\partial \lambda_k} = \sum_n \left(\frac{\partial}{\partial \lambda_k} \log \sum_{\langle \boldsymbol{e}, \boldsymbol{r}_e \rangle \in \mathcal{E}} \sum_{\boldsymbol{r}: r_T^C = l} \exp\left(\sum_k \boldsymbol{\Psi}_k(\boldsymbol{e}, \boldsymbol{r}_e, \boldsymbol{r}_e^P, \boldsymbol{r}^C, \boldsymbol{x}) \right) - \frac{\partial}{\partial \lambda_k} \log Z(\boldsymbol{x}) \right) \quad (2)$$

return $\mathscr{E}$

where edits $\boldsymbol{e}$, their semantic relations $\boldsymbol{r}_e$, projected semantic relations $\boldsymbol{r}_e^P$ and joined relations excluding the sentence-level semantic relation are all hidden variables. Given $\boldsymbol{r}_e$, $\boldsymbol{r}_e^P$ and $\boldsymbol{r}^C$ can be identified uniquely by using projection and composition rules. Since the objective function is non-convex, estimated parameters can be local-optima.

In optimization, only the parameters in Ψ_A and Ψ_S are updated, and the parameters in Ψ_P and Ψ_C are left to initial values. In order to update the parameters, we need to calculate marginal probabilities of the alignments. However, unlike sequential or tree models, calculating exact values of alignments is prohibitively difficult. We use only N-bests provided by the extended MANLI algorithm to calculate an approximate partition function $\widetilde{Z}(\boldsymbol{x})$ instead of $Z(\boldsymbol{x})$, and approximate marginal probabilities.

3.4 Inference of Alignments

Given two sentences, the problem of alignment inference in our model is predicting the best edits and their semantic relations $\widehat{\langle \boldsymbol{e}, \boldsymbol{r}_e \rangle} = \arg\max_{\langle \boldsymbol{e}, \boldsymbol{r}_e \rangle \in \mathscr{E}} \sum_{\langle e_i, r_{e_i} \rangle \in \langle \boldsymbol{e}, \boldsymbol{r}_e \rangle} \Psi_A(e_i, \boldsymbol{x}; \boldsymbol{\lambda}) + \sum_{\langle e_i, r_{e_i} \rangle \in \langle \boldsymbol{e}, \boldsymbol{r}_e \rangle} \Psi_S(e_i, r_{e_i}, \boldsymbol{x}; \boldsymbol{\lambda})$ where $\mathscr{E}$ is a set of all possible edits and their semantic relations between two sentences. The original MANLI algorithm (MacCartney et al., 2008) only provides the best edits, so we extend the algorithm so as to provide not only edits, but also their semantic relations.

The extended version of MANLI is shown in Algorithm 1. Given two sentences, the algorithm starts at an initial alignment $\boldsymbol{e}_0$ which consists of deletion edits of *bunsetsus* in T and insertion edits of *bunsetsu* in H, and then searches for more good alignments by changing edits from a pair of a deletion and an insertion edit to a substitution edit, or changing semantic labels. The main differences between the original MANLI and our algorithm are: (1) alignments have their semantic relations, (2) keeps a set of alignments ordered by scores provided by Ψ_A and Ψ_S to provide N-bests. We omitted the annealing procedure which is included in the original

MANLI because our algorithm need to keep an ordered set of alignments based on scores. If we introduce a temperature value, we have to update all of the alignments in the set when the value is changed. However this is computationally expensive.

3.5 The Order of Composition

The composition order of semantic relations defined in Natural Logic is non-commutative. Let us consider joining an alternation ($|$) and a forward-entailment ($\sqsubset$). The pair of semantic relations frequently appear in contradiction examples. $\sqsubset$ joined with $|$ yields $|$, on the other hand, $|$ joined with $\sqsubset$ yields $\bigcup\{\equiv, ^\wedge, |, \cup, \#\}$. The former way of composition derives the desired result, however, the latter way derives an ambiguous result. We defined the order of composition so as to keep joined semantic relations unambiguous as far as possible. Our proposed model at first joins $\equiv$ and $\sqsubset$, then $|$, then $^\wedge$, and $\sqsupset$ in the end [4].

4 Experiments

4.1 Data

We developed a dataset for semantic relation recognition which includes a diverse selection of linguistic phenomena. Although there is an textual entailment recognition data set for Japanese (RITE (Shima et al., 2011)), we do not consider it an appropriate target for evaluation and instead construct our own dataset. Our motivation is as follows. Much of the progress made in textual entailment recognition has been on a set of phenomena that can be handled with methods of lexical and phrasal similarity, however, there are many other phenomena that have not been addressed.

Sammons et al. (2010) make a case for more detailed analysis of the linguistic phenomena important to textual entailment recognition so that their impact on existing approaches can be properly measured. In that spirit, we investigated textual entailment recognition phenomena and found that quantification, negation, and monotonicity require consideration of their semantic structure and are beyond the scope of similarity-based methods. Constructing systematic and robust models of handling these phenomena is the focus of this paper. It is reasonable to target these phenomena next because many of the remaining problems for textual entailment recognition require world knowledge and are thus problems of inference or AI. Existing datasets for textual entailment recognition are insufficient for our purposes because the phenomena they contain are too broad and they do not contain enough examples of the phenomena we are targeting to draw meaningful conclusions.

We selected the categories based on FraCaS (Cooper et al., 1996), the corpus developed by Bentivogli et al. (2010) and the categories discussed in (MacCartney, 2009): lexical semantic relation (e.g. synonym, antonym, hypernym-hyponym relation), quantifiers, modifiers, negation, coordination, relative clauses, apposition, temporal and numerical expressions, active/passive, factive verbs and functional relations.

The statistics of the dataset is shown in Table 4.1. The distribution of the categories is not balanced: the quantifier category accounts for approximately 30% of the total. One of our interests is whether the model can automatically capture behaviour of functional expressions such as quantifiers from sentence-level semantic relations. In order to conform this point, we developed many examples for quantifiers.

[4] NatLog uses a different strategy from ours. The system at first joins semantic relations of deletion edits, then substitution edits, next edits involve operators with non-default projectivity, and, finally, insertion edits.

Category	#	Category	#	Category	#
Quantifier	182	Coordination	27	Part-Whole	13
Numerical/Temporal	53	Argument Mismatch	26	Condition	8
Modifier	55	Negation + Lexical semantic Rel.	23	Apposition	7
Lexical semantic relation	44	Paraphrase	21	World Knowledge	3
Implicative/Factive	36	Predicate Mismatch	17	Other	37
Relation between entities/events	27	Coordination	27	Total	598

Table 2: Category statistics.

Category	Example	Sem. Rel.
Quantifier	*T: Almost all mammals have molars in the back of their rows of teeth.* *H: There are mammals that do not have molars.*	Forward-Ent.
Paraphrase	*T: Not all smokers get cancer.* *H: Even if you smoke, you might not get cancer.*	Paraphrase
Modifier	*T: There aren't many students.* *H: There aren't many students who have had a heat stroke.*	Forward-Ent.
Lexical semantic rel.	*T: Japan got a bronze medal in Team Fencing.* *H: Japan hasn't gotten a bronze medal in any sports.*	Contradiction
Implicative/Factive	*T: Earthquake-proofing prevented the house's collapse.* *H: The house did not collapse.*	Forward-Ent.
Coordination	*T: Tokyo has a population of 13,000,000 and Miyagi has a population of 2,300,000.* *H: Tokyo has a population of 2,300,000.*	Contradiction

Table 3: Some examples in the dataset (translated in English).

For each example, we annotated one of the four types of sentence-level semantic relations (paraphrase, forward-entailment, contradiction and independence), and alignment edits and their semantic relations in Natural Logic. In the dataset, the number of paraphrase examples is 97, forward-entailment is 313, contradiction is 100, and independence is 88. Table 4.1 shows some examples in the dataset. The dataset was developed by one annotator, who is a professionally trained linguist unaffiliated with this research project, and the set of annotated semantic relations does not always provide the correct semantic relation. 55.2% of the gold annotations derive correct sentence-level semantic relation (332 examples). The remaining examples include inconsistencies between sentence-level semantic relations and semantic relations of alignments, linguistic phenomena that the current model can not deal with (e.g. syntactic transformation, some quantifiers), etc.

Whereas there are seven types of relations in Natural Logic, our annotation uses only four types of relations. So in the experiments, we mapped *contradiction* to $\{\wedge, |\}$ and *other* to $\{\cup, \#\}$ in the training and the testing phase.

4.2 Settings

In order to explore the effectiveness of the proposed model, we evaluated the following approaches in the experiments.

Initial Weight Initial weights of the model are used for testing.

Resource-based Alignment Alignments are determined based on a surface-based similarity measures and lexical resources. In this setting, a pair of two phrases is aligned if the character-bigram cosine similarity is greater than a pre-defined threshold (we set it to 0.8), or the pair matches an entry in the lexical resources such as Japanese WordNet, Hypernym-Hyponym relations, Verb Entailment Relations, and Verb Relation Dictionary.

Semantic relations of alignment edits are determined as follows: $\equiv$ if the pair of the *bunsetsus* $\langle b_1, b_2 \rangle$ is the same, similar or is synonym, | if the pair is antonym, $\sqsubset$ if b_2 is the hypernym of b_1 or b_1 entails b_2, $\sqsupset$ if b_1 is the hypernym of b_2 or b_2 entails b_1. The *bunsetsus* not aligned by the similarity measure or the resources are converted to *deletion* or *insertion* edits, and their semantic relations are set to $\sqsubset$ and $\sqsupset$ respectively with exceptions described later.

Alignment Supervised The model is trained using gold alignments which have correct semantic relations defined in Natural Logic. In this setting, sentence-level semantic relations are not considered in training. As in the proposed model, we constructed the model using a log-linear discriminative model, and the model was trained log-likelihood maximization of gold alignments. The objective function used in training was $\mathcal{L}_{\boldsymbol{\lambda}} = \sum_n \log p(\boldsymbol{e}, \boldsymbol{r}_e | \boldsymbol{x}^n; \boldsymbol{\lambda})$.

Weakly Supervised (proposed) The model is trained by marginal likelihood maximization over sentence-level semantic relations.

The dataset we used in the experiments include the examples whose correct sentence-level semantic relations can not be derived from the pre-annotated semantic relations of alignment edits. It seems that these are hard to derive correct sentence-level semantic relations from the current possible edits. So, we conducted experiments on the examples whose correct sentence-level semantic relations can be derived from the gold alignments (hereafter, we say *reachable*).

For the factors Ψ_P and Ψ_C, we initialized the weights to 0.0 if the semantic relation tuple is covered by our projection rules and composition rules, and $-\infty$ otherwise. For the factors Ψ_A and Ψ_S, we set initial weights to some features [5]. In training of the model, we update the parameters in Ψ_A and Ψ_S, and the parameters in Ψ_P and Ψ_C are left to the initial values. Parameter updating was performed using stochastic gradient descent (SGD), and the number of iterations was set to 2. Also, we applied L_2 regularization. As for the alignment algorithm, the number of iterations was set to 40, and the number of N-bests was set to 10. For each edit type, we restricted the maximum size of units: only allows one-to-one for substitution, allows at most three units for insertion and deletion edits. Also, we constrained the types of semantic relations for each edit type. Substitution edits can have one of the five types of semantic relations: $\equiv$, $\sqsubset$, $\sqsupset$, $\wedge$ and | with an exception. If the lemma sequences of the two *bunsetsus* are the same, the edit can have only $\equiv$. Deletion edits and insertion edits can have $\sqsubset$ and $\sqsupset$ respectively with exceptions. They can have | if the head of *bunsetsu* matches an entry in the list of *counter-factive expressions* [6], and they can have $\equiv$ if the head of *bunsetsu* matches an entry in the list of *less-informative expressions* [7].

4.3 Evaluation Measures

We use the following measures in evaluation: **(1) Alignment (Unlabeled):** A predicted alignment is correct if there is a gold alignment which has the same span, but the semantic label is not considered, **(2) Alignment (Labeled):** A predicted alignment is correct only if there is a gold alignment which has the same span and their semantic relations are also the same, and **(3) Sem. Rel.:** Accuracy of sentence-level semantic relations.

[5] For instance, the weights of the combination feature "NEGATION=0" and "JAPANESE_WORDNET=antonym" are set to 1.0 if label is | and -1.0 otherwise

[6] A hand-crafted list which contains 13 entries.

[7] As with the list of *counter-factive expressions*, the list was hand-crafted, and contains 30 entries.

Table 4: Performance of alignment prediction and sentence-level semantic relation recognition.

4.4 Preprocessing

For each sentence, we conducted various forms of linguistic analysis: morphological analysis using MeCab (Kudo et al., 2004), syntactic parsing using the Japanese dependency parser, CaboCha (Kudo and Matsumoto, 2002) and predicate-argument structure analysis (Watanabe et al., 2010) to provide a basis for alignment and semantic relation classification.

4.5 Results

Table 4 shows the experimental results of 10-fold cross validation for alignment prediction and sentence level semantic relation recognition. We can see that while the proposed method is less successful at reproducing gold standard alignments, it greatly outperforms Supervised Learning for sentence-level semantic relation recognition[8]. We expected Supervised Learning to perform best on reachable examples, which should have the most straightforward connection between alignment semantic relation labels and sentence level semantic relations. Nevertheless, our proposed method achieved the best performance on this dataset as well. These results support our theory that gold standard alignment data is necessary for semantic relation recognition. Indeed, alignment labels appear to degrade performance in several cases.

Table 5 shows the sentence-level performance for each semantic relation type. This breakdown shows that the proposed method is particularly good at Contradiction and Forward-Entailment relations, outperforming all other methods on all data sets. When considering reachable examples only, it is also the top-performing method for Paraphrase detection as well. Resource-based Alignment and Initial Weights both perform poorly, producing significantly worse results than the supervised methods in every evaluation setting with the exception of Contradiction on reachable examples only and Independence on both data sets.

The poor performance by Resource-based Alignment and Initial Weights is likely due to inaccurate alignments, especially of functional expressions (e.g. *sometimes - not always*). Since deletion and an insertion edits are assigned $\sqsubset$ and $\sqsupset$ respectively by default and joining them yields independence (#), these methods over-produce Independence relations. Most of the errors in Alignment Supervised are caused by lower precision for alternation (|). Since alternation relations can greatly impact the sentence-level semantic relation prediction, this severely impacted the overall performance of the supervised model.

Table 6 shows the performances of semantic relation classification of alignments for each type. As discussed before, supervised alignment is the most successful at recovering gold standard

[8] We compared the sentence-level semantic relation recognition results of Weakly Supervised and Alignment Supervised with the McNemar test, and the difference was statistically significant ($p < 0.01$).

alignments and semantic relation labels. However, it is interesting to note that while Resource Alignment performs competitively at alignment prediction (it rivals Alignment Supervised on Forward-Entailment and outperforms all other methods on Alternation/Negation), it performs drastically worse on sentence-level semantic relation recognition, sometimes with an f-score that is more than 20 points lower than the best performing method. These results suggest that it is important to jointly model alignment prediction and sentence-level semantic relation recognition so that globally optimal alignments are promoted.

5 Related Work

There are a number of existing works which explore the use of latent variable or structure models for recognizing textual entailment. Chang et al. (2010) proposed a discriminative linear model where alignments are treated as hidden structures, and the sentence-level semantic relation is derived based on the best latent alignment structure. They formulated the problem of predicting the best hidden structure as an Integer Linear Programming problem, where domain knowledge is encoded as constraints. Wang and Manning (2010) proposed a latent variable model where the model provides a conditional distribution of a sequence of edits, which can be seen as a transformation-based approach. In the model, edits are treated as hidden variables that populate a positive set and a negative set in the search space. Sentence-level semantic relations are predicted based on the sum of the scores of edit sequences in the positive set and the negative set.

The differences between our proposed model and theirs are that the number of semantic relations and compositionality. Both Wang and Manning (2010) and Chang et al. (2010) consider only *entailment* and *non-entailment*, while our proposed model identifies a rich set of relations: *paraphrase*, *forward entailment*, *backward entailment*, *contradiction*, and *independence*.

Furthermore, as discussed in Section 2, our model exhibits compositionality by incorporating Natural Logic at two different levels. First, it incorporates information about upward and downward monotonicity into a projection layer, allow it to handle flips in entailment direction caused by scope of negation that can influence the final sentence-level semantic relation. In addition, it considers the result of combining projected semantic relations of alignment edits, allowing it to handle complex interactions between linguistic phenomena in sentences. The alignment models of Wang and Manning (2010) and Chang et al. (2010) do not consider the interaction between alignments that we model with Natural Logic making it difficult for them to classify examples that contain complex semantic structures.

Conclusion

In this paper, we proposed a novel latent variable model for compositional entailment relation recognition. We gave the proposed model compositionality by incorporating a set of semantic relations and their composition rules of Natural Logic. The model has ability to predict local correspondences (alignments) between sentences, the semantic relations, and the sentence-level semantic relation simultaneously. The model can be trained from only sentence-level semantic relations by using marginal-likelihood maximization. In evaluation, our proposed method outperformed a supervised alignment method on a sentence-level semantic relation recognition task, and detailed analysis on that task and an alignment prediction task did not provide evidence that gold standard alignment labels contributed to semantic relation recognition performance and instead suggests that they can be detrimental to performance if used in a manner that prevents the learning of globally optimal alignments.

A future research direction we are investigating is extending the model so as to deal with structural transformations. The current model has a big drawback: the model assumes that all of sentence-level semantic relations can be derived from only *bunsetsu* -level transformations. We would like to explore how to incorporate transformation rules (used in e.g. (Stern et al., 2011)) into the proposed model.

ABSTRACT
One of the biggest bottlenecks for conversational systems is large-scale provision of suitable content. In this paper, we present the use of content mined from online question-and-answer forums to automatically construct system utterances. Although this content is mined in the form of question-answer pairs, our system is able to use it to formulate utterances that drive a conversation, not just for answering user questions as has been done in previous work. We use a collection of strategies that specify how and when the question-answer pairs can be used and augmented with a small number of generic hand-crafted text snippets to generate natural and coherent system utterances. Our experiments involving 11 human participants demonstrated that this approach can indeed produce relatively natural and coherent interaction.

KEYWORDS: conversational system; question-answer pairs; conversational strategies.

1 Introduction

A major bottleneck for any kind of *conversational system* is provision of sufficient content, and if one wishes to avoid repetition and to cover the many possible user inputs, there must be a substantial amount of content. In the case of chatbots such as ALICE (Wallace, 2009), the content is custom-crafted to be as generic and deflective as possible to cover the needs of open-ended conversations. This approach, which reduces the amount of content that the system needs despite the relatively broad range of user inputs, is essentially only capable of content-free, small talk. This kind of conversational ability is, however, inadequate for virtual characters that need to contribute relevant content in their conversations. In systems that require domain-specific content, for example about health in a virtual nurse (Bickmore et al., 2009) or about children-related topics in an intelligent toy (Chen et al., 2011), the custom-crafting of content to cover the depth and breadth of the domain as well as to keep it current becomes an impractical task. This work reports on our use of an abundant type of data, sourced from the Web, to equip a conversational agent with the content it needs to engage users in a coherent and natural way over a wide range of domains.

To overcome the bottleneck of custom- or hand-crafting conversational content, researchers have recently investigated mining online resources such as Web pages returned by search engines (e.g., `Yahoo!` (Shibata et al., 2009)). The problem with this approach, however, is that most content on the Web is not suitable for conversational agents, for various reasons. The verbose, non-colloquial and monologue nature of much of Web text is not a good match for the characteristics of human-human dialogue. However, there are some other sources on the Web that have more potential for this purpose, such as human-written comments on news websites (e.g., `NYTimes.com` (Marge et al., 2010)) and online forums (e.g., `RottenTomatoes.com`

Proceedings of COLING 2012: Technical Papers, pages 2821–2834,
COLING 2012, Mumbai, December 2012.

(Huang et al., 2007), `2ch.net` (Inoue et al., 2011)). We use text of this nature in the current work for obtaining content with which our conversational agent constructs its utterances.

In this paper, we propose the use of question-answer (QA) pairs from community-driven question-and-answer websites such as `AskKids.com` and `Answers.com` as content for our conversational agent. QA pairs from the Web are essentially individual pairings of questions and the corresponding answers contributed by online communities. By nature, the QA pairs extracted from a particular source on a certain topic are disjointed, in that they do not have any temporal or structural information that could immediately lend themselves to straightforwardly building conversations. We see the potential of QA pairs for use in a conversational agent as they are a reasonable embodiment of human-human communication, unlike text extracted from other sources such as Wikipedia or online news articles. The abundance and self-contained nature of QA pairs means that they can be extracted easily over a wide range of topics covered by the respective online communities. QA pairs have also been used in the past with some success for interactive question answering (IQA), driven solely by the user's information needs. We developed an IQA system (Wong et al., 2011) in the past that supports interactivity and does not require inputs to be formulated as questions. This system, however, still interprets inputs as questions and service them with answers. The approach in this paper, on the other hand, is able to share the initiative with the human user for determining conversation content and direction, and is able to engage with the user using a range of different *conversational strategies* such as 'question asking', 'fact telling' and 'question answering'. Context is maintained, similar to our previous work (Wong et al., 2011), but instead of using this purely to identify a question, which is then answered, it is now used to identify a QA pair of relevance for crafting system utterances to further a conversation.

The key contributions of this paper lie in the conversational strategies that we describe that specify how the different parts of the QA pairs can be used and combined with a small number of generic hand-crafted fragments to generate natural system utterances. These system contributions, when interplayed with cooperative user inputs, will produce seemingly coherent conversations. Unlike existing dialogue systems that rely on deep language processing to achieve 'understanding' from input (e.g., (Schulman et al., 2011)), our conversational agent relies only on shallow analysis for efficiency to extract and assign weights to terms and to identify domain information for building *conversational context*. To examine the level of coherence and naturalness that our system can achieve in the absence of standard dialogue management, custom language resources, and deep semantic analysis of user inputs, we perform a pilot study involving 11 human assessors. The results, which show that our approach does indeed produce natural and coherent interaction relative to the human assessment, are discussed in Section 5. Prior to that, we look at the state of the art in conversational agents in terms of their dialogue management approaches and language resource requirements in Section 2. In Section 3, we provide some background on the system architecture and the overall process, including the structure of our QA pairs, the processing of input and the building of context. We then describe in Section 4 the way in which we use the QA pairs according to several strategies, to form a variety of system utterances, using these to build natural, reasonably coherent conversations. After the system evaluation in Section 5, we conclude in Section 6 with discussion of future work to incorporate this into a more complete virtual companion, integrating these conversational agent abilities into a fully fledged companion with a range of capabilities.

2 Related Work

Mining content from the Web to support human-computer interaction applications (e.g., question answering (Radev et al., 2001; Clarke et al., 2001; Yao et al., 2012), interactive question answering (Wong et al., 2011), conversational systems (Huang et al., 2007; Wu et al., 2008; Shibata et al., 2009)) has been investigated since the advent of the read-write Web. In particular, the practice of mining the Web to alleviate the bottleneck of conversational content acquisition is increasing in popularity. Huang et al. (Huang et al., 2007), for example, proposed a supervised technique for extracting `<thread-title><reply>` pairs from online forums as 'knowledge' for chatbots. The authors used `RottenTomatoes.com` as their source of title-reply pairs. The extraction is done in a cascaded manner, given the semi-structured and relatively noisy nature of text in online forums. All replies relevant to the thread title are first extracted using an SVM classifier based on features related to the structure and content. The candidate pairs are then ranked according to the quality of the content, and the top *n* pairs are selected as chatbot 'knowledge'. However, no details were provided on how the pairs could be used in a chatbot. Yao et al. (Yao et al., 2012), on the other hand, describe a technique for extracting factoid QA pairs from standard text, such as Wikipedia[1]. In their approach, natural language processing techniques are used to create a QA pair from a declarative sentence. These QA pairs are then used by virtual characters to answer queries from a user. As such, they are only using the QA pairs reactively, whereas our novel proposal is to also use them proactively. Moreover, by mining our content from social media sites, we are more likely to obtain more conversational fragments, as opposed to the strictly factoid style QA pairs that Yao et al. are interested in. However, they do demonstrate encouraging performance for their techniques and it may be possible to use such an approach to further increase our content with such (factoid) QA pairs.

Overall, despite the rise in interest in deriving content from the Web for conversational systems, there is little research on how this content can be used more effectively to maximise the traits that should ideally be present in human-computer dialogue. These traits include the coherence of system-generated outputs with respect to preceding exchanges, the naturalness of system utterances (e.g., is the utterance too lengthy or formal for supposedly casual conversations), and the ability to support mixed-initiative interactions (i.e., no strict adherence to whether the system or the user leads the conversations). In the next section, we present our approach to a system which mines the Web for QA pairs, and specifies how and when this content can be used to generate coherent, natural system contributions to mixed-initiative conversation.

3 System Overview

An overview of the main components of our conversational system is shown in Figure 1. We briefly describe the collection of QA pairs, and the *Input Analysis*, *Context Management* and *QA pair Retrieval and Ranking* components in this section. We focus in more detail in Section 4 on the *Strategiser*, which is the major novel contribution of this paper.

3.1 QA Pair Collection

The content for generating system utterances is primarily a set of QA pairs, mined from community-driven question-and-answer websites. During output generation, the different parts of the selected QA pairs are augmented by a small number of strategy-specific fragments, which we describe together with the strategies, to create natural system utterances. As our focus

[1]They actually use the Simple English version of Wikipedia.

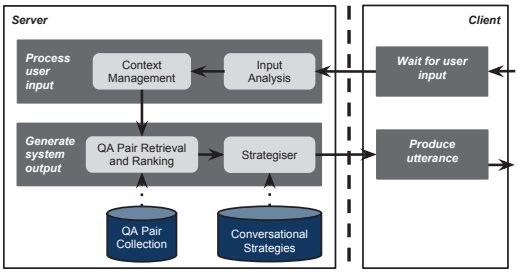

Figure 1: Conversational system architecture

is a companion for children, in this work we have used websites such as `AskKids.com` and `Answers.com` for collecting our QA pairs. This collection is constructed offline, using an interface similar to that described in (Wong et al., 2011) which allows the system administrator to specify the source (e.g., *"askkids*"), domain (e.g., *"animal*") and a seed word (e.g., *"lion*") to represent a topic in the domain for localising and indexing QA pairs. Each QA pair consists of the question and the answer to that question, and some metadata, which are the domain tag, the topic tag and the source tag. These QA pairs are then organised into a database according to the metadata. The tags are used to move between topics of the same domain during a conversation, and to define the scope (i.e., subset of fragments) that the conversational agent has to deal with at any one time. Currently, the collection contains a total of 23,295 QA pairs across 150 topics in the animal domain.

3.2 Input Analysis

Analysis of input utterances is relatively shallow, deliberately avoiding any attempt at sophisticated natural language understanding. The input is first tagged with parts of speech using FastTag[2] for its speed. Noun phrases are then identified using simple regular expression patterns. Pronouns are resolved to the most prominent entities from previous inputs, using a method loosely similar to the backward looking centering approach (Mitkov, 2001). The phrases and words are then assigned weights to reflect their content bearing property. These weighted phrases and words are referred to as terms. Our system has two different weighting schemes implemented, the deviation from Poisson approach (Church and Gale, 1995) and *tf-idf*, with the former being the default. The higher the weight of a term, the more content-bearing it is. Content-bearing terms play a more discriminatory role in selecting relevant QA pairs for utterance generation during the retrieval and ranking process. Stopwords, on the other hand, are removed by virtue of them being non-content bearing. In addition, a dictionary-based approach, operating over the input string, is used to detect if an input is an explicit question or a request for session termination.

3.3 Context Management

Context, which is essentially a collection of weighted terms decayed over time, is used to select QA pairs which are sufficiently relevant to the user inputs to generate system utterances. By

[2] markwatson.com/opensource

collecting the weighted terms from the user inputs (and potentially system output), and then decaying them over time, we maintain sufficient contextual information to make good choices of QA pairs for building system utterances. Each time a new input is processed, the corresponding weighted terms are combined into the existing conversational context. For example, if the current input is the $5th$ utterance by the user, then the context at that turn would contain all the terms and their weights extracted from the previous four inputs. The context management process at turn 5 would then assimilate the terms from the recent input into the current context to create a revised conversational context for turn 6.

The rule for combining new terms to the context is as follows. If a term is already present in the context, the weight associated with the recent occurrence is added to the term's existing decayed weight in the context to reinforce what we perceive as an important term. If the term is absent from the context, the new term and its weight are added to the context. In other words, recurrence is an important factor for a term to maintain its prominence in the context, where the more times a term occurs in the conversation, the more significant it will become through the compounding of its weights. During the process of combining, the weights of all other terms in the context that are not encountered in the most recent input are decayed based on the turn in the conversation, the decay factor and the part of speech. Those term used less recently thus have a greatly reduced weight. Different parts of speech are decayed at different rates, with nouns decaying less quickly than verbs, which decay slower than adjectives, adverbs and other parts of speech. Terms are decayed according to $v' = v \exp(-t\lambda\alpha)$ where v' is the decayed weight, v is the original weight, λ is the decay factor set to 0.8 during our experiments. The α value has been set to the following empirically-selected values to reflect the bias that we introduced according to a term's part of speech: 0.25 for nouns, 0.75 for adjectives and adverbs, 1.25 for verbs, and 2.50 for others.

3.4 QA Pair Retrieval and Ranking

QA pair retrieval and ranking are performed to determine the QA pair that has the highest relevance to the conversational context. Initially, a set of all candidate QA pairs containing at least one term from the context is retrieved. The relevance of the candidates with respect to the conversational context is then determined in terms of (1) the extent of the overlap of words in the question and answer parts of QA pairs with those in the conversational context, and (2) the string similarity between the question component and the user input. Edit distance (Levenshtein, 1966) is used to determine the similarity between the user input and the question part of the candidate QA pairs. As for overlap, the more highly weighted terms from the conversational context that appear in a QA pair, the higher the pair's score will be. The sum of the weights of terms from the context that appear in the question as well as the answer of a QA pair is determined. This sum is augmented by the location of appearance, where term matches in the questions are scored twice as high as matches in the answers. At the end of retrieval and ranking, the top scoring QA pair is selected for utterance generation.

4 Conversational Strategies

The core of our system's abilities are two *reactive* and four *proactive* strategies. These strategies attempt to recreate the types of human-to-human communications that are commonly encountered. The strategies is also divided into *progression* or *conclusion* depending on their roles, to either progress or conclude a conversation. The content used by these strategies to produce utterances are the QA pairs and a small number of specialised *hand crafted fragments*

which include speech disfluencies to produce more natural outputs (Marge et al., 2010). These fragments are assigned tags and are contained in the strategy library. This library can be extended to increase the variety of specialised fragments, independently of the actual strategies.

4.1 Reactive Strategies

This group of strategies is characterised by the agent following the user's lead. There are two strategies in this group, the first being a *reactive progression* strategy called UAQ, and a *reactive conclusion* strategy called UEC. The details are discussed below.

UAQ (User Asks Questions) Strategy: This strategy is initiated when the input parsing detects that the user has asked a question. In this case the keywords from the parsed input, weighted as described in *Context Management*, are used to select a QA pair where the context has an optimal match with the question portion of the QA pair. The answer portion of the pair (or if it is too long, the initial part) is then used as output. If it is desired to continue this strategy beyond a single interaction in the conversation, then subsequent inputs are essentially treated as refinements of the initial question. This is essentially the approach used in our IQA system (Wong et al., 2011). We do not use any specialised fragments to augment the selected QA pair in this strategy.

UEC (User Ends Conversation) Strategy: This strategy is used when input processing detects signs that the user wants to conclude the conversation. When a termination is detected, the Strategiser removes all pending outputs in the queue and adopts this strategy to access the associated fragments shown in Table 1, which are used to generate farewell messages.

1	OK. Nice chatting with you. Cya.	[UEC]
2	Bye.	[UEC]

Table 1: Some fragments for the UEC strategy

4.2 Proactive Strategies

We have five proactive strategies, two for progressing and three for concluding a conversation. The *proactive progression* strategies are the ones that we make most use of in our conversational agent. In these strategies the system takes the initiative by either asking a question or sharing some information. The three *proactive conclusion* strategies deal with certain circumstances that necessitate the conclusion of conversation sessions, namely, (1) lack of user participation, and (2) system's inability to carry on the conversation. These conclusion strategies are the result of the system interpreting various signs and initiating the ending. The conclusion strategies do not use any components of QA pairs for generating system utterances.

SSK (System Shares Knowledge) Strategy: This strategy attempts to simulate conversations involving the sharing of knowledge between two participants in a chat. In the SSK strategy, the system assumes the role of imparting knowledge, with the user on the receiving end. This strategy uses the answer component of QA pairs to formulate system utterances to create this effect. To illustrate, consider the following QA pair:

```
Q: What is a panda?
```

```
A: The Panda is the bear-like black and white mammals which lives in
China. These cute and cuddly like bears eats mainly bamboo shoots
and are becoming extinct. Some experts refer to them as bears while
others believe they are more like a raccoon.
```

The SSK strategy uses the first sentence in the answer and augments it with a selection of fragments such as *"Did you know that $X*" and *"I just learnt that $X*". In this example, the first system utterance generated using this strategy, which will be placed in a queue, is *"Did you know that the panda is the bear-like black and white mammals which lives in China.*". The subsequent sentences in the answer are stored in the queue for generation but their order of use will depend on the evolving conversation context in the next n iterations. For example, assume that the system sends the first utterance in the queue to the user, and the user provides *"They look like a racoon*" as the next input. Since this new input is not an explicit question and the queue of the next things to utter is not empty, the strategy remains the same, i.e., SSK, and the system utterance generation process does not invoke the QA pair retrieval and ranking process. The Strategiser is used to reorder the utterances in the queue based on their overlap with the current conversational context that contains the term *"racoon*". Since the overlap of the words in the second sentence in the queue (i.e., the third sentence in the answer of the selected QA pair) with the context is likely to be higher (due to the word *"racoon*"), this sentence will be selected, augmented with the appropriate fragments and moved to the front of the queue as the next system utterance. This next utterance will appear as *"And some experts refer to them as bears while others believe they are more like a raccoon*". In the third iteration, only one sentence from the 3-sentence answer remains. Unless the next user input is a question, the system will generate its next utterance as *"What's more is that these cute and cuddly like bears eats mainly bamboo shoots and are becoming extinct*". This process of reordering the sentences that the system utters takes place for all sentences in the answer of the selected QA pair.

1	Did you know that $\$X$?	[SSK-1]
2	I just learnt that $\$X$.	[SSK-1]
3	What's more, $\$X$.	[SSK-2]
4	What's more is that $\$X$.	[SSK-2]
5	And $\$X_3$... Well... $\$X$.	[SSK-2]
6	And $\$X_3$... Umm... $\$X$.	[SSK-2]

Table 2: Some fragments for the SSK strategy

Table 2 shows the list of fragments associated with the SSK strategy. Fragments labelled [SSK-1] are used by the strategy to prepend to the first sentence of the selected answer, while those labelled [SSK-2] are used for augmenting the subsequent sentences. Fragments 5 and 6 are three examples containing false starts, where $\$X_3$ and $\$X_4$ represents the first three and four words in $\$X$, respectively.

SAQ (System Asks Questions) Strategy: This strategy attempts to recreate a conversational scenario where a conversation participant explicitly asks the other participant a question. In this strategy, the system poses as the participant asking the question. Both the question as well as the answer components of QA pairs are used to generate the system utterances in this strategy.

1	Can you tell me, $\$X$?	[SAQ-1]
2	Tell me, $\$X$?	[SAQ-1]
3	Erm... $\$X$.	[SAQ-2]
4	$\$X_3$... Well... $\$X$.	[SAQ-2]

Table 3: Some fragments for the SAQ strategy

When this strategy is selected, the question component of the selected QA pair is used to construct the first system utterance. Fragments shown in Table 3 which are labelled [SAQ-1] are used to augment the question. The second utterance is then constructed using the first three sentences of the corresponding answer and a fragment tagged with [SAQ-2]. With regard to [SAQ-2] fragments, 3 contains fillers while 4 contains a false start to add to the 'natural' effect of the resulting utterances. To illustrate, consider the QA pair above. The first and second utterances in the queue would appear as *"Can you tell me, what is a panda?*" and *"The Panda is... Well... The Panda is the bear-like black and white mammals which lives in China. These cute and cuddly like bears eats mainly bamboo shoots and are becoming extinct. Some experts refer to them as bears while others believe they are more like a raccoon.*". The use of only the first three sentences in the answer to generate the second system utterance is motivated by the average sentences in answers of QA pairs from AskKids.com being around three.

UNI (User Not Interested) Strategy: This strategy is chosen by the Strategiser when input processing detects three empty input sentences in a row, likely to be the result of the expiration of the 60-second timer imposed by the input waiting process at the client side. The system assumes the three successive timeouts to be a sign of the user losing focus to other tasks, or lacking interest in pursuing the conversation further. Similar to the UEC strategy, the Strategiser cancels all pending utterances when this strategy is chosen, and uses one of the fragments lablled [UNI] shown in Table 4 to generate the system's final utterance.

1	You don't seem very interested in continuing the chat. Let's do this some other time. Bye!	[UNI]
2	It seems that you're in the middle of something. Let's talk some other time. Cya.	[UNI]

Table 4: Some fragments for the UNI strategy

LTT (Lost Train of Thought) and SEC (System Ends Conversation) Strategies: The second circumstance that necessitates the conclusion of a conversation, from the system's point of view, is the repeated inability of the retrieval and ranking modules to select a QA pair that the Strategiser can work on using the conversational context maintained by the system. There are two main causes of this: (1) the user's successive use of non-content bearing words in his or her inputs, and (2) the exhaustion of QA pairs. Two strategies are involved in this circumstance. Whenever the Strategiser does not receive a selected QA pair from the retrieval and ranking modules, the LTT strategy is used to generate utterances with fragments, shown in Table 5, designed to prompt the user to repeat the recent input(s). When this strategy is used, the conversational context is emptied and rebuilt using the latest input with the hope that the new context can be used to select some useful QA pairs. In the event that the LTT strategy is being selected for the third time in a row, the system will consider this as a sign that it is unable to further pursue the conversation. In such cases, the Strategiser uses the SEC strategy

to conclude the current session. Table 6 shows the fragments associated with the SEC strategy for ending a conversation.

1	Oops. I got distracted. You were saying?	[LTT]
2	Sorry, can you please repeat what you just said?	[LTT]
3	Where were we? I was talking to someone else.	[LTT]

Table 5: Some fragments for the LTT strategy

1	I've got something that I have to attend to now. Talk to you later.	[SEC]
2	Sorry. I'm tired now. Let's continue this some other time. Bye.	[SEC]
3	We'll need to stop here now. I've got to run. Bye.	[SEC]

Table 6: Some fragments for the SEC strategy

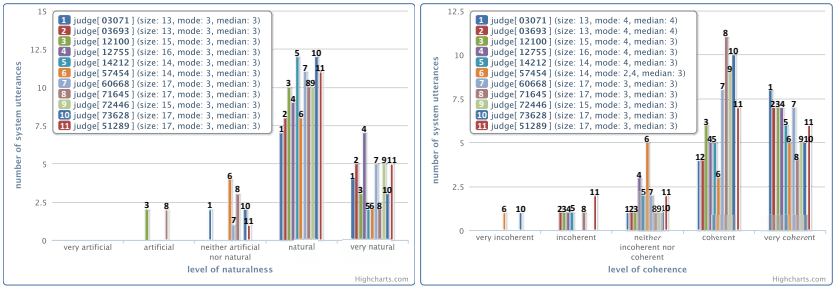
5 Evaluation

We conducted a pilot study to assess the naturalness and coherence of utterances generated by our conversational agent using only QA pairs and 41 generic fragments. We first discuss the experimental setup, before moving on to present the results of humans' judgements of our system outputs. Error analysis is also performed, where we analyse the causes of those system utterances that were perceived as less natural and coherent by the judges. An actual interaction between the system and one of the judges is presented at the end to illustrate a typical conversation with the conversational agent.

5.1 Experimental Setup

The domain that we have selected to test our conversational agent is that of *"animal*". The question-answer pairs are downloaded from two sources, namely, `AskKids.com` and `Answers.com`, solely for this experiment. 150 topics in the *"animal*" domain were manually identified and used as seed words, where 17,790 QA pairs were retrieved from `Answers.com` and 5,505 from `AskKids.com`. We were only able to download QA pairs about 96 out of the total 150 topics from `AskKids.com`. To ensure that the Strategiser has the option of using QA pairs from both sources during utterance generation, a topic is randomly selected by the system from amongst the 96 seed words to initiate every conversation with the participants.

For the experiment, we obtained the assistance of 11 human participants. For privacy reasons, the participants' names, genders and other personal information were not collected, and their names were never used by the conversational agent during conversations. The experiments were conducted over the Internet where the participants were provided with a text interface accessible via a Web browser. The interface is made up of two main parts, a user input field at the bottom, and a panel to display the exchanges between the user and the system. The instructions that we provide to the participants were as follows: (1) We requested the participants to limit their conversations to a 10-minute duration; and (2) At the end of every conversation, the participants were requested to rate the system utterances for naturalness and coherence using two 5-point Likert scales (the naturalness scale has scores that range from 0-`very artificial` to 4-`very natural`, while the coherence scale ranges from 0-`very incoherent` to 4-`very coherent`).



(a) Distribution of "naturalness"

(b) Distribution of "coherence"

Figure 2: Distribution of human judgements

5.2 Results

A total of 168 system utterances were recorded for all 11 conversations involving the 11 participants, with 16 − 17 system utterances on average per conversation.

Naturalness of system utterances: Figure 2(a) shows the distribution of the naturalness rating of system-generated outputs. Out of the 168 system utterances, only about 10% (17 utterances) are rated at or below level 2, with 13 system utterances being judged as `neither artificial nor natural` and 4 as `artificial`. The other 26% (43 utterances) and 64% (108 utterances) are judged as `very natural` and `natural`, respectively. In other words, the chart is left-skewed, with the majority (90%) of the judgements tending towards the `very natural` end of the scale, with both the mode and median for all 11 conversations being at level 3, which is `natural`.

Coherence of system utterances: Figure 2(b) summarises the human judgements of coherence of system-generated outputs. The trend appears to be quite similar to the judgements of naturalness in terms of skewness. However, instead of being concentrated at level 3, the judgements of coherence are slightly more spread over the neighbouring levels 2 and 4. The modes and medians shown in the legend in Figure 2(b) also demonstrate this spread. About 17% (29 utterances) of all system outputs were considered as `neither coherent nor incoherent` (20 utterances), `incoherent` (7 utterances) or `very incoherent` (2 utterances). At the same time, the numbers of utterances rated as `very coherent` (67 utterances) and as `coherent` (72 utterances) are approximately equal and when tallied up constitute 83% of all system-generated outputs.

Ability to maintain coherence: While the majority of the system-generated outputs are coherent (i.e., 83% of utterances are `coherent` or better), we are also interested in whether coherence of the conversations is sustained throughout, or whether coherence deteriorates with conversation length. Figure 3 shows coherence of individual system utterances over time for all 11 conversations. The figure shows that the coherence of the system contributions was consistently above level 2 (i.e., `neither incoherent nor coherent`), with 9 sporadic valleys reaching level 1 and 0.

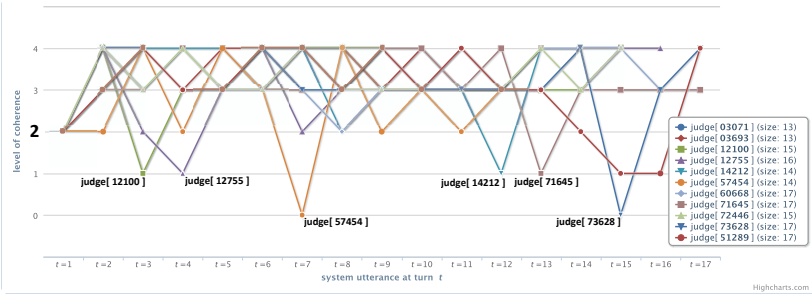


Figure 3: Level of coherence over the course of a conversation

causes	1	2	total
repetition of utterances	3	2	5
verbose utterances	0	4	4
perceived non-responsiveness to user questions	0	4	4
quality of QA pairs and wrongly judged utterances	1	3	4

Table 7: The causes behind the system utterances that were rated as `artificial` (score 1) or `neither artificial nor natural` (score 2) on the naturalness scale by the judges.

5.3 Error Analysis

After collecting judgements from the human participants, we analysed chat logs for naturalness and coherence ratings of the individual system utterances. We identified a number of causes behind the average and poorly-rated outputs: we discuss these here. Possible ways to remove these problems are discussed in Section 6.

Causes of artificial utterances: We identified four main causes behind the 17 system utterances that were judged as `artificial` or `neither artificial nor natural`, as summarised in Table 7. The first cause, i.e., repetition occurred when QA pairs which are different on the surface but semantically similar were used in succession to generate system utterances. For example, there were two distinct QA pairs with the questions *"What is cougar*" and *"What is the cougar?*" in our collection. During the system's conversation with judge 71645, these two pairs were used to generate the two different utterances *"Can you tell me, what is cougar?*" and *"Tell me, what is the cougar?*", four turns apart. From the judge's point of view, these utterances appeared as unnatural in that such blatant repetitions would not normally be encountered in human-human dialogue. The second cause, not surprisingly, is the artificiality of verbose utterances. The number of words in a typical system output ranges between 8 to 20. There are, however, a small number of utterances that go beyond this range, with some approaching or exceeding length 60. In this experiment, 8 utterances were considered to be lengthy, and of these, 4 were rated down by the participants (were rated as `neither artificial nor natural`) that encountered them during their interactions with the system. The third cause is the user perceiving the system as not responding to their questions. This problem occurred due to the system's more restrictive interpretation of what

causes	0	1	2	total
alternation between topics	0	4	2	6
utterances which are out-of-place	1	1	1	3
perceived non-responsiveness to user questions	1	0	3	4
issues with context management	0	2	3	5
initial system utterance	0	0	11	11

Table 8: The causes behind the system utterances that were rated as `very incoherent` (score 0), `incoherent` (score 1) or `neither incoherent nor coherent` (score 2) on the coherence scale by the judges.

constitutes a question. Out of the 4 utterances in the `quality of QA pairs and wrongly judged utterances` row of Table 7, 2 were the result of poorly-written QA pairs by the online human contributors. As an example, one of the sentences in the answer of a selected QA pair was incomplete, producing the system utterance *"And the interesting bit is that the giant panda lives in Asia and is most commonly known [sic]*", which was rated as 1 for naturalness by judge 12100. As for the other two utterances rated as `neither artificial nor natural` in the same row, the causes were unclear.

Causes of incoherent utterances: Next, we discuss the causes that contributed to some of the system utterances being judged poorly on the coherence scale. Table 8 summarises these causes. The first cause is the generation of utterances that give the users the impression of abrupt transitions. This may happen when the system moves to a new topic that is semantically less related (hence the abruptness), or alternates between topics due to the presence of multiple influential terms within the same domain in the context. The second cause is the generation of utterances that appear out of context. This may be due to the ways the QA pairs were written (poorly) or structured (i.e., the sentences in the answers may not lend well to the generation of individual, successive system utterances). Consider the following QA pair as an example:

```
Q: What do american cockroaches eat?
A: Just about everything! American cockroaches eat plants, garbage,
   people food, glue found in book bindings and other glues and
   pet foods are just a few.
```

This particular QA pair was used as part of the SSK strategy to produce the utterance *"Do you know that just about everything?*" when interacting with judge 03693. The utterance, which appeared in the following context, was in no way related to the previous exchanges and was ill-formed. For this reason, the judge rated its coherence as 1.

```
SYSM: erm... some types of cockroaches can fly but not all of them.
      the american cockroach can fly but the german one cannot.
      these are the most common cockroaches found.
USER: american cockroach?
SYSM: do you know that just about everything?
...
```

The third cause is the system's inability to detect and handle questions that were not formulated using typical *wh*-words. This cause also negatively affects the naturalness of system utterances,

as previously discussed. The fourth cause is due to problems with context management. As we have discussed before, the LTT strategy is used to recover from inadequate context for QA pair selection. This can happen when users repeatedly provide inputs that do not contain words that are useful for selecting QA pairs. Unfortunately, some of the judges do perceive this system-initiated solicitation for more useful inputs as unnatural. As for the 11 utterances judged as `neither incoherent nor coherent` on the fifth row of Table 8, these outputs were simply the first utterances generated by the system in their respective conversations. Since these utterances do not have any preceding inputs or outputs to be benchmarked against for coherence, these level 2 ratings were expected.

6 Discussion

Conversational systems that are required to engage users in conversations that cover the breadth and depth of certain topics face the bottleneck of custom- or hand-crafting the necessary content. Mining conversational content from the Web is increasingly being seen as a promising solution to this problem. However, the verbose, non-colloquial and monologue nature of typical Web text means that such content is not straightforwardly usable for responding to users by conversational systems for various reasons. In this work, we propose the use of question-answer (QA) pairs mined from community-driven question-and-answer websites as content for a conversational system. The main contribution of this paper lies in the conversational strategies we have defined that specify how and when the different parts of QA pairs can be used and augmented with a small number of generic fragments to generate natural system utterances. The coherence of system contributions in a conversation is managed using context. To assess the naturalness and coherence of system-generated utterances, we conducted a small pilot study involving 11 human participants. Out of the 168 system outputs, over 80% were judged as natural and coherent by the participants. The coherence of system contributions is generally maintained throughout the course of all 11 conversations, with sporadic incoherences. We also analysed the causes behind the $10-20$% of artificial and incoherent system outputs.

Limitations and potential improvements on the naturalness of system utterances: The two main causes that contributed to a number of outputs being judged as artificial were the appearance of repetitive and lengthy utterances. The problem of repetition arises when QA pairs with different surface patterns that are semantically similar are selected within the same conversation to generate system utterances. One possible way to overcome this is to use a string similarity measure to compare the questions of potential QA pairs against the QA pairs that have already been used. Candidate pairs that are similar to the previously used ones on the surface can then be excluded from future use. As for coping with lengthy utterances, a range of approaches are available, from detecting sentence boundaries with some heuristics for recombining them, to more elaborate summarisation techniques.

Limitations and potential improvements on the coherence of system utterances: Incoherent utterances are caused mainly by the lack of management of the implicit transitions between topics in the same domain during a conversation. The problem of topic transitioning can be managed, for example, using local *wellformedness* constraints, e.g., semantic relatedness measures. The other causes of poor coherence and artificial outputs, i.e., the non-responsiveness to certain questions (that have surface patterns not recognised by the system) and the quality of QA pairs, are more difficult to address. Adding new patterns to support more types of questions or using punctuation to detect questions may seem to be straightforward solutions. However,

our intention to potentially incorporate speech input will render the latter option useless, while the former solution will increase false positives during question detection. In regard to the quality of QA pairs, manual intervention is necessary to proof-read and edit the pairs. Currently, no manual effort is required to make our system operational, except providing seed terms to populate the QA pair collection.

Abstract
Among various neural network language models (NNLMs), recurrent neural network-based language models (RNNLMs) are very competitive in many cases. Most current RNNLMs only use one single feature stream, i.e., surface words. However, previous studies proved that language models with additional linguistic information achieve better performance. In this study, we extend RNNLM by explicitly integrating additional linguistic information, including morphological, syntactic, or semantic factors. Our proposed RNNLM is called a factored RNNLM that is expected to enhance RNNLMs. A number of experiments are carried out that show the factored RNNLM improves the performance for all considered tasks: consistent perplexity and word error rate (WER) reductions. In the Penn Treebank corpus, the relative improvements over n-gram LM and RNNLM are 29.0% and 13.0%, respectively. In the IWSLT-2011 TED ASR test set, absolute WER reductions over RNNLM and n-gram LM reach 0.63 and 0.73 points.

Title and Abstract in another language (Chinese)

基于递归神经网络的因素语言模型

在多种神经网络语言模型（NNLM）中，递归神经网络语言模型（RNNLM）在很多场合都表现出优异的性能。目前，大多数的RNNLM只使用词汇这一种特征。然而，以往的研究表明利用了语言学特征的语言模型可进一步提高模型性能。本文通过引入语言学特征，包括形态，语法，或语义特征，对RNNLM进行扩展。我们称之为基于递归神经网络的因素语言模型（fRNNLM）。一系列的实验表明：本文提出的fRNNLM在多个任务中均显著地提高了RNNLM的性能：即一致地降低了困惑度和单词错误率（WER）。在宾州树库上，fRNNLM的困惑度相对相对于n元语言模型和RNNLM分别降低了29.0%和13.0%。在IWSLT-2011 TED语音识别测试集上，fRNNLM的单词错误率分别提高了0.63（相对于n元语言模型）和0.73（相对于RNNLM）。

1 Introduction

Language models (LM) are a critical component of many application systems such as automatic speech recognition (ASR), machine translation (MT) and optical character recognition (OCR). In the past, statistical back-off n-gram language models with sophisticated smoothing techniques have gained great popularity because of their simplicity and good performance. In n-gram language models, words are represented in a discrete space: the vocabulary. Standard back-off n-gram language models predict the following word based on the previous n-1 words, which can be expressed as,

$$p(w_i|w_{i-1},...,w_1) \approx p(w_i|w_{i-n+1},...,w_{i-2},w_{i-1}) \quad (1)$$

Even though n is usually limited to three or four, the number of parameters in a back-off n-gram LM is still enormous. Assuming the vocabulary size is $64K$, a 4-gram language model needs to estimate $64K^2$ bigrams, $64K^3$ trigrams and $64K^4$ 4-grams. Due to data sparseness, many are not observed during the training phase. This means that n-gram LMs have poor generalization to low-frequency and unseen n-grams. This problem becomes more severe as the vocabulary size increases. Many interesting approaches have been proposed to overcome it in large vocabulary continuous speech recognition (LVCSR) and statistical machine translation systems, especially smoothing techniques (Chen and Goodman, 1996), class n-gram language models (Brown et al., 1992), topic language models (Gildea and Hofmann, 1999; Hsu and Glass, 2006), structured language models (Chelba and Jelinek, 2000), maximum entropy language models (Rosenfeld, 1996) and random forests language models (Xu and Jelinek, 2004).

Among these techniques, one of the most successful schemes is the neural network language model (NNLM), such as the feed-forward NNLM (Bengio et al., 2003; Schwenk, 2007; Kuo et al., 2012), the recurrent NNLM (RNNLM) (Mikolov et al., 2010, 2011b) and the deep NNLM (Arisoy et al., 2012). Compared to other LMs, recurrent NNLMs, which are state-of-the art (Mikolov et al., 2011a; Arisoy et al., 2012), embed words in a continuous space in which probability estimation is performed using artificial neural networks consisting of input layer, single or multiple hidden layers, and output layer. Due to consistent improvement in terms of perplexity and word error rate and their inherently strong generalization, they have become an increasingly popular choice for LVCSR and statistical MT tasks.

Many of these RNNLMs only use one single feature stream, i.e., surface words, which are limited to generalize over words without using linguistic information, including morphological, syntactic, or semantic. In surface word RNNLMs, such words as “prices" and “price" and “developed" and “developing" are completely independent training instances. In this paper, we integrate additional linguistic information into a RNNLM, called a factored RNNLM, which can further improve the generalization of RNNLM using multiple factors (or features) of words (stems, lemmas, parts-of-speech, etc.) instead of surface forms of words as input to recurrent neural networks. Let us use an example to illustrate the shortcomings of surface word RNNLM. In extreme cases, the training data might only contain the following sentence: “difference between developed countries and developing countries". During training in the RNNLM that treats each word as a token in itself, the bi-gram “developing countries" is a completely unseen instance. However, for our factored RNNLM that incorporates stem features, “developing countries" belongs to seen instances in a sense because it shares the same stem bi-gram “develop countri" with the previous bi-gram “developed countries." This coincides with our intuition; “developed" and “developing" should add knowledge to each other during training. Our factored RNNLM may be more effective for such morphologically rich

languages as Czech, Arabic, or Russian. In this paper, we only evaluate it on English, and our experiments show that it significantly enhances performance measured in perplexity and WER.

To the best of our knowledge, few studies have been done on this perspective. Our approach provides the following advantages:

- It predicts the following word based on the entire history (due to a recurrent connection between input and hidden layers) in the low-dimensional representation (due to the neural network architecture).
- It integrates the additional rich information of words in particular morphological and syntactic features to overcome the data sparseness problem caused by limited in-domain training data, such as in academic lecture ASR and MT tasks.
- It simultaneously interpolates all possible factors and the entire history in stead of backing-off to fewer factors and shorter context, which can address the optimization problem well in factored n-gram language models.
- Since it converges faster than RNNLM due to the integration of additional features, it can save several days of training if the training data are large.

This paper is organized as follows: We introduce related studies in Section 2. In Section 3, we describe our proposed factored RNNLM in detail. Section 4 shows the performance of our model as measured by both perplexity and WER. We finally summarize our findings and outline future plans in Section 5.

2 Related work

Recently, deep neural networks are experiencing significant improvements in the fields of image processing, acoustic modeling (Seide et al., 2011), language modeling, etc. Neural network language models to LVCSR were first presented in (Bengio et al., 2003), which was a feed-forward NNLM with a fixed-length context consisting of projection, input, hidden, and output layers. Arisoy et al. (2012) proposed a deep NNLM that uses multiple hidden layers instead of single hidden layer in feed-forward NNLMs. Furthermore, several speedup techniques such as shortlists, regrouping and block models have been proposed (Schwenk, 2007). Feed-forward NNLMs, which predict following word w_i based on any possible context of length n-1 history, remain a kind of n-gram language model.

Recurrent NNLM (RNNLM) (Mikolov et al., 2010, 2011b), which has different architecture at the input and output layers, can be considered as a deep neural network LMs because of its recurrent connections between input and hidden layers, which enable RNNLMs to use their entire history. Compared with feed-forward NNLMs, recurrent NNLMs reduce computational complexity and have relatively fast training due to the factorization of the output layer. Other experiments (Mikolov et al., 2011a; Arisoy et al., 2012; Kuo et al., 2012) demonstrated that RNNLM significantly outperforms feed-forward NNLM. Therefore, this paper uses RNNLM as a baseline and improves it by incorporating additional information other than surface words, such as morphological or syntactic features.

Although few studies incorporate morphological and syntactic features into RNNLM, using multiple features in language modeling is not novel. For example, Duh and Kirchhoff (2004) presented

a factored back-off n-gram LM (FLM) that assumes each word is equivalent to a fixed number (K) of factors, i.e., $W \equiv f^{1:K}$, and produces a statistic model of the following form: $p(f_i^{1:K}|f_{i-n+1:i-1}^{1:K})$. The standard back-off in an n-gram LM first drops the most distant word (w_{i-n+1} in the case of Eq. (1)), and then the second most distant word etc. until the unigram is reached. However, the factors in FLM occur simultaneously, i.e., without forming a temporal sequence, so the order in which they should be dropped is not immediately obvious. In this case, FLM creates a large space of back-off graphs that cannot be exhaustively searched. Duh and Kirchhoff (2004) employed a genetic algorithm (GA) that, however, provides no guarantee of finding the optimal back-off graph. Our factored RNNLM addresses this optimization problem well, as described in Section 3. In addition, Emami and Jelinek (2004); Alexandrescu and Kirchhoff (2006); Kuo et al. (2009); Collins et al. (2005) introduced various syntactic features into their feed-forward NNLMs and discriminative language models. Table 1 summarizes FLM, RNNLM, and our approach from three points of view.

	Conditioning variables	History	Pros and Cons
FLM	Word and its linguistic features	n-1 preceding history	Better than n-gram LM due to linguistic features; Creating a large space of models that cannot be searched exhaustively.
RNNLM	Word	Entire history	Further enhancing FLM due to RNN architecture; Conditioning variables are only words, no morphological or syntactic linguistic features are used.
factored RNNLM	Word and its linguistic features	Entire history	Combining the above merits, but more parameters and computation complexity, which actually does not cause problems, as described in Section 4.4.

Table 1: Comparison of FLM, RNNLM, and factored RNNLM

Koehn and Hoang (2007) introduced various features from linguistic tools or word classes into phrase-based MT models for better translation performance.

3 Factored RNNLM

The architecture of our factored RNNLM is illustrated in Fig. 1. It consists of input layer x, hidden layer s (state layer), and output layer y. The connection weights among layers are denoted by matrixes U and W. Unlike RNNLM, which predicts probability $P(w_i|w_{i-1}, s_{i-1})$, our factored RNNLM predicts probability $P(w_i|F(w_{i-1}), s_{i-1})$ of generating following word w_i and is explicitly conditioned on a collection or bundle of K factors of one preceding word. It is implicitly conditioned on the factors of the entire history by the delay copy of hidden layer s_{i-1}. Here, $F(w_{i-1})$ is the vector concatenated from K factor vectors f_{i-1}^k ($k = 1, ..., K$), f_{i-1}^k stands for the k-th factor vector encoded from the k-th factor of preceding word w_{i-1}, and the functions of factor extraction $f^k(\cdot)$ are used to extract the corresponding factors. A word's factors can be anything, including the word itself, its morphological class, its root, and any other linguistic features. An example is shown in Table 2.

In the input layer, the extracted factors are encoded into the factor vectors using the 1-of-n coding.

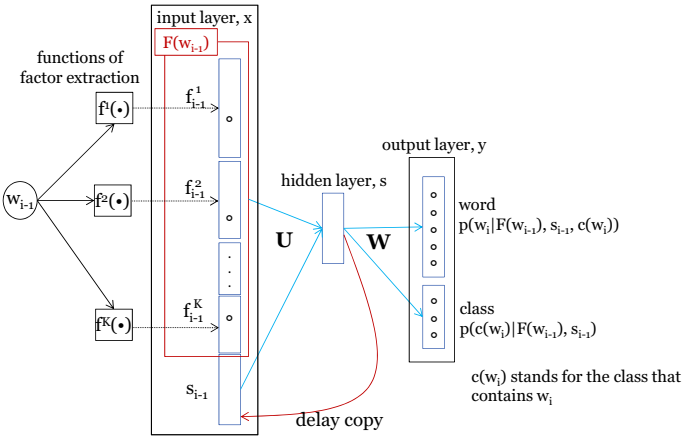

Figure 1: Architecture of factored recurrent NNLM.

Assume, for example, that the factor extracted by function $f^k(w_{i-1})$ is the m-th element in the k-th factor vocabulary, which is then encoded to $|f^k|$-dimension vector f^k_{i-1} by setting the m-th element of the vector to 1 and all the other elements to 0. Here, $|f^k|$ stands for the size of the k-th factor vocabulary. The K factor vectors are concatenated into $F(w_{i-1})$ as expressed in Eq. (2). Finally, the input layer is formed by concatenating factor vectors $F(w_{i-1})$ of the preceding word w_{i-1} and hidden layer s_{i-1} at the preceding time step, as shown in Eq. (3).

Word:	difference	between	developed	countries	and	developing	countries
Lemma:	difference	between	developed	country	and	developing	country
Stem:	differ	between	develop	countri	and	develop	countri
Part-of-speech[1]:	NN	IN	JJ	NNS	CC	VBG	NNS

Table 2: An example of factor sequences.

$$F(w_{i-1}) = [f^1_{i-1},\ f^2_{i-1},\ ...,\ f^K_{i-1}] \tag{2}$$

$$x_i = [F(w_{i-1}),\ s_{i-1}] \tag{3}$$

Using the concatenation vector, our proposed factored RNNLM can simultaneously integrate all factors and the entire history in stead of backing-off to fewer factors and a shorter context. The weight of each factor is represented in connection weight matrix U. Therefore, it can address the optimization problem well in factored n-gram LM (Duh and Kirchhoff, 2004). In the special case that f^1_{i-1} is a surface word factor vector and f^k_{i-1} $(k = 2, ..., K)$ are dropped, the factored RNNLM goes back to the RNNLM.

[1] http://www.cis.upenn.edu/~treebank/

The hidden layer employs a sigmoid activation function:

$$s_i^m = f(\sum_j (x_i^j \times u_{mj})) \quad \forall m \in [1, H]$$
$$f(z) = \frac{1}{1+e^{-z}} \tag{4}$$

where H is the number of hidden neurons in the hidden layer and u_{mj} is an element in matrix U denoting the corresponding connection weight.

Like (Goodman, 2001; Mikolov et al., 2011b), we assume that each word belongs to exactly one class and divide the output layer into two parts: the first estimates the posterior probability distribution over all classes,

$$y_c^l = g(\sum_j (s_i^j \times w_{lj})) \quad \forall l \in [1, C] \tag{5}$$

where C is the number of predefined classes. The second computes the posterior probability distribution over the words that belong to class $c(w_i)$, the one that contains predicted word w_i:

$$y_w^o = g(\sum_j (s_i^j \times w_{oj})) \quad \forall o \in [1, nc(w_i)] \tag{6}$$

where $nc(w_i)$ is the number of words belonging to class $c(w_i)$ and w_{lj} and w_{oj} are the corresponding connection weights.

To ensure that all outputs are between 0 and 1, and their sum equals to 1, the output layer employs a softmax activation function shown below:

$$g(z_d) = \frac{e^{z_d}}{\sum_x e^{z_x}} \tag{7}$$

Finally, probability $P(w_i|F(w_{i-1}), s_{i-1})$ is the product of two posterior probability distributions:

$$\begin{aligned} P(w_i|F(w_{i-1}), s_{i-1}) &= P(c(w_i)|F(w_{i-1}), s_{i-1}) \times P(w_i|F(w_{i-1}), s_{i-1}, c(w_i)) \\ &= y_c^l|_{l=classid(c(w_i))} \times y_w^o|_{o=wordid(w_i)} \end{aligned} \tag{8}$$

The architecture of splitting the output layer into two parts can greatly speedup the training and the test processes of RNNLM without sacrificing much performance. Many word clustering techniques can be employed. In this paper, we map words into classes with frequency binning (Mikolov et al., 2011b), which proportionally assigns words to classes based on their frequencies. The pseudo codes are shown in Fig. 2.

3.1 Training

To use the factored RNNLM, connection weight matrixes U and W must be learned. To learn them, training is performed with the back-propagation through time (BPTT) algorithm (Boden, 2002) by minimizing an error function defined in Eq. (9).

$$L = \frac{1}{2} \times \sum_{i=1}^{N} (t_i - p_i)^2 + \gamma \times (\sum_{lk} u_{lk}^2 + \sum_{tl} w_{tl}^2) \tag{9}$$

```
#vocab[i].cn denotes the number of the i-th word that occurs
#vocab[i].classid denotes the class index of the i-th word
#nclass is the number of classes predefined
 double df=0, a=0, b=0;
 for (i=0; i<|V|; i++) b+=vocab[i].cn;
 for (i=0; i<|V|; i++) {
    df+=vocab[i].cn/b;
    if (df>1) df=1;
    if (df>(a+1)/nclass) {
       vocab[i].classid=a;
       if (a<nclass-1) a++;
    }
    else {
       vocab[i].classid=a;
    }
 }
```

Figure 2: Frequency binning. $|V|$ is the word vocabulary's size.

where N is the number of training instances, t_i denotes the desired output; i.e., the probability should be 1.0 for the predicted word in the training sentence and 0.0 for all others. The first part of this equation is the summed squared error between the output and the desired probability distributions, and the second part is a regularization term that prevents RNNLM from over-fitting the training data. γ is the regularization term's weight, which is determined experimentally using a validation set.

The training algorithm randomly initializes the matrixes and updates them with Eq. (10) over all the training instances in several iterations. In Eq. (10), ψ stands for one of the connection weights in the neural network and η is the learning rate. After each iteration, it uses validation data for stopping and controlling the learning rate. Usually, the factored RNNLM needs 10 to 20 iterations.

$$\psi^{new} = \psi^{previous} - \eta \times \frac{\partial L}{\partial \psi} \tag{10}$$

3.2 Free parameter & time complexity

To better understand the differences between RNNLM and our factored RNNLM, we compare them in terms of the number of free parameters and computational complexity of one training step in Table 3. τ is the amount of steps used in BPTT.

	Free Parameter	Computational Complexity
RNNLM (1)	$(\|V\|+H)\times H + H\times(C+\|V\|)$	$(1+H)\times H\times\tau + H\times\|V\|$
fRNNLM (2)	$(\|f^1\|+...+\|f^K\|+H)\times H + H\times(C+\|V\|)$	$(K+H)\times H\times\tau + H\times\|V\|$
Difference (2)-(1)	$(\|f^1\|+...+\|f^K\|-\|V\|)\times H$	$(K-1)\times H\times\tau$

Table 3: RNNLM vs. factored RNNLM (fRNNLM).

From this table we can observe that the factored RNNLM has more free parameters and larger computational complexity. If the factored RNNLM only employs word factor (f^1) and POS factors

(f^2), then, it has $39 \times H$ additional free parameters. The additional computational complexity is $(K-1) \times H \times \tau$. In experiments, H is usually set to $300-1000$, τ is usually set to 4, $|V|$ is usually set to several hundreds of thousands. This means that $H \times |V| \gg (K-1) \times H \times \tau$, and the increased complexity can be neglected. Owing to the additional free parameters, our factored RNNLM converges faster and reduces training time. Section 4.4 shows the exact running time spent on experiments.

4 Experiments

In this section, we show the performance of our factored RNNLM as measured by perplexity. After analyzing these results, we present the performance measured by word error rate when the factored RNNLM is used in a LVCSR system. In our experiments, we mainly compare our factored RNNLMs with a 4-gram LM with modified Kneser-Ney smoothing (Chen and Goodman, 1996) and RNNLM (Mikolov et al., 2011b). In the factored RNNLM, we investigate four commonly used types of factors: word, stem[2], lemma[3] and part-of-speech (POS).

For perplexity results, we use the WSJ portion of Penn Treebank (LDC99T42). The WSJ portion is divided into training (sections 00-20), heldout (sections 21-22), and test (sections 23- 24) sets containing 930K, 101K, and 97K words respectively. The vocabulary is limited to 10K words. This setting is the same as that used by other studies (Xu and Jelinek, 2004; Mikolov et al., 2011b). The sizes of the factor vocabularies in the training set are shown in Table 4[4]. Note that the word vocabulary (10001 in Table 4) contains 10K words and one special token "<unk>" denoting words not in the vocabulary.

Factors	Word	Lemma	Stem	POS
Sizes	10001	7356	6892	37

Table 4: Statistics of factor vocabularies.

4.1 Impacts of factors

This experiment analyzes the contribution from each factor to the factored RNNLM in terms of the perplexities on the heldout and test sets. We set the number of hidden neurons in the hidden layer and the number of classes in the output layer for both the RNNLM and factored RNNLM to 320 and 300. Table 5 shows the experimental results. fRNNLM$_{wslp}$ denotes the factored RNNLM incorporating the word, stem, lemma, and POS factors, and so forth, the ratio is computed using $\frac{|U|_{factored\ RNNLM} - |U|_{RNNLM}}{|U|_{RNNLM}}$ that indicates the percentage of additional parameters in matrix U against the RNNLM. Subscript numbers are the relative improvements over RNNLM.

From this table, we observe the following: (1) All of the factored RNNLMs significantly improve their performances. For example, the improvement of fRNNLM$_{wsp}$ against the RNNLM on the test set reaches 14.4%. (2) No significant differences are found among the factored RNNLMs with various combinations of factors. The contributions from stem and lemma factors are less than 1.0%. In particular, it is not necessary to use both stem and lemma because they are very similar and obviously do not complement each other. (3) Although the size of the parts-of-speech is the

[4] We directly use manually tagged parts-of-speech in the Penn Treebank corpus. Section 4.6 investigates automatically tagged parts-of-speech.

	Ratio	Heldout	Test
4-gramLM		156.26	156.41
RNNLM	-	146.94	145.63
fRNNLM$_{wp}$	0.4%	$128.14_{12.8\%}$	$126.47_{13.1\%}$
fRNNLM$_{wsp}$	67.5%	$127.09_{13.4\%}$	$124.63_{14.4\%}$
fRNNLM$_{wlp}$	72.0%	$126.81_{13.7\%}$	$124.76_{14.3\%}$
fRNNLM$_{wslp}$	138.8%	$126.06_{14.2\%}$	$124.76_{14.3\%}$

Table 5: Impacts of factors measured by perplexities.

smallest (only 37, Table 4), they have the largest impact on our factored RNNLM. The main reason may lie in that syntactic factor (POS) has stronger complementariness to the surface word factor, while morphological factors (stem and lemma) are too similar to the word itself, limiting such complementariness. Therefore, in the following experiments we only use word, stem, and POS in our factored RNNLM.

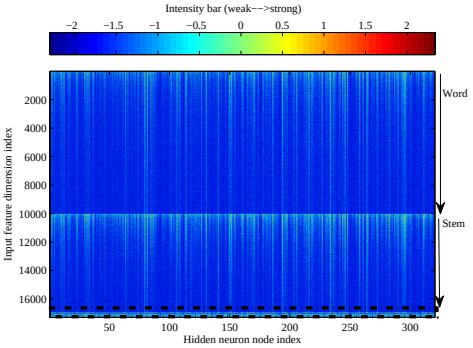
For a better understanding of the contribution of each factor to the factored RNNLM, we do a quantitative analysis of the connection weight values. The basic assumption in this analysis is that if one feature has a strong correlation or contribution to the factored RNNLM, the connections between the input features to the hidden neurons have large values (either positive or negative corresponding to positive or negative correlations). We show connection weight matrix U (corresponding to the logs of the absolute values of neural connection weights) in Figs. 3 (a) and (b). The horizontal and vertical axis denote the hidden neurons and the input feature dimensions. Since feature streams (word, stem, POS and history) are organized in blocks in matrix U, we mark each feature stream in blocks on the right vertical axis. In these figures, the connection intensity is marked by color, the brighter the color, the stronger the connection. From these figures, we can see that the POS feature stream shows the strongest connection intensity among all feature streams. The POS feature stream contributes the most to the factored RNNLM. However, RNNLM (Mikolov et al., 2011b) does not use it. In addition, the feature stream of the history also shows relatively strong intensity that confirms that the entire history is important.

4.2 Hidden neurons

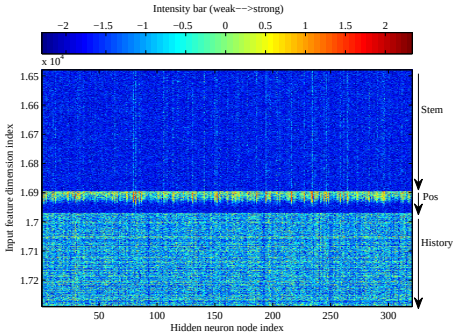
In this subsection, we evaluate the impacts from various numbers of hidden neurons in the hidden layer. Table 6 shows the results of the heldout set and the relative gains over the RNNLM. The experiments prove that factored RNNLMs consistently reduce perplexity. With increasing hidden neurons, both RNNLM and fRNNLM$_{wsp}$ enhance performance. The biggest improvement over RNNLM is 13.4%. The convergence column denotes the difference of the fRNNLM and RNNLM iterations, showing that factored RNNLM converges using fewer iterations. For example, RNNLM converges after 15 iterations, while fRNNLM$_{wsp}$ takes 12 iterations.

4.3 Convergence study

Figure 4 demonstrates the training progress of RNNLM and fRNNLM$_{wsp}$. In the same way, the number of hidden neurons in the hidden layer and the number of classes are set to 320 and 300, respectively. From this figure, we can observe that fRNNLM$_{wsp}$ significantly outperforms RNNLM at all iterations, especially at iterations 1-4 where the improvements exceed 20.0% and iterations



(a) Connection weight intensities of word, stem, POS and history



(b) Locally amplified view in rectangle marked position.

Figure 3: Neural connection weight intensity: between input feature and hidden neural nodes.

#Hidden neurons	RNNLM	fRNNLM$_{wsp}$	Gain	Convergence
60	163.71	147.00	10.2%	-3
120	152.33	133.07	12.6%	-2
240	147.74	128.75	12.8%	-2
320	146.94	127.09	13.4%	-1
480	143.18	126.70	11.5%	-2
640	142.22	126.04	11.4%	-1
1000	141.91	125.76	11.4%	0

Table 6: Impact from hidden layer on heldout data set.

5-10 where they exceed 15.0%, the final improvement reaches 13.5%. In other words, the relative

improvements decrease with increasing iterations.

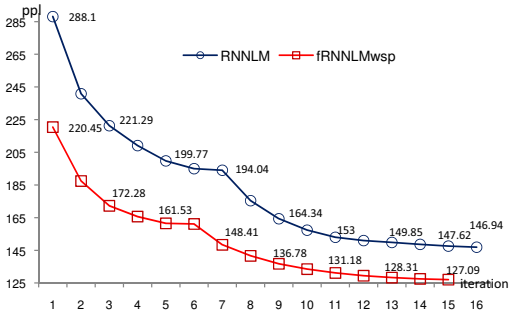


Figure 4: Convergence curve.

4.4 Running-time analysis

This subsection analyzes the time complexity of the two RNNLMs. Table 7 shows the training time of an iteration, the training time of all iterations, and the test time on a PC with 1006G of memory and 24 2.66Ghz CPUs with 144 cores. We observe the following: (1) No significant difference of elapsed time is found between RNNLM and fRNNLM$_{wsp}$ during an iteration of training and test stage. (2) RNNLM requires more time than fRNNLM$_{wsp}$ because it takes 18 iterations to reach a convergence and fRNNLM$_{wsp}$ uses 16 iterations. This experiment shows that although fRNNLM$_{wsp}$ has more free parameters and time complexities (shown in Table 3), it saves time owing to its fast convergence.

	An iteration during training	All iterations during training	During test
RNNLM	48.92m	880m19s	29.18s
fRNNLM$_{wsp}$	49.58m	792m39s	29.35s

Table 7: Elapsed time during training and test. m=minute, s=second.

4.5 Hybrid LM

In the experiments described above, RNNLMs are compared to a 4-gram back-off n-gram language model with modified Kneser-Ney smoothing trained using the SRILM toolkit (Stolcke, 2002). It is also useful to interpolate the recurrent neural network with a back-off n-gram language model to reduce the perplexity and the word error rate. In the following this interpolated model will be denoted by a hybrid language model. Table 8 compares the hybrid RNNLMs in terms of perplexity.

This table demonstrates that the hybrid factored RNNLM also outperforms the hybrid of RNNLM, as we expected. For example, the perplexity reductions of n-gram+fRNNLM over n-gramLM+RNNLM on the heldout and test sets are 8.8% and 9.4%, respectively, and n-gramLM+fRNNLM largely improves the 4-gramLM on the heldout and test sets by 28.9% and 29.6%.

	Heldout	Test
4-gramLM	156.26	156.41
RNNLM	146.94	145.63
fRNNLM$_{wsp}$	127.09	124.63
4-gramLM+RNNLM	121.89	121.62
4-gramLM+fRNNLM$_{wsp}$	$111.20_{+8.8\%}$	$110.19_{+9.4\%}$

Table 8: Perplexities of hybrid language models.

4.6 N-best re-scoring

To evaluate the factored RNNLM in the context of large vocabulary speech recognition, we use the data sets for the IWSLT-2011 large vocabulary continuous speech recognition shared task (Federico et al., 2011) to recognize TED talks published on the TED website[5]. TED talks touch on the environment, photography and psychology without adhering to a single genre. This task reflects the recent increase of interest in automatically transcribing lectures to make them either searchable or accessible.

For LM, the IWSLT-2011 campaign defines a closed set of publicly available English texts, including a small collection of TED transcriptions (in-domain corpus) and a large collection of news sentences (general-domain). All training data are preprocessed by a non-standard-word-expansion tool that converts non-standard words (such as CO2 or 95%) to their pronunciations (CO two, ninety five percent). The most frequent 100K words are extracted from the preprocessed corpora, which, with the CMU.v0.7a pronunciation dictionary[6], are used as the LM vocabulary. Our vocabulary contains 157K entries with an OOV rate of 0.78% on the test2010 data set. For the re-scoring test, we use the IWSLT data sets of tests 2010 and 2011. Their statistics are shown in Table 9.

LM training data			
	#sentences		#words
in-domain	124K		2,063K
general-domain	115,101K		2,458,626K
Test sets			
data	#talks	#utterances	#words
test2010	11	1664	27.0K
test2011	8	818	12.4K

Table 9: Summary of IWSLT2011 data sets

The acoustic models are trained on 170h speech segmented from 788 TED talks that were published prior to 2011. We employ two types of schemes, a Hidden Markov Model (HMM) and a Subspace Gaussian Mixture Model (SGMM) for each context-dependent phone and train them with the Kaldi toolkit (Povey et al., 2011). HMM consists of 6.7K states and 240K Gaussians that are discriminatively trained using the boosted Maximum Mutual Information criterion. SGMM con-

[5] http://www.ted.com/
[6] http://www.speech.cs.cmu.edu/cgi-bin/cmudict

sists of 9.2K states. In addition, we apply speaker adaptive training with feature space maximum likelihood linear regression on top of the HMM and SGMM. The acoustic feature vectors have 40 dimensions. For each frame, we extract 13 static MFCCs, splice 9 adjacent frames, and apply LDA to reduce its dimension with maximum likelihood linear transform. For the in-domain and general-domain corpora, modified Kneser-Ney smoothed 3- and 4-gram LMs are constructed using SRILM (Stolcke, 2002), and interpolated to form a baseline of 3- and 4-gram LMs by optimizing the perplexity of the development data set.

First, we employ a Kaldi speech recognizer (Povey et al., 2011) to decode each utterance using the trained AM and the 3-gram LM. Second, we use the 4-gram LM for lattice re-scoring and generate n-best lists. The n-best size is at most 100 for each utterance. Finally, we use RNNLM and factored RNNLM to re-score the n-best. Note that since it is very time consuming to train RNNLM and factored RNNLM on large data, we only use the in-domain corpus for training them, and the corpus is automatically tagged with parts-of-speech[7] before training fRNNLM$_{wp}$ and fRNNLM$_{wsp}$. The best re-scoring results measured by word error rate are demonstrated in Table 10. We also conduct utterance-level significance tests.

	test2010(%)	**test2011(%)**
4-gram LM	14.34	15.32
4-gram+RNNLM	14.12	15.22
4-gram+fRNNLM$_{wp}$	13.57$^{\dagger}{}_{0.55}$	14.64$^{\dagger}{}_{0.58}$
4-gram+fRNNLM$_{wsp}$	13.65$^{\dagger}{}_{0.47}$	14.59$^{\dagger}{}_{0.63}$

Table 10: n-best re-scoring performance in word-error-rate. Subscript numbers are the absolute improvements over RNNLM. † indicates significantly better results than RNNLM at the p = 0.01 level using a two-sided t-test.

The experimental results show that fRNNLM$_{wp}$ and fRNNLM$_{wsp}$ significantly improves upon 4-gram LM and RNNLM. For example, the absolute improvements of fRNNLM$_{wsp}$ over the 4-gram LM on the sets of tests 2010 and 2011 are 0.69 and 0.73 points, respectively. However, fRNNLM$_{wsp}$ doest not significantly outperforms fRNNLM$_{wp}$. Table 11 demonstrates the re-scoring results sampled from RNNLM and fRNNLM$_{wp}$. This table shows that the results of fRNNLM$_{wp}$ are more grammatically fluent. Fig. 5 illustrates the absolute improvements of fRNNLM$_{wp}$ over RNNLM for each talk in the sets of tests 2010 and 2011. Our approach improves most talks, expect talks 824 and 1183.

Conclusion

In this paper we follow the architecture of a state-of-the-art recurrent neural network language model (RNNLM) and present a factored RNNLM by integrating additional morphological, syntactic, and/or semantic information into RNNLM. Our approach, which is a hybrid of factored n-gram LM and RNNLM, addresses the problems in them. In experiments, we investigate the influences of four commonly used types of features on our factored RNNLM: word, stem, lemma and part-of-speech. We carry out many experiments to evaluate the factored RNNLM performance and analyze the influencing factors. Our experimental results prove that factored RNNLM consistently outperforms n-gram LM and RNNLM for all considered tasks.

Recently, syntactic parse trees are used in many advanced LMs (Chelba and Jelinek, 1998; Khudanpur and Wu, 2000; Xu et al., 2002; Collins et al., 2005; Rastrow et al., 2012). For future work, we intend to investigate topic information (Shi et al., 2012) and richer syntactic structure features into factored RNNLM, such as context-free rule productions, constituent/head features, and head-to-head dependencies that can be extracted using parser tools. Second, neural networks are notorious for being time consuming during training, future studies will also focus on speeding up the training of factored RNNLM using graphical processing units (Schwenk et al., 2012). Furthermore, factored RNNLMs need to be evaluated on other tasks like MT and with other languages such as Czech, Arabic, and Turkish.

minxiao@temple.edu, yuhong@temple.edu

ABSTRACT
Subjectivity analysis has received increasing attention in natural language processing field. Most of the subjectivity analysis works however are conducted on single languages. In this paper, we propose to perform multilingual subjectivity analysis by combining multi-view learning and AdaBoost techniques. We aim to show that by boosting multi-view classifiers we can develop more effective multilingual subjectivity analysis tools for new languages as well as increase the classification performance for English data. We empirically evaluate our two multi-view AdaBoost approaches on the multilingual MPQA dataset. The experimental results show the multi-view AdaBoost approaches significantly outperform existing monolingual and multilingual methods.

KEYWORDS: Multi-view learning, AdaBoost, Multilingual subjectivity analysis.

Proceedings of COLING 2012: Technical Papers, pages 2851–2866,
COLING 2012, Mumbai, December 2012.

1 Introduction

Subjectivity analysis has received increasing interest in natural language processing (NLP) area (Banea et al., 2010; Alm, 2011; Abdul-Mageed and Diab, 2011; Abdul-Mageed et al., 2011). Subjectivity refers to the expression of emotions, sentiments, opinions, beliefs, speculations, evaluations, as well as other private states (Banfield, 1982; Wiebe, 1994). Subjectivity classification aims to distinguish whether a given text expresses subjective or objective meaning (Wiebe and Cardie, 2005; Abdul-Mageed et al., 2011; Banea et al., 2008, 2010). Subjectivity analysis has been intensively studied, particularly motivated by the prevalent need for opinion-related applications, including mining opinions from product reviews (Pang et al., 2002; Hu and Liu, 2004) or political news (Abbott et al., 2011), and recognizing stances in online debates (Somasundaran and Wiebe, 2009, 2010). Moreover, many NLP tasks employ subjectivity analysis as an additional layering to filter data. Research that benefited from this phase ranges from conversation summarization (Seki et al., 2005; Carenini et al., 2008) and information extraction (Riloff et al., 2005) to text semantic analysis (Wiebe and Mihalcea, 2006) and question answering (Li et al., 2008; Yu and Hatzivassiloglou, 2003).

Although subjectivity analysis has been widely studied in NLP area, much work has only focused on English data. Recently, some researchers propose to carry out subjectivity analysis in a multilingual framework based on machine translation, where resources or tools of subjectivity analysis developed in one language are used to support developing resources or tools in another language (Mihalcea and Banea, 2007; Banea et al., 2008, 2010). The approaches in (Mihalcea and Banea, 2007; Banea et al., 2008) however only exploit the translated target-language-view of the data to develop a subjectivity analysis tool, which is a waste of resources in a multilingual setting since possible parallel views of the data are ignored. Banea et al. (2010) propose to overcome this shortcoming by conducting subjectivity analysis based on concatenated multilingual input feature vectors. This simple feature combination method nevertheless is still very preliminary in exploring the capacity of multi-view learning for subjectivity analysis on multilingual data.

In this paper, we propose to use multi-view AdaBoost approaches for multilingual subjectivity analysis, which combine the advantages of both multi-view learning and AdaBoost learning in one integrated framework. By exploring multi-view learning, we expect to exploit the complementary discriminative information in different language views. By incorporating the multi-view learning into an AdaBoost framework, we expect to further boost the classification accuracy of the integrated models. Based on different strategies of exploring multilingual information, we develop two approaches in this paper: Multi-View Majority Voting AdaBoost (*MVAB1*) and Multi-View Weighted Voting AdaBoost (*MVAB2*).

To demonstrate the effectiveness of the proposed approaches, we empirically evaluate them on a multilingual subjectivity analysis dataset, the Multilingual Multi-Perspective Question Answering (MPQA) corpus. To justify the robustness of our boosting framework, we conduct experiments using two types of base classifiers, Support Vector Machines (SVM) and Naïve Bayes (NB). The experimental results show that the proposed approaches can significantly outperform other comparison methods for multilingual subjectivity analysis. Overall, the contributions of this paper can be summarized as below:

- We propose two multi-view AdaBoost algorithms, Multi-View Majority Voting AdaBoost and Multi-View Weighted Voting AdaBoost, which can be widely used for multilingual classification tasks when parallel corpora or machine translation is available.

- Experimentally, we evaluate our approaches on Multilingual MPQA corpus and obtain a subjectivity classifier with *accuracy* as high as 78.19% and *macro F1* as high as 77.44% over all six languages.

The remainder of the paper is organized as follows. Related work is presented in Section 2. In Section 3, we present the multilingual subjectivity analysis problem and two proposed multi-view AdaBoost approaches. In Section 4, we present the experimental results and discussions. We then conclude the paper.

2 Related Work

The importance of subjectivity analysis has been widely acknowledged by language analysts, including computational linguists. Due to the availability of data resources, much work on subjectivity analysis has focused on English data alone. However, recently, some work tries to generate resources and develop tools for other languages by transferring labeled English subjectivity resources and corresponding analysis tools.

Mihalcea and Banea (2007) proposed to build subjectivity classifiers for Romanian data by leveraging the resources and tools available in English. They developed a lexicon-based approach and a corpus-based approach. For the lexicon-based approach, they first created a target-language subjectivity lexicon by translating the existing annotated English subjectivity lexicon via bilingual dictionaries and then trained a rule-based classifier relying on the translated lexicon. For the corpus-based approach, they first manually translated an automatically annotated English corpus into Romanian language and projected the subjectivity annotations correspondingly, and then trained a statistical classifier on the resulting corpus. They empirically evaluated their approaches on MPQA corpus and SemCor corpus (Miller et al., 1993), showing that the corpus translations preserve subjectivity more reliably than the lexicon translations. Nevertheless, the requirement for manual translation is a big restriction for potential usage of the proposed approaches.

Banea et al. (2008) then proposed to generate resources and tools for new languages (Spanish and Romanian) using machine translation and cross-lingual annotation projections. Specifically, they used machine translation to transfer the manually or automatically annotated training data from the source language (English) into the target languages, and projected the subjectivity annotations of the transferred data across language correspondingly. Then they employed statistical machine learning techniques such as Support Vector Machines and Naïve Bayes to produce a subjectivity classifier on the translated corpus in the target language. The advantage of this approach is that it does not need any original target language data for training. Thus it can be widely used for any new target language as long as a source-target-language machine translation engine is available. Nonetheless, the subjectivity analysis tool developed by this approach is dependent on the quality of machine translation since only translated data is used in training.

Banea et al. (2010) proposed to combine multiple language spaces altogether in an expanded feature space. Specifically they combined the original English feature vector of an instance and its translated feature vectors in different target languages together into one feature vector, and then used the training instances expressed in this expanded feature space to train multilingual subjectivity classifiers. They empirically evaluated their approach on MPQA corpus, by translating English sentences into five other languages. Their empirical results showed that multiple languages can complement each other to greatly increase subjectivity classification

performance for target languages as well as for English source data, comparing to training subjectivity classifiers on the target language alone. Nevertheless, the parallel texts in multiple languages can be approximately taken as label-conditionally independent multiple views of the same set of data objects, and their simple feature space expanding method is still far from fully exploiting this multilingual information. Thus, in this work we investigate new multi-view AdaBoost approaches to improve the performance of multilingual subjectivity analysis.

Multilingual views have also been exploited in sentiment analysis (Wan, 2009; Lu et al., 2011). Wan (2009) used co-training on bilingual views (Chinese and English) generated from machine translation to perform sentiment analysis on Amazon product reviews. Their approach however requires in-domain data from the target language for training. Lu et al. (2011) developed a maximum entropy based statistical model to jointly train two monolingual sentiment classifiers using an EM-algorithm. They also only studied the bilingual situation with experiments on English and Chinese. Combining multi-view learning and boosting has been studied in a few different ways on application problems outside of NLP field, including a semi-supervised boosting method for object category recognition and visual object tracking (Saffari et al., 2010), and an embedded two-view AdaBoost method for UCI data (Xu and Sun, 2010). But our work is the first one that combines multi-view learning and AdaBoost learning to address supervised subjectivity analysis with multiple languages.

3 Multi-View AdaBoost for Multilingual Subjectivity Analysis

In this section, we introduce two multi-view AdaBoost approaches, which combines the advantages of both multi-view learning and boosting learning to achieve better multilingual subjectivity classifiers. Below, we will first describe the general framework of multilingual subjectivity analysis and briefly introduce the AdaBoost algorithm, and then present the two proposed multi-view AdaBoost approaches.

3.1 Multilingual Subjectivity Analysis

Banea et al. (2010) pointed out that training a subjectivity classifier on the resulting target monolingual corpus alone, though works, is not good enough. There are two main reasons. First, in order to correctly predict labels based on statistical information, a sufficient amount of training data is needed, which may not be available in the monolingual corpus. Second, in the monolingual corpus alone, some discriminative features present in the test data may not appear in the training data and therefore their information cannot be used to generate an effective classifier. In both cases, multilingual subjectivity analysis can have advantages.

Below we demonstrate the problems of learning with monolingual corpus using examples from the multilingual MPQA dataset. Following (Banea et al., 2010)'s suggestions, we assume that only the words in italics carry potential subjective meaning and their surrounding contexts would be objective if without them. Therefore, their association with an either subjective or objective sense imparts the same label to the whole segment.

We explore the first data sparseness problem through the following two examples (En 1 and En 2) from the English version of the MPQA dataset as well as their respective translations in Spanish (Es 1 and Es 2):

> "En 1: The source said that the ministry would soon deliver copies of the report to the various ministries *concerned*, especially the Interior and Municipalities Ministry,

prior to relaying its observations to the State Department in Washington."

"Es 1: La fuente dijo que el ministerio pronto entregar copias del informe a los distintos ministerios *interesados*, en particular el Ministerio del Interior y de los Municipios, antes de transmitir sus observaciones al Departamento de Estado en Washington."

"En 2: Still, the overseers of the prison are *concerned* that detainees aren't getting enough pita bread with their meals, and they're planning to make the food spicier, just the way the prisoners like it back home. "

"Es 2: Sin embargo, los supervisores de la prisión tienen la *preocupación* de que los detenidos no están recibiendo suficiente pan pita con sus comidas, y que está pensando en hacer la comida spicier, sólo la forma en la que los reclusos como para volver a casa."

We focus on the word *concerned*. In the first example (En 1), it is used with an objective sense, which means a group of ministries defined earlier in the context. While in the second example (En 2), *concerned* serves as a subjective carrier. If we train a monolingual classifier on the English data alone, due to the data sparseness paradigm, our machine learning model may not distinguish between the word's subjective and objective senses when inferring a label for the whole sentence. However, the corresponding translations of *concerned* in Spanish are functionally different because of the surrounding context. We denote the respective translations in the Spanish context (Es 1 and Es 2) using the italic form. If we take the Spanish translation into consideration during training, we may obtain a classifier, which can potentially differentiate between the senses and predict the correct sentence label.

Next, we explore the second problem with two other examples below (En 3 and En 4) extracted from the MPQA dataset and their corresponding machine translations in Romanian:

"En 3: What is the point of engaging in dialogue with a government that is only interested in buying time while it fervently escalates a campaign of bludgeoning its citizens in the hope of frightening voters into *supporting* Mugabe? "

"Ro 3: Ce este pe punctul de angajarea in dialog cu un guvern doar ca este interesat de cumpararea timp in timp ce aceasta inflacarare e o campanie de forta cetatenilor sai in speranta de infricosator electoratul in *sprijinirea* lideri? "

"En 4: According to the sources, the EU which was barred by the Government from observing the election because some of its members were openly *supporting* the MDC, sent a Ms Maria Macchiaverna to "support the financial management of our assistance" to the Sadc Parliamentary Forum and ZESN."

"Ro 4: Potrivit surselor, UE care a fost oprita de guvernul de la observarea alegerilor pentru ca unii dintre membrii sai s-au deschis *sustinerea* mdc, a trimis un MS Maria macchiaverna sa "sprijin financiar de gestiune noastra de asistenta" la parlamentare sadc Forumului si zesn. "

In both of the two examples (En 3 and En 4), *supporting* carries subjective senses. However, the corresponding translations of *supporting* in Romanian for En 3 and En 4 are different: *sprijinirea* (in Ro 3) and *sustinerea* (in Ro 4). If we train a monolingual classifier on Romanian corpus alone, and the training set contains *sprijinirea* but not *sustinerea*, it is hard to infer the correct label for a context containing *sustinerea* by leveraging information from *sprijinirea*. However, if we adopt a multilingual classifier, we may be able to predict a correct label for the

context containing *sustinerea* by using the English information, or the associations between *supporting* and *sprijinirea*, as well as *supporting* and *sustinerea*.

As suggested in these examples above, exploiting multilingual information can compensate the shortcomings of learning from monolingual data. Multilingual subjectivity analysis has been previously studied in (Banea et al., 2008, 2010). We propose to conduct multilingual subjectivity analysis following the general framework suggested in these works. Assume we have manually annotated subjectivity corpus in English, and aim to develop subjectivity resources and tools for other languages, such as Arabic, French, German, Romanian, and Spanish, for which there are few text processing resources and tools to date. The multilingual subjectivity analysis framework contains three steps:

- Translating English sentences into target languages by using machine translation.
- Projecting subjectivity annotations from English to translated target languages.
- Producing subjectivity analysis tools on the resulting labeled corpora by using statistical machine learning techniques.

Banea et al. (2010) empirically studied the multilingual subjectivity analysis problem and provided a simple solution by expanding the feature space with multiple languages. In this work, we propose to further improve multilingual subjectivity analysis by exploiting multi-view learning in the framework of AdaBoost. In addition to the multilingual analysis problem discussed above, our approaches have the following two standpoints. First, Amini et al. (2009) provided theoretical bounds for multi-view classifiers and showed that additional views generated by machine translation may significantly improve classification performance. Second, within an AdaBoost framework, the algorithms can deal with hard examples which are difficult to be recognized using base multi-view learners. Moreover, an exponential loss function is guaranteed to be minimized over the multilingual data.

3.2 AdaBoost

Boosting is a general method for improving accuracy of any given learning algorithm by combining many weak or base learners. A well-known boosting algorithm is AdaBoost, which was introduced by (Freund and Schapire, 1997). AdaBoost takes a set of training instances $(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)$ as input, where each x_i belongs to some instance space $\mathscr{X}$, and each label y_i is in some label space $\mathscr{Y}$. For a binary classification problem, we assume $\mathscr{Y} = \{+1, -1\}$. AdaBoost calls a given base learning algorithm repeatedly in a series of rounds $t = 1 \cdots T$ and maintains a set of weights or a distribution over the training instances during the rounds. All weights are initialized equally; but in each round, the weights of misclassified instances are increased so that the weak learner will be forced to focus on the hard instances in the training set in the next round.

In each round, the weak learner trains a base classifier $h_t : \mathscr{X} \rightarrow \mathscr{Y}$ over the training instances with the weighted distribution D_t. For the binary classification problem, the base learner's job is to minimize the error

$$\epsilon_t = Pr_{i \sim D_t}[h_t(x_i) \neq y_i] \tag{1}$$

Once the base classifier h_t has been found, AdaBoost chooses a parameter α_t that intuitively

Algorithm 1 Multi-view Majority Voting AdaBoost

Input: A multi-view binary training set $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$, with $y_i \in \{+1, -1\}$.
Output: The final classifier H.
Initialize: $D_1(i) = \frac{1}{n}$.
for $t = 1$ **to** T **do**

- Separately train a set of single view classifiers $\{h_{tv}\}$ using distribution D_t.
- Compute the base classifier h_t using the majority voting scheme in Eq. (5).
- Set $\epsilon_t = Pr_{i \sim D_t}[h_t(\mathbf{x}) \neq y_i]$
- Set $\alpha_t = \frac{1}{2} \ln \frac{1-\epsilon_t}{\epsilon_t}$.
- Update $D_{t+1}(i) = D_t(i) \frac{e^{-\alpha_t y_i h_t(\mathbf{x}_i)}}{Z_t}$, where Z_t is a normalization factor.

end for
$H(\mathbf{x}) = sign(\sum_{t=1}^{T} \alpha_t h_t(\mathbf{x}))$

measures the confidence or importance that it assigns to h_t. For binary h_t, α_t is set as

$$\alpha_t = \frac{1}{2} \ln(\frac{1-\epsilon_t}{\epsilon_t}) \tag{2}$$

in (Freund and Schapire, 1997). The distribution D_t is then updated as

$$D_{t+1}(i) = \frac{D_t(i) e^{-\alpha_t y_i h_t(x_i)}}{Z_t} \tag{3}$$

where Z_t is a normalization factor.

The final classifier H produced by AdaBoost is a weighted majority vote of the T base classifiers

$$H(x) = sign(\sum_{t=1}^{T} \alpha_t h_t(x)) \tag{4}$$

where α_t is the weight assigned to h_t.

3.3 Multi-View AdaBoost for Multilingual Subjectivity Analysis

In the multilingual setting, each instance (sentence) is described using feature sets from multiple languages, where each feature set from one language can be treated as one view of the instance. To address multilingual subjectivity analysis in an AdaBoost framework, we propose to integrate multi-view learning into the AdaBoost. In particular, we develop two approaches using different multi-view learning strategies: a multi-view majority voting AdaBoost (MVAB1) and a multi-view weighted voting AdaBoost (MVAB2).

3.3.1 Multi-View Majority Voting AdaBoost

Each view of the multi-view data is expect to be able to learn a classifier independently. Combining different views to achieve a better classification model is the key idea of multi-view learning. Due to the noise and strength of different views, a majority voting scheme has been shown to be effective in multi-view learning (Amini et al., 2009). Amini et al. (2009) proposed to use multi-view majority voting to perform multilingual text classification on parallel data.

Algorithm 2 Multi-view Weighted Voting AdaBoost

Input: A multi-view binary training set $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$, with $y_i \in \{+1, -1\}$.
Output: The final classifier H.
Initialize: $D_1(i) = \frac{1}{n}$.
for $t = 1$ **to** T **do**

- Separately train a set of single view classifiers $\{h_{tv}\}$ using distribution D_t.
- Compute the weights $\{\beta_v\}$ by minimizing the weighted least square loss in Eq. (7).
- Compute the base classifier h_t using the weighted voting scheme in Eq. (6).
- Set $\epsilon_t = Pr_{i \sim D_t}[h_t(\mathbf{x}_i)) \neq y_i]$
- Set $\alpha_t = \frac{1}{2} \ln \frac{1-\epsilon_t}{\epsilon_t}$.
- Update $D_{t+1}(i) = D_t(i) \frac{e^{-\alpha_t y_i h_t(\mathbf{x}_i)}}{Z_t}$, where Z_t is a normalization factor.

end for
$H(\mathbf{x}) = sign(\sum_{t=1}^{T} \alpha_t h_t(\mathbf{x}))$

They derived a generalization error bound for classifiers learned on examples with multiple artificially views created using machine translation. They empirically evaluated their approach on a comparable multilingual corpus, Reuters RCV1/RCV2, showing that additional views obtained using a machine translation system can significantly increase classification performance, especially when few labeled data are available for training.

We propose to use multi-view majority voting to produce a base learner within the AdaBoost framework, aiming to improve subjectivity classification performance. Given a weighted training set with multiple views, a multi-view instance can be expressed as $\mathbf{x} = (x^1, x^2, \ldots, x^V)$, where each sub-vector x^v provides a representation of the same object in one feature space $\mathcal{X}^v$. In multilingual subjectivity analysis, each view is the textual representation of instances in a given language (e.g. Arabic, English, French, German, Romania, and Spanish). The Multi-view Majority Voting AdaBoost approach is then carried out in the following way. At each round t, a set of view-specific binary classifiers $\{h_{tv}(x^v)\}$ can be separately trained using specific views on the weighted training data with a distribution D_t. The base classifier is then obtained using a majority voting scheme:

$$h_t(\mathbf{x}) = sign(\sum_{v=1}^{V} h_{tv}(x^v)) \tag{5}$$

where $h_{tv}(x^v) \in \{1, -1\}$. The remaining steps of the AdaBoost procedure for training instance reweighting and final combination parameter determination are same as the standard AdaBoost for binary classifications. The overall procedure of the algorithm is described in Algorithm 1. With this algorithm, we expect to integrate the strengths of the subjectivity analysis data in different languages and boost the subjectivity classification performance.

3.3.2 Multi-View Weighted Voting AdaBoost

The multi-view majority voting scheme assumes the set of view-specific classifiers contribute equally for the final classifier. This assumption is too strong in many cases. We thus propose to pursue a more advanced multi-view combination scheme, where the combination classifier is a linear weighted combination of the view-specific classifiers. This leads to our next approach,

a Multi-view Weighted Voting AdaBoost approach. Similar to Multi-view Majority Voting AdaBoost, at each round t of Multi-view Weighted Voting AdaBoost, we separately train a set of single view classifiers $\{h_{tv}\}$ over the training instances with a weighted distribution D_t, one for each language (view) v. But instead of taking a majority vote, we set the combination base classifier h_t as a linear combination of the single view classifiers with a set of weight parameters $\{\beta_v\}$; i.e.,

$$h_t(\mathbf{x}) = sign(\sum_{v=1}^{V} \beta_v h_{tv}(x^v)) \tag{6}$$

where $0 \leq \beta_v \leq 1$ and $\sum_{v=1}^{V} \beta_v = 1$. In order to obtain the weight parameters, we train this linear combination model on the weighted training set, using the outputs of the single-view classifiers as features. Specifically, we minimize the following weighted least square loss on the training instances to to obtain the β values:

$$L = \sum_{i=1}^{n} D(i)(\sum_{v=1}^{V} \beta_v h_{tv}(x_i^v) - y_i)^2 \tag{7}$$

With the obtained base classifier h_t in Eq. (6), we can then find its importance weight α_t and update the distribution D_t. We proceed with this procedure for T rounds and output the final hypothesis H by combining the importance weighted multilingual base classifiers. The overall algorithm is presented in Algorithm 2.

4 Experiments

In this section, we empirically evaluate our proposed approaches for the task of subjectivity analysis on Multilingual Multi-Perspective Question Answering corpus. We first introduce the dataset and describe implementations, and then present the experimental results.

4.1 Multilingual Dataset

We use the same dataset as studied in (Banea et al., 2010). This is a multilingual subjectivity analysis dataset constructed from the Multi-Perspective Question Answering (MPQA) corpus. The original MPQA corpus contains 535 English newswire articles, which are collected from various sources. Each article is manually annotated for subjectivity labels (Wiebe and Cardie, 2005). Although the original corpus is labeled at the phrase and clause levels, we adopt the sentence-level annotations as suggested by (Banea et al., 2008, 2010). If the sentence contains at least one private state, whose opinion strength is higher or medium, we regard it as *subjective*. Otherwise, we see it as *objective*. Thus, we collected 9732 sentences. Among the 9732 sentences in this corpus, 5380 of them are annotated as subjective, while the rest 4352 sentences are labeled as objective.

In order to obtain comparable corpora to MPQA in other languages, Banea et al. (2010) translated the original English (En) newswire articles into five other languages, namely Arabic (Ar), French (Fr), German (De), Romanian (Ro) and Spanish (Es), using machine translation. To generate subjectivity labeling for target languages, they projected the original sentence-level subjectivity annotation from the source English data onto the target language data. Thus, we get a multilingual subjectivity analysis dataset with six languages. [1]

[1]The original English MPQA corpus can be downloaded from http://www.cs.pitt.edu/mpqa.

Based on this multilingual corpus, we first performed the following preprocessing steps as (Banea et al., 2010) employed. We removed all the numbers, diacritics, all punctuation marks except ' and -. We kept ' and - because they may mark contractions, such as in "they're" (for English) and "s-ar" (for Romanian). Although Arabic has a different encoding, we treated it in a similar way as the Roman language. We then used the library (Lingua::AR::Word PERL Library) to map Arabic script to Roman-alphabet letters. In the multilingual corpus, there are six languages. Then for each language, we removed the rare words and selected the top 20% of (unigram) features to use as suggested by (Banea et al., 2010). We used term presence as weighting scheme for all features, which means if the sentence contains one specific feature, then its corresponding value for that feature is 1, otherwise, the value is 0. We did this for two reasons. First, (Pang et al., 2002) explored different feature weighting schemes for sentiment classification, showing that term presence is better than term frequency in sentiment classification tasks. Second, (Banea et al., 2010) adopted term presence as a weighting scheme in their experiments.

4.2 Implementation

In the experiments, we compared the empirical performance of the following approaches for subjectivity analysis, including the two proposed approaches.

- TDe, TEn, TEs, TFr, TRo: (Banea et al., 2008) proposed to train a subjectivity classifier for a new language on the translated data in the target language alone. We use *TDe* to denote the method that trains a subjectivity classifier on the target German language alone. Similarly, *TEn, TEs, TFr, TRo* denote that we use English, Spanish, French and Romania as the target language respectively.
- MLS: (Banea et al., 2010) proposed to train a multilingual subjectivity classifier by combining all different languages together to expand the feature space. We denote it as a MultiLingual Space method (MLS).
- MVMV: The multi-view majority voting method developed in (Amini et al., 2009).
- MVAB1: The multi-view majority voting AdaBoost approach.
- MVAB2: The multi-view weighted voting AdaBoost approach.

The last four approaches are multilingual approaches and the others are single language based approaches. For all these approaches, we experimented with two different classifiers: Naïve Bayes (NB) and Support Vector Machines (SVM), which are also used in previous studies on multilingual subjectivity analysis (Banea et al., 2008, 2010). We chose them due to their robust performances and the diversity of their learning methodologies. For Naïve Bayes, we used the multinomial model (McCallum and Nigam, 1998). For Support Vector Machines, we used the LIBLINEAR package (Fan et al., 2008). The LIBLINEAR is an open source library and works very efficiently on large sparse data sets. For LIBLINEAR, we set the tradeoff parameter c with the default value, $c = 1$. For the two boosting approaches, MVAB1 and MVAB2, we set the maximum iteration number T as 50.

4.3 Experimental Results

We take all the subjective sentences as positive instances and all the objective sentences as negative instances. The six single view approaches are experimented on each of the six target lan-

Table 1: Average results for the comparison approaches based on SVM classifiers.

Method	SubjP	SubjR	SubjF	ObjP	ObjR	ObjF	AllP	AllR	AllF	MAcc
TEn	75.92	73.78	74.82	68.57	70.96	69.73	72.25	72.37	72.28	72.53

TFr	75.04	73.00	73.99	67.21	69.48	68.31	71.13	71.24	71.15	71.47
TDe	72.97	71.93	72.44	65.91	67.05	66.46	69.44	69.49	69.45	69.75
TAr	72.70	72.06	72.35	65.76	66.47	66.08	69.23	69.26	69.22	69.55
MLS	76.72	76.00	76.34	70.45	71.29	70.84	73.59	73.65	73.59	73.89
MVMV	76.78	77.99	77.37	72.79	71.36	72.06	74.79	74.68	74.72	75.01
MVAB1	77.95	79.15	78.53	74.68	73.29	73.95	76.32	76.22	76.24	76.47
MVAB2	78.62	79.39	78.98	75.03	74.12	74.54	76.83	76.75	76.76	76.97

guages alone. The four multilingual approaches use all the parallel texts in the six languages. We performed ten-fold cross validation on the multilingual dataset as did in (Banea et al., 2010). Two sets of such experiments are conducted, with Support Vector machines and Naïve Bayes as base classifiers respectively. The average test results of different approaches are reported in Table 1 for SVM and in Table 2 for Naïve Bayes.

Each test result is evaluated with 10 measurements denoted with the following abbreviation style: *Obj* represents objective, *Subj* represents subjective, and *All* stands for overall macro measures, computed over the objective and subjective classes; *P*, *R*, *F*, and *MAcc* correspond to precision, recall, F1-measure and macro-accuracy, where

$$Precision = \frac{\#\text{ of correct positive predictions}}{\#\text{ of positive predictions}},$$

$$Recall = \frac{\#\text{ of correct positive predictions}}{\#\text{ of positive instances}},$$

$$F1 = 2\,\frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}.$$

From Table 1, we can see that all the four multilingual methods consistently outperform the single-view methods across all languages in terms of all 10 measurements. This verifies the hypothesis that training on translated target language alone is not enough and multilingual subjectivity analysis is useful. Among the four multilingual methods, *MVMV* performs slightly better than *MLS* in terms of subjective precision and objective recall, while *MVAB1* and *MVAB2* significantly outperform both *MLS* and *MVMV* in terms of all ten measurements. The *MVAB2* performs slightly better than *MVAB1* in terms of all ten measurements. Comparing to *MLS*, *MVAB1* improves the accuracy by 2.58%, and improves the macro F1-measure by 2.65%; *MVAB2* improves the accuracy by 3.08%, and improves the macro F1-measure by 3.17%. Comparing to *MVMV*, *MVAB1* improves the accuracy by 1.46% and improves the macro F1-measure by 1.52%; *MVAB2* improves the accuracy by 1.96%, and improves the macro F1-measure by

Table 2: Average results for the comparison approaches based on Naïve Bayes classifiers.

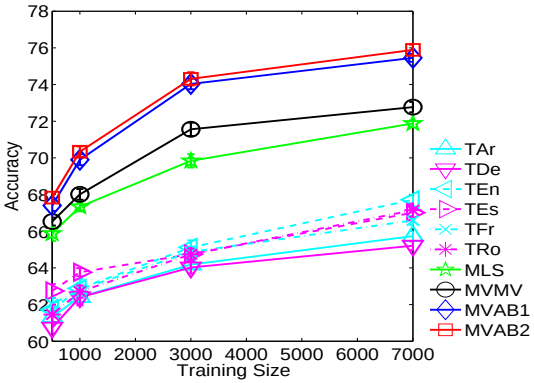
TRo	73.50	82.06	77.54	74.08	63.40	68.33	73.79	72.73	72.94	73.72
TEs	74.02	82.84	78.19	75.11	63.05	69.14	74.57	73.44	73.66	74.44
TFr	73.83	83.03	78.16	75.19	63.61	68.92	74.51	73.32	73.54	74.35
TDe	73.26	83.49	78.04	75.32	62.30	68.19	74.29	72.90	73.12	74.02
TAr	71.98	81.47	76.43	72.62	60.78	66.17	72.30	71.13	71.30	72.22
MLS	75.43	83.66	79.33	76.64	66.30	71.10	76.04	74.98	75.21	75.89
MVMV	75.91	84.56	79.98	77.47	66.38	71.46	76.69	75.47	75.72	76.49
MVAB1	76.95	85.49	80.98	78.92	67.91	72.98	77.93	76.70	76.98	77.68
MVAB2	77.74	85.73	81.53	78.96	68.52	73.34	78.35	77.13	77.44	78.19

2.04%. It is worth mentioning that both *MVAB1* and *MVAB2* increase the overall precision and recall levels to above 76%. Using a paired t-test, all these improvements were found to be significant at p=0.001. Those improvements demonstrate that our Multi-view AdaBoost approaches are more effective than simply expanding the feature space with multiple languages, or only using a simple multi-view majority voting strategy.

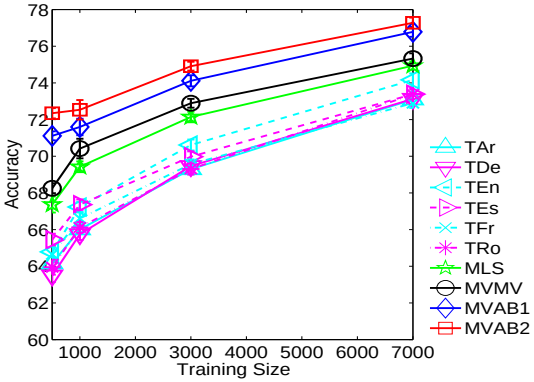
From Table 2 we can see that again the four multilingual methods outperform the single language methods in terms of macro precision, recall and F1-measure as well as macro accuracy. However, *MLS* achieves almost the same performance in terms of subjective recall measurement as the single language methods, *TEn* and *TDe*, which implied that more advanced multilingual models are needed. The two proposed multi-view AdaBoost approaches, *MVAB1* and *MVAB2*, outperform all the other comparison methods in terms of macro precision, and F1-measure as well as macro accuracy. Even in term of recall for subjective and objective classes, both of *MVAB1* and *MVAB2* outperform all other methods. Comparing to *MLS*, *MVAB1* improves the accuracy by 1.79%, and improves the macro F1-measure by 1.77%; *MVAB2* improves the accuracy by 2.30%, and improves the macro F1-measure by 2.23%. Comparing to *MVMV*, *MVAB1* improves the accuracy by 1.19%, and improves the macro F1-measure by 1.26%; *MVAB2* improves the accuracy by 1.70%, and improves the macro F1-measure by 1.72%. All the improvements were found to be significant at p=0.001 by using a paired t-test. These results demonstrate that our proposed multi-view AdaBoost approaches are robust to different types of base classifiers, and their advantages can be maintained. This again suggests the proposed multi-view AdaBoost approaches provide a more effective framework to exploit multilingual information for multilingual subjectivity analysis than the existing methods.

4.4 Impact of Training Size

Next we studied the impact of the training size for different approaches. Among the 9732 sentences, we randomly selected 2732 (about 1500 subjective sentences and 1232 objective sentences) as test data. From the rest 7000 sentences, we randomly selected training instances with a range of different sizes $m \in \{500, 1000, 3000, 7000\}$. For each training size, we repeated



(a) Results based on SVM classifiers.



(b) Results based on Naïve Bayes classifiers.

Figure 1: Average classification accuracies ± standard deviations across a range of different training sizes. The top figure presents results based on Support Vector Machine classifiers and the bottom figure presents results based on Naïve Bayes classifiers.

the experiments over 10 runs by randomly selecting the training instances from the 7000 sentences. We again experimented with the same two base classifiers: SVM and Naïve Bayes (NB). We compared the four multilingual methods with the six single language methods. We reported the average test accuracies and standard deviations in Figure 1. We can see that for both SVM-based classifiers and Naïve Bayes-based classifiers, the four multilingual methods consistently outperform the six single language methods across the range of different training sizes. The improvements of multilingual methods over the single language methods are clearly significant across all range of training sizes for both SVM-based classifiers and Naïve Bayes-based classifiers, which justified that using multilingual information enables every single

Table 3: Results for Statistical Significance (McNemar's) test.

Null Hypothesis	p-value (SVM, Trainsize=500)	p-value (NB, Trainsize=7000)
MVAB1 vs. TEn	6.3×10^{-10}	4.1×10^{-9}
MVAB1 vs. MLS	7.9×10^{-7}	8.5×10^{-8}
MVAB1 vs. MVMV	3.5×10^{-4}	2.7×10^{-5}
MVAB2 vs. TEn	1.3×10^{-10}	1.8×10^{-9}
MVAB2 vs. MLS	2.6×10^{-7}	3.1×10^{-8}
MVAB2 vs. MVMV	1.2×10^{-4}	1.9×10^{-5}

language to reach a high accuracy that is not individually obtainable. Among the four multilingual methods, our proposed two multi-view AdaBoost methods, *MVAB1* and *MVAB2*, significantly outperform the other two simple multi-view methods, *MLS* and *MVMV*. With the more sophisticated view weighted training, *MVAB2* outperforms *MVAB1*. More specifically, for the SVM-based classifiers, when the training size is 3000, *MVAB1* increases the accuracy by 4.19% over *MLS* and by 2.47% over *MVMV*; *MVAB2* increases the accuracy by 4.50% over *MLS* and by 2.75% over *MVMV*. Their advantages over the single language methods are even much larger. *MVAB1* increases the accuracy of the best single language method (over English) by 8.91%. *MVAB2* increases the accuracy of the best single language method (over English) by 9.19%. For NB-based classifiers, our proposed approaches achieve their best improvements when the training size is small (500). In this case, *MVAB1* increases the accuracy by 6.33% comparing to the best single language method over English, increases the accuracy by 3.74% comparing to *MLS*, and increases the accuracy by 2.86% comparing to *MVMV*. *MVAB2* performs even better, and it increases the accuracy by 7.56% comparing to the best single language method over English, increases the accuracy by 4.98% comparing to *MLS*, and increases the accuracy by 4.10% comparing to *MVMV*.

To justify the significance of those improvements across ranges, we used a McNemar paired test for labeling disagreements (Gillick and Cox, 1989) with $p < 0.05$ being significant. We focus on the improvements the two proposed approaches obtained over other methods. Since *TEn* works the best among models trained with monolingual corpus, we select it as the representative for all six monolingual methods. From Figure 1, we can see that the two proposed approaches achieve the smallest improvement when the training size is very small (500) for SVM-based classifiers, and when the training size is very big (7000) for NB-based classifiers. We thus select those results to conduct significance test. We report the p values in Table 3. From Table 3, we can see that all the improvements made by *MVAB1* and *MVAB2* over other methods are statistically significant. These results again demonstrate the efficacy of the proposed multi-view AdaBoost framework on multilingual subjectivity analysis.

Conclusion

In this paper, we proposed to integrate multi-view learning into the AdaBoost framework to perform multilingual subjectivity analysis, with the aim of developing more effective subjectivity analysis tools for both English and languages beyond English. Our experimental results on multilingual MPQA corpus show that the approaches developed within our proposed framework can significantly outperform other existing methods.

Semi-supervised Representation Learning for Domain Adaptation using Dynamic Dependency Networks

Min Xiao *Yuhong Guo* *Alexander Yates*

{minxiao, yuhong, yates}@temple.edu

ABSTRACT
Recently, various unsupervised representation learning approaches have been investigated to produce augmenting features for natural language processing systems in the open-domain learning scenarios. In this paper, we propose a dynamic dependency network model to conduct semi-supervised representation learning. It exploits existing task-specific labels in the source domain in addition to the large amount of unlabeled data from both the source and target domains to produce informative features for NLP tasks. We empirically evaluate the proposed learning technique on the part-of-speech tagging task using Wall Street Journal and MEDLINE sentences and on the syntactic chunking task using Wall Street Journal corpus and Brown corpus. Our experimental results show that the proposed semi-supervised learning model can produce more effective features than unsupervised representation learning methods for open-domain part-of-speech taggers and syntactic chunkers.

KEYWORDS: Domain Adaptation, Representation Learning, POS Tagging, Syntactic Chunking.

1 Introduction

Existing supervised natural language processing (NLP) systems are highly domain-dependent, whose performance degrades significantly when tested on a new domain. Previous works in a variety of NLP tasks, like part-of-speech (POS) tagging (Blitzer et al., 2006; Huang and Yates, 2010; Blitzer et al., 2011), syntactic chunking (Huang and Yates, 2009; Carreras and Màrquez, 2005), named entity recognition (NER) (Daumé III, 2007; Turian et al., 2010; Daumé III and Marcu, 2006), or parsing (Sekine, 1997; McClosky et al., 2010) show that the performance of supervised NLP systems drops a lot on domains whose vocabulary differs from the vocabulary of the training data.

The major reason that causes the increasing of test error on out-of-domain texts is the traditional representation used in the supervised NLP systems. Most NLP systems use the lexical features for predictions. Though it works very well for various in-domain NLP tasks, they perform poorly when tested on a different domain. There are two main reasons. First, the source and target domains may have very different vocabularies, thus some test words may never appear during the training phase. For example, "sequencing", "metastases" and "genomic" show up frequently as lexical features in biomedical text but rarely in newswire articles. A classifier trained on newswire data thus will have seen few training examples related to sentences with lexical features "sequencing", "metastases" and "genomic" (Ben-David et al., 2010, 2007). Second, the prediction function based on lexical features may change across domains. For example, "signaling" appears in "signaling that ..." from a Wall Street Journal (WSJ) article primarily as a present participle (VBG) (Marcus et al., 1993), but predominantly as a noun in "signaling pathway" from a MEDLINE text (PennBioIE, 2005).

Recently, various unsupervised representation learning techniques are proposed to induce generalizable latent features across domains by exploiting large amount of unlabeled data from both the source and the target domains. Blitzer et al. (2006) and Huang and Yates (2009, 2010) show that their learned representations can yield significant improvements for out-of-domain POS taggers or syntactic chunkers. However, the latent features produced by these unsupervised representation learning techniques provide no task-specific discriminative information over the labels of NLP tasks.

To tackle this issue, in this paper we propose a semi-supervised Dynamic Dependency Network (DDN) model to induce task-specific discriminative latent features across domains. In addition to exploiting large amount of unlabeled data from two domains, the DDN model will also leverage the already-existing task labels from the source domain. It combines the advantages of semi-supervised learning methods from (Blitzer et al., 2006; Daumé III, 2007) with the sequence models from (Huang and Yates, 2009, 2010), while maintaining desirable properties like computational tractability and modeling flexibility to incorporate many features. This model is more appealing than unsupervised representation learning techniques when a target NLP task is known. Moreover, though we perform representation learning in a semi-supervised manner, we only exploit the existing labeled data in the source domain. Thus our model can be applied to arbitrary new domains without any extra annotation effort. The proposed model is empirically evaluated for out-of-domain POS tagging systems on articles from WSJ and MEDLINE, and for out-of-domain syntactic chunking systems on articles from WSJ and Brown corpora. It is shown to outperform unsupervised representation learning techniques. Overall, the contributions of this paper include

- We propose a novel probabilistic graphical model, Dynamic Dependency Networks

(DDNs), which is computationally tractable for inference and training.

- We demonstrate how to apply DDNs on cross-domain semi-supervised representation learning for sequence labeling systems.

- Our empirical results show that DDN-based semi-supervised representation learning is superior to unsupervised representation learning for out-of-domain POS tagging and syntactic chunking.

The remainder of the paper is organized as follows. The next section discusses previous work. Section 3 describes representation learning. Section 4 presents the proposed DDN model and semi-supervised representation learning. Section 5 presents experimental results for out-of-domain POS tagging systems. Section 6 presents empirical results for out-of-domain syntactic chunking systems. We then conclude the paper.

2 Previous Work

Most previous work for domain adaptation tasks has focused on the setting where some labeled data is available in the target domain (Daumé III and Marcu, 2006; Daumé III, 2007; Jiang and Zhai, 2007; Dredze et al., 2010; Daumé III et al., 2010). Daumé III and Marcu (2006) proposed to tackle domain adaptation tasks by training three separate models to distinguish source-specific, target-specific and general information using maximum entropy classifiers. Jiang and Zhai (2007) adopted instance weighting method for semi-supervised domain adaptation by removing misleading training instances in the source domain, assigning more weights to labeled data, and augmenting training data using target instances with predicted labels. Daumé III (2007) proposed to perform supervised domain adaptation with feature augmentation for various NLP tasks. Daumé III et al. (2010) used co-regularization to incorporate unlabeled data for semi-supervised domain adaptation. In contrast, we investigate a more practical setting for domain adaptation where we have no labeled data in the target domain.

Recently, various unsupervised representation learning techniques have been proposed to tackle domain adaptation tasks by exploiting large amount of unlabeled data from two domains (Ando and Zhang, 2005; Blitzer et al., 2006; Huang and Yates, 2009, 2010; Blitzer et al., 2011). Blitzer et al. (2006) proposed a structural correspondence learning (SCL) method to seek for generalizable features by modeling the correlation between pivot features and non-pivot features. Turian et al. (2010) empirically evaluated Collobert and Weston embeddings (Collobert and Weston, 2008), Brown clusters, and HLBL embeddings (Mnih and Hinton, 2009) of words on both syntactic chunking and named entity recognition tasks. Their experimental results demonstrated that those three word representations can improve the performance of out-of-domain named entity recognition systems and in-domain syntactic chunking systems. Huang and Yates (2009) employed Hidden Markov Models (HMMs) to induce hidden states of the sentence words as latent features. Later, Huang and Yates (2010) proposed to learn a multi-dimensional feature representation by simultaneously train multiple HMMs with different initializations. Though unsupervised representation learning achieves good empirical performance for out-of-domain NLP tasks, it underutilizes the source data, since it completely neglects the existing task-specific labels when performing representation learning. The DDN model we propose in this work can suitably address this problem by exploiting task labels when performing semi-supervised representation learning.

3 Representation Learning

A *representation* is a set of features describing instances in a classification problem. Let $\mathbb{X}$ be the set of all instances. For example, for a sequence labeling task in NLP, $\mathbb{X}$ is the set of all sentences. Let $\mathbb{Z}$ be the label set of the classification problem. For POS tagging, $\mathbb{Z}$ is the set of all sequences of part-of-speech tags. For syntactic chunking, $\mathbb{Z}$ is the set of all sequences of syntactic chunks. Let $f : \mathbb{X} \rightarrow \mathbb{Z}$ be the prediction function. A representation is a function $R : \mathbb{X} \rightarrow \mathbb{Y}$, for some suitable feature space $\mathbb{Y}$ (such as $\mathbb{R}^d$). A *domain* $\mathcal{D}$ is defined as a distribution over the instance set $\mathbb{X}$. An open-domain system learns a classification model from a set of training instances $(R(x), f(x))$, where each instance $x \in \mathbb{X}$ is drawn from a *source* domain $\mathcal{D}_s$ and expressed in a representation space defined by function R, and classifies test instances drawn from a separate *target* domain $\mathcal{D}_t$.

It has been shown in recent theoretical work that the performance of domain adaptation greatly depends on the data representation employed, and traditional data representations in NLP prevent learning systems from generalizing appropriately across domains (Ben-David et al., 2010). Previous work by Ben-David et al. (2007) uses Vapnik-Chervonenkis (VC) theory (Vapnik, 1995) to prove theoretical bounds on an open-domain learning machine's performance. It demonstrates that the choice of representation is crucial for domain adaptation. It is customary in VC theory that a good choice of representation must allow a learning machine to achieve low error rates during training.

In light of Ben-David et al.'s theory findings, traditional representations in NLP are inadequate or problematic for domain adaptation. Traditional representations in NLP tasks are lexical features based on local context. Although many previous studies have shown that lexical features allow learning systems to achieve impressively low error rates during training, they also make texts from different domains look very dissimilar and create domain divergence problems. For example, a sentence containing "CEO" may be common in a domain of newswire text but scarce or nonexistent in a different domain like biomedical articles. Likewise, a sentence containing "path-way" is almost certainly from a biomedical literature rather than from a newswire article. Thus with traditional representations of NLP, a prediction model trained in one source domain can hardly work well in a different target domain.

At the same time, traditional representations contribute to *data sparsity*, a lack of sufficient training data for the relevant parameters of the system. In traditional supervised NLP systems, there are parameters for each word type in the data, or perhaps even combinations of word types. Since vocabularies can be extremely large, this leads to an explosion in the number of parameters. As a consequence, for many of their parameters, supervised NLP systems have zero or only a handful of labeled examples. No matter how sophisticated the learning technique, it is difficult to estimate parameters without relevant data. Because vocabularies differ across domains, domain adaptation greatly exacerbates this issue of data sparsity.

Huang and Yates (2009) show how to use language models, HMMs, to induce latent-variable states as generalizable features for various open-domain NLP tasks, such as POS tagging and syntactic chunking. These learned representations have proven to meet the criteria for open-domain representations. It would be difficult to tell two domains apart based on the HMM labels since the same HMM states may generate many similar words from a variety of domains. However, these unsupervised representations are not specifically discriminative for any NLP tasks. This is the main motivation of the research in this paper. Unsupervised representation learning based on HMMs nevertheless serves as one of the comparisons in our experiments.

4 Dynamic Dependency Network for Semi-supervised Representation Learning

In this section, we present a Dynamic Dependency Network (DDN) model to incorporate task-specific label information in the source domain for semi-supervised representation learning. A dynamic dependency network is a dynamic extension of dependency networks (Heckerman et al., 2000) for modeling data with sequential observations and labels. Dependency networks are cyclic directed graphical models. Similar to directed acyclic Bayesian networks, dependency networks allow simple local parameter estimations given fully observed data. But by dropping acyclicity constraints, dependency networks are more flexible on modeling interdependencies between variables than acyclic Bayesian networks. Following the same principle of Dynamic Bayesian Networks (DBNs) (Murphy, 2002), we extend dependency networks into sequential models to form Dynamic Dependency Networks. Although with directed cycles a DDN model will lose the ability of handling time series data that requires time forward directed arcs (not vice versa), it has increased the capacity of modeling word or label interdependencies within local contexts of sentences, comparing to DBNs. Figure 1 demonstrates an example of the DDN models we will use for semi-supervised representation learning.

In this DDN model (Figure 1), the variables are partitioned into three interconnected sequences $X = \{X_1, \ldots, X_T\}$, $Y = \{Y_1, \ldots, Y_T\}$ and $Z = \{Z_1, \ldots, Z_T\}$, representing observations, hidden states and labels respectively. Similar to the HMM model used in (Huang and Yates, 2009), the state sequence is hidden in our model and the state variable Y_t at location t takes values from a predefined set of state values; the observation sequence X is produced from the observed sentence; given Y_t, we assume X_t is conditionally independent of $X_{t'}$ for $t \neq t'$. But in addition to the two layers, X and Y in HMMs, our DDN model adds another task-specific label layer Z. For example, for the POS tagging task, Z will be the sequence of POS tags. Moreover, we take the bi-directional sequential dependency between labels into consideration by connecting each neighbor pairs of labels using bi-directional arcs. At each location t, X_t, Y_t are both parents of Z_t, since we assume both the sentence observation and the hidden state representation determine the sequence label. This DDN model maintains the same inference complexity as the HMM, since only the state sequence Y is latent during training. While by allowing bi-directional arcs over the label sequence Z, it has a natural capacity of modeling and incorporating task-specific label information for representation learning. By incorporating the label sequence Z into the model, we expect to identify more task discriminative latent sequence representations.

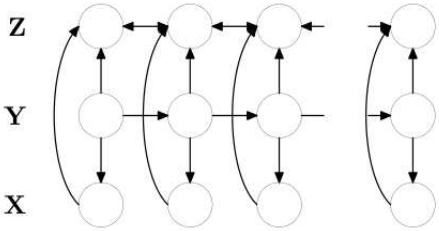

Figure 1: A Dynamic Dependency Network (DDN)

4.1 Training and Inference

Although we have an additional bi-directional Z layer in DDNs, the structures over the hidden layer Y, and between Y and the observed sequence X are similar to in HMMs. Thus inference over the hidden states and parameter learning in DDNs are as tractable as in HMMs. Assume that we are given a data set of N i.i.d. samples, $\{(X^i, Z^i)\}$ for $i = 1, 2, \ldots, N$, where X^i is the ith sentence and Z^i is the corresponding sequence of labels, e.g., POS tags, for X^i. Given the training data, its log-likelihood is

$$L(\theta) = \sum_{i=1}^{N} \log P(X^i, Z^i|\theta)$$

where θ denotes the set of model parameters.

Let $q(Y)$ be any non-zero distribution over hidden variables Y, we can get a lower bound for $L(\theta)$. For notational convenience, we will drop the superscript i in the following formulas.

$$\begin{aligned} \ell(\theta) &= \log \sum_{Y} q(Y) \frac{P(X, Y, Z|\theta)}{q(Y)} && (1) \\ &\geq \sum_{Y} q(Y) \log \frac{P(X, Y, Z|\theta)}{q(Y)} \\ &= L(\theta) - D_{KL}(q(Y) \,\|\, P(Y|X, Z, \theta)) && (2) \end{aligned}$$

where $D_{KL}(\cdot)$ denotes the Kullback-Leibler divergence measure. We denote the objective in (2) as $F(q, \theta)$. We then conduct training by maximizing $F(q, \theta)$ using iterative Expectation-Maximization (EM) algorithm (Baum et al., 1970; Dempster et al., 1977). For the $(k+1)$th iteration, in the E-step, we update q given fixed θ^k from previous iteration by

$$q^{k+1} = \arg\max_{q} F(q, \theta^k) \quad (3)$$

which has the following solution when the KL divergence becomes zero

$$q^{k+1}(Y) = P(Y|X, Z, \theta^k). \quad (4)$$

In the M-Step, we update θ given fixed q^{k+1}

$$\theta^{k+1} = \arg\max_{\theta} F(q^{k+1}, \theta) \quad (5)$$

Similar to HMMs, the parameter estimation in (5) requires computation of $P(Y_{t-1}, Y_t|X, Z)$ and $P(Y_t|X, Z)$ for all t in the E-step. We extend the Baum-Welch algorithm used in HMMs to conduct the required computation with the current model parameters θ. Let $\alpha_t(y) = P(X_1, Z_1, \cdots, X_t, Z_t, Y_t = y|\theta)$ and $\beta_t(y) = P(X_{t+1}, Z_{t+1}, \cdots, X_T, Z_T|Y_t = y, \theta)$. The set of $\{\alpha_t(y)\}$ and $\{\beta_t(y)\}$ can be solved inductively using a forward procedure and a backward procedure respectively, which are analogous to the forward and backward procedures used for HMMs. Then the marginal probabilities can be computed as

$$P(Y_t = y|X, Z, \theta) = \frac{\alpha_t(y)\beta_t(y)}{\sum_{\widehat{y}} \alpha_T(\widehat{y})} \quad (6)$$

$$P(Y_t = y, Y_{t+1} = y\prime|X, Z, \theta) = \tag{7}$$
$$\frac{\alpha_t(y)\beta_{t+1}(y\prime)}{\sum_{\widehat{y}} \alpha_T(\widehat{y})} P(Y_{t+1} = y\prime|Y_t = y) P(Z_{t+1}|Z_t, Z_{t+2}, X_{t+1}, Y_{t+1} = y\prime)$$

The major difference from HMMs is that the computation of (7) requires the additional local probabilities, $P(Z_t|Z_{t-1}, Z_{t+1}, X_t, Y_t)$, in the bi-directional Z sequence. The typical conditional probability table (CPT) parameters for $P(Z_t|Z_{t-1}, Z_{t+1}, X_t, Y_t)$ requires a storage space in the size of $(L-1) \times L^2 \times V \times S$, where L is the number of discrete label values for Z, V is the number of discrete word features for X, and S is the number of discrete states for Y. To reduce the computational cost and memory size for storing such a large CPT and increase the scalability of the proposed model, we exploit a multi-class logistic regression model to model this conditional probability distribution and store the model parameters of the logistic regression model instead.

The logistic regression classifier is trained in the M-step with data collected at each location t, over four types of features $Z_{t-1}, Z_{t+1}, X_t, Y_t$. Given the model parameters θ, the hidden state values of sequence Y are computed using the Viterbi inference algorithm used in HMMs. Thus the trained logistic regression model only requires a model parameter matrix W in the size of $L \times (2L + V + S + 1)$ to calculate the probability $P(Z_t|Z_{t-1}, Z_{t+1}, X_t, Y_t, W)$ for any inputs. The space required to store the W matrix is much smaller than the space required for the original conditional probability table. To avoid overfitting, we trained a $L2$-norm regularized logistic regression model using a second-order Newton method.

With the computed marginal probabilities and induced hidden states, the model parameters θ of the DDN can be re-estimated in a similar way as in HMMs in addition to the retraining of the logistic regression classifier.

4.2 Semi-supervised Representation Learning

We have introduced above how to train DDNs with labeled sentences and conduct inference to induce the hidden states. For cross-domain semi-supervised representation learning, we have a small amount of labeled sentences $\{(X^l, Z^l)\}$ in the source domain and a large amount of unlabeled sentences $\{X^u\}$ in both the source and target domains. This requires the DDN model to handle unlabeled sentences as well. Note in the DDN model we introduced, dropping the label layer Z does not affect either the structure nor the parameter of the other two layers, but simplify a DDN model into a HMM. Thus we can use DDNs as HMMs on unlabeled sentences by sharing common model parameters across labeled and unlabeled sentences. With this semi-supervised representation learning, we expect to inference latent features that are not only generalizable in different domains, but also more informative or discriminative about the target task labels.

Our overall system follows a similar procedure of (Huang and Yates, 2009). First we train a DDN model over both the labeled sentences in the source domain and the unlabeled sentences in both domains, as we described above. Then we use the trained DDN model to produce latent features (i.e, hidden state values Y) for the training and test sentences using Viterbi inference algorithm. Finally we train a classification model, e.g., CRFs, over the training sentences for the target task, e.g. POS tagging, using the latent features as augmented inputs, and then perform classification on the test sentences. We expect semi-supervised representation learning to help improve out-of-domain prediction performance with more discriminative latent features.

5 Domain Adaptation for Part-of-Speech Tagging

In this section, we report our empirical study on how semi-supervised representation learning can improve out-of-domain part-of-speech tagging accuracy.

5.1 Datasets

We used the same datasets as (Blitzer et al., 2006; Huang and Yates, 2009, 2010). The source domain contains articles from Wall Street Journal (WSJ), with 39,832 manually tagged sentences from sections 02-21 and 100,000 unlabeled sentences from a 1988 subset. The target domain contains bio-medical articles from MEDLINE, with 561 labeled sentences[1] and 100,000 unlabeled sentences. The task is to assign words with one of the POS tags from the Penn Treebank POS tags (Marcus et al., 1993) and two more tags from MEDLINE dataset. Among the tags, two tags cannot be seen in the newswire articles, *HYPH* (hyphens) and *AFX* (common post-modifiers for biomedical entities such as genes). These two tags were introduced because of the importance of hyphenated entities in biomedical text, which are about 1.8% of the words in the 561 labeled sentences.

5.2 Representation Learning

We explored both unsupervised representation learning using HMMs and semi-supervised representation learning using the proposed DDNs. We built a vocabulary with all sentences from the source and target domains. In order to reduce the vocabulary size, we further applied the preprocessing steps used in (Huang and Yates, 2009, 2010): we mapped lower frequency (0-2) words to a single unique identifier and sole-digit words into a single unique identifier in our vocabulary. With these preprocessed sentences, we applied representation learning models (DDNs and HMMs) to derive hidden states as additional features for supervised POS taggers.

We used HMMs to perform unsupervised representation learning on 139,832 newswire sentences and 100,000 unlabeled biomedical sentences following the work (Huang and Yates, 2009). Then we decoded the hidden states for 39,832 newswire sentences (the labeled sentences in the source domain) as well as 561 biomedical sentences (the test sentences in the target domain) as additional features for supervised POS tagging. In the unsupervised representation training, one hyperparameter, the number of hidden states, has to be set. A large number of hidden states would make the model more capable to derive latent features, however, it also needs more memory storage and high computation cost. We used 80 states in our experiments, following (Huang and Yates, 2009), to produce fair comparisons.

We used the proposed DDN model for semi-supervised representation learning on 39,832 labeled and 100,000 unlabeled newswire sentences as well as 100,000 unlabeled biomedical sentences. The labels we used in semi-supervised representation learning are the same labels we will use later to train POS taggers. Thus comparing to unsupervised representation learning, the semi-supervised representation learning does not require additional annotation effort, but makes use of the existing labels in the source domain. For our semi-supervised representation learning, we need to choose two hyperparameters, the number of hidden states and the L2 regularization parameter. We set the former as 80, same as in unsupervised representation learning. Our model is not sensitive to the L2 regularization parameter and we set it as 0.5.

[1] Sentences are manually annotated as part of the Penn BioIE project.

5.3 Part-of-Speech Tagging Accuracy

For supervised POS tagging, the training data contains 39,832 labeled newswire sentences and the test data contains 561 biomedical sentences. The 561 biomedical sentences contain 14,554 tokens, of which 23% are OOV (Out-Of-Vocabulary) tokens. We tested our semi-supervised representation learning using supervised Conditional Random Field (CRF) POS taggers and used a fast-training CRF package developed by Okazaki (2007). The feature set used for the CRF POS tagger is presented in Table 1. Specifically, we extracted unigram features. We also added orthographical features such as suffix (-ing, -ogy, -ed, -ly, -s, -ion, -tion, -ity), as well as capitalization. Orthographical features contribute to improving tagging accuracy for out-of-vocabulary words as is demonstrated by (Lafferty, 2001). In addition, we added the latent states as state features for each word from the learned representations. For example, a sentence like "He is the CEO ." contains 5 words: 4 regular words and a "period". A state feature is learned for each of them.

Table 1: CRF feature set used in our supervised CRF POS taggers. Z_i variables stand for labels to be predicted, W_is represent word tokens. Y_is stand for hidden state values decoded from HMM or DDN models, i.e., the new representation features.

Feature Type	Feature Description
Transition	$Z_i = t$ $Z_i = t$ and $Z_{i-1} = t'$
Word	$W_i = w$ and $Z_i = t$
Orthography	For every s $\in$ {-ing, -ogy, -ed, -s, -ly, -ion, -tion, -ity}, suffix(W_i)=s and $Z_i = t$ W_i is capitalized and $Z_i = t$ W_i has a digit and $Z_i = t$
HMM features	$Z_i = t$ and $Y_i = y$
DDN features	$Z_i = t$ and $Y_i = y$

Our experimental results in term of per-token accuracy with different representation learning methods are presented in Table 2. For all test results reported in this paper, the "*All Words*" results are average accuracies over all words in the test data, the "*OOV Words*" results are average accuracies over only OOV words in the test data that appeared less than 3 times in the training data. We reported the empirical results for the following approaches:

- **Baseline:** the baseline CRF POS-tagger trained without representation learning.
- **ASO:** the Alternating Structural Optimization technique in (Ando and Zhang, 2005).
- **SELF-CRF:** the comparison method using a self-training paradigm. We first train a CRF without representation learning on the training data and apply it on the test data, then retrain it on the training data plus the test data with predicted labels.
- **PLAIN-SEM:** the method based on the representation learning technique using contrastive estimation (Smith and Eisner, 2005). We used the modified version in (Huang and Yates, 2010).

Table 2: Per-token accuracy for out-of-domain words on MEDLINE domain trained with Wall Street Journal articles.

Approaches	All Words	OOV Words
Baseline	88.3%	67.3%
ASO	88.4%	70.9%
SELF-CRF	88.5%	70.4%
PLAIN-SEM	88.5%	69.8%
SCL	88.9%	72.0%
SEM-CRF	90.0%	71.9%
HMM	90.5%	75.2%
DDN	**91.3**%	**76.1**%

- **SCL:** the method based on the representation learning with the Structural Correspondence Learning (SCL) technique, developed by (Blitzer et al., 2006).
- **SEM-CRF:** the method based on the representation learning in (Huang and Yates, 2010).
- **HMM:** the method based on the unsupervised representation learning using HMMs in (Huang and Yates, 2009).
- **DDN:** the method based on the proposed semi-supervised representation learning.

We also investigated how our representation learning benefits supervised POS taggers by varying the number of labeled training sentences from the source domain. For comparison, we considered *Baseline*, *SCL* and *HMM*, since *SCL* and *HMM* work very well among all the other comparison methods. The per-token accuracies on test data are reported in Figure 2.

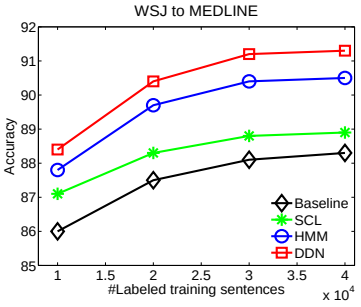

Figure 2: Per-token accuracies for out-of-domain POS tagging. WSJ is used as the source domain and MEDLINE is used as the target domain.

From Table 2 and Figure 2, we can see that with semi-supervised representation learning, DDN consistently outperforms other comparison methods for out-of-domain POS tagging. From Figure 2, we can see that by increasing the number of labeled training data, *DDN* can gain

Table 3: Statistical Significance (McNemar's) tests for out-of-domain experiments with CRF POS taggers. Results are significant with $p < 0.05$.

Null Hypothesis	p-value
HMM vs. Baseline	2.3×10^{-9}
DDN vs. Baseline	3.4×10^{-10}
DDN vs. SCL	6.7×10^{-7}
DDN vs. HMM	2.9×10^{-4}

more improvements in accuracy compared with *Baseline*, *SCL* and *HMM*. Specifically, *DDN* increases accuracy by 2.4% compared with *Baseline*, by 1.3% compared with *SCL*, and by 0.6% compared with *HMM* when the labeled training data is 1,000. When the labeled training data reaches 39,832, *DDN* increases accuracy by 3.0% compared with *Baseline*, by 2.4% compared with *SCL*, and by 0.8% compared with *HMM*. Those results suggest that *DDN* can produce more effective task-specific features by incorporating existing labels from the source domain, and further assist out-of-domain POS tagging.

We also present results for corresponding significance tests over comparisons between *Baseline*, *SCL*, *HMM* and *DDN* in Table 3. We followed the experiments in (Blitzer et al., 2006), and used a McNemar paired test for labeling disagreements (Gillick and Cox, 1989) with $p < 0.05$ being significant on all test words. We report the p values in Table 3. We can see that *DDN* significantly improves out-of-domain tagging accuracy over *Baseline*, *SCL* and *HMM*.

6 Domain Adaptation for Syntactic Chunking

In this section, we empirically study how our proposed semi-supervised representation learning can improve out-of-domain performance on syntactic chunking.

6.1 Datasets

We used the datasets from the CoNLL 2005 shared task (Carreras and Màrquez, 2005) for our second set of experiments on syntactic chunking. We used the standard training set, consisting of sections 02-21 of the Wall Street Journal (WSJ) portion of the Penn Treebank, and conducted tests on the Brown corpus (Kucera and Francis, 1967). The test data contains 3 sections (ck01-ck03) of propbanked Brown corpus data, which consists of 426 sentences containing 7,159 tokens. Besides these labeled data, we also incorporated unlabeled data from both domains. We added 100,000 unlabeled news sentences for the source domain and 57,000 unlabeled sentences for the target domain. In this setting, while the source domain contains newswire text, the test sentences are drawn from the domain of "general fiction" and contain entirely different styles of English.

The original training data and test data from the CoNLL 2005 shared task contain POS tags as well as partial syntax, namely chunks and clauses. In order to perform syntactic chunking task, we mapped the partial syntax labels to chunking labels in IOB2 format. IOB2 format is a standard format for various sequence tasks like syntactic chunking and it is widely used in previous works including the CoNLL 2000 shared task[2]. In IOB2 format, the chunk tags

[2]http://www.clips.ua.ac.be/conll2000/chunking/.

Table 4: Average chunking performance on Brown corpus, with Wall Street Journal articles as training data.

Methods	F1
Baseline	89.93%
SELF-CRF	90.21%
SCL	90.62%
HMM	91.79%
DDN	**93.05**%
UPC Chunker	91.73%

consist of two parts. The first part represents the position of the token in this chunk and the second part stands for the name of the chunk type. For example, the chunking type of *VP* is used for verb phrase words and the chunking type of *NP* is used for noun phrase words. For words forming a chunk of type k, the first word receives the B-k tag (Begin), and the remaining words receive the tag I-k (Inside). Words outside a chunk receive the tag O. Below we give an example of a sentence labeled with chunking tags in IOB2 format from the source domain:

The/B-NP $/I-NP 1.4/I-NP billion/I-NP robot/I-NP spacecraft/I-NP faces/B-VP a/B-NP six-year/I-NP journey/I-NP to/B-VP explore/I-VP Jupiter/B-NP and/O its/B-NP 16/I-NP known/I-NP moons/I-NP ./O

6.2 Representation Learning

We built a vocabulary with all sentences from the source and target domains. In order to reduce the vocabulary size, we used the same preprocessing steps as in POS tagging experiments, mapping lower frequency (0-2) words to a single unique identifier in our vocabulary and sole-digit words into a single unique identifier. On the preprocessed sentences, we then applied representation learning models (DDNs or HMMs) to derive hidden states of the sentence words, which can be used as additional features for supervised syntactic chunking systems.

We used HMMs to perform unsupervised representation learning on 139,832 newswire source sentences and 57,000 unlabeled "general fiction" sentences from Brown corpus. Then we decoded the hidden states for 39,832 labeled newswire sentences and 426 "general fiction" test sentences as additional features for supervised syntactic chunking, using the trained HMM. In the unsupervised representation training, one hyperparameter, the number of hidden states, has to be set. We used 80 states in our experiments in consideration of the model capability, memory storage and computation cost.

We used the proposed DDN model for semi-supervised representation learning on the same data as for HMMs, i.e., 139,832 newswire sentences from the source domain and 57,000 unlabeled "general fiction" sentences from the target domain. But different from unsupervised representation learning, our proposed semi-supervised representation learning makes use of the existing labels of the 39,832 sentences in the source domain. In our semi-supervised representation learning, we need to choose two hyperparameters, the number of hidden states and the L2 regularization parameter. We set the former as 80 and the latter as 0.5, which are same as in our previous experiments for POS-tagging.

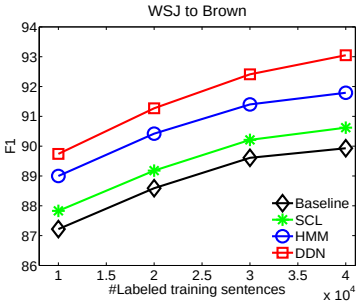

Figure 3: Results in term of F1 measure for out-of-domain syntactic chunking. WSJ is used as the source domain and Brown corpus is used as the target domain.

6.3 Syntactic Chunking Results

For supervised syntactic chunking, the training data contains 39,832 labeled newswire sentences and the test data contains 426 "general fiction" sentences. The 426 "general fiction" sentences contain 7,159 tokens. We tested our semi-supervised representation learning with supervised Conditional Random Field (CRF) syntactic chunking. We used the same fast-training CRF package developed by Okazaki (2007). For syntactic chunking, in addition to the CRF feature set in Table1 which we used in POS tagging experiments, we also extracted POS tag features. All features are represented with boolean values.

Our experimental results with different representation learning methods are presented in Table 4. The results are in term of F1 measure, since F1 measure is widely used in syntactic chunking tasks (Huang and Yates, 2009; Carreras and Màrquez, 2005). We reported the empirical results of the following approaches for comparison:

- **UPC Chunker:** a chunking system based on Voted Perceptrons (Carreras and Màrquez, 2003). Carreras and Màrquez (2005) trained such a chunker on WSJ sections 02-21 and tested it on three sections of the Brown corpus (ck01-03). The reported results serve as the current *state-of-the-art* performance on this experimental setting.
- **Baseline:** the baseline CRF chunker without representation learning.
- **SELF-CRF:** the CRF chunker with a self-training paradigm. We first train a CRF without representation learning on the training data and apply it to the test data, then retrain it on the training data plus the test data with predicted labels.
- **SCL:** the method based on the representation learning produced using the Structural Correspondence Learning (SCL) technique (Blitzer et al., 2006).
- **HMM:** the method based on unsupervised representation learning using Hidden Markov Models (Huang and Yates, 2009).
- **DDN:** the method based on the proposed semi-supervised representation learning.

We also investigated the performance of the proposed DDN-based chunker by varying the

number of labeled training sentences from the source domain. Its comparison results with *Baseline*, *SCL* and *HMM* are presented in Figure 3.

From Table 4 and Figure 3, we can see that with semi-supervised representation learning, the DDN based chunker consistently outperforms other methods for out-of-domain syntactic chunking. According to Figure 3, by increasing the number of labeled training data, *DDN* can gain more improvements in term of F1 measure comparing to *Baseline*, *SCL* and *HMM*. Specifically, *DDN* increases the F1 by 2.52% comparing with *Baseline*, by 1.91% comparing with *SCL*, and by 0.74% comparing with *HMM* when the number of labeled training sentences is 1,000. When the number of labeled training sentences reaches 39,832, *DDN* outperforms *Baseline* by 3.08%, outperforms *SCL* by 2.43%, and outperforms *HMM* by 1.26%, in term of F1-measure. These results again suggest that the semi-supervised representation learning method, *DDN*, can produce more effective task-specific features by incorporating existing labels from the source domain.

We also produced the results of corresponding significance tests, reported in Table 5. We used a McNemar paired test for labeling disagreements (Gillick and Cox, 1989) with $p < 0.05$ being significant on all test words. We reported the p values in Table 5, from which we can see that *DDN* significantly improves out-of-domain chunking performance over *Baseline*, *SCL* and *HMM*.

Table 5: Statistical Significance (McNemar's) tests for out-of-domain experiments with CRF syntactic chunkers. Results are statistical significant with $p < 0.05$.

Null Hypothesis	p-value
HMM vs. Baseline	5.6×10^{-8}
DDN vs. Baseline	2.9×10^{-10}
DDN vs. SCL	7.1×10^{-8}
DDN vs. HMM	4.7×10^{-4}

Conclusion

In this paper, we proposed a Dynamic Dependency Network model for semi-supervised representation learning. In addition to the large amount of unlabeled data from two domains, it incorporates the task-specific labels from the source training data into representation learning. We then used the induced generalizable state features to augment source training sentences and target test sentences for two cross domain NLP tasks: part-of-speech tagging and syntactic chunking. Our empirical studies show that the proposed semi-supervised representation learning outperforms unsupervised representation learning based on HMMs on out-of-domain test data for both POS tagging system and syntactic chunking system. With the proposed semi-supervised representation learning, the POS taggers and the syntactic chunkers resulted also outperform a set of other POS tagging methods and syntactic chunking methods for out-of-domain predictions. All results suggest the proposed semi-supervised representation learning can better bridge the domain gap between training sentences and test sentences by exploiting task-specific label information in the representation learning process.

ABSTRACT
We present a global log-linear model for synchronous grammar induction, which is capable of incorporating arbitrary features. The parameters in the model are trained in an unsupervised fashion from parallel sentences without word alignments. To make parameter training tractable, we also propose a novel and efficient cube pruning based synchronous parsing algorithm. Using learned synchronous grammar rules with millions of features that contain rule level, word level and translation boundary information, we significantly outperform a competitive hierarchical phrased-based baseline system by +1.4 BLEU on average on three NIST test sets.

KEYWORDS: synchronous grammar induction, discriminative model, unsupervised learning, machine translation.

COLING 2012, Mumbai, December 2012.

1 Introduction

In the last decade, statistical machine translation (SMT) has been advanced by expanding the basic unit of translation from word to phrase (Koehn et al., 2003) and grammar (Galley et al., 2006; Liu et al., 2006; Chiang, 2007). Most systems induce synchronous grammars (including phrases) from parallel corpora using a heuristic two-step pipeline. This pipeline first aligns a parallel corpus at the word level with heuristic word alignment combination strategies (e.g., grow-diag-final-and) (Koehn et al., 2003), and then extracts translation rules from word-aligned sentence pairs. It is working well in practice and therefore widely adopted. However, such a pipeline artificially brings an undesirable disconnection between translation model and word alignment model (Blunsom et al., 2009; DeNero and Klein, 2010).

Recently, researchers have resorted to principled probabilistic formulations. Various generative models are proposed to learn translation rules directly from sentence pairs without word alignments (Marcu and Wong, 2002; Cherry and Lin, 2007; Zhang et al., 2008; DeNero et al., 2008; Blunsom et al., 2009; Cohn and Blunsom, 2009; Neubig et al., 2011; Levenberg et al., 2012). Due to the independency assumptions in such generative models, it is hard to extend them to incorporate arbitrary features, especially word alignment information as used in the traditional two-step pipeline. As a result, despite theoretical advantages of these models over the two-step pipeline, in practice they can only produce comparable translation quality with the two-step pipeline in some scenarios, and usually even worse results.

Yet another alternative for synchronous grammar induction is unsupervised discriminative model. Unsupervised discriminative model can directly learn synchronous grammars in a theoretically justified manner just like generative model. However, the advantage over generative model is that it is able to easily incorporate word alignment information which has been proved useful in the two-step pipeline.

In this paper, we propose a global log-linear model (Sec. 2) for the induction of synchronous context free grammar (SCFG) (Chiang, 2007). The log-linear model is able to incorporate arbitrary features. Furthermore, it is trained from sentence pairs without word alignments in an unsupervised fashion. In particular:

- We approximate the exact conditional log-likelihood objective inspired by contrastive estimation (Smith and Eisner, 2005) as the optimization of the exact objective is very expensive. The key idea is to estimate parameters via *synchronous hypergraphs* of sentence pairs and *neighbor source hypergraphs* of source sentences (Sec. 3).
- Synchronous parsing is often impractical in large-scale learning applications due to its high complexity $O(n^6)$. We address this challenge by proposing a novel and efficient $O(n^3)$ cube pruning based synchronous parsing algorithm (Sec. 4).
- Aiming to enhance the ability to predict whether a translation derivation is good or not, we incorporate a variety of fine-grained features into our model, including rule level features, word level features and phrase boundary features (Xiong et al., 2010) (Sec. 5).

We evaluate our approach on the NIST Chinese-English translation task. According to the analysis of grammar (Sec. 6.2), our induced grammar is more reusable, and is able to generate better (+8.3 BLEU points) oracle translations than the grammar of the baseline. Meanwhile, in the end-to-end machine translation experiments, our approach outperforms the two-step pipeline by +1.4 BLEU points (Sec. 6.3).

2 Global Log-linear Model

We propose a log-linear model to induce SCFG rules for hierarchical phrase-based translation (Chiang, 2007) which transforms a source sentence $\mathbf{s}$ into a target sentence $\mathbf{t}$ by a sequence of SCFG rules. Such a sequence of rules $\{r\}$ is called a **derivation d**.

As the training data only contains sentence pairs, we model the derivation as a latent variable. The conditional probability $p(\mathbf{t}|\mathbf{s})$ of a target sentence given a source sentence is defined as the sum over all possible derivations $\mathbf{d}$:

$$p(\mathbf{t}|\mathbf{s}) = \sum_{\mathbf{d} \in \triangle(\mathbf{t},\mathbf{s})} p(\mathbf{d},\mathbf{t}|\mathbf{s}) \tag{1}$$

where $\triangle(\mathbf{t},\mathbf{s})$ is the set of all possible derivations that translate $\mathbf{s}$ into $\mathbf{t}$, and $\mathbf{d}$ is one such derivation. Given a source sentence $\mathbf{s}$, the conditional probability of a derivation $\mathbf{d}$ and the corresponding translation $\mathbf{t}$ is:

$$p(\mathbf{d},\mathbf{t}|\mathbf{s}) = \frac{\exp \sum_i \lambda_i H_i(\mathbf{d},\mathbf{t},\mathbf{s})}{Z(\mathbf{s})} \tag{2}$$

where $H_i(\mathbf{d},\mathbf{t},\mathbf{s}) = \sum_{r \in \mathbf{d}} h_i(r,\mathbf{s})$ is feature function. We assume H_i decomposes with derivation $\mathbf{d}$ in terms of local feature function h_i, which is related to a rule r and a source sentence $\mathbf{s}$. λ_i is the correspondent feature weight. $Z(\mathbf{s})$ is the partition function:

$$Z(\mathbf{s}) = \sum_{\mathbf{t}} \sum_{\mathbf{d} \in \triangle(\mathbf{t},\mathbf{s})} \exp \sum_i \lambda_i H_i(\mathbf{d},\mathbf{t},\mathbf{s}) \tag{3}$$

Such a discriminative latent variable model is not new to SMT (Blunsom et al., 2008; Kääriäinen, 2009; Xiao et al., 2011). However, we are distinguished from previous work by applying this model to synchronous grammar induction. The purpose of the latent variable model in such previous work is to do max-translation decoding and training (Blunsom et al., 2008), or to eliminate the gap between heuristic extraction and decoding (Kääriäinen, 2009), instead of grammar induction as synchronous rules are still extracted by the heuristic two-step pipeline. In contrast, our interest lies in using latent variable model to learn synchronous grammar directly from sentence pairs. Overall, to the best of our knowledge, this is the first attempt to apply this log-linear model for synchronous grammar induction.

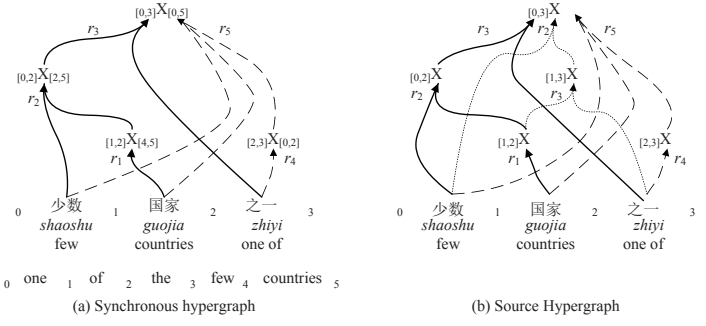
3 Training

We use maximum a posteriori estimator with stochastic gradient descent algorithm for optimization. We maximize the log-likelihood $\mathbb{L}$ of the bilingual corpus $\mathbf{T} = \{(\mathbf{s}^n, \mathbf{t}^n)\}_{n=1}^N$, penalized by a gaussian prior with mean 0 and variance σ (L_2 norm):

$$\mathbb{L} = \sum_{(\mathbf{s}^n,\mathbf{t}^n) \in \mathbf{T}} \log p(\mathbf{t}|\mathbf{s}) + \sum_i \log p_0(\lambda_i) \tag{4}$$

The gradient of the above objective is as follows:

$$\frac{\partial \mathbb{L}}{\partial \lambda_i} = E_{p(\mathbf{d}|\mathbf{t},\mathbf{s})}[H_i] - E_{p(\mathbf{d},\mathbf{t}|\mathbf{s})}[H_i] - \frac{\lambda_i}{\sigma^2} \tag{5}$$



r_1: $\langle$ *guojia* $\Rightarrow$ countries $\rangle$ r_2: $\langle$ *shaoshu* X $\Rightarrow$ the few X $\rangle$
r_3: $\langle$ X *zhiyi* $\Rightarrow$ one of X $\rangle$ r_4: $\langle$ *zhiyi* $\Rightarrow$ one of $\rangle$
r_5: $\langle$ *shaoshu guojia* X $\Rightarrow$ X the few countries $\rangle$

Figure 1: Synchronous hypergraph and source hypergraph of a sentence pair from Chinese segment "*shaoshu guojia zhiyi*" aligned with an English string "one of the few countries". These two hypergraphs are constructed in order to calculate the expectation in Eq. (5). Here, a hyperedge corresponds to an SCFG rule. A node is a bispan in synchronous hypergraph and is a source span in source hypergraph. Notably, the dotted derivation in Figure (b), which contains dotted hyperedges and goes through the source-span [1,3], is a "wrong" derivation, because it results in a translation inconsistent with the target string. Intuitively, we achieve the unsupervised learning by moving the probability of such "wrong" derivations in source hypergraph into the derivations in synchronous hypergraph.

Eq. (5) clearly shows that there are two expectations need to be calculated. The first one is the expectation $E_{p(\mathbf{d}|\mathbf{t},\mathbf{s})}[H_i]$ of a parameter given a sentence pair, and the second one $E_{p(\mathbf{d},\mathbf{t}|\mathbf{s})}[H_i]$ is the expectation of a parameter given the source sentence.

In the following sections, we first introduce how to use hypergraph to compute these expectations by synchronous hypergraph and source hypergraph respectively (Sec. 3.1). Then, we discuss the intractability of the exact training, and achieve tractable training by approximation (Sec. 3.2). Finally, we describe the training algorithm in detail to explain how the rules is induced (Sec. 3.3).

3.1 Inference with Hypergraph

We use hypergraph (Klein and Manning, 2001) to compactly represent the space of derivations. Based on hypergraphs, it's straightforward to calculate the two expectations in Eq. (5). The first expectation $E_{p(\mathbf{d}|\mathbf{t},\mathbf{s})}[H_i]$ is the expected value when observing both source sentence $\mathbf{s}$ and target sentence $\mathbf{t}$. The second expectation $E_{p(\mathbf{d},\mathbf{t}|\mathbf{s})}[H_i]$ is a similar function, but only the source sentence is observed. Thus, in order to calculate the first expectation, we construct a synchronous hypergraph to represent all derivations of a sentence pair. Similarly, for the second expectation, we use a source hypergraph to represent all derivations of a source sentence.

Figure 1 shows a synchronous hypergraph (a) and a source hypergraph (b). Each hyperedge is associated with an SCFG rule. In a synchronous hypergraph, a node is denoted by a nonterminal with a bispan. In contrast, a node in the source hypergraph is a nonterminal that spans

a continuous sequence of words of source sentence.

More formally, a **hypergraph** is a pair $\langle V, E \rangle$, where V is the set of **nodes**, E is the set of **hyperedges**. Each hyperedge $e \in E$ connects a set of antecedent nodes to a single consequent node. And each hyperedge corresponds to an SCFG rule r. In a **synchronous hypergraph**, a node $v \in V$ is in the form $X_{i,j,k,l}$, which denotes the nonterminal X spanning from i to j (that is $s_{i+1}...s_j$) in the source sentence, and from k to l in the target sentence. In a **source hypergraph**, each node $v \in V$ is in the form $X_{i,j}$, which spans from i to j in the source sentence.

Based on these hypergraphs, we compute the two expectations by applying the inside-outside algorithm as described in Li et al. (2009). The computation complexity is linear to the size of hypergraph $O(|E|)$. More exactly, $O(|E|)$ denotes $O(|\mathbf{s}|^3|\mathbf{t}|^3)$ for synchronous hypergraph, and $O(|\mathbf{G}||\mathbf{s}|^3)$ for source hypergraph. Here, $\mathbf{G}$ denotes all potential synchronous grammars.

3.2 Tractable Estimation by Approximation

However, the size of potential SCFGs $\mathbf{G}$ is extremely large given a vocabulary Ω, resulting in a large number of hyperedges in source hypergraph. See the rule r_2 in Figure 1. In reality, there are many potential translation rules that share the same source side "*shaoshu X*" as r_2, but with different target side. Suppose n is the maximum number of terminals in the target side, the number of such rules is up to $O(|\Omega|^n)$. All these rules can connect the source word "*shaoshu*" and the node $X_{1,2}$ to the node $X_{0,2}$, which produces a large number of incoming hyperedges for node $X_{0,2}$. Therefore, due to the large number of potential SCFGs, the number of hyperedges in a source hypergraph is very large. The computation on such a huge source hypergraph makes the exact inference intractable.

To make inference tractable and efficient, we shrink the size of source hypergraph by defining a smaller neighborhood with the synchronous hypergraph. We parse the source hypergraph using the neighbor grammar $\mathbf{NG}$ of synchronous hypergraph $\mathbf{H}$:

$$\mathbf{NG} = \text{Neighbor}(\mathbf{G}', \mathbf{H}) = \{r | r \in \mathbf{G}' \wedge src(r) \in \{src(r') | r' \in G(\mathbf{H})\}\} \quad (6)$$

Here, $\mathbf{G}'$ is the set of translation rules discovered in the training corpus by our algorithm. $src()$ denotes the source side of a rule. $G()$ is the set of rules in a hypergraph. The neighbor grammar contains those rules that are discovered during training (rather than all potential rules), and whose source sides occur in the synchronous hypergraph. Sine the size of $\mathbf{NG}$ is typical fairly small, the parsing of our source hypergraph becomes tractable in practice.

The definition of neighbor source hypergraph is inspired by contrastive estimation (Smith and Eisner, 2005). Similar shrinkage of discriminative neighborhood is also used in Dyer et al. (2011a). Notably, our approximation is consistent with the purpose of synchronous grammar induction for SMT. In SMT, the goal of grammar induction is for translation rather than synchronous parsing. Our source hypergraph corresponds to the potential translation space during SMT decoding. Thus, we expect such approximation to be suitable for SMT.

3.3 Training Algorithm

Based on the synchronous hypergraph and source hypergraph introduced above, we optimize $\mathbb{L}$ in an online style as shown in Algorithm 1. For each sentence pair, we first use cube-pruning based biparsing (Sec. 4) to construct a synchronous hypergraph $\mathbf{H}_1$ (line 4). Rules are discovered in the construction of hypergraph in $\mathbf{H}_1$. We then collect these learnt rules $G(\mathbf{H}_1)$ in $\mathbf{H}_1$,

Algorithm 1: Training($\{(\mathbf{s}^n, \mathbf{t}^n)\}_{n=1}^N$)

1 $\mathbf{G}' \leftarrow \varnothing$, $\lambda \leftarrow \mathbf{0}$
2 **for** $t = 0$ **to** T **do**
3 **for** $n = 0$ *to* N **do**
4 $\mathbf{H}_1 \leftarrow \textsc{BiParse}(\mathbf{s}, \mathbf{t})$ ▷ generate synchronous hypergraph
5 $\mathbf{G}' \leftarrow \mathbf{G}' + G(\mathbf{H}_1)$ ▷ collect grammars in $\mathbf{H}_1$
6 $\mathbf{NG} \leftarrow \textsc{Neighbor}(\mathbf{G}', \mathbf{H}_1)$
7 $\mathbf{H}_2 \leftarrow \textsc{ExhaustiveParse}(\mathbf{NG}, \mathbf{s})$ ▷ generate neighbor source hypergraph
8 $\lambda \leftarrow \lambda + \eta \times \frac{\partial \mathbb{L}}{\partial \lambda}(\mathbf{H}_1, \mathbf{H}_2)$ ▷ η is learning rate
9 **return** $\mathbf{G}'$, λ

and store them in $\mathbf{G}'$. After that, we create the neighbor source hypergraph $\mathbf{H}_2$ by exhaustive bottom-up chart parsing using the neighbor grammar **NG** (line 6). Finally, we calculate the gradient by these two hypergraphs and update the feature weights (line 8). When the algorithm is complete, we learn a grammar $\mathbf{G}'$ and also the feature weights λ of the model.

We implement an stochastic gradient descent (SGD) recommended by Bottou.[1] We schedule the learning rate η by an exponential decay (Tsuruoka et al., 2009). We set the regularization strength, initial learning rate and the base of exponential decay as 1.0, 0.2, 0.9 respectively. We choose these values by maximizing the translation performance measured by BLEU on the NIST 2002 development set with a subset of our training data including 20k sentence pairs.

4 Cube Pruning-based Synchronous Parsing

The approximation makes the training algorithm tractable. However, there is still one problem: how to efficiently construct the synchronous hypergraph? Exhaustive synchronous parsing requires $O(|\mathbf{s}|^3|\mathbf{t}|^3)$ time.[2] To overcome this challenge, we propose a novel and efficient cube-pruning based synchronous parsing algorithm. Given a sentence pair, this algorithm constructs the synchronous hypergraph and discovers rules in the sentence pair.

Instead of enumerating all possible hyperedges, we only create k-best hyperedges for each source span. This is achieved by exploiting the substructure in a hyperedge. For example, the hyperedge in Figure 2(b) contains two substructures: alignment of source sub-span $X_{0,2}$ and alignment of the third source word s_3. We maintain sorted candidate lists for every substructure, and create cubes that represent the potential combinations of these candidates (see Fig. 2(a)). In this way, we are able to create k-best hyperedges by cube pruning.

More specifically, we maintain charts for source words and source spans respectively:

- **s-chart** for each source word. The cell $chart[s, i]$ in s-chart stores a list of candidate alignments for the i-th source word. A candidate alignment is represented by a list of target index. The vertical dimension in Figure 2(a) is an instance of $chart[s, 3]$.

[1] http://leon.bottou.org/projects/sgd

[2] Dyer (2010) has shown that two monolingual parses can be more efficient than one synchronous parse, due to the sparsity of pre-fixed translation rules. Such rules are extracted by the heuristic two-step pipeline. In contrast, there are no pre-fixed translation rules in our case.

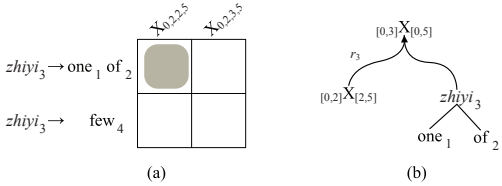


Figure 2: Construct hyperedge from a cube. (a) Cube $X_{0,2}$*zhiyi*$_3$ for source span (0,3). The vertical direction represents the candidate list of *zhiyi*$_3$, while the horizontal direction is a list of nodes that share the same source span (0,2). (b) the hyperedge corresponds to the gray grid in cube (a).

- **X-chart** for each source span. The cell $chart[X,i,j]$ in X-chart stores a list of nodes of the synchronous hypergraph. The nodes in $chart[X,i,j]$ share the same source span (i,j). The horizontal direction in Figure 2(a) is an instance of $chart[X,0,2]$.

These two charts are created by cube-pruning from the bottom up. When processing a source span, we infer all potential source parses and create cubes as shown in Figure 2(a) for every source parses. A cube represents the space of hyperedges for a source parse, where each dimension of a cube denotes the candidate list of a substructure for a hyperedge. Thus, the point in a cube corresponds to a hyperedge (see Fig. 2(b)). Based on these cubes, we create k-best hyperedges, store them into the chart, and then proceed to larger source spans.

4.1 Cube

Formally, a **cube** is a tuple of lists $\mathbf{L} = \langle L_1, ..., L_d, ..., L_{|L|} \rangle$, where $|L|$ is the dimension of the cube and L_d is a list for the d-th dimension. Although $|L|$ can be larger than 3 (a hypercube is defined in that case), we still call it cube for consistency. Given a point $\mathbf{p}$ in the cube, multiplication operator $\otimes$ constructs a hypothesis by $L_1[p_1] \otimes ... \otimes L_{|L|}[p_{|L|}]$. Particularly, there are two types of cubes: *word cube* and *span cube*.

Word Cube A word cube represents the alignment space for a source word s_i, and is used to create the items for $chart[s,i]$. A word cube has $|\mathbf{t}|$ dimensions. The d-th dimension list L_d contains two elements: ε (null translation) and t_d (the d-th target word). The hypothesis of a point $\mathbf{p}$ is a set of target words that aligns to the source word.

Span Cube A span cube represents the space of hyperedges for a source parse of source span (i,j), and is used for creating $chart[X,i,j]$. As a span cube denotes a deduction of the source span, it is represented by a source sequence of symbol γ, which is a mixture of words and nonterminals. For example, the cube in Figure 2(a) is represented by $X_{0,2}$*zhiyi*$_3$. According to γ, the d-th dimension L_d of a span cube $\mathbf{L}$ is defined according to γ_d:

$$L_d = \begin{cases} chart[s,i_1] & \text{if} \quad \gamma_d = s_{i_1} \\ chart[X,i_1,j_1] & \text{if} \quad \gamma_d = X_{i_1,j_1} \end{cases} \tag{7}$$

The hypothesis of a point $\mathbf{p}$ in a span cube corresponds to a hyperedge. The tail nodes of such a hyperedge is the set of nodes $\{v | v \in \{L_d[p_d]\}\}$, where $\{L_d[p_d]\}$ is the set of elements for

Algorithm 2: BiParse($\mathbf{s}, \mathbf{t}$)

```
1  for i ← 1,.., |s| do
2      for j ← 1,.., |t| do                          ▷ create a |t|-dimension word cube
3          L_j ← {ε, t_j}
4      𝒮 ← ⟨L_1, ..., L_|t|⟩
5      chart[s, i] ← MergeProducts(𝒮, ⊗)              ▷ create k-best alignments
6  for h ← 1,.., |s| do                              ▷ h is the size of span
7      forall the i, j s.t. j − i = h do
8          𝒮 ← ∅
9          for γ inferable from chart do             ▷ create all inferable span cubes
10             𝒮 ← 𝒮 + ⟨chart[γ_1], ..., chart[γ_|γ|]⟩
11         chart[X, i, j] ← MergeProducts(𝒮, ⊗)       ▷ create k-best hyperedges
```

the point $\mathbf{p}$ in the cube. The head node of the hyperedge $X_{i,j,k,l}$ has a target span that is the maximum target span covered by $\{L_d[p_d]\}$. See the Figure 2(b), for point (0,0), since the word "*zhiyi*$_3$" aligns to "one$_1$" and "of$_2$", and the tail node is $X_{0,2,2,5}$, the max target coverage is $(0,5)$. Therefore the head node is $X_{0,3,0,5}$.

However, for a point $\mathbf{p}$ in source cube, the elements in each dimension $\{L_d[p_d]\}$ may conflict with each other. See Figure 2(a). Point (0,1) in the cube denotes two elements: an alignment for "*zhiyi*$_3$" to "*few*$_4$" and a node $X_{0,2,2,5}$. The target alignment of "*zhiyi*$_3$" overlaps with the target span of node $X_{0,2,2,5}$. We say this is a *conflict*. Such a conflict denotes an inconsistent alignment. Therefore, we skip those conflicting points in a cube when constructing hyperedge.

Notably, a point in a span cube clearly expresses the inside word alignments of a hyperedge, allowing us to encode word level features for hyperedges.

4.2 Biparsing Algorithm

Algorithm 2 shows the main process of our cube-pruning based biparsing algorithm.

The algorithm begins with the construction of s-chart (lines 1-5). We first construct a $|\mathbf{t}|$-dimension word cube for every source word (lines 2-3). Secondly, by MergeProducts function as described in Chiang (2007), we create k-best alignments for every source word, and add them to the $chart[s,i]$ (line 5).

After that, we create each cell $chart[X,i,j]$ for X-chart (lines 6-11) from the bottom up. For a source span (i,j), all span cubes inferable from s-chart and X-chart are established. Every span cube is a tuple of $|\gamma|$-lists according to Eq. (7), and is append to $\mathscr{L}$ (lines 9,10). After creating all cubes, we construct k-best hyperedges and store them into $chart[X,i,j]$ (line 11).

Obviously, hyperedges and nodes have been created during the construction of the two charts, which means Algorithm 2 produces a synchronous hypergraph. As each hyperedge corresponds to an SCFG rule, Algorithm 2 is also a procedure to discover SCFG rules. On the other hand, the complexity of our biparsing algorithm is $O(|\mathbf{s}||\mathbf{t}| + |\mathbf{s}|k\log k + |\mathbf{s}|^3 + |\mathbf{s}|^2 k\log k)$. Considering k is prefixed and $|\mathbf{t}|$ is linear to $|\mathbf{s}|$ in reality, the complexity can be simplified into $O(|\mathbf{s}|^3)$.

4.3 Scoring Function and Future Cost

The hypothesis, that is created by the operator $\otimes$, corresponds to a hyperedge e and an SCFG rule r. Suppose the head node of a hyperedge e is $X_{i,j,k,l}$, we calculate the score of e by:

$$S(e) = \sum_i \lambda_i h_i(r, \mathbf{t}, \mathbf{s}) + F(i,j,k,l) \tag{8}$$

The first part is the feature score, while the second part $F()$ denotes the future cost. This future cost is an approximation of the outside score of bispan $[i,j,k,l]$, which denotes the cost to generate strings outside the head node $X[i,j,k,l]$. We estimate the future cost by using word level features as follows:

$$F(i,j,k,l) = \sum_{g \notin (i,j)} \operatorname*{argmax}_{h \notin (k,l)} S(s_g, t_h) + \sum_{h \notin (k,l)} \operatorname*{argmax}_{g \notin (i,j)} S(s_g, t_h) \tag{9}$$

$S(s_g, t_h)$ calculates the score of features for a word pair. The future cost can be calculated before inference.

Notably, a rule is not factorized into hypothesis in each dimension of a cube. Because rule features are used in our model, the multiplication operator $\otimes$ is only approximately monotonic under this scoring function. Thus, the MERGEPRODUCTS only produces approximate k-best hypotheses.

4.4 Implementation

Here, we discuss some engineering details of our algorithm.

For efficiency, we only construct 30-best hyperedges for each cube. These hyperedges are recombined, and the top-10 nodes are saved to the chart.

We prune the SCFG rules (corresponding to hyperedge) that are already discovered from synchronous hypergraphs using two constraints. Firstly, we prune a hypergraph by viterbi pruning with $p = 1$ (Huang, 2008). Secondly, we maintain a rule cache with size limit of 20M. When the cache is full, we drop those rules containing nonterminals that are discovered in only one sentence pair. For rules sharing the same source side, we retain the 50 most frequent ones.

Sometimes, a hyperedge produced by the cube corresponds to an illegal SCFG rule as defined in Chiang (2007). For example, rules without source terminals, target terminals and ITG rules (Dekai, 1997). We allow such edges to be added to the hypergraph, in order to make sure that most sentences are reachable. By this setting, the failure of biparsing only occurs in less than 1% of the whole training corpus. However, due to the ambiguity of these rules, we do not use them during end-to-end translation.

Overall, by these implementations, our synchronous algorithm (Alg. 2) runs in a speed of 0.41 second/sentece-pair.

5 Features

The log-linear model allows us to incorporate arbitrary features. In addition to the rules that we are interested in, we also incorporate word-level information and translation boundary information, both of which have proved useful for SMT. Through these features, we can enhance the ability of our model to predict whether a translation derivation is good or not. Notably, previous work typically use such information in locally normalization, while we learn weights of these features by globally normalization on the entire sentence structure.

Rule features We associate each rule with a single feature. Each rule feature counts the number of times that a rule appears in a derivation. In this way, we are able to learn a weight for every rule by global normalization. This is quite different from traditional pipeline that gives each rule with relative frequency that is locally normalized by rules with the same source side or target side.

Word association features As shown in section 4, our inference algorithm also induces inside word alignments for each derivation. Thus, it is straightforward to introduce features that contain word level information. Here, we associate each word pair with a fine-grained boolean feature. We also include the two lexical weights as described by Koehn et al. (2003), estimated by word translation probabilities output by GIZA++. We set the initial weight of these two lexical weights as 1.0. The lexical weights enable our system to score and rank the hyperedges at the beginning. Although word alignment features are used, our system is neither constrained by prefixed word alignment nor requires heuristic alignment combination strategy.

Phrase Boundary features As shown in Figure 1(b), although the rule sequence of the solid derivation and dotted derivation are exactly the same, only solid derivation produces correct translation. They can be distinguished by taking into account boundary information (Xiong et al., 2010; Dyer et al., 2011b). We design two feature templates here: $BE{:}s_i + 1, s_j$ denotes the bigrams of beginning and ending source words. $PS{:}s_i, s_{j+1}$ means the preceding and succeeding source words. We do not use target word information, since this is non-local for hypergraph, and will largely increase the size of hypergraph.

Length Feature Finally, we also integrate the length feature of target side that is used in traditional SMT system.

6 Experiments

In this section, we present our experiments on Chinese-to-English translation tasks. The experiments are aimed at measuring the quality and effectiveness of grammar induced by our method. We present the performance of our unsupervised discriminate synchronous grammar induction (UDSGI) using two groups of features during decoding. We test the translation performance of UDSGI and the baseline on the same decoder.

Baseline The baseline system is an in-house implementation of hierarchical phrase-based translation system(Chiang, 2007). The grammar is extracted from word-aligned corpus by traditional two-step pipeline. Symmetric word alignments were created by first running GIZA++ (Och and Ney, 2003) in both directions and then applying refinement rule "grow-diag-final-and" (Koehn et al., 2003). The system uses 8 dense features including: forward and backward translation probabilities; forward and backward lexical weights; language model; 3 penalties for word count, extracted rule count, and glue rule count.

UDSGI Dense This configuration uses the same feature set as the baseline. Our log-linear model for grammar induction does not contain the forward and backward translation probabilities. However, we still compute the forward and backward translation probabilities for UDSGI by normalizing the expectation $E_{p(\mathbf{d}|\mathbf{t},\mathbf{s})}[H_i]$ of a rule, when algorithm 1 is complete. The normalization is similar to the traditional estimation of these two probabilities.

	|Source Words|		|Target Words|		Number of rules	
Rule Type	Baseline	UDSGI	Baseline	UDSGI	Baseline	UDSGI
Phrase	3.16	2.39	3.97	2.59	2.0M	6.6M
One-NT	3.20	2.31	3.91	2.51	6.4M	2.9M
Two-NT-Mono	2.62	2.52	3.47	2.81	4.2M	2.7M
Two-NT-Swap	2.55	2.46	3.65	2.87	0.5M	0.8M
All Rule	2.89	2.40	3.77	2.63	13.2M	13.1M

Table 1: Comparison of grammars induced by Baseline and UDSGI. Phrase represents the phrase rule. One-NT and two-NT denotes rules contain one or two nonterminals. Mono and Swap means that the two nonterminals are monotone or swapping in the target side. |Source Words| and |Target Words| denotes the average count of source and target terminals in a rule.

UDSGI Dense+Sparse Our global log-linear model encodes millions of sparse features including rule, word pair and phrase boundary features. During decoding, we also enhance our model by these sparse features. In order to optimize these sparse features with the dense features by minimum error rate training (MERT), we group features of the same type into one coarse "summary feature", and get three such features including: rule, word-pair and phrase-boundary features. In this way, we rescale the weights of the three "summary features" with the 8 dense features by MERT. Such approach is similar to Dyer et al. (2011b).

6.1 Data

We used the NIST evaluation set of 2002 (MT02) as our development set for MERT, and test the translation performance on the NIST 2003-2005 (MT03-05) evaluation sets. Case-insensitive NIST BLEU-4 (Papineni et al., 2002) is used to measure translation performance.

We used a bilingual corpus that contains 200K sentence pairs of up to length 40 from the LDC data. [3] There are 8.8M words in the 200K data. We trained a 5-grams language model by the SRILM toolkit (Stolcke, 2002). The monolingual data for language model training includes the Xinhua portion of the GIGAWORD corpus and the English side of the entire LDC data, which contains 432 million words.

We used MERT (Och, 2003) to optimize the feature weights for decoding by maximizing BLEU. Since the instability of MERT has a substantial impact on results, we follow Clark et al. (2011) to report the average scores of 3 independent runs.

6.2 Grammar Analysis and Oracle Results

The synchronous grammar generated by UDSGI has 13.1 millions rules. The number of these rules is comparable with that of grammar extracted by the traditional pipeline, which has 13.2 millions rules. However, the two grammars are quite different as shown in Table 1. Our grammar is more reusable than the baseline's, because it contains less source words and less target words. Interestingly, even we discard the rules which occur only once (See Sec. 4.4), we still learn 60% more swapping rules with two nonterminals (Two-NT-Swap) than the baseline.

[3]The 200K data comes from the following corpus: LDC2002E18, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005T06 and Hansards portion of LDC2004T08 (part of).

System	MT03	MT04	MT05	Avg.
Baseline	64.96	69.48	65.45	66.63
UDSGI	73.37	77.13	74.29	74.93

Table 2: BLEU-4 scores of oracle translations generated by grammars of Baseline and UDSGI. *Avg.* reports the average score on the three test set.

System	$\|\mathbf{G}'\|$	MT03	MT04	MT05	Avg.
Moses-Chart	45.0M	32.93	34.73	31.24	32.97
Baseline	13.2M	32.36	34.51	31.86	32.91
Baseline-expand	46.2M	33.04	35.13	32.08	33.42
UDSGI Dense	13.1M	33.46	35.43	32.74	33.87
UDSGI Dense+Sparse	13.1M	33.58	36.27	33.05	34.30

Table 3: Evaluation of translation quality in terms of BLEU. *Moses-Chart* is the running of hierarchical phrased-model in Moses. *Baseline-expand* uses a similar extraction constraint to Moses-Chart and the same decoder as Baseline. The improvement of UDSGI over Baseline is statistically significant (Koehn, 2004) ($p < 0.01$).

We can not directly evaluate the quality of grammar, since there is not a golden grammar. However, as grammar is used to generate target translations, it's reasonable to decide the quality of a grammar by testing what best translations it can produce. Therefore, we compare the oracle translation result of the grammar in baseline and the grammar in UDSGI, with four reference translations given.[4] As shown in Table 2, our grammar achieves a much higher oracle BLEU (+8.3 BLEU points) than the baseline grammar. This suggests that the grammar induced by our method is able to generate better translations than the grammar extracted by the traditional two-step pipeline.

6.3 Translation Results

Table 3 compares the translation performance of our approach and the baseline on the test sets. When extracting rules as Chiang (2007), the baseline produces an average BLEU of 32.91. We also run Moses-Chart, the implementation of hierarchical phrased-model in Moses (Koehn et al., 2007), on our data with its default settings. As shown in the table, our Baseline is comparable with Moses-Chart. However, Moses-Chart extracts much more rules, because it uses a different extraction constraint from Chiang (2007). The differences mainly include edges of initial phrases can be unaligned and minimum size of source part of sub-phrases is 2.

We also relax the Baseline by applying these two options, and call such setting as *Baseline-expand*. Baseline-expand outperforms Baseline by +0.51 BLEU with 3.5 times of rules. As our UDSGI method learns a similar size of rules with the Baseline's, we only compare our method with the Baseline in the following sections.

Using the same 8 dense features as used in the baseline system, we obtain an average improve-

[4]We calculate the oracle translation by the traditional decoder using sentence BLEU score as feature function. We use add 0.1 smoothing for the ngram precision, and set the reference length for a source span (i,j) as $\lceil \frac{L_{min} \times (j-i)}{|\mathbf{s}|} \rceil$. Here, L_{min} is the shortest length of references for a sentence.

System	$\|G'\|$	MT03	MT04	MT05	Avg.
Baseline	17.6M	33.83	35.94	33.23	34.33
UDSGI Dense+Sparse	13.5M	35.28	37.43	34.25	35.65

Table 4: Experiment results by integrating the entire LDC corpus.

ment of +0.96 BLEU score on the three test sets over the Baseline. As the difference between Baseline and UDSGI Dense only lies in the grammar, the improvement indicates that the grammar induced by UDSGI does outperform that extracted by the traditional two-step pipeline. When we incorporate the sparse features learnt by our training algorithm, we achieve a further improvement of +0.43 BLEU point. Therefore, our training algorithm is able to learn the useful information encoded by the sparse features for translation.

6.4 Exploiting the Entire LDC Data

Since the previous experiment only runs on a medium-scale corpus, we want to know whether the improvement only comes from poor word alignment performance in the baseline system. Therefore, we want to verify the improvement on large-scale data set. Unfortunately, our approach needs to store all rules in memory, which is impractical for large scale data. Instead of directly training on LDC data (357M words), which is 40-times larger than the medium-scale data, we try to explore these data in a different way.

The baseline still extracts rules from the 200K data, while our approach also learns grammar on 200K data. However, we run GIZA++ on the entire LDC data. The word alignment performance of the baseline is therefore enhanced by using all entire data. We used the word translation probabilities of this large-scale trained GIZA++ to calculate lexical weights in our model during training.

Table 4 shows the results. Not surprisingly, the performance of baseline significantly increases by 1.4 points, due to the improvement of word alignment quality and the larger number of extracted rules. Interestingly, our method also achieves similar improvements with enhanced GIZA++. Still, our approach outperforms the baseline by +1.3 points, which is quite close to the improvement in medium-scale corpus experiments. Furthermore, the grammar in UDSGI is smaller than the grammar of the baseline (76.7%). Therefore, we believe that our improvement comes from the theoretical advantage of our approach, and that such advantage does exist even on large-scale data.

7 Related Work

Because of the great importance of synchronous grammars to SMT systems, researchers have proposed various methods in order to improve the quality of grammars. In addition to the generative model introduced in Section 1, researchers also have made efforts on word alignment and grammar rescoring.

The first effort is to improve word alignment by considering phrase/syntax information (May and Knight, 2007; DeNero and Klein, 2010; Pauls et al., 2010; Burkett et al., 2010; Riesa et al., 2011). Such approaches also use discriminative framework to combine word alignment and syntactic alignment information. In this way, they prefer word alignments that are consistent with syntactic structure alignments. However, labeled word alignment data are required in order to learn the discriminative model.

Researchers also try to rescore the weights of translation rules. They rescore the weights of rules extracted from the two-step pipeline, by using the similar latent log-linear model as us (Blunsom et al., 2008; Kääriäinen, 2009), or incorporating various features using labeled data (Huang and Xiang, 2010). Such methods still need to run the heuristic two-step pipeline to extract the grammar, while our method can directly learn the grammar and correspondent weights.

Our work also has a connection to the research direction that exploits resources-rich languages to construct similar tools for resource-poor languages. This can be done with parallel data (Pauls et al., 2010) or without parallel data (Cohen et al., 2011).

Saers et al. (2009) also propose a cubic biparsing algorithm based on beam pruning. They apply this algorithm for generative model-based ITG grammar induction.

Conclusion and Future Work

We have presented a global log-linear model for synchronous grammar induction, and have also proposed efficient training and inference algorithms. In addition to the theoretical advantage, we also achieve significant improvements over the traditional heuristic two-stage pipeline on both medium-scale and large-scale training data.

In the future, we hope to find efficient algorithms that are capable of incorporating contextual features, especially language model and context-based translation model, and optimizing parameters by maximizing BLEU. Because our proposed model is quite general, we are also interested in applying this method to linguistically syntax-based SMT.

ABSTRACT
We present initial investigation into the task of paraphrasing language while targeting a particular writing style. The plays of William Shakespeare and their modern translations are used as a testbed for evaluating paraphrase systems targeting a specific style of writing. We show that even with a relatively small amount of parallel training data, it is possible to learn paraphrase models which capture stylistic phenomena, and these models outperform baselines based on dictionaries and out-of-domain parallel text. In addition we present an initial investigation into automatic evaluation metrics for paraphrasing writing style. To the best of our knowledge this is the first work to investigate the task of paraphrasing text with the goal of targeting a specific style of writing.

KEYWORDS: Paraphrase, Writing Style.

Proceedings of COLING 2012: Technical Papers, pages 2899–2914,
COLING 2012, Mumbai, December 2012.

1 Introduction

The same meaning can be expressed or *paraphrased* in many different ways; automatically detecting or generating different expressions with the same meaning is fundamental to many natural language understanding tasks(Giampiccolo et al., 2007), so much previous work has investigated methods for automatic paraphrasing(Madnani and Dorr, 2010).

Paraphrases can differ along many dimensions, including utterance length, diction level, and speech register. There is a significant literature in sentence compression aimed at modeling the first of these, length: producing meaning-preserving alternations that reduce the length of the input string (Chandrasekar et al., 1996; Vanderwende et al., 2007; Clarke and Lapata, 2008; Cohn and Lapata, 2009; Yatskar et al., 2010). However, we know of no previous work aimed at modeling meaning-preserving transformations that systematically transform the register or style of an input string. Can we learn to reliably map from one form of language to another, transforming formal prose into a more colloquial form, or a casual email into a more formal equivalent?

Systems capable of paraphrasing text targeting a specific writing style could be useful for a variety of applications. For example, they could:

1. Help authors of technical documents to adhere to appropriate stylistic guidelines.

2. Enable non-experts to better consume technical information, for example by translating legalese or medical jargon into nontechnical English.

3. Benefit educational applications, allowing students to:

   (a) Access *modern English* versions of works by authors they are studying.

   (b) Experiment with writing in the style of an author they are studying.

In this paper, we investigate the task of automatic paraphrasing while targeting a particular writing style, focusing specifically on the style of Early Modern English employed by William Shakespeare. We explored several different methods, all of which rely on techniques from phrase-based MT, but which were trained on different types of parallel monolingual data. The first system was trained on the text of Shakespeare's plays, along with parallel modern English "translations" that were written to help students better understand Shakespeare's work. We also developed several baselines which do not make use of this parallel text and instead rely on manually compiled dictionaries of expressions commonly found in Shakespearean English, or existing corpora of out-of-domain parallel monolingual text.

We evaluate these models both through human judgments and standard evaluation metrics from the Machine Translation (MT) and Paraphrase literature, however no previous work has investigated the ability of automatic evaluation metrics to capture the notion of writing style. We show that previously proposed metrics do not provide the complete picture of a system's performance when the task is to generate paraphrases targeting a specific style of writing. We therefore propose three new metrics for evaluating paraphrases targeting a specific style, and show that these metrics correlate well with human judgments.

corpus	initial size	aligned size	No-Change BLEU
http://nfs.sparknotes.com	31,718	21,079	24.67
http://enotes.com	13,640	10,365	52.30

Table 1: Parallel corpora generated form modern translations of Shakespeare's plays

2 Shakespearean Paraphrasing

We use Shakespeare's plays as a testbed for the task of paraphrasing while targeting a specific writing style. Because these plays are some of the most highly-regarded examples of English literature and are written in a style that is now 400 years out of date, many linguistic resources are available to help modern readers pick their way through these Elizabethan texts. Among these are "translations" of the plays into colloquial English, as well as dictionaries that provide modern equivalents for archaic words and phrases.

We compare 3 different stylistic paraphrase systems targeting Shakespearean English which rely on different types of linguistic resources. One leverages parallel "translations", another exploits dictionary resources, and a third relies on modern, out-of-domain monolingual parallel data and an in-domain language model.

2.1 Modern Translations

Access to parallel text in the target style allows us to train statistical models that generate paraphrases, and also perform automatic evaluation of semantic adequacy using BLEU, which requires availability of reference translations. For this purpose we scraped modern translations of 17 Shakespeare plays from `http://nfs.sparknotes.com`, and additional translations of 8 of these plays from `http://enotes.com`.

After tokenizing and lowercasing, the plays were sentence aligned (Moore, 2002), producing 21,079 alignments from the 31,718 sentence pairs in the Sparknotes data, and 10,365 sentence pairs from the 13,640 original pairs in the Enotes data. The modern translations from the two sources are qualitatively quite different. The Sparknotes paraphrases tend to differ significantly from the original text, whereas the Enotes translations are much more conservative, making fewer changes. To illustrate these differences empirically and provide an initial paraphrase baseline, we computed BLEU scores of the modern translations against Shakespeare's original text; the Sparknotes paraphrases yield a BLEU score of 24.67, whereas the Enotes paraphrases produce a much higher BLEU of 52.30 reflecting their strong similarity to the original texts. These results are summarized in Table 1.

To generate paraphrases, we applied a typical phrase-based statistical MT pipeline, performing word alignment on the data described in table 1 using GIZA++ (Och and Ney, 2003), then extracting phrase pairs and performing decoding using Moses (Koehn et al., 2007).

For evaluation purposes, the parallel text of one play, Romeo and Juliet, was held out of the training corpus for this system and the baseline systems described in the following section.

2.2 Baselines

Phrase-based translation has been demonstrated as an effective approach to paraphrasing (Quirk et al., 2004; Chen and Dolan, 2011). However, this approach does require the existence

target	source	target	source
ABATE	shorten	AYE	always
CAUTEL	deceit	GLASS	mirror
SUP	have supper	VOICE	vote

Smoothed Probability Estimate	target	source
0.0000790755	PERCHANCE	maybe
0.00003691883	PERADVENTURE	maybe
0.00007524298	HAPLY	maybe
0.00007141065	HAPPILY	maybe
total 0.00026264791		

Table 3: Example ngram probabilities in target language

of parallel corpora of aligned phrases and sentences, resources which may not be available for many writing styles that we might wish to target. For this reason we were motivated to investigate alternative approaches in order to help quantify how critical this type of parallel data is for the task of stylistic paraphrasing.

2.2.1 Dictionary Based Paraphrase

Several dictionaries of stylistically representative words of Shakespearean English and their modern equivalents are available on the web. These dictionaries can be used to define a translation model which can be used in combination with a language model as in standard phrase-based MT.

To build a phrase table, we scraped a set of 68,709 phrase/word pairs from `http://www.shakespeareswords.com/`; example dictionary entries are presented in table 2. As described in (Koehn and Knight, 2000), we estimate phrase translation probabilities based on the frequencies of the translation words/phrases in the target language (Shakespearean English). For instance, if we look at the modern English word *maybe*, our dictionary lists 4 possible Shakespearean translations. We obtained the probabilities for each translation according to the n-gram back-off model built from 36 of Shakespeare's plays using the SRILM toolkit (Stolcke, 2002), normalizing the probabilities for each source phrase, for example $p(\text{PERCHANGE}|\text{maybe}) = \frac{0.0000790755}{0.00026264791} = 0.30107035689$. An example is presented in Table 3. This method allows us to estimate reasonable translation probabilities for use in a phrase table, which is used in combination with a language model built from the 36 plays, which are then fed into the Moses decoder (Koehn et al., 2007).

2.2.2 Out of Domain Monolingual Parallel Data

As a final baseline we consider a paraphrase system which is trained on out-of-domain data gathered by asking users of Amazon's Mechanical Turk Service (Snow et al., 2008) to caption the action in short video segments (Chen and Dolan, 2011). We combined a phrase table extracted from this modern, out of domain parallel text, with an in-domain language model consisting of Shakespeare's 36 plays, applying the Moses decoder (Koehn et al., 2007) to find the best

paraphrases. Although this monolingual parallel data does not include text in the target writing style, the in-domain language model does bias the system's output towards Shakespeare's style of writing. We found that performing Minimum Error Rate Training (Och, 2003) using a small set of held out parallel text from Romeo and Juliet was necessary in order to tune the video corpus baseline to generate reasonable paraphrases.

2.3 Comparison Using Existing Automatic Evaluation Metrics

Figure 1 compares a variety of systems targeting Shakespearean English using the previously proposed BLEU (Papineni et al., 2002) and PINC (Chen and Dolan, 2011) automatic evaluation metrics which have been demonstrated to correlate with human judgments on semantic adequacy and lexical dissimilarity with the input. A description of each of the systems compared in this experiment is presented in Table 4. As mentioned in §2.1, the Enotes paraphrases diverge little from the original text, resulting in a BLEU score of 52.3 when compared directly to the original lines from Shakespeare's plays. Because our goal is to produce paraphrases which make more dramatic stylistic changes to the input, in the remainder of this paper, we focus on the Sparknotes data for evaluation.

2.3.1 Discussion

Two main trends are evident in Figure 1. First, notice that all of the systems trained using parallel text achieve higher BLEU scores than the unmodified modern translations. While the dictionary baseline achieves a competitive PINC score, indicating it is making a significant number of changes to the input, its BLEU is lower than that of the modern translations. Secondly, it seems apparent that the systems whose parameters are tuned using Minimum Error Rate Training tend to be more conservative, making fewer changes to the input and thus achieving lower PINC scores, while not improving BLEU on the test data. Finally we note that using the larger target language model seems to yield a slight improvement in BLEU score.

2.4 Examples

Example paraphrases of lines from *Romeo and Juliet* and several Hollywood movies, generated by the top performing system according to BLEU and PINC, are presented in table 5.

3 Human Evaluation

Figure 1 provides some insight into the performance of the various systems, but it is initially unclear how well the BLEU and PINC automatic evaluation metrics perform when applied to paraphrases that target a specific style of writing. BLEU and PINC have previously been shown to have high correlation with human judgments of semantic adequacy and lexical dissimilarity of paraphrase candidates, but the implications of this for the more specialized task of stylistic paraphrasing are unclear.

While BLEU is typically used to measure semantic adequacy, it seems reasonable to assume that it could also be useful for measuring stylistic alternations, since utterances are more likely to contain overlapping ngrams if they are both semantically and stylistically similar. What BLEU cannot tell us, however is what portion of its improvements are due to stylistic similarity or semantic equivalence. For this reason, we were motivated to perform an evaluation based on human judgments of semantic adequacy, lexical dissimilarity and stylistic similarity.

For this purpose, we randomly sampled 100 lines from *Romeo and Juliet*, then two of the authors

System	Description
16and7plays_36LM	Phrase table extracted from all 16 Sparknotes plays and 7 Enotes plays (holding out R&J) and language model built from all 36 of Shakespeare's plays, again excluding R&J. Uses default Moses parameters.
16and7plays_36LM_MERT	Same as 16and7plays_36LM except parameters are tuned using Minimum Error Rate Training (Och, 2003).
16and7plays_16LM	Phrase table is built from both Sparknotes and Enotes data, and Language model is built from the 16 plays with modern translations
16and7plays_16LM_MERT	Same as 16and7plays_16LM except parameters are tuned using MERT.
16plays_36LM	Only Sparknotes modern translations are used. All 36 plays are used to train Shakespearean language model.
16plays_36LM_MERT	Same as 16plays_36LM except parameters are tuned using MERT.
video_corpus_baseline	Paraphrase system combining out of domain parallel text (Chen and Dolan, 2011) with an in-domain language model. Described in detail in §2.2.2.
modern (no change)	No changes are made to the input, modern translations are left unchanged.
Dictionary	Dictionary baseline described in §2.2.1

Table 4: Descriptions of various systems for Shakespearean paraphrase. *Romeo and Juliet* is held out for testing.

annotated each sentence and its Shakespearean translation to indicate semantic adequacy, lexical dissimilarity, stylistic similarity, and overall quality. The aggregate results of the human evaluation are displayed in Figure 2. Agreement between annotators measured using Pearson's ρ is displayed in Table 6.

Based on the human evaluation, it appears that the baseline combining paraphrases collected from Mechanical Turk (Chen and Dolan, 2011) with a Shakespearean language model has the highest semantic adequacy, yet this approach is also fairly conservative in that it makes few changes to the input.

The dictionary baseline, and the paraphrase system trained on parallel modern translations are roughly comparable in terms of the number of changes made to the input, but the system trained on modern translations achieves higher semantic adequacy, while also being rated higher on style and overall.

These results are roughly in line with the automatic metrics presented in Figure 1. However we also see several important trends which are not apparent from the automatic evaluation. Although the video baseline achieves the highest semantic adequacy in the human evaluation,

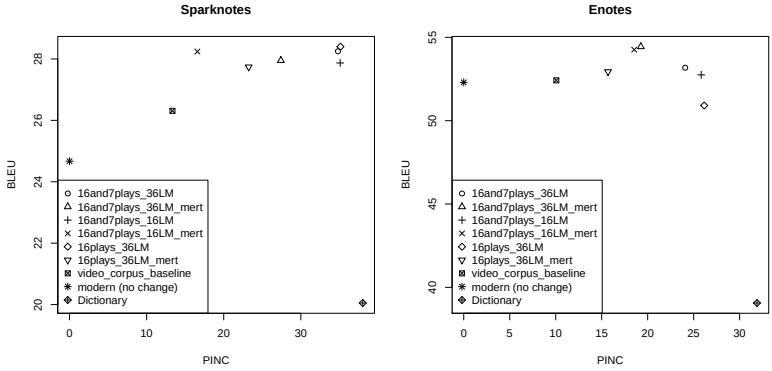

Figure 1: Various Shakespearean paraphrase systems compared using BLEU and PINC. A brief description of each system is presented in table 4.

its BLEU score is significantly lower than 16plays_36LM on the Sparknotes data.[1] It would appear that in this case BLEU is conflating semantic adequacy with writing style. Although the paraphrases produced by the video baseline have high semantic adequacy, their style tends to differ substantially from the reference translations resulting in fewer ngram matches, and thus a lower BLEU score.

4 Automatic Metrics Evaluating Writing Style

While PINC and BLEU do seem useful for automatically evaluating stylistic paraphrases, BLEU tends to conflate the notions of semantic adequacy with writing style. When comparing various systems using automatic metrics, it would seem useful to separate the effects caused by these two distinct criteria. We would like our automatic evaluation metrics to distinguish between a system which generates perfect paraphrases which do not match the target style of writing versus a system which generates sentences in the correct style, but which convey different meaning.

To help address this issue we propose three new automatic evaluation metrics whose goal is to measure the degree to which automatic paraphrases match the target style. These metrics assume existence of large corpora in both the source and target style, but do not require access to any parallel text, or human judgments.

We present a preliminary evaluation of the proposed metrics by measuring their correlation with human judgments, but it should be emphasized that we are only evaluating these metrics with respect to one specific style of writing. We are optimistic that these results will generalize across writing styles, however, since they are based entirely on ngram statistics.

[1] Note that the BLEU score of 16plays_36LM is significantly lower when evaluated on the Enotes data. This makes sense, because the 16 plays come from Sparknotes. This system is not trained on the 7 Enotes plays which, whose modern translations tend to be slightly different in style.

Source	Speaker	Input	Output
Romeo & Juliet	Benvolio	He killed your relative, brave Mercutio, and then young Romeo killed him.	he slew thy kinsman , brave mercutio , and then young romeo kill him .
Romeo & Juliet	Romeo	I can read my own fortune in my misery.	i can read mine own fortune in my woes .
Star Wars	Palpatine	If you will not be turned, you will be destroyed!	if you will not be turn 'd , you will be undone !
Star Wars	Luke	Father, please! Help me!	father , i pray you , help me !
The Matrix	Agent Smith	Good bye, Mr. Anderson.	fare you well , good master anderson .
The Matrix	Morpheus	I'm trying to free your mind, Neo. But I can only show you the door. You're the one that has to walk through it.	i 'll to free your mind , neo. but i can but show you the door. you 're the one that hath to tread it .
Raiders of the Lost Ark	Belloq	Good afternoon, Dr. Jones.	well met , dr. jones .
Raiders of the Lost Ark	Jones	I ought to kill you right now.	i should kill thee straight .

Table 5: Example Shakespearean paraphrases generated by the best overall system.

Semantic Adequacy	Lexical Dissimilarity	Style	Overall
0.73	0.82	0.64	0.62

Table 6: Agreement between annotators measured using Pearson's ρ.

4.1 Cosine Similarity Style Metric

As a first approach to automatic evaluation of writing style, we present a vector-space model of similarity between the system output and a large corpus of text in both the source and target style. The intuition behind this metric is that a large ngram overlap between the system's output and a corpus of text in the target style should indicate that the output is likely to be stylistically appropriate.

More concretely, we extract ngrams from both the source and target corpus which are represented as binary vectors $\vec{s}$, and $\vec{t}$; similarly the output sentence is represented using a vector of ngrams $\vec{o}$. The proposed metric is the normalized cosine similarity between the source and target corpora:

$$S_{\text{Cosine}}(\vec{o}) = \frac{\frac{\vec{o}\cdot\vec{t}}{\|\vec{o}\|\times\|\vec{t}\|}}{\frac{\vec{o}\cdot\vec{t}}{\|\vec{o}\|\times\|\vec{t}\|} + \frac{\vec{o}\cdot\vec{s}}{\|\vec{o}\|\times\|\vec{s}\|}}$$

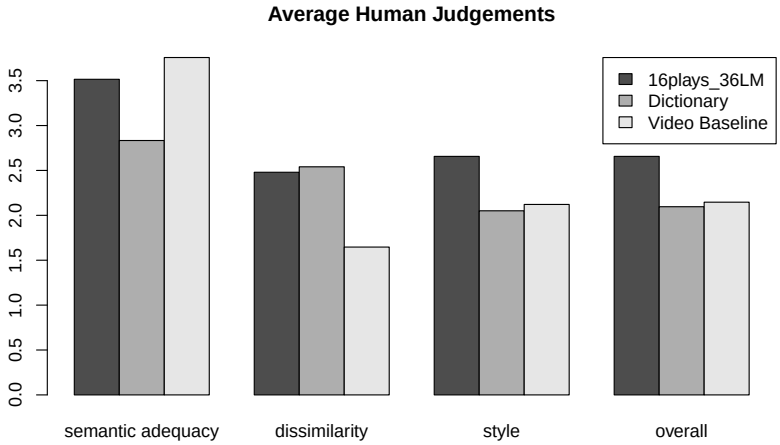

Figure 2: Average human judgments evaluating semantic adequacy, lexical dissimilarity, stylistic similarity, and overall quality of Shakespearean paraphrase systems

4.2 Language Model Style Metric

Another approach is to build a language model from a corpus of text in the target style and a background language model from text outside the style, then apply Bayes' rule to estimate the posterior probability that a sentence was generated from the target language model[2]:

$$\begin{aligned} P(\text{style} = \text{target}|\text{sentence}) &= \frac{P_{\text{LM}}(\text{sentence}|\text{target})P(\text{target})}{P(\text{sentence})} \\ &= \frac{P_{\text{LM}}(\text{sentence}|\text{target}) \times 0.5}{P_{\text{LM}}(\text{sentence}|\text{target}) \times 0.5 + P_{\text{LM}}(\text{sentence}|\text{source}) \times 0.5} \\ &= \frac{P_{\text{LM}}(\text{sentence}|\text{target})}{P_{\text{LM}}(\text{sentence}|\text{target}) + P_{\text{LM}}(\text{sentence}|\text{source})} \end{aligned}$$

4.3 Logistic Regression Style Metric

We also consider an approach to measuring style which is based on logistic regression. Here the idea is to estimate the probability that each sentence belongs to the target style based on the ngrams it contains, using large corpora of *in domain* and *out-of domain* sentences to learn parameters of a logistic regression model.

The probability that a sentence belongs to the target style is estimated as follows:

$$P(\text{style} = \text{target}|\text{sentence}) = \frac{1}{1 + e^{-\left(\vec{\theta} \cdot f(\vec{\text{sentence}})\right)}}$$

[2] Here we assume an uninformative prior, that is $P(\text{source}) = P(\text{target}) = 0.5$.

		ρ (Annotator 1)	ρ (Annotator 2)
semantic adequacy	BLEU	0.35	0.31
dissimilarity	PINC	0.78	0.82
style	BLEU	0.07	0.06
style	PINC	0.20	0.45
style	Cosine	0.37	0.41
style	LM	0.46	0.51
style	Logistic regression	0.47	0.47

Table 7: Correlation between various human judgments and automatic evaluation metrics. Pearson's correlation coefficient is displayed between the automatic metrics and human judgments from each annotator.

Where $f(\vec{\text{sentence}})$ is a vector of ngrams contained by the sentence, and $\vec{\theta}$ is a vector of weights corresponding to each possible ngram.

The parameters, $\vec{\theta}$, are optimized to maximize conditional likelihood on the source and target corpus, where the assumption is that the target corpus is in the target style, whereas the source corpus is not.[3]

4.4 Evaluation

We trained the logistic regression, language model and cosine similarity evaluation metrics using the original Shakespeare plays and modern translations as the source and target corpus respectively, then measured Pearson's Correlation Coefficient between the automatic evaluation metrics and human judgments described in §3. These results are reported in table 7.

As can be seen in table 7, the correlation between semantic adequacy and BLEU appears smaller than that reported in previous work (Chen and Dolan, 2011). Presumably this is due to the conflation of stylistic differences and semantic adequacy discussed in §3. However it also appears that the correlation between BLEU and human style judgments is too low to be of practical use for evaluating style.

PINC, on the other hand has high correlation with judgments on dissimilarity, and is also correlated with human style judgments. We believe PINC has correlation with writing style, because the systems we are evaluating all target Shakespearean English, so whenever changes are made to the input, they are likely to make it similar to the target style. Although PINC has relatively high correlation with human judgments, it is likely not a very useful measure of writing style in practice. For example, consider a paraphrase system which makes many changes to the input and thus gets a high PINC score, but targets a completely different writing style.

Both the language model and logistic regression style metrics achieve the highest overall correlation with human writing style judgments, achieving comparable performance.

We note that overall the automatic metrics tend to agree with human judgments as displayed in Figure 3.[4]

[3] Parameters were optimized using MEGAM `http://www.cs.utah.edu/~hal/megam/`.

[4] Although the automatic style metrics rate the dictionary system higher than the video corpus baseline, both systems have very comparable style scores in the automatic and human evaluations.

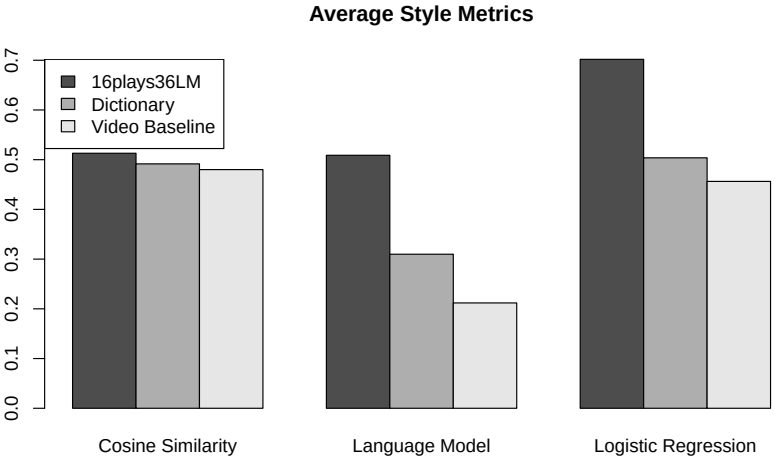

Figure 3: Results comparing the 3 systems using the automatic style metrics.

		ρ (Annotator 1)
semantic adequacy	BLEU	0.27
dissimilarity	PINC	0.79
style	BLEU	0.12
style	PINC	0.41
style	Cosine	0.37
style	LM	0.45
style	Logistic regression	0.46

Table 8: Correlation between human judgments and automatic evaluation metrics when paraphrasing Shakespeare's plays into modern prose.

5 Translating Shakespeare's Plays to Modern English

Finally we perform an evaluation on the task of automatically translating Shakespeare's plays into modern English.

For the purposes of this evaluation, we make use of the same paraphrase systems previously described, but swap the source and target languages. Additionally, each system makes use of a language model constructed from the 16 modern translations, with *Romeo and Juliet* held out for testing. 100 lines from *Romeo and Juliet* were automatically translated into modern English using each system, and the aligned modern translations were used as a reference when computing BLEU. The results of evaluating each of the automatic evaluation metrics on this data are presented in Figure 5, correlation of the automatic metrics with with human judgments are presented in Table 8 and average human judgments are presented in Figure 4.

These results suggest that in comparison to the dictionary and video corpus baselines, our

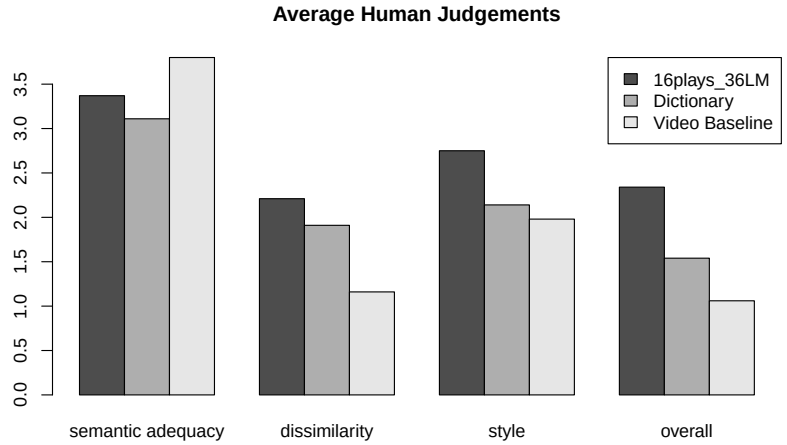

Figure 4: Average human judgments translating Shakespeare's plays into modern English.

system trained on modern translations generates a large number of paraphrases which match the target style. Note that the paraphrase system based on the out-of-domain video corpus makes very few changes to the input, and thus achieves a very low PINC score. This is due to the many out of vocabulary words in Shakespeare's plays which result in very few matching source phrases in the video baseline's phrase table. Several automatic paraphrases into modern English are presented in Table 9.

6 Related Work

Much previous work has addressed the task of automatically generating paraphrases (Barzilay and Lee, 2003; Dolan et al., 2004; Shinyama and Sekine, 2003; Das and Smith, 2009; Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Kok and Brockett, 2010). In addition several authors have previously proposed automatic metrics specifically for evaluating paraphrases (Chen and Dolan, 2011; Callison-Burch et al., 2008; Liu et al., 2010). We are not aware, however, of any work that has addressed the task of generating or evaluating paraphrases targeting a specific style of writing.

Perhaps most relevant, however, is recent work on automatic generation of rhythmic poetry (Greene et al., 2010). This work focuses on automatically generating and translating poetry in an appropriate meter (e.g. iambic pentameter) using finite-state transducers, but does not investigate the task of paraphrase. Their generation system is trained on Shakespeare's sonnets, and they investigate the task of automatically translating Dante's Divine Comedy from Italian to English. While our work does not address the issue of meter, it should be possible to combine our translation models with their weighted finite state transducers to produce Shakespearean paraphrase models which produce output in an appropriate meter.

Finally we highlight related work on authorship classification which can be seen as detecting a specific style of writing (Gamon, 2004; Raghavan et al., 2010). This work has not specifically

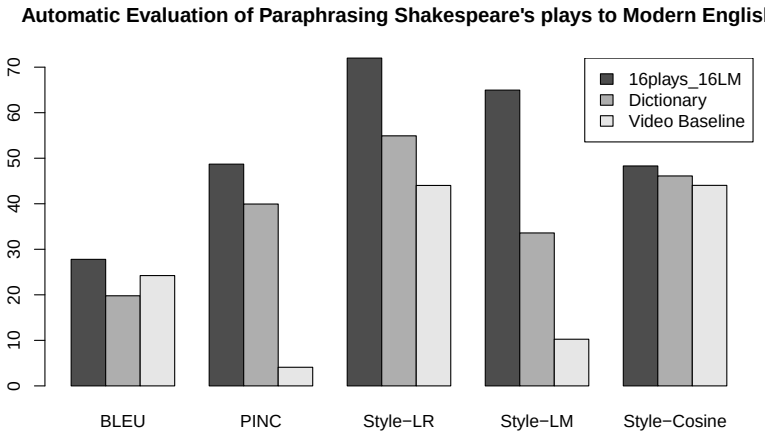

Figure 5: Automatic evaluation of paraphrasing Shakespeare's plays into modern English comparing a system based on parallel text (16plays_16LM), a Dictionary baseline, and a system trained on out of domain parallel monolingual text. Note that the video corpus baseline achieves low overall PINC score, as few phrases in the input match phrases found in its phrase table, resulting in a small number of changes to the input.

Speaker	Input	Output
MERCUTIO	i will bite thee by the ear for that jest .	i ' ll bite you by the ear for that joke .
MONTAGUE	what further woe conspires against mine age ?	what ' s true despair conspires against my old age ?
ROMEO	how doth my lady ?	how is my lady ?
FRIAR LAURENCE	hast thou slain tybalt ?	have you killed tybalt ?
NURSE	an i might live to see thee married once , i have my wish .	if i could live to see you married , i ' ve my wish .
PRINCE	benvolio , who began this bloody fray ?	benvolio , who started this bloody fight itself ?
JULIET	what is your will ?	what do you want ?
LADY CAPULET	call her forth to me .	bring her out to me .

Table 9: Example modern paraphrases of lines from Romeo and Juliet generated using our system.

addressed the task of automatically generating or evaluating paraphrases in a specific style, however.

7 Conclusions

We have presented the first investigation into the task of automatic paraphrasing while targeting a specific writing style. Using Shakespeare's plays and their modern translations as a testbed for this task, we developed a series of paraphrase systems targeting Shakespearean English. We showed that while existing evaluation metrics are useful for evaluating paraphrases in this context, BLEU tends to conflate semantic equivalence with writing style and thus gives an incomplete picture of system performance on these different dimensions.

To address this problem, we introduced three new metrics for evaluating writing style, one based on cosine similarity one based on language models, and the third based on logistic regression. We measured correlation between automatic metrics and human judgments, and showed that our new metrics have better correlation with human judgments than existing metrics in the context of our task. While this evaluation is limited to one specific style of writing, we are optimistic that these or similar metrics will also perform well when evaluating paraphrase systems targeting other writing styles.

We have shown that access to even a small amount of parallel text produces paraphrase systems capable of generating a large number of stylistically appropriate paraphrases while preserving the meaning of the input text. Our paraphrase systems targeting Shakespearean English could be beneficial for educational applications, for example helping to make Shakespeare's work accessible to a broader audience. Future work could investigate stylistic paraphrasing in other domains, such as paraphrasing emails into formal documents, or translating legal documents into nontechnical English.

ABSTRACT
Automatic error correction systems for English as a Second Language(ESL) speakers often rely on the use of a *confusion set* to limit the choices of possible correction candidates. Typically, the confusion sets are either manually constructed or extracted from a corpus of manually corrected ESL writings. Both options require the involvement of English teachers. This paper proposes a method to automatically construct confusion sets for commonly used prepositions from non-ESL corpus without manual intervention. The proposed method simulates how ESL learners learn both the intensions and extensions of English words from standard English text. Our experimental results suggest that the automatically constructed confusion sets based on the similarities between the learned words' intensions is competitive with those directly learned from an ESL corpus containing about 150K preposition usages.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE, L_2 (OPTIONAL, AND ON SAME PAGE)

通过分析单词的内涵和外延来对用词混淆建模

针对把英语作为第二语言的人群的自动语法纠错系统，通常会需要使用“混淆集”来限制系统纠错的种类。一般来说，这些混淆集或者是由专家总结经验得出，或者是从被专家纠错过的文字当中提取的。这两种方法都需要英语专家的介入。在这篇论文当中，我们提出了一种无需专家介入，自动建立常用介词混淆集的方法。在此方法中，我们对英语单词的内涵和外延建模，并且模拟了英语学习者们学习单词内涵和外延的过程。实验表明，使用单词内涵之间的相似度来创建的混淆集，与从含15万介词的标注语料当中提取的混淆集质量是相当的。

1 Introduction

A large portion of the English text (e.g., on the web) is written by people whose native language is not English. Many *English as a Second Language* (ESL) writers, even those with a high level of proficiency, make common grammatical mistakes. Researchers working on Grammar Error Correction (GEC) try to analyze the patterns of these mistakes in order to understand the underlying reasons for their occurrence and to build tools that help ESL writers to correct their errors (Leacock et al., 2010).

Many recently developed GEC systems (Chodorow et al., 2007; J. R. Tetreault & Chodorow, 2008; Gamon et al., 2009; Liu et al., 2010; Rozovskaya & Roth, 2011; Dahlmeier & Ng, 2011a) share a similar infrastructure: first, they isolate some specific types of errors (e.g., preposition errors, article errors, or word choice errors); then, they propose a correction for each instance by treating it as a classification problem. To cast the correction problem as a classification problem, the system has to know, a priori, what are the set of possible corrections for an error. That is, the system needs to pre-define a *confusion set* for each error type.

Previous work has shown the importance of the role of confusion sets. However, the construction of confusion sets requires a great deal of human involvement. English teachers are involved in Liu et al. (2010) to manually filter the initial large verb confusion sets; Rozovskaya & Roth (2010a) used annotated ESL corpus to limit their confusion sets for prepositions. They have shown that even for closed word classes such as prepositions, limiting the confusion sets help simplify the classifiers' tasks and finally lead to both a better precision and recall.

In this paper, we propose a method to automatically construct confusion sets without manual intervention or an annotated ESL corpus. Our approach is to model and simulate how ESL learners might learn words from reading English text. In the process of mastering the language, the learners are often confused about how to choose between similar words. Our goal in this work is to build a model that analyzes which words might appear similar to each other to an ESL learner and then builds up confusion sets with those words. The work presented in this paper addresses learning frequently used *prepositions*, but the idea may be generalized to open word classes.

Our simulation focuses on two main aspects of learning new words: learning their intensions and extensions. The intension of a word is often implied by its definition and its relations to other words; the extension of a word is often characterized by its usages[1]. Ultimately, ESL learners need to achieve a compatible understanding of both the word's intensions and extensions; but before that happens, they may confuse words that have either similar intensions or extensions. Our proposed model applies an algorithm called Relevance Component Analysis (Bar-Hillel et al., 2006) to describe how an ESL learner might organize the extensional representations of words onto an intensional space. We then build up confusion sets with words that have similar intensions.

We compare our model against two models that simulate how learners obtain words' intensions and extensions separately. Under the intensions-only model, word choice confusions are directly measured by the semantic similarity between words. Under the extensions-only model, word choice confusions are attributed to the learner not having completely mastered a word's usages; it can be seen as a faulty language model. In our experiments, we found that, by considering the

[1]We use the terms *intension* and *extension* following the definitions from from Linguistics literature(see, for example, Chalmers (2002)).

interaction of word intensions and extensions, our proposed model produces better confusion sets than those which consider them separately; moreover, the resulting confusion sets are competitive with those directly learned from an error-annotated ESL corpus containing 150K preposition usages.

2 Background

The mistakes made by ESL writers are not random. In their studies, Rozovskaya & Roth (2011) find that those who share the same native language tend to make similar types of mistakes. The natural question that arises is: what are the underlying causes for the mistakes? In the frame of computational linguistics research, the question might be rephrased as: Can we build a mathematical model that simulates ESL writing mistakes?

A model that builds a table of **confusion sets** whose distributions correlate well with the mistakes made by ESL writers is an important component in simulating ESL writing. For instance, Brockett et al. (2006) simulates an ESL corpus according to a set of manually constructed rules, which would not be available until confusion sets are established.

In addition to aiding our understanding of the underlying causes of ESL writing mistakes, confusion sets also have useful practical applications. Generally speaking, reducing the confusion set helps lead the classifiers in the GEC system to a better performance by prohibiting them from considering the outcomes that are both *unlikely* and *misleading*. For example, although ESL learners normally would not confuse *within* with *in*, classifiers may have difficulties telling them apart. Therefore, eliminating *within* from *in*'s confusion set may help the classifier. Generally speaking, by reducing the confusion set's size to rule out these outcomes, although the systems will be disabled from correcting certain types of mistakes, they will often increase the accuracies on more prevalent error types and finally lead to a better *overall* performance. In the past, Rozovskaya & Roth (2010a) showed that by limiting the size of the confusion set for prepositions, their GEC system's performance improved.

One challenge in building a model of confusion sets is that automatic methods typically generate huge lists of words, given the many possible factors that contribute to confound ESL writers. For instance, Dahlmeier & Ng (2011a) observed that ESL collocation errors may be due to similarities of the words' spellings, pronunciations, synonyms, and paraphrases in the writer's native language (L1). However, by including all words that are similar according to any of these factors, one would end up with a large confusion set which introduces difficulties for the classification tasks down the GEC pipeline.

A possible solution is to ask human experts using their knowledge about ESL mistakes to restrict the confusion set. This is the approach taken by Liu et al. (2010) for their GEC system for verb selection. Another alternative is to make use of an ESL corpus in which the mistakes have been corrected by an English teacher; in this case, the confusion sets can be tabulated from the annotations (Rozovskaya & Roth, 2010a; Dahlmeier & Ng, 2011a). A benefit of the corpus-driven approach is that the resulting confusion sets provide a reliable estimation of the distributions of the underlying error patterns. However, this type of annotated corpora take time and effort to develop. Moreover, even when an ESL student makes many mistakes, the proportion of the writing that contains no error is still much greater. For example, in the NUS Corpus of Learner English (NUCLE) corpus (Dahlmeier & Ng, 2011b), there are a total of 3,302 preposition mistakes out of a total of 147,087 prepositions. Therefore, to build confusion sets for open class words such as verbs, one would need a very large annotated corpus.

To address the challenge without relying on extensive human involvement, this paper proposes methods to construct confusion sets directly from standard English corpora (Section 3). We conjecture that standard English corpora contain enough information for us to infer ESL learners confusions. This is because learners' confusions are mainly caused by learners' understandings of word similarities, which is developed while studying standard English texts.

What knowledge do ESL learners learn about words? There are mainly two views. One view is that learning words mean understanding the words' meanings and their relations to one another. Another view is that learning words mainly means understanding which word to choose under which conditions.

In *lexical semantics*, people hold the first view. In this area, researchers try to find how and what words mean, denote, and their relations/similarities. This view tends to explain the cause of confusions to be the similarities between words. Dahlmeier & Ng (2011a); Liu et al. (2010) take this view in confusion set construction. They build confusion sets containing the words that are similar in semantic meanings.

In *language modeling*, people hold the second view. People consider the ability of choosing the appropriate word under each context to imply the mastery of the *language*, which include the understandings of the *words* in the language. This view tends to explain the cause of confusions to be the learners' incapability to completely manage how to use words.

3 Automatic Confusion Sets Construction

ESL writers are more likely to confuse words that they find to be similar during their language learning. In this section we present three models that simulates how ESL learners might learn words. In the first two subsections, we describe models of separately learning words' intensions and extensions, respectively. In the last subsection, we introduce a model that is optimized for learning the intensions and extensions of words all together. Within each subsection, we also develop the reason of ESL writers' confusions, and propose the corresponding way to automatically construct confusion sets.

3.1 Learning Words' Intensions – Distributional Models

Under an *intension based* perspective, a learner's primary goal is to understand word meanings, and it is the similarities between words' intensions that cause word choice confusions. However, this is not to say that learners ignore word usages. Indeed, although dictionary entries contain direct definitions of words, researches in the past showed that learners do not learn by memorizing dictionary entries; instead, they infer words' meaning/function from the context, and then connecting the new words to the words they are already feel familiar(Fischer, 1990). Under this perspective, learning the extensions of words is not explicit, it is a means to achieve the primary goal of understanding word meanings.

To simulates an intension based learner, we build a model of word similarity metrics from processing standard English text. Specifically, we build *distributional models* in which the similarities of words are calculated from a comparison of the contexts they appear in (Pereira et al., 1993; Lin, 1998; Lee, 1999). Then, to fill in a word's confusion set, we pick the words that are most similar according to the metric. Pantel & Lin (2002) showed this method is able to yield similarities that correlate well with the similarities of words' intensions.

In our work, we calculate the words' intension similarity by using a distributional model (Pereira et al., 1993; Lee, 1999), in which each preposition is represented as a distributional vector of its

context features. Examples of usage contexts that have been shown to be relevant for the task of preposition selection in previous work (De Felice, 2008; J. Tetreault et al., 2010; Dahlmeier & Ng, 2011a) include:

Gov: the syntactic dependency governors of the preposition

Obj: the dependency objects of the preposition

GovTag, ObjTag: the part-of-speech tags of the dependency governors and objects

L1-Trans: L1 translations of the preposition

We employ **Gov, Obj, GovTag, ObjTag** features to capture the grammatical context of the preposition selection. We also employ **L1-Trans** to capture both the intended semantic meaning of the preposition and the **L1** background information which was shown to be relevant to confusions(Rozovskaya & Roth, 2010a; Dahlmeier & Ng, 2011a).

The distribution of each preposition's usage context can be estimated from a standard English corpus. Then the similarity between any pair of preposition vectors can be computed using common distance metrics such as: KL-Divergence, Euclidean distance, and cosine similarity.

This approach, however, may not be appropriate for our problem for the following two reasons:

Firstly, under a distributional model, two prepositions are considered similar only if the distribution of all their usages are similar. This is a strong restriction in the sense that two prepositions might only be similar under certain specific usage contexts but are not generally similar. For example, the prepositions *of* and *for* typically have fairly distinctive usages; however, ESL writers often confuse the two if the previous word was *need*.

Secondly, even if two words have similar usages under certain usage context, i.e. have similar probabilities of being used(e.g. both with 0.2 probability), people still may not be likely to confuse them with each other – instead, they are more likely to confuse them with a third word which have higher probabilities(e.g. 0.5). This is because the learner is more likely to pick the word that seems most plausible in the context, if without further information.

3.2 Learning Words' Extensions – Preposition Selector

Under an *extension-only* model, it is assumed that the learners' main goal is to understand how to choose words in a given context, and that they learn about such knowledge from standard English text. Because classifiers can also be trained to choose words, we simulate ESL learners' learning process as training a classifier for the word selections task(J. R. Tetreault & Chodorow, 2008; J. Tetreault et al., 2010) on standard English text. The trained classifier can be seen as a type of language model: given a context, it predicts the most likely word in that context.

Under this model, it is expected that the word choice confusions are mainly caused by the learners' incapability to completely master the word usages. Therefore, to see what confusions an ESL learner may have, we then rerun the trained classifier on the training data to collect the mistakes it makes.

3.3 Learning Both Intensions and Extensions – RCA

We believe the knowledge of word intensions and extensions build on top of each other while learners learn English words. Therefore we propose a model that reflects the interactions between the understandings of words' intensions and extensions; it works toward making the intensions and extensions compatible with each other. Similar with the model in section 3.1, in the end, we build words' confusion sets by filling them in with words that are most similar in their intensions.

Our new model describes a two step process when a learner makes word selection choices: by examining the context, he/she will first think about an intension to convey; then he/she chooses a word that conveys as similar an intension as possible. We will refer to the first step as making *intension decisions*, and the second step as making *word choice decisions*. The goal of their learning is to become more comfortable about the word choices in standard English texts.

We formalize the learning process described above mathematically, to facilitate further analysis:

Intension Space We firstly assume that all possible intensions may be embedded in an Euclidean space S. Two intensions are similar when their locations in S are close to each other. The n prepositions $w_1, \ldots, w_n$ have corresponding intensions $\vec{v}_1, \ldots, \vec{v}_n \in S$. Because we mainly focus on these n prepositions, we assume that all intensions during learners' learning process can be described by a linear interpolation of the n prepositions' intension vectors $v_1, \ldots, v_n$. That is, the subspace containing all intensions learners consider has at most n dimensions. We therefore may assume $S = \mathbb{R}^n$, without loss of generality. Further, we denote $V = (\vec{v}_1, \ldots, \vec{v}_n)$, $I_i = (\underbrace{0, \ldots, 0}_{i-1}, 1, \underbrace{0, \ldots, 0}_{n-i})^T$, so that $\vec{v}_i = VI_i$. Because the n prepositions cannot be too similar to each other, their intensions $\vec{v}_1, \ldots, \vec{v}_n$ cannot clutter. We ensure this by forcing $|\det(V)| \geq 1$[2].

Intension Decisions We model the learners' ability to make *intension decisions* as a function $\vec{f}$ which maps a context C to a point in the intension space $\vec{f}(C) \in S$, which points to the intension the learner would like to choose under context C. C is in the format of a set of relevant contextual features for the preposition choice decisions. Following the discussion in section 3.1, we consider the relevant contextual features **Gov, Obj, GovTag, ObjTag, L1-Trans**.

The Uncomfortness of Word Choice Decisions For one word usage sample (C, w_i), where C is the context, and w_i is the actual preposition choice, we define the "uncomfortness" of the ESL learner by $||\vec{f}(C) - \vec{v}_i||^2$. This means: the more difference between the learner's expected word choice $\vec{f}(C)$ and the actual word choice $\vec{v}_i$, the more "uncomfortable" the learners are.

Learning Goal We assume that the learners learn about the word usages from some standard English corpus[3] D, containing word usage samples in the format (C, w_i). The learners' learning goal is to find V and $\vec{f}$ which get them most "comfortable" with the word usages in D. Therefore, mathematically, the learners' objective is to minimize the overall uncomfortness on the English text D: $\min_{\vec{f},V} \sum_{(C,w_i)\in D} ||\vec{f}(C) - v_i||^2$.

[2]Because $|\det(V)|$ is the area circled by the word vectors in V, forcing it to be higher than 1 can be interpreted as assuming the learners know beforehand that the prepositions cannot be too similar to the others.

[3]Although there may be other sources where the learners may obtain English knowledge from, such as dictionaries, the learners would learn word usages better from texts(Fischer, 1990).

Following the discussion above, we formalize the learning process of ESL learners as finding the best *uncluttered* word vectors V and word usage patterns $\vec{f}$ which together minimize the "uncomfortness" function over some standard English corpus D:

$$\min_{\vec{f},V} \sum_{(C,w_i)\in D} ||\vec{f}(C) - VI_i||^2 \quad s.t. |\det(V)| \geq 1 \tag{1}$$

We calculate the optimal set of word vectors V in the optimization problem above by firstly reducing the problem into a Minimization of Within Class Distances problem, as shown in Appendix A, and then solving it using the Relevance Component Analysis(RCA) algorithm(Bar-Hillel et al., 2006).

In the end, we will be able to obtain the word vectors for prepositions $VI_1, \ldots, VI_n$, and therefore also their similarities by calculating the distance between them (the distance between prepositions w_i, w_j is $||VI_i - VI_j||$). According to our model's assumption, after ESL learners' learning, the similarities of intensions of two words' will highly correlate to this distance. We can therefore fill in the confusion set for every preposition with the prepositions that have the least distances to it.

This approach is similar to the approach described in Section 3.2 in that it also focuses on the similarities of preposition usages under specific contexts. The two approaches differ, however, in their treatments of the degrees to which words are considered to be similar. For example, consider a corpus where under some certain context C, prepositions p_a, p_b and p_c occur 101, 100, 100 times, respectively. Using RCA, the system would consider all three to be mutually confusable because they appear almost equally frequently in the same context. On the other hand, while the preposition selector considers p_b and p_c to be confusable with p_a, it does not conclude that p_b and p_c are also mutually confusable under context C.

Thus, if most usage contexts contain only one or two preposition types, the preposition selector and RCA may produce similar confusion sets; but if the data also include usage contexts that contain three or more preposition types, RCA may offer confusion sets based on a more globally optimized similarity metric.

4 Experimental Setup

We conduct experiments to compare different methods for constructing confusion sets. To evaluate the confusion sets' qualities, we examine how they impact the performance of an end-to-end grammar error correction (GEC) system. In particular, we train a separate classifier for each preposition using only training examples that are covered by the confusion set, a setup similar to the **NegL1** system as described in (Rozovskaya & Roth, 2010a). Additionally, we also compare the confusion sets with an intrinsic evaluation; we measure how well each method's confusion sets match real ESL mistakes by calculating their *coverage* on an annotated ESL corpus.

4.1 Data

As the ground-truth for our experiments, we use the NUS Corpus of Learner English(NUCLE) (Dahlmeier & Ng, 2011b). This is an error-annotated ESL corpus; that is, the writers' mistakes have been identified and corrected by an English teacher. In this collection, many writers' native (L1) language is Chinese. Following the methodologies established in other studies on the

preposition selection problem, we focus on the 36 most frequent prepositions[4]. We used 80% of the full corpus for training, 10% for development and 10% for testing.

We use the NUCLE corpus in several ways. First, it is used to establish upper-bound confusion sets. We constructed these "gold" confusion sets by tabulating the observed preposition errors in the corpus. Second, it is used as a source of training data for the end-to-end GEC system[5]. For each confusion set construction method, we extract from the training portion of NUCLE those instances that are consistent with the proposed confusion sets to train the GEC system. The trained systems are then tested on the unfiltered test set. Third, it is used as the ground truth for computing the coverage metric.

The non-ESL corpus used for constructing confusion sets is the Foreign Broadcast Information Service (FBIS) corpus, which is a Chinese-English bilingual corpus. For most experiments, only the English portion is used. For experiments that make use of L1 translations, we extracted the Chinese translations for English prepositions using the GIZA++ (Och & Ney, 2004) implementation of the IBM word alignment model (Brown et al., 1993). Of the FBIS corpus, we used its first 32,000 sentences, which contain 151,767 prepositions.

4.2 Metrics

4.2.1 Extrinsic Evaluation

We use F_1-measure to evaluate the confusion sets' effects on the GEC system

$$F_1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

where **precision** is the number of suggested corrections that agree with the human annotator divided by the total number of proposed corrections by the system, and **recall** is the number of suggested corrections that agree with the human annotator divided by the total number of errors annotated by the human annotator.

A challenge faced by automatic GEC system is that ESL writers do not make mistakes on most of the usual cases. In NUCLE, 1.3% of the preposition instances contain an error. To reduce the class imbalance for the underlying classifiers during training, we follow the methodology used by Dahlmeier & Ng (2011b) to keep all instances that contain an error and retain a random sample of q percent of the correct instances in the training data. In our experiments, the value of q ($20\% \leq q \leq 40\%$) is tuned on development data. We keep the test data as it is. That is, the filtering we discussed above is only applied on the training data.

4.2.2 Intrinsic Evaluation: Coverage

When an ESL student mistakenly uses some preposition instead of the correct one, the wrong preposition is not necessarily in the proposed confusion set list. We refer to the proportion of

[4]These preposition words include *about, along, among, around, as, at, beside, besides, between, by, down, during, except, for, from, in, inside, into, of, off, on, onto, outside, over, through, to, toward, towards, under, underneath, until, up, upon, with, within, without*

[5]While using NUCLE to train the GEC system seems in contradiction with our overall aim of reducing our reliance on error-annotated corpus, we argue that the usage is appropriate here because we need to compare different approaches of constructing confusion sets without interference from other factors. We do not pursue alternatives such as injecting noise into standard English as training data (Rozovskaya & Roth, 2010a,b) to avoid unintended interactions between the confusion sets and the error generation methods.

ESL students' mistakes in a corpus that fall into the proposed confusion set list as the *coverage* of the confusion set list on that corpus.

The coverage metric can be seen as measuring *recall*: how well does the proposed confusion set table cover the mistakes in some ESL corpus? If each confusion set includes all the prepositions, then the coverage would be 100%. As discussed earlier, in order for the confusion sets to be useful, they cannot be too large. A high quality confusion set table is one whose confusion sets are small in their sizes but cover the majority of the mistakes seen in the ESL corpus.

4.3 Confusion Set Construction Methods

Our experiments compare the following confusion set construction methods:

The Trivial Confusion Sets(all preps) To show the confusion sets' effect in general from comparison, we establish a baseline by using the trivial confusion sets, in which all prepositions are considered to be confusable to each other.

Construction from NUCLE(gold) We establish the upper-bound of the confusion set table by tabulating the preposition mistakes in NUCLE. This confusion set table contains the most prepositions, and therefore is the one with the highest coverage of ESL mistakes.

Construction by Distributional Similarity Metrics As described in Section 3.1, this model represents a preposition as a feature vector and directly computes the distance between pairs of prepositions to construct confusion sets. The values of the feature vectors are computed from the FBIS corpus. Three standard distance/similarity measures are used: KL-Divergence(kl div), Euclidean Distance(euc dist) and Cosine Similarity(cos sim).

Construction from Preposition Selector Errors(selector) Section 3.2 proposes generating confusion sets from classification errors. Here, we train a Maximum Entropy classifier[6] for the preposition selection task on the FBIS corpus, and rerun the classifier on the same data to collect the mistakes it still makes.

Construction by Word Usage Similarity Modeling(RCA) In Section 3.3 we proposed to simulate ESL learners' learning of both words' intensions and extensions. We formalize their learning as an optimization problem and then calculate words' intensions and extensions using the RCA algorithm(Bar-Hillel et al., 2006). The final confusion sets contain words which have similar intensions.

4.3.1 Fixing Sizes of Confusion Sets

Our evaluation fixes the size of the confusion sets in the final confusion set tables to be N, where $3 \leq N \leq 7$. This is mainly because confusion sets tables with sizes greater than 7 are able to cover over 90% of the ESL mistakes, and increasing confusion sets' sizes from there start to hurt the GEC systems' performance. On the other hand, when the sizes are too small, the confusion set lists prevents the GEC system from making reasonable corrections.

5 Experiments

We compare the proposed methods of constructing confusion sets by using the resulting confusion sets in an end-to-end GEC system as described in Section 4. The experiments aim

[6]We used the package downloaded from `http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html`

to address the following questions: (1) How does the proposed method for automatically constructing confusion sets from non-ESL corpus compare against those developed from error-annotated ESL corpus? (2) Regarding the models for ESL learners' word learning, does considering the interactions between their learning of words' intensions and extensions help to capture the learners' confusions? (3) How are these models affected by the choices of different context feature groups? (4) How would the quality be affected by the choice of confusion set sizes?

Figure 1 shows a summary of the results. Each plot shows the GEC system's *performance* versus the *size* of the confusion sets for each confusion sets construction method under a different set of context feature choices [7]. In the baseline all preps, because we always fix the confusion sets' size to be a constant number 36 to contain all prepositions, the resulting curves are displayed as horizontal lines in the figures.

We make four observations:

First, regarding the use of non-ESL corpus, the experimental results suggest that confusion sets that are automatically constructed from non-ESL corpus is competitive with those constructed from an error-corrected ESL corpus. When picking the best feature sets **Gov,Obj,L1-Trans** in RCA, the GEC system can perform as well as if it were using the gold confusion sets constructed from a corpus containing 150K preposition usages.

Second, regarding the models for ESL learners' word learning, our experiments suggest that the learners' confusions are better captured when we model their learning of both words' intensions and extensions altogether. In our experimental results, confusion sets constructed by RCA model, which considers the interaction of words' intensions and extensions, consistently outperforms the other automatic methods selector, kl div, euc dist, cos sim, which only consider the learning of either words' intensions or their extensions.

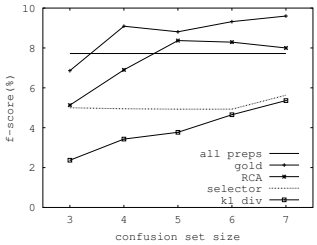
Third, regarding the feature sets used in constructing confusion sets, we find that in general all the models tend to perform better when they use more features. For example, by using **Gov,Obj** in addition to **L1-Trans**, selector raises the GEC system's F-score from 5.00% to 8.81%. RCA, however, is more stable with respect to the feature set changes. We separately show, for these two models, a comparison of the features' effects on them in Figure 2.

Fourth, our evaluation confirms that, in general, using confusion sets helps improving the GEC system's performance. This is because by limiting the confusion set's sizes, one can greatly reduce the underlying classifiers' mis-classification errors, at the cost of reducing their coverage a little. These two factors together lead to positive changes overall. To further demonstrate this effect, we show in Table 1 statistics of the decomposition of GEC systems' errors on the testing dataset. Also worth noticing is that our proposed approach (RCA), although having a slightly less coverage compared to the (gold), reduces mis-classification errors even further.

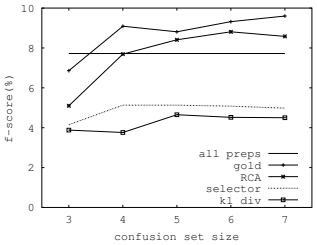
5.1 Discussions

The experiments above demonstrated RCA's strength over other methods. In this section we provide more in-depth analysis on the differences between RCA and other methods, by comparing those methods' effects on the GEC system's precision and recall separately.

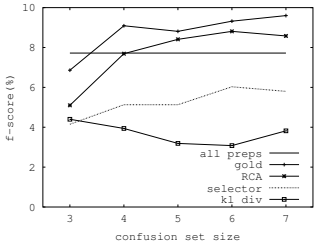
[7] Note that among the standard similarity metrics, we only plot kl div's F_1-scores because it performs better or similar to the other two methods in most of the cases. In later experiments, we will also only demonstrate the best of the three when all of them are performing similarly.



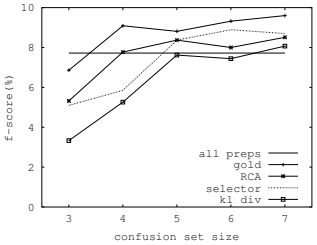
(a) Using **L1-Trans**



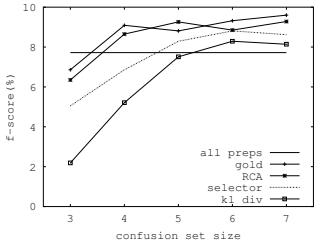
(b) Using **GovTag,ObjTag**



(c) Using **GovTag,ObjTag,L1-Trans**

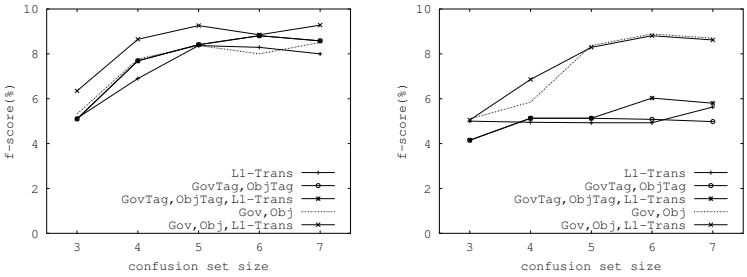


(d) Using **Gov,Obj**



(e) Using **Gov,Obj,L1-Trans**

Figure 1: F_1-Scores of different confusion set construction methods. For each of the five feature combinations, a plot demonstrates the performance of different methods using that feature combination. We display every method's performance as a curve in which each point represents the GEC system's F_1-Score when using that method to construct confusion set list of a particular size for the 36 prepositions.



(a) RCA methods' F_1 scores

(b) Selector methods' F_1 scores

Figure 2: F_1-scores of models using different feature sets to build confusion sets for all 36 prepositions.

	all	size=3		size=4		size=5		size=6		size=7	
	preps	gold	RCA	gold	RCA	gold	RCA	gold	RCA	gold	RCA
Out of Coverage	0	54	58	37	42	33	37	24	29	22	19
Mis-classification	284	135	119	162	147	173	158	189	176	203	195

Table 1: Confusion sets help reducing mis-classification errors. Here we categorize the GEC system's mistakes by whether they are caused by the confusion sets. *Out of Coverage* represents the cases where confusion sets precluded the right correction to be made, while *Mis-classification* includes all the other cases where the underlying classifiers are responsible for the prediction mistakes. The RCA we demonstrate here uses **Gov,Obj,L1-Trans** features.

We fix the feature set that all methods use to be **Gov,Obj,L1-Trans** in the discussion, because it allows all models to perform their best.

5.1.1 Precision

In Figure 3, comparing with the all prep baseline, we see that by limiting the classifiers' choices, confusion sets are indeed able to raise up GEC systems' precision. The confusion sets computed by RCA and euc dist are more helpful in raising the GEC system's precision, in contrast with selector. The difference is more significant when the confusion sets are small.

5.1.2 Confusion Set Coverage

Furthermore, we would like to provide an analysis of the GEC system's recalls, which is, in our setup, mainly *affected* by the number of ESL mistakes that are precluded from classifiers' consideration by the confusion sets. We measure this by calculating the proportion of ESL mistakes they cover using the metrics developed in 4.2.2. The coverage also reflects one confusion set's match to ESL students' real mistakes.

Shown in Figure 4 are the coverage of confusion sets constructed by different models, of different sizes. RCA and the selector greatly outperform other automatic approaches.

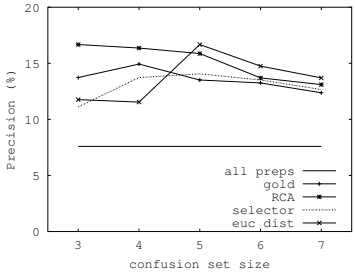


Figure 3: Precision of different methods on NUCLE

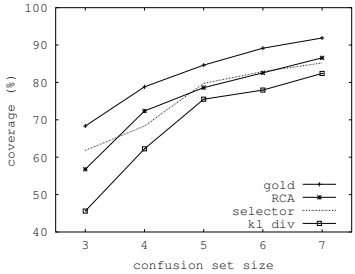

Figure 4: Coverage of confusion sets in different models using features **Gov,Obj,L1-Trans**

6 Conclusions

We proposed a method to automatically construct confusion sets for preposition errors without relying on any annotated ESL corpus or human post-processing. Based on the notion that ESL word selection errors are mainly because ESL learners are not able to choose between similar words, we build a model that analyzes which words might appear similar to each other to an ESL learner. Our model applies an algorithm called Relevance Component Analysis (Bar-Hillel et al., 2006) to describe how an ESL learner might learn both words' intensions and extensions from reading English text. The resulting confusion sets have been shown to both improve GEC system's performance, and correlate well with real ESL mistakes. Also, by modeling the interaction between the intensional and extensional knowledge in ESL learners' learning, our model ends up with better confusion sets than the models considering the development of *only* intensional or extensional knowledge. One key strength of our proposed technique is that because it only relies on standard English corpora, it is more scalable. Although this paper focuses on prepositions, the proposed approach may be applicable to other word classes.

A Solving the Optimization Problem for Word Usage Similarity

To solve the minimization problem in formula 1, we will first cast it into a Minimization of Within Class Distances problem.

Firstly, suppose there are N unique contexts $C_1, \ldots, C_N$ in the corpus, note that by grouping the samples with same contexts together, we may rewrite formula 1 as:

$$\min_{f,V} \sum_{1\le k\le N} \sum_{(C_k,w_i)\in D_k} ||\vec{f}(C_k) - VI_i||^2 \quad s.t. |\det(V)| \ge 1$$

where $D_k = \{(C, w_i) \in D \mid C = C_k\}$.

Secondly, for a certain V, the optimal function $\vec{f}$ which minimizes the cost function should satisfy: $\vec{f}(C_k) = \frac{\sum_{(C_k,w_i)\in D_k} VI_i}{|D_k|} = V\vec{m}_k$, where $\vec{m}_k = \frac{\sum_{(C_k,w_i)\in D_k} I_i}{|D_k|}$. That is, $\vec{f}$ should map context C_k to the centroid of the word choice vectors in group D_k. We may therefore rewrite the formula above as:

$$\min_{V} \sum_{1\le k\le N} \sum_{(C_k,w_i)\in D_k} ||V\vec{m}_k - VI_i||^2 \quad s.t. |\det(V)| \ge 1$$

$$\Leftrightarrow \quad \min_{V} \sum_{1\le k\le N} \sum_{(C_k,w_i)\in D_k} ||\vec{m}_k - I_i||^2_{V^TV} \quad s.t. \det(V^TV) \ge 1$$

where the notation $||\vec{t}||_B$ is the Mahalanobis distance: $||\vec{t}||_B = \sqrt{\vec{t}^T B \vec{t}}$. Together, this gives us the exact equation for the minimization of within class distances problem that the RCA algorithm may solve(Bar-Hillel et al., 2006, p. 945). We therefore directly apply the RCA algorithm to calculate the optimal V: $V = T\hat{R}^{-\frac{1}{2}}$ where T is a constant number and

$$\hat{R} = \sum_{1\le k\le N} \sum_{(C_k,w_i)\in D_k} (I_i - \vec{m}_k)(I_i - \vec{m}_k)^T$$

ABSTRACT

Recognizing TimeML events and identifying their attributes, are important tasks in natural language processing (NLP). Several NLP applications like question answering, information retrieval, summarization, and temporal information extraction need to have some knowledge about events of the input documents. Existing methods developed for this task are restricted to limited number of languages, and for many other languages including Persian, there has not been any effort yet. In this paper, we introduce two different approaches for automatic event recognition and classification in Persian. For this purpose, a corpus of events has been built based on a specific version of ISO-TimeML for Persian. We present the specification of this corpus together with the results of applying mentioned approaches to the corpus. Considering these methods are the first effort towards Persian event extraction, the results are comparable to that of successful methods in English.

TITLE AND ABSTRACT IN PERSIAN

استخراج رویدادها از متون فارسی بنا بر تعریف ISO-TimeML

یافتن رویدادها و ویژگی‌های آنها بر اساس TimeML یکی از مسائل مهم در حوزه‌ی پردازش زبان های طبیعی است. بسیاری از کاربردهای پردازش زبان‌های طبیعی مانند سامانه‌های پرسش و پاسخ، استخراج اطلاعات، خلاصه سازی و استخراج اطلاعات زمانی نیاز دارند تا دانشی درباره رویدادهای موجود در متون ورودی داشته باشند. روش‌هایی که تاکنون در مورد این مسئله ایجاد شده، محدود به چند زبان خاص است و در بسیاری از زبان‌ها از جمله زبان فارسی، تاکنون کاری در این رابطه انجام نشده است. در این مقاله، ما دو روش مختلف برای استخراج رویدادها در زبان فارسی ارائه می‌دهیم. برای این کار، پیکره‌ای مطابق با ISO-TimeML، البته نسخه‌ی خاص فارسی آن، ساخته شد. ما مشخصات این پیکره و نتایج حاصل بر روی آن، را نشان می‌دهیم. نتایج روش‌های ارائه‌شده در این مقاله، به عنوان اولین روش‌های پیاده‌سازی شده بر روی زبان فارسی، با روش های موفق در زبان انگلیسی قابل مقایسه است.

1 Introduction

Event extraction is a demanding task in natural language processing (NLP). Several applications like question answering (QA), information retrieval (IR), summarization, and temporal information extraction need to have some knowledge about events for better operation. This task remains a challenging task. Recognizing the various forms in which an event may be expressed (verbs, nouns, adjectives and prepositions), distinguishing events of different classes, and finding the features of an event are all difficult task (Verhagen et al., 2010).

In this paper, the events are defined based on TimeML view. In TimeML, events are "*situations* that *occur* or *happen*, or predicates that describe *states* or *circumstances* in which something obtains or holds the truth" (Pustejovsky et al., 2003). The task of event extraction includes two major stages that are introduced by TimeML: 1) detection and annotation of a text span (i.e., verbs, nouns, predicative constructions, prepositional phrases, and adjectival phrases) that is an event, and 2) determining the semantic class of events (i.e., *Reporting*, *Perception*, *I_Action*, *I_State*, *State*, *Occurrence*, and *Aspectual*).

Performing these two tasks (event mention detection and classification) in any language requires a corpus of annotated events, at least for measuring the accuracy of the algorithm. Currently, there are no such corpora for many languages including Persian, which is the native natural language of Iran, Afghanistan and Tajikistan. We have developed a corpus of annotated events in order to extract events from Persian texts. This corpus contains 4237 events. The annotation process has been based on an adapted version of ISO-TimeML guidelines. We have applied some changes to event attributes, the value of these attributes, annotation rules, and event extents.

In this paper, we also propose a system for automatic event recognition. In the system, various morphological, syntactic, and semantic features have been used. The syntactic features are in the form of dependency parse trees. Semantic features are taken from a Persian version of WordNet. For identification of event mentions and classifying them, the system uses these features in two different methods: a rule-based and a learning-based method. In the rule-based method, we proposed several rules for different types of events. In the learning-based method, a classification technique has been used for identification of events. We have used different models for different forms of events (i.e., verb, noun, and adjective). Our experiments show that the proposed methods, which are the first attempt in Persian event extraction, are quite effective.

The remainder of this paper is organized as follows: section 2 is about ISO-TimeML adaptation for Persian. Section 3 explains previous work in event extraction. Our event extraction system is proposed in section 4. The experimental results of the system are presented in section 5. Finally, the last section of the paper includes conclusion and some possible future work.

2 Adapting ISO-TimeML Event Guidelines for Persian

To apply ISO-TimeML as an annotation scheme to a new language, the language specific issues should be considered carefully. Accordingly, some aspects of scheme must be modified and some others must be restated for target language. The adapted schema may go through various changes regarding event attributes, event attribute values, event annotation rules and event extent rules according to the target language structure.

A number of languages including Korean (Im et al., 2009), Italian (Caselli et al., 2011), French (Bittar et al., 2011) have already adapted TimeML and ISO-TimeML guidelines to their needs. In the following subsections, we present the adapted version of ISO-TimeML for Persian (let us call it PersTimeML) in three main categories: event annotation, event extent and event attributes.

2.1 Event Annotation

Event annotation in PersTimeML is mostly based on ISO-TimeML. Generally, for simplicity it is assumed in current version of PersTimeML that generic events must be annotated. Also there have been special cases that have been tailored particularly for the specific properties of Persian. Here, we only discuss these cases disregarding common situations with ISO-TimeML.

2.1.1 Nouns

In Persian, gerund phrases, known as "esm-e masdar", must always be annotated as events, even when they represent generic events. These are built by affixing a particular Persian letter, i.e. "nôn", to the verb stem. There are also some categories of nouns that function like gerund phrases but do not have any lexical mark. These nouns were named *predicative nouns* and defined as nouns that inherit some verb and some noun characteristics (Karimi-Doostan, 2011). In Persian sentences, these nouns are usually the starting point of an NP or a PP. We always annotate these nouns as events, too. Following examples are instances of these cases:

a. **Barresê-e** (Review) maqâle-hâ (papers) chand (a few) rôz (day) tôl mikeshad (takes).
   Translation: **Reviewing** of the papers takes a few days.
b. Ostâd (Instructor) bâ (with) **taavêq-e** (postpone) emtehân (exam) mokhâlefat kard (disagreed).
   Translation: The professor disagreed with **postponing** the exam.
c. Alê (Ali) be (to) **jostojô** (search) dar miân-e (through) sâyt (site) edâme dâd (continued).
   Translation: Ali continued to **search** in the site.

In examples (a) and (b), "barresêy-e" (review) and "taavêq-e" (postpone) are *predicative nouns*, when have an "e" mark in their end and are linked to their subsequent nouns. In example (c), "jostojô" (search) is followed by "be" (in) as a preposition.

2.1.2 Adjectives

In addition to TimeML guidelines for annotating adjectives, we must also consider *objective deverbal adjectives* in PersTimeML. These are adjectives that derived from passive modes of verbs (Lesani, 2003). Two examples are "neveshte shode" (written) and "gerefte shode" (taken). *Objective deverbal adjectives* translate to the past participle form of the verbs in English. These adjectives always must be annotated as events because they are implying verbal events that have occurred in the past. For example, in the following sentence the "neveshte shode" (written) is an *objective deverbal adjective* that must be tagged as an event.

a. Ô (He) dastân-e (story) **neveshte shode** (written) dar (in) ân (that) rôzname (newspaper) râ bâvar nakard (didn't believe).
   Translation: He didn't believe the **written** story in that newspaper.

2.2 Event Extents

According to the new paradigm in ISO-TimeML about the stand-off annotation instead of in-line annotation (Pustejovsky et al., 2010), we can annotate multiple tokens in an event tag even though the tokens are not located consecutively in the sentence. This new approach simplifies the handling of compound words (e.g. compound verbs in Persian) by tagging all the associated tokens as just one event. The majority of the Persian verbs are compound. Persian compound verbs consist of a light verb and a number of non-verbal elements. For example, "barkhord kardan" (to hit) is a compound verb including the light verb of "kardan" (do) and the non-verbal element of "barkhord" (hit) (Rasooli et al., 2011).

Since there is not a fixed list of compound verbs, recognizing them in the sentences is difficult. Besides, detecting all parts of compound verbs can be challenging for an annotator because they may be located separately with long distances. The following examples show how we annotate compound verbs with event tags.

a. Bârân (Rain) be (to) mantaq-e (area) **sadame-e** (damage) zyâdê (large) **khâhad zad** (will do).
   Translation: The rain will largely damage the area.
   - Part of PersTimeML output will be:
     <Event xml:id="e1" target="#token3#token5" text= "sadame-e khâhad zad"… />
b. Bâ (with) oo (he) **sohbat** (talk) **kardam** (did).
   Translation: I talked with him.
   - Part of PersTimeML output will be:
     <Event xml:id="e1" target="#token2#token3" text=" sohbat kardam"… />

Segmentation of Persian verbs is another difficulty regarding annotation of verbs (Shamsfard, 2011). For tackling this problem, we need to pre-process the sentences to merge all Tense/Aspect/Mood (TMA) mark tokens with their verbal head. Therefore, in example (a) above, in the pre-processing, the whole "khâhad zad" (will do) will be merged as one token by inserting short space between the verb parts.

2.3 Event Attributes

Persian, as a natural language has its own specific aspects in event attributes. As we currently know, in Persian TMAs are not separated. However, we can map the TMA values to *tense*, *aspect* and *mood* appropriately to follow the ISO-TimeML guideline. According to this mapping, the possible values for each of these attributes will be: *tense***:** "past", "present", "future", "none", *aspect***:** "perfective", "progressive", "imperfective_perfective", "imperfective", "none" and *mood***:** "subjunctive", "imperative", "indicative", "none".

3 Automatic Event Extraction Methods

There are many ongoing researches on event extraction according to TimeML specification language. Almost all detection systems act in three following stages: 1) pre-processing; 2) event mention detection; and 3) event attributes detection. Existing methods can be divided into rule-based, statistical, and combined approaches, which are explained in more details in the next following subsections.

3.1 Rule-based Methods

One of the first event recognition systems in French used a rule-based method (Bittar, 2009). The system utilizes specific hand-made dictionaries for event detection and classification. Besides, a number of rules were used to reduce the errors. In other words, event recognition in this system includes two types of processing: lexical, using specific dictionaries and contextual, using a number of rules.

The first system on Italian also used a rule-based approach that utilized dependency parse trees of the input sentences (Robaldo et al., 2011). The rules of this system have designed based on both syntactic and lexical information using a number of keywords. Some extra resources like WordNet (Fellbaum, 1998) plus a list of specific words were used to build a comprehensive keyword list. To identify the class of events, in addition to dependency structure of sentences, a list of Italian verbs with three different semantic categories (state, process, and movement) has been also utilized.

Edinburg is another rule-based system that used a named entity recognition system for nominal event detection. Special lists, which were extracted from an annotated corpus, in conjunction with WordNet were also used for detection of nominal events (Grover et al., 2010).

3.2 Statistical Methods

Bethard and Martin proposed a statistical system for event extraction using a multi-class classification method (Bethard and Martin, 2006). The system automatically annotated each token by "Inside", "Outside", or "Begin" tags. It also determined the semantic class of each event. This system used various morphological, syntactic, and semantic features. Their reported results have shown an acceptable rate in event detection.

Another statistical method for event extraction applied a classification algorithm based on Support Vector Machines (SVM) in both sentence and word levels (March and Baldwin, 2008). First, it filters out the sentences without events. Then, in the remaining sentences, it searches for events. This method does not determine the features of events (i.e., the third stage of the event extraction task).

TipSem is one of the most successful TimeML event extraction methods, which has used Conditional Random Fields (CRF) classification technique (Llorens et al., 2010). It utilizes morphological, syntactic, and semantic features in addition to semantic roles for event extraction.

3.3 Combined Methods

Evita is the first system that has been designed for extraction of TimeML events (Sauri et al., 2005). The system has benefited from both statistical and rule-based techniques. In pre-processing stage, it extracts part of speech tags, phrase chunks, and lemmas of the sentences' tokens using some existing tools. For event detection of nouns, Evita uses WordNet, and in ambiguous cases, i.e. nouns that may or may not be an event in sentences, a Bayesian classifier is used for disambiguation. This classifier has been trained on the SemCore data. For adjectives, the cases that have been annotated in TimeBank are considered as events. The heads of the predicative complements are also regarded as events. Evita uses TimeBank information for finding the class of events. It simply chooses the majority class for the specific event in the corpus.

TRIOS is another combined method, which first utilizes the TRIPS semantic parser (UzZaman and Allen, 2010). Based on the output of the parser and applying some rules, it detects the events. Then, for improving the accuracy, a Markov Logic Network (MLN) classifier is used. This classifier is also used for extraction of event features.

4 Automatic Event Extraction from Persian Text

As mentioned before, most of the event recognition and classification methods include three phases: pre-processing, event mention detection and event attributes extraction. These phases also exist in our system for Persian texts. We called this system Persian Event Tagger (PET). In pre-processing stage of PET, we convert input documents into the CoNLL-2009 Shared Task (CoNLL09) format by using Dadegan tools[1]. It means that the Dadegan tools extract part of speech (POS) tags, dependency labels, and other necessary information from input documents. The dependency labels are according to Persian dependency Treebank, which is the first released dependency Treebank for Persian. This corpus currently contains 30,000 sentences that were manually annotated[2].

We apply our feature extractor subsystem to the converted document to obtain useful and meaningful features for recognizing and classifying of events. The outputs are data set files, which contain all features for each token in a separate line. We employ these data set files to perform event mention detection and event attribute detection stages. A rule-based and a statistical learning-based approach are implemented for both of these stages. In event attribute detection, we just find *class* because other attributes like *tense*, *mood,* and *aspect* were previously found with Dadegan tools. For other event attributes, we just choose the default values; for instance, we set *polarity* to "Positive". In section 4.1, the features are discussed. The rule-based and learning-based subsystems are explained in sections 4.2 and 4.3, respectively.

4.1 Features

The features that have been used in PET can be clustered into three types: lexical, syntactic, and semantic. In the following, each type of these features is explained in more details:

4.1.1 Lexical Features

Lexical features that we have used in the system are token's text, coarse-grained POS, fine-grained POS, word's stem, word's postfix (i.e., last three letters of word), and a Boolean feature *isModAux, which* is "true" for modal or auxiliary verbs. For recognizing these features, we rely on the raw text, coarse-grained, and fine-grained POS from the pre-processed input file.

4.1.2 Syntactic Features

In some event tagging situations, PET requires deeper knowledge about sentences. Dependency parsing is a new and effective approach for obtaining this knowledge. We can extract various syntactic features from dependency labels of the input sentences.

The extracted syntactic features, for each candidate, include: dependency label, lemma of the head token, text of the head token, POS of the head token, dependency label of the head token, governing verb text, governing verb lemma, governing noun text, and governing noun lemma.

[1] Freely abailable for download at http://dadegan.ir/en/tools
[2] Freely available for download at http://dadegan.ir/en/persiandependencytreebank

Other extracted syntactic features are *isPartOfCompoundVerb* and *isPartOfCompoundNoun*, which indicate that candidate word is part of a compound verb or noun, respectively. These features can be assigned by searching the dependency parse tree of the input sentence.

4.1.3 Semantic Features

A number of semantic features are required for recognizing nominal events. They are also needed for classification of both nominal and verbal events. These features can be obtained from resources like WordNet by searching through word senses and checking their hypernyms. In Persian, we have two resources that are similar to WordNet. One of them is FarsNet, which has been developed semi-automatically with 9,266 synsets and 13,155 words (Shamsfard et al., 2010). Another resource, which we call it PersianWN, has been developed automatically. This resource, has covered 29,716 Persian phrases with reported precision 82.6% (Montazery and Faili, 2010).

To recognize nominal events, a number of Boolean features are extracted from both FarsNet and PersianWN. We consider several synsets including: "event", "human_action", "human_activity", "act", "phenomenon", and "action" to be eventive. Thus, when hypernyms of a sense fall into these synsets, we will consider this sense to be eventive. In this way, we can extract following features for each noun according to its senses: *isAllSensesEvent*, *isAllSensesState*, *isMainSenseEvent* (i.e., "true" when more than 1/3 of senses are eventive), *isOneSenseEvent*, *isOneSenseState*.

To classify events, some other features are extracted. For each event *class*, a list of phrases is created. These lists are initially filled by sample phrases that have been mentioned in the ISO-TimeML guideline. Then, we augment these lists by adding their synonyms taken from FarsNet. After creating and enriching these lists, we set a number of features (i.e., *isReporting*, *isAspectual*, *isPerception*, *isI_Action*, *isI_State*, *isState*, and *IsOccurance*) for each input phrase. We search a phrase in each list and if it is successfully found, the corresponding feature, which is related to that list, will be assigned to "true". For instance, when verb lemma exists in the aspectual phrase list, the *isAspectual* feature will be set to "true".

It must be noted that there is a difficulty in searching compound nouns/verbs in a list, lexicon, or dictionary. In these cases, the system has to combine all parts of the noun/verb before starting to look up. These parts can be obtained and then combined using related labels. For example, in sentence (a) we must look up the whole text "bazgoo kard" (restate) in dictionaries or lexicons.

a. Ô (He) moshkelât (problems) râ (-) **bâzgô** (restate) **kard** (did)**.**
Translation: He **restated** the problems.

4.2 Rule-based Method

For event mention detection, we apply PersTimeML guidelines to the input text by utilizing the previously mentioned features. Besides, a number of lists including special phrases like aspectual and causative signal words are used for event tagging. Therefore, for each candidate word, we apply a number of if-then-else rules, which are based on one or more features. These rules are explained in the following subsections.

4.2.1 Recognizing Verbal Events

According to PersTimeML, we annotate all verbs as events except for modals, auxiliary verbs, and verb "to be". We can easily find these verbs by checking the Boolean feature *isModAux*.

Furthermore, for each verb, we search the sentence for its probable non-verbal elements. If any such elements are found, they will be combined with the verb. These searches can be performed using related syntactic features, i.e., *isPartOfCompoundVerb* and position of the head token.

4.2.2 Recognizing Nominal Events

Recognizing nominal events is more challenging than other forms of events and requires a deeper analysis of input sentences. Some PersTimeML rules can be applied to the nouns by utilizing the mentioned syntactic features. In current version of PET, we apply causative and aspectual rules. This means that a noun when appears in a specific position in an aspectual or a causative structure is tagged as an event. These aspectual and causative structures are found by searching the context of the noun for occurrence of an aspectual or a causative signal word.

For instance, in sentence (a) below, there is a causative structure and therefore according to the PersTimeML, we must annotate all of "bârân-e" (rain), "seyl" (flooding), and "môjeb-e" (cause) as separate events. With dependency labels, we can determine the subject of a causative sentence. Then, if the subject is a phenomenal noun, we will annotate it as an event. Furthermore, "seyl" (flooding) can be recognized by annotating the head of the noun phrase that immediately appear after the signal word "môjeb-e" (cause).

Sentence (b), has an aspectual structure, which is triggered when encountering the verb "âghâz shod" (has started). We must annotate the subject of this structure, i.e., "marg" (death), as an event. In other structures, when an aspectual or a causative signal word is triggered, we can apply similar rules for finding the events.

a. [Bârân-e] (Rain) zyâd (heavy) **[môjeb-e]** (cause) [seyl] (flooding) shod (become).
   Translation: The heavy rain **caused** flooding.
b. [Marg-e] (Death) khôkhây-e (pigs) **âghâz shod** (has started).
   Translation: The death of pigs **has started**.

For other nouns, we first disregard each noun that have *isPartOfCompoundVerb* feature with value of "true", because in fact, it is part of a compound verb in the sentence. Besides, if a noun is part of another noun, i.e., has value of "true" for *isPartOfCompoundNoun* feature, it will be annotated in conjunction with its governing noun as an event tag.

Finally, for remaining nouns, our rule-based module can only use the semantic features, because currently there is not any acceptable Word Sense Disambiguation (WSD) system or even a semantic tagged corpus for Persian. In the module, we only use the feature *isAllSensesEvent*. When value of this feature is "true" for a noun, the noun will be annotated as an event. Another solution for improving the result of event recognition for nouns is creating a list of all *predicative nouns*. This is discussed in the evaluation section in more detail.

4.2.3 Recognizing Adjective Events

To recognize adjective events, the system first checks to see if the adjective is a predicative complement in the sentence. It can be performed by using the both dependency label and governing verb of the adjective. The adjective will be regarded as an event, if its dependency label is "MOS" (i.e., the adjective is predicate in the sentence) and its governing verb exists in a list of special predicate verbs such as "shodan" (become) and "kardan" (do).

A second rule is employed for recognizing objective deverbal adjectives by watching the postfix feature. When the value of this feature equals to "shode", we will annotate the adjective as an event.

4.2.4 Identifying the *Class* of Events

To determine *class* of events, we rely only on event *class* features (e.g., *isAspectual, isPerception, isI_State* and so on). For instance, if the value of *isReporting* feature is equal to "true", we will assign the "Reporting" value to *class* attribute. For those events, not having any of these features with value of "true", we consider the default values (i.e., "occurrence" for nouns and verbs and "state" for adjectives)

4.3 Learning-based Method

By applying the TempEval 2010 format to the developed corpus and using the previously mentioned features, a learning model can be trained. The whole relevant processes including data loading, data pre-processing, creating and applying a model, and the evaluation can be performed using an open source software called RapidMiner[3].

By RapidMiner GUI, we can easily design our learning process and obtain various desired evaluations. Therefore, our learning-based module identifies event mentions and determines the *class* of them using RapidMiner processes. We utilize a feature selection process based on a naïve Bayesian classifier in this module. The process detects optimized subsets of features for each classification task individually. The classification cases are expressed in the evaluation section.

5 Evaluation

For evaluating both PersTimeML and PET, we built a suitable corpus with annotated events. The corpus is in fact the first and a preliminary Persian version of well-known English corpus, TimeBank. We called this corpus PTB. An iterative incremental process has been used to create PersTimeML, PTB, and PET.

The input documents have been taken from Peykareh, also known as Bijankhan corpus. Peykareh is currently the most popular Persian corpus, which contains more than seven million tokens (Bijankhan et al., 2010). We selected a number of documents from diverse topics including political, economic, sport news, stories, etc. Then, we pre-processed these selected documents with Dadegan tools for tokenizing and converting to the conll09 format. We had extracted sentence texts from Conll09 files because of the necessary tokenization pre-processing that input sentences had required. Then, we applied the rule-based PET to primarily annotate events, followed by a manual correction of the system output. The manual correction was performed using the MAE (Multi-purpose Annotation Environment) annotation tool[4]. The MAE output files then converted into the TempEval 2010 data format for simplifying the evaluations.

We annotated 43 documents from Peykareh. This contained 26,949 tokens and 4,237 events. Statistics about frequency of events for each POS tag and also, frequency of events in each event *class* are shown in TABLE 1.

[3] Freely available at: http://rapid-i.com/
[4] Freely available at: http://pages.cs.brandeis.edu/~astubbs/mae.html

POS of Event	Frequency		Event Class	Frequency
Noun	1,960		*Occurrence*	2,488
Verb	1,875		*State*	623
Adjective	312		*Reporting*	433
Preposition	51		*I_Action*	276
None	39		*I_State*	218
			Aspectual	133
			Perception	66

TABLE 1 – Some statistics about PTB

To evaluate the PET, the corpus was split into a development set, a training set, and an evaluation set. The evaluation was performed token by token even for multi token events. It means that the scorer programs took each token individually and then calculated the value of each performance property like recall, precision and f-measure. The training and evaluation sets were both used in evaluating the rule-based method. We used a five-fold cross-validation with a stratified sampling over the training and evaluation sets for evaluating the learning-based method.

The results of the PET in event mention detection for both rule-based and learning-based methods are shown in TABLE 2. In order to calculate the results for each event category, we only considered tokens in that category in evaluations. In the learning-based method, this led to an individual model for each individual event category. It should also be noted that the learning-based method assigns each individual token to either an *event* class or a *non-event* one.

	Rule-based			Learning-based		
Category	Precision	Recall	F	Precision	Recall	F
All	78.9	72.5	75.6	79.2	87.5	83.1
Verb	96.5	99.3	97.9	97.1	99.5	98.3
Noun	66.3	64.4	65.3	82.1	81.8	82.0
Adjective	88.5	55.8	68.4	78.3	76.4	77.3

TABLE 2 – Evaluation results for PET for event recognition

In the evaluation for all categories, the both modules showed high precisions, while for recall the learning-based method is 15% better than the rule-based one. This weaker recall for the rule-based method is due to the lower recall for nouns and adjectives. Therefore, it showed that although the existing rules have gained a satisfactory precision, we should add extra rules or modify the lexicons for finding more event tokens.

For nouns, the most effective features that have been used in the PET are semantic features. These features had been extracted from special dictionaries and lexicons. An experiment on six random documents of the PTB showed that 60.7% of nominal events were *predicative nouns*. As we said before, *predicative nouns* in Persian when function as gerunds, are events. Therefore, it must be noted that the quality of these resources for finding eventive nouns or having a list of all *predicative nouns* immensely affects the performance of the event tagger systems.

Some coverage tests of the lexical databases were performed for the nouns of the PTB corpus. From 11,942 nouns of PTB, 7,625 nouns were found in FarsNet (63.8%) and 7,934 nouns were found in PersianWN (66.4%). Although the PersianWN has had greater coverage, it suffers from

lower accuracy because as we mentioned in 4.1, it was developed in a fully automatic process with 82.6% accuracy. On the other hand, the FarsNet was manually validated and therefore, has had high accuracy. When we experimented with PersianWN for recognizing noun events, we gained a low recall (35.1%) but a high precision (80.0%) that is a sign for its incorrect senses or hypernyms relationship between synsets.

	Rule-based			Learning-based
Category	Correct	Incorrect	Accuracy (%)	Accuracy (%)
All	1,946	819	70.3	74.9
Verb	475	353	57.4	73.5
Noun	1,301	398	76.5	82.3
Adjective	147	79	65.0	78.8

TABLE 3 – Evaluation results for event class detection

The evaluation results represented in TABLE 3 show the accuracy for detection the *class* of events. In the learning-based method, one model is created for each POS category and one classification per event is performed to assign the proper *class* to each event. The high F-measure of the rule-based approach (70.3%) is just achieved by using event *class* lists. One reason is that the majority of events have "occurrence" value in their *class* attribute. According to TABLE 2, 2,488 out of 4,237 events (i.e., 58.7% of events) have *class* attribute with value of "occurrence". Thus, a baseline system that assign "occurrence" to all events, will achieve 58.7% accuracy. By this baseline, the accuracy of 74.9% by learning-based module is both acceptable and remarkable.

	Learning-based event class detection		
Classes	Precision	Recall	F
Occurrence	73.8	91.5	81.7
State	72.2	30.7	43.1
I_State	58.2	61.5	59.8
I_Action	67.8	35.2	46.3
Reporting	92.9	86.7	89.7
Perception	75.0	46.1	57.1
Aspectual	86.2	60.1	70.9

TABLE 4 – Evaluation results for each event class

Evaluation results for the various event classes in the learning-based method are shown in TABLE 4. The worst results are in "state", "I_Action" and "perception" classes. "Perception" is scarcely occurred in the corpus and therefore, had low result. "State" and "I_Action" classes occurred in more distinct phrases in comparison with "reporting" and "aspectual" classes and thus, had lower accuracies.

Conclusion and Perspectives

In this paper, we have addressed the problem of event recognition and classification, which has been a challenging task since early days of statistical natural language processing. More specifically, we focused on ISO-TimeML event annotation for Persian. Since there have not been any suitably tagged corpus in Persian, we have developed an annotated corpus. In the annotation process, we adapted the ISO-TimeML standard for Persian. We have also proposed two different methods for automatic identifying event mentions and their corresponding attributes as part of a

Persian event tagger system. The first was utilized a rule-based approach with different rules. The second was a statistical learning-based approach, which used a classification technique for tackling the problem. Our experimental results show an acceptable accuracy, considering our system as being the first effort for event recognition in Persian.

Currently, we are working on finding ways for further improvement of our system, PET, and at the same time annotating more documents for increasing the size of the corpus. It seems that using cross-lingual techniques can further improve the accuracy of existing methods for Persian (and languages that currently lack rich resources for NLP applications). Other possible future work includes employing richer learning models such as Conditional Random Fields (CRFs) for event recognition and classification. It is also the case that PTB should be retagged by other annotators to meet the inter-annotator agreement criterion. PTB can also be further improved by annotating other ISO-TimeML tags such as time expressions and temporal relations.

ABSTRACT

This paper presents a novel method of measuring the similarity between TV programs by using summaries of the Electronic Program Guide (EPG). Most previous methods use statistics such as the TFIDF based cosine measure of word vectors, whose elements are words appearing in the summaries. However, these approaches are not effective because TV program summaries, especially short ones, do not necessarily share many words even when they have similar meanings. The proposed method generates a graph structure whose nodes are TV programs and nouns. These nouns are connected by semantic relations that are extracted from the Web automatically. The similarity between two TV programs is measured in terms of the relativeness of two TV program's nodes in the graph structure by using a random walk algorithm. Experiments showed that our method is better at measuring similarities between two TV programs compared with baseline methods.

1 Introduction

Japanese broadcasting stations have started services to provide viewers with previously broadcast TV programs on demand. Since these services are becoming popular, it is important for them to have an efficient way to find programs that a viewer wants to watch amidst huge program archives. Many on-demand services have the ability to present TV programs related to a selected program and rank them. This function makes it possible for viewers to find programs they would be interested in but would not have known about in advance. The TV program that the viewer selects from such a list is highly dependent on its presentation rank given by the on-demand service. FIGURE 1 shows how the number of selected programs depends on the presentation rank in a major Japanese on-demand service, NHK on demand. The higher ranked TV programs are selected more frequently than the lower ranked ones. For this reason, it is important to find out how to select related programs in huge program archives and how to rank them for better on-demand services. In order to select the related programs and rank them, NHK on-demand system measures the similarity between TV program summaries in Electronic Program Guides (EPGs) in advance. The system ranks TV programs according to their similarities to the selected program by a viewer. Since the viewer might interested in watching TV programs which are relevant, but not exactly similar in content, the technique for measuring the similarity between programs can exclude exactly similar content and select only related programs and rank them[1].

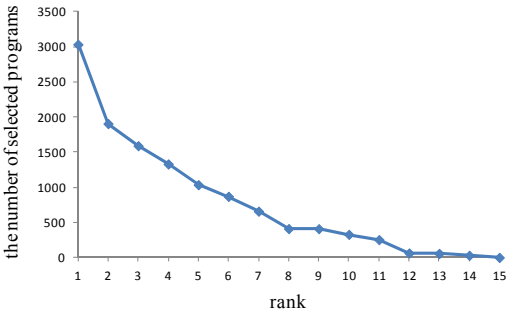

FIGURE 1 – The number of selected programs depends on the presentation rank in the NHK on demand service. (2010/9-2011/5)

NHK on-demand adopts a method of Goto et al. (2010) for measuring the similarity between TV program summaries. This method is based on word co-occurrences. Each summary is represented using words or n-grams of words as a vector, and the similarity between two summaries is calculated from their corresponding vectors. However, this method sometimes gives inappropriate similarity values for summaries (especially short ones) that have similar meanings but do not share many words. For example, the following sentences in program summaries were judged as dissimilar.

(1) This TV program conveys aspects about the treatment of diabetes.
(2) The doctor describes measures to alleviate hypertension, such as low-salt diet and drug therapy.

[1] A function for excluding exactly similar content has not been implemented on the NHK on-demand system yet.

If we knew that *low-salt diet* and *drug therapy* are *treatments* and *diabetes* and *hypertension* have the same hypernym *lifestyle-related diseases*, these sentences could be judged to have some semantic relevance.

This paper proposes a method for measuring such semantic relevance, that is, similarity between two TV program summaries by using semantic relations between nouns, such as causality and hyponymy. These semantic relations are extracted from the Web automatically and make it possible to judge the similarity of sentences appropriately even if they do not share many words. Our method generates a graph structure whose nodes are TV programs and nouns. These noun nodes are connected by the semantic relations. The similarity between two TV program summaries is calculated in terms of the relativeness of two TV program's nodes in the graph structure by using a random walk algorithm. Through experiments on ranking related TV programs provided by the NHK on demand service, we found that our method provides a proper similarity measure that shows a better correlation with human intuition than the baseline approaches we tested for comparison.

In the remainder of this paper, section 2 reviews related work on recommender systems. Section 3 introduces the methods of extracting semantic relations from Web data that we use for measuring the similarities between TV program summaries. Section 4 describes our method of measuring the similarities and ranking related TV programs. We present experimental results in section 5 before concluding the paper.

2 Related work

Many studies have been conducted on recommendation systems which offer relative products in relation to the user selected one. These systems are classified into content-based filtering and a user based approach known as collaborative filtering.

The content-based filtering is based on word co-occurrences in text relating to products, and it is commonly used in traditional information retrieval systems. Goto et al. (2010) proposed a method of TV program recommendation using content-based filtering. They used a score based on Okapi BM25 (Robertson 1999) and put weights on semantically significant words, such as named entities and compound words. Oku et al. (2007) proposed a context-aware recommendation system. Their system suggested products according to the user's context, such as time, weather, accompanying persons, and price, which change according to the situation. However, these methods rely on the assumption that more similar documents share more of the same words, even though it is true that similar pieces of content do not necessarily share the same words. Moreover, summaries in the EPG use a great variety of expressions; such summaries would not use the same word frequently to express a similar meaning.

Statistical models are useful for measuring the similarities between documents that do not share words but express similar meanings. Latent Semantic Indexing (LSI) represents terms in a latent semantic space by using the SVD of the corresponding term-document matrix (Deerwester et al. 1990). Hofmann et al. (1999) proposed PLSI which uses a latent variable model. However, these models are not good for measuring the similarities of TV program summaries, as determined in the experiment (Section 5).

Collaborative filtering is now used by several real-world recommendation systems. Amazon.com proposed item-to-item collaborative filtering (Linden et al. 2003). They produce

recommendations from customers who bought similar items to the ones in your shopping cart. Their algorithm works online and uses computation scales independent of the number of customers and number of items. Koren et al. (2009) proposed an approach based on matrix factorization; it characterizes both items and users by using vectors of factors inferred from an item rating pattern. Their system won the Netflix Prize, which was an open competition to predict user ratings for films. However, collaborative filtering suffers from the cold start problem wherein it cannot estimate the rating of new items and users, and recommendation systems for TV programs must handle new items (TV programs) frequently.

The proposed method is based on content-based filtering. We can put a high similarity value on documents that have similar meanings even if they do not share many words. These similarities between two items can be applied to the collaborative filtering approach by using not only the user's preference but similar items to the user's preference. Melville et al. (2010) proposed hybrid techniques which use both content-based and collaborative filtering. The proposed method can be used with such hybrid techniques, and it is expected to have promising results.

3 Acquisition of relations between nouns

This section describes three methods for acquiring semantic relations between nouns. The acquired relations are then used for measuring similarities between TV program summaries. We used the following four semantic relations.

- Hyponymy: A is a hypernym of B.

  Ex.) *lifestyle-related diseases* / *hypertension*

- Causality: B is caused by A.

  Ex.) *stroke* / *hypertension*

- Specialty: A is famous for B.

  Ex.) *Kyoto* / *temples*

- Material: A is made from B.

  Ex.) *beer* / *wheat*

We selected these relations because they are effective at capturing the VOD user's attention when it comes to TV program suggestions. For example, someone who is interested in *Kyoto* would probably like TV programs concerning *temples*.

We also use the entity-attribute-value relation. It can be considered that the entity word and the value word have the relation of attribute. For example, in the relation "*hypertension* / *management* / *weight loss*," the relation between *hypertension* and *weight loss* can be considered to be *management*.

In the following subsection, we describe the methods of acquiring these semantic relations.

3.1 Relation acquisition from Wikipedia

For the hyponymy relation and entity-attribute-value relation acquisition, we used an open-source software[2] based on the extraction methods of Sumida et al. (2008) and Yamada et al. (2010). Sumida et al. (2008) proposed a method of automatically acquiring hyponymy relations of nouns from Wikipedia. They focused on the hierarchical layout of articles in Wikipedia, which is made of titles, sections, sub-sections, itemizations, and so on. For example, in the article titled *lifestyle-related diseases*, there are itemizations *hypertension*, *diabetes*, and *history*. Relations such as the one between *lifestyle-related diseases* and *hypertension* and the one between *lifestyle-related diseases* and *diabetes* can be considered to be hyponymy relations, but the one between *lifestyle-related diseases* and *history* cannot be considered a hyponymy relation. Their method first extracts hyponymy relation candidates from the hierarchical structure of Wikipedia. The candidates are then classified into plausible and implausible ones by using a support vector machine (SVM) classifier.

Sumida et al. (2008) also proposed another method for hyponymy acquisition that exploits other information sources: the first sentence of Wikipedia articles, which is regarded as the article's definition, and category names. This method generates hyponymy relation candidates in which the hyponymy corresponds to the article titles and the hypernym comes from either of the information sources. The candidates are classified in the same process of analyzing a hierarchical layout.

We expanded their hyponymy acquisition method to generate entity-attribute-value relations (Yamada et al. 2010). We confirmed our assumption that if two words located in the layout structure can be regarded as a hyponymy relation, the article title, hypernym word and hyponym word can be interpreted as an entity, the attribute, and its attribute value independently. Take, for example, the hyponymy relation *management* and *weight loss* from the Wikipedia article *hypertension*; it can be interpreted that the entity *hypertension*'s *management* (attribute) is *weight loss* (value).

3.2 Relation acquisition from Web text

Causality, specialty, and material relations are extracted by using a semantic relation acquisition service provided by the ALGIN forum[3] in Japan. This service is based on a method proposed by Stijn et al. (2009) and can extract large-scale relations between nouns from 6 million Japanese Web pages by inputting a small number of seed patterns. The service learns linguistic patterns that express each relation such as "X gives rise to Y" for causality with semantic word classes of X and Y acquired by large-scale clustering (Kazama et al. 2008). For example, if we know that the pattern "X gives rise to Y" expresses causality and the phrase "*hypertension* gives rise to *stroke*" appears frequently on the Web, the relation between *hypertension* and *stroke* will be regarded as causal. Moreover, *heart attack*, which belongs to the same class as *stroke*, can be also considered to have a causality relation with *hypertension*.

However, the relations acquired by this method include some obvious errors and ambiguities. For example, the method erroneously regards the relation between *disease* and *stroke* as being causal from the pattern "The *disease* gave rise to the *stroke*". This is because the word *disease* belongs to the same class of *hypertension*. To avoid this error, we generated a stop-word list manually to

[2] http://alaginrc.nict.go.jp/hyponymy/index.html
[3] http://alaginrc.nict.go.jp

exclude these erroneous relations from the results of the semantic relation acquisition service.

3.3 Hypernym acquisition using compound nouns

A suffix of a compound noun sometimes becomes a hypernym of the original noun in a head-final language (Kuroda et al. 2009). For example, the suffix *disease* is considered to be the hypernym of *lifestyle-related diseases*. Since our target language in the experiment was Japanese, we first decomposed a compound noun into a sequence of nouns using a morphological analyzer and then checked whether the suffix sequence was a valid hypernym of the compound noun. We judged that the suffix is a valid hypernym if it is registered in a dictionary. In the experiment described in section 5, we used the Japanese WordNet (Bond et al. 2012) as the dictionary.

3.4 Acquired relations

We acquired hyponymy and entity-attribute-value relations by using the relation extraction software mentioned in section 3.1, targeting 5 years of Wikipedia dump data from 2007 to 2011. We also extracted causality, specialty, and material relations by using the semantic relation acquisition service mentioned in section 3.2, by inputting a few seed patterns, and acquired reliable patterns. We extracted hypernyms by using the suffixes of nouns appearing in the extracted relations and TV program summaries. TABLE 1 shows examples of the acquired relations.

We randomly sampled 200 of the automatically acquired relations respectively, and one of the authors checked whether the relations were valid or not. TABLE 2 shows the number of acquired

Word *X*	Relation	Word Y
hikkigu (writing material)	hyponymy	shapu-pen (mechanical pencil)
eiga (movie)	hyponymy	Star Trek
ice cream	hyponymy	vanilla ice cream
allergen	causality	kikanshi zensoku (asthma bronchiale)
El Nino	causality	ondo josho (rising water temperatures)
Canada	specialty	winter sports
Chiang Mai	specialty	bukkyo-jiin (Buddhist temple)
miso	material	soybean
pannacotta	material	coconut
John Woo	directed film	Red Cliff
J. D. Salinger	work	A boy in France

TABLE 1 – Examples of acquired relations between nouns.

Relation	Number of relations	Accuracy
hyponymy(Wikipedia)	8,591,469	90.0%*
hyponymy(suffix)	1,347,382	82.5%
entity-attribute-value	5,213,455	94.0%*
causality	77,636	75.0%
specialty	183,093	49.0%
material	49,711	73.0%

TABLE 2 – Number of acquired relations and accuracies. * indicates accuracies obtained from the original literature.

Relation	Coverage
All relations	72.8% (68,726/94,456)
Relations other than the hyponymy acquired using suffix information.	47.7% (45,042/94,456)

TABLE 3 – Coverage rate of the acquired relation relative to nouns in the TV program summaries.

relations and the evaluation results.

The total number of relations was 15,462,746, and 3,458,913 nouns appeared in the relations. We checked how these nouns covered the TV program summaries. We picked 25,769 summaries containing 94,456 nouns whose TV programs were available from NHK on demand. TABLE 3 shows the coverage of the acquired relation.

The acquired relations contained 6% ~ 51% errors (TABLE 2). TABLE 3 indicates the nouns in all relations cover 72.8% of the TV program summaries, but that is overstated because the hyponymy relations acquired by using suffix information target the nouns of the summaries. Relations other than the hyponymy relations by suffix cover 47.7% of nouns of the summaries. Although there is room for improvement in accuracy and coverage, we can acquire a huge number of relations and this holds promise for measuring similarities between summaries.

4 Proposed method for measuring similarities between summaries

Here, we describe the proposed method for measuring the similarity between the TV program summaries in NHK on demand using the acquired relations. The average number of characters in the summaries is about 170, and the average number of nouns included in the summaries is 26. These nouns are used as a clue to measure the similarities. The proposed method first generates graph structures which include the TV programs as their nodes. Then it measures the similarity between summaries by measuring the strength of binding of two TV program nodes on the graph. The following subsections describe each step of measuring similarities.

4.1 Generating graph structures

Graph structures are generated from TV program summaries as follows:

1. The TV program names and each noun appearing in the TV program summaries are put on graph nodes.
2. The TV program node and nodes of summary nouns are connected by non-directional edges. The weight to put on each edge between program node p_i and noun node n_j is defined as follows.

$$e(p_i, n_j) = tf(n_j) idf(n_j) / Z_{p_i} \quad (1)$$

   Here, $tf(n_j)$ represents the frequency of noun n_j, $idf(n_j)$ is the inverse document frequency of noun n_j in the summary of TV program p_i, and Z_p is a normalization factor calculated as the sum of the weights of edges which start from node p.
3. The non-directional edges between noun nodes are constructed from the automatically acquired relations between nouns. If two nouns are related, their nodes are connected. For example, if we acquired the hyponymy relation "*lifestyle-related diseases* / *hypertension*", the causality relation "*hypertension* / *smoking*", and the material relation "*smoking* / *Tabaco*",

the edges "*lifestyle-related diseases* ↔ *hypertension* ↔ *smoking* ↔ *Tabaco*" are constructed. The weights for the edges are defined as

$$e(n_i, n_j) = 1/Z_{n_i} \tag{2}$$

Here, Z_n is the normalization factor calculated as the sum of the weights of edges which start from node n.

4.2 Measuring similarities

The next step measures the similarities between summaries by estimating how much one TV program node is related to another program node on the graph. We use a Markov chain theory, called Green Measures (Kemeny et al. 1966), which is a random walk algorithm to measure the similarity of nodes. This method uses a matrix M whose element m_{ij} corresponds to the transition probability from node i to node j. Here, $\Sigma_j m_{ij}=1$. We use the normalized weight for edge defined by equation (1) or (2) for the element m_{ij}. That is, $m_{ij} = e(p_i, n_j)$ if there is an edge between program node p_i and noun node n_j, $m_{ij}=e(n_i, n_j)$ if there is an edge between noun node p_i and noun node n_j, and $m_{ij}=0$ if there is no edge between node i and node j. The Green matrix G is defined as

$$G = \sum_{t=0}^{\infty} (M^t - M^{\infty}) \tag{3}$$

Here, M^t corresponds to the transition matrix of t steps in the random walk. It is known that the Markov chain converges if the chain is both irreducible and aperiodic. Because the chain of our generated graph structure satisfies those conditions, M^t converges exponentially to M^{∞}. The value of element g_{ij} in G indicates how much node i is related to node j. Using the Green matrix G, Yann et al. (2007) proposed a score $S(i, j)$ to indicate the relativeness between two nodes i and j:

$$S(i, j) = g_{ij} \log(1/v_j) \tag{4}$$

Here, v_j is the j-th element of vector v, which is a unique invariant probability measure of the matrix M where $vM=v$. Moreover, against any measure μ where $\Sigma\mu_j=1$, μM^n converges to v as $n \rightarrow \infty$. The logarithmic term $\log(1/v_j)$ can modify the g_{ij} which corresponds to the relativeness score between node i and node j when the value v_j is high. This logarithmic term works like the *idf* value which is used in information retrieval.

We devised two methods for measuring the similarity between two TV program summaries using the relativeness score (eq. (2)) between two nodes. The first method directly uses the relativeness score of the target node directory. The similarity between program nodes p_i and p_j is defined as follows.

$$S_{direct}(p_i, p_j) = S(p_i, p_j) \tag{5}$$

This is the relativeness score of node p_j when the random walk starts from node p_i.

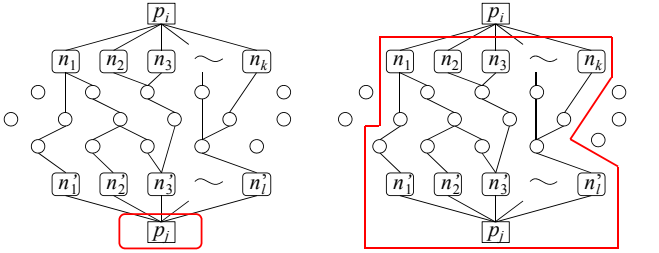

FIGURE 2 – Two methods of measuring similarities between TV program summaries.

The second method uses the scores of all nodes on the route from p_i to p_j. The similarity is defined as follows.

$$S_{related}(p_i, p_j) = \sum_{v \in node(p_i, p_j)} S(p_i, v) \tag{6}$$

Here, $node(p_i, p_j)$ is the set of nodes on the route from p_i to p_j. FIGURE 2 shows the concept of measuring similarities between the summaries of TV programs by the two methods.

5 Experiments

To confirm the effectiveness of the proposed methods, we conducted experiments on measuring the similarities of TV program summaries by using the two proposed methods and four baseline methods. To make the test data, we sampled 352 summaries with the following restrictions.

- All the summaries had different TV program titles
- More than one related TV program were presented for the selected summary in the NHK on-demand service.

The average number of related TV programs to the sampled 352 TV programs was 10.4.

Next, three judges who were not authors ranked the relativeness of the related TV programs against 352 samples. We used Spearman's rank correlation to confirm whether the three judge's rankings were in reasonable agreement. The correlation, which takes into account tie scores of ranks is defined as follows:

$$\rho = T_x + T_y - \sum D^2 \Big/ 2\sqrt{T_x T_y} \tag{7}$$
$$T_x = \left(N^3 - N - \sum_{i=1}^{n_x} (t_i^3 - t_i)\right) \Big/ 12$$
$$T_y = \left(N^3 - N - \sum_{j=1}^{n_y} (t_j^3 - t_j)\right) \Big/ 12$$

Here, D and N indicate the difference between two ranks and the number of related programs. n_x and n_y are the number of tie ranks, and t_i and t_j are the ranks of n_x and n_y. The average correlation between the ranks by the three judges was 0.565, which indicates moderate agreement. We generated the data by arranging these related programs in descending order of average rank and regarded this manually-generated data as the gold-standard ranking data.

We used his gold-standard ranking data as a reference to evaluate the ranking results.

5.1 Baseline methods

Baseline method 1: Okapi BM25

Goto et al. (2010) proposed a method for measuring the similarity between two summaries of TV programs by using Okapi BM25. Okapi BM25 ranks documents according to the relevance to a given query. They substituted the documents and query with summaries. The similarity score $S_{BM}(p_1,p_2)$ between two summaries p_1 and p_2 is defined by the following equation.

$$S_{BM}(p_1,p_2)=\sum_{n\in p_1} idf(n)\cdot\frac{tf_{p_2}(n)\cdot(k+1)}{tf_{p_2}(n)+k\cdot(1-b+\frac{|p_2|}{avgdl})}\cdot\frac{(k'+1)tf_{p_1}(n)}{k'+tf_{p_1}(n)} \quad (8)$$

Here, $tf_p(n)$ is a frequency of noun n in the summary p, $idf(n)$ is the inverse document frequency of n, $|p|$ is the length of the summary p, $avgdl$ is the average length of the summary, and k and k' and b are parameters for which we used k=3.0, k'=100.0, and b=0.75 from the original literature.

Baseline method 2: Cosine with nouns appearing in the summary

Each summary is represented by a vector whose elements are nouns appearing in the summary. The weight $w_{TFIDF}(n)$ for each element is defined by TFIDF.

$$w_{TFIDF}(n)=tf_p(n)\cdot idf(n) \quad (9)$$

The similarity between two summaries p_1 and p_2 is defined by the cosine value of these vectors.

$$S_{TFIDF}(\vec{p}_1,\vec{p}_2)=\frac{\vec{p}_1\cdot\vec{p}_2}{|\vec{p}_1||\vec{p}_2|} \quad (10)$$

Baseline method 3: Cosine with related nouns

This method also represents each summary by a vector. The elements of the vector are composed by nouns appearing in the summary and nouns that are related with any nouns in the summary. For example, if *stroke* appears in a summary, we will add *hypertension* as an element of the vector because *stroke* and *hypertension* have a causality relation. The weight for each noun appearing in the summary is calculated by equation (9). The weight for the expanded noun n_{rel} is defined as follows.

$$w_{rel}(n_{rel}) = w_{TFIDF}(n) / N_{rel}(n) \quad (11)$$

Here, $N_{rel}(n)$ is the number of relations of noun n. The similarity between two summaries is calculated by equation (10).

Baseline method 4 : PLSI

Baseline method 4 uses a statistical latent class model, called PLSI (Hofmann et al. 1999), which associates an unobserved class variable $z \in Z = \{z_1, \ldots, z_k\}$ with each observation of noun $w \in W = \{w_1, \ldots, w_M\}$ in a document $d \in D = \{d_1, \ldots, d_N\}$. The distribution of probability $P(z|d)$ is estimated for each class z and document d by using the EM algorithm. The similarity between two summaries is calculated by computing the distance (Jensen-Shannon divergence) between two probability distributions. The Jensen-Shannon divergence between two probabilities, $P(z|d_1)$ and $P(z|d_2)$, can be calculated as follows.

$$D_{JS}(P(z \mid d_1) \| P(z \mid d_2) = \frac{1}{2}(D_{KL} P(z \mid d_1) \| \frac{P(z \mid d_1) + P(z \mid d_2)}{2}) + D_{KL} P(z \mid d_2) \| \frac{P(z \mid d_1) + P(z \mid d_2)}{2})) \quad (12)$$

Here, D_{KL} indicates the Kullback-Leibler divergence:

$$D_{KL}(P(z \mid d_1) \| P(z \mid d_2) = \sum P(z \mid d_1) \log \frac{P(z \mid d_1)}{P(z \mid d_2)} \quad (13)$$

By using the latent class, it becomes possible to put a non-zero similarity value on summaries that express similar meanings even if they do not share words.

5.2 Experimental results

Targeting the selected summaries for 352 TV programs, we conducted an experiment on ranking related TV programs using the proposed methods and four baseline methods. TABLE 4 shows Spearman's rank correlation with the gold-standard data. In baseline method 4, we tried the following parameter values for the number of unobserved classes z and the temperature parameter β in the process of the EM algorithm and selected z=200 and β=0.75, which gave the best result.

Methods	Rank correlation
Baseline 1 (Okapi-BM25)	0.370
Baseline 2 (cosine with nouns appearing in the summary)	0.350
Baseline 3 (cosine with related words)	0.371
Baseline 4 (PLSI)	0.190
Proposed 1 (using the score of related program node)	0.351
Proposed 2 (using the scores of all nodes on the route to the related program node)	0.423

TABLE 4 – Evaluation result for each method.

z ={10, 50, 100, 200, 300, 400, 500, 1000}

β ={0.6, 0.65, 0.7, 0.75 0.8, 0.85, 0.9, 0.95, 1.0}

The results for proposed method 2, which uses the scores of all nodes on the route between the program nodes, were far better than those of the other methods (TABLE 4). On the other hand, proposed method 1 was not better than baseline methods 1 ~ 3. The score of the node which is connected directly with the start node of the random walk is much larger than one of the nodes which are connected indirectly with the start node. The scores for the related program nodes, which are far from the target program node, are too small to compare with each other. This arises from the shortage of noun relations. If we can acquire enough noun relations, we could avoid this problem. The correlation of baseline method 4 which uses PLSI is much lower than the other methods. This is because the results of the clustering by PLSI were not useful for making TV program recommendations. For example, the words *politics*, *economics*, and *international* belong

[Target TV program title] Marutoku-magazine, exercise ~ hip joint and legs

[Nouns appearing in the corresponding summary] hip joint, stretch, movement, you, easily, range of movement, up, posture, around hip joint, five minutes, velocity, length of stride, exercise, muscle, coverage, one day

Related TV program titles and nouns appearing in the corresponding summary	Gold-standard data (score)	Proposed method 2 (score)	Baseline method 2 (score)
Marutoku-magazine, exercise ~ arm and back [Nouns] back, body, arm, five minutes, condition, tension, everyday, you, head, exercise, posture, muscle, one day	1 (1.333)	1 (0.913)	1 (0.328)
Tameshite-Gatten, Banana revolution ~ declaration of new ingredient [Nouns] banana, fruit, vegetable, cooking, taste, exposure, nourishment, full marks, hand, product, No. 1 of consumption, clear, world, shipping, I, easy, expensive ingredient, ability, ingredient, Gatten's way of cooking bananas, majority, method	2 (1.667)	2 (0.582)	2 (0.0)
Fudangi-no-onsen, Aomori Shimofuro hot spring [Nouns] therapeutic bath, body, bitter cold, Muromachi era, scene, strait, role, people, two, shared hot spring, fishing herring, before World War II, large spa, Yasushi Inoue, place, home town, fist, exchange, information, fisherman, friend, Tsugaru Straits, novel, variety, famous, importance, Shimofuro hot spring, hot spring, core, new hot water	3 (3.333)	3 (0.561)	2 (0.0)
Asaichi, Japan navigation ~ Kyoto [Nouns] Kyoto, Daihachi car, talk, huge, Daikaku temple, autumn, surface of water, Osawa pond, travel, kimono, Maho, vegetable farmer, autumn leaves, fantastic, together, meeting, vegetarian dish, popular, Kyoto vegetable, lighting-up, scene, Hisako Noguchi, 82 years old, temple, Sagano, actor, finding antique kimono, full of autumn leaves, 13th, airiness, world, sight to see, temple master, ancient city	4 (3.667)	4 (0.203)	2 (0.0)

TABLE 5 – Ranking results of proposed method 2 and baseline method 2. All titles and nouns are translated from Japanese nouns.

to the same class, which resulted in miss-selection of the related program for *politics*. The clustering based approach sometimes is affected by from the granularity of each cluster.

TABLE 5 shows a sample of the rankings of proposed method 2 and baseline method 2. The scores of baseline method 2 were zero for three programs, whose summaries did not share words with that of the target program. In contrast, proposed method 2 properly scored these programs. This caused its results to have a higher correlation with the gold-standard data.

5.3 Effectiveness of the using relations

We randomly sampled from all acquired relations in order to investigate the effectiveness of the relations. FIGURE 3 shows the correlation versus the number of sampled relations. Here, the correlation is 0.400 when the number of relations is zero. This value is higher than those of the baseline methods. In the case that we do not use any relations, the edges in the graph structure are composed of one between the program node and the noun node appearing in the program summary. This arises from a heuristic that "the words in the same program summary are similar to each other". This result shows that the more relations we used, the higher the correlation became. We used about 15.5 million relations in this experiment, and we hope we can get higher correlations if we use more relations.

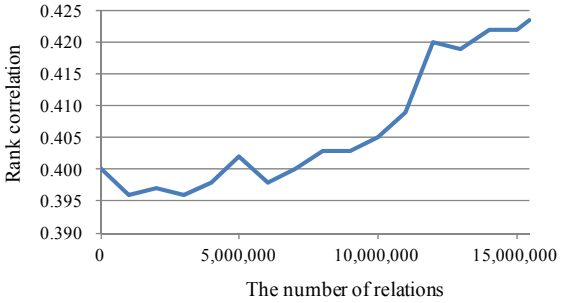

FIGURE 3 – The correlation depended on the number of sampled relations.

5.4 Considerations regarding the edge weighting

In the process of generating graph structures, each edge between the program node and the noun node is weighted by the TFIDF value in equation (1). A random walk tends to move to the node whose TFIDF value is high and which is considered important. However, if a noun node has links to the other nouns appearing in the same summary, the random walk will move on the noun node with higher probability because there are several routes to get to the node.

We experimented with ranking related TV programs by using proposed method 2 without an edge weighting by TFIDF. As a result, the rank correlation value was 0.427, which is comparable to the result of using the weighting. This means that the graph structure implicitly defines the node's importance.

Conclusion

We proposed a method for measuring the similarity between two TV program summaries. The method generates a graph structure whose nodes are composed of TV programs and nouns appearing in the corresponding summary and whose edges are generated from four kinds of relations automatically acquired from the Web and Wikipedia. The similarity between two TV program summaries is calculated on the basis of the relativeness of the two TV program's nodes in the graph structure by using a random walk algorithm. Experiments confirmed that our method provided a proper similarity measure that showed a better correlation with the gold-standard data than the baseline approaches. The experiments using several relations indicated that we would get a higher correlation if we used more relations. Furthermore, we confirmed that we did not need to use the edge weighting by TFIDF because the graph structure implicitly defines the importance for each node.

We used four types of relations in the experiments. Enlarging the number of relations will be of further help in measuring the similarity. Moreover, the relations in the experiments contained 6% ~ 51% errors and covered 47.7% of the nouns appearing in the TV program summaries. In the future, we will determine whether using more relations with higher accuracy and broader coverage.

ABSTRACT
Most existing learning to rank based summarization methods only used content relevance of sentences with respect to queries to rank or estimate sentences, while neglecting sentence relationships. In our work, we propose a novel model, RelationListwise, by integrating relation information among all the estimated sentences into listMLE-Top K, a basic listwise learning to rank model, to improve the quality of top-ranked sentences. In addition, we present some unique sentence features as well as a novel measure of sentence semantic relation, aiming to enhance the performance of training model. Experimental results on DUC2005-2007 standard summarization data sets demonstrate the effectiveness of our proposed method.

KEYWORDS: Query-focused multi-document summarization, Listwise, Sentence relation.

1 Introduction

In this paper, we focus on the task of producing extraction-based query-focused multi-document summaries given a collection of documents, which is usually considered as a sentence ranking problem. Typically, ranking methods calculate the combinational effects of various features which are designed to identify the different aspects of sentences and/or their relevance to queries. Yet so far not much attention has been paid to it. Most commonly, the features are simply combined by a linear function in which the weights are assigned manually or tuned experimentally. In the past, machine learning approaches have been successfully applied in extractive summarization (Ouyang et al., 2007; Shen and Li, 2011), and a new research branch named “learning to rank" has emerged. Its objective is to explore how the optimal weights can be obtained automatically by developing learning strategies. However, previous work mainly considered the content relevance of sentences with respect to certain query while ignoring the relationships among sentences. In this paper, we try to study how to use sentence relatedness to improve the performance of a ranking model. Further, we notice that many learning to rank algorithms have been proposed in recent literature, and these algorithms can be categorized into three types: pointwise, pairwise, and listwise approaches. The pointwise and pairwise approaches transform ranking problem into regression or classification on single object and object pairs respectively, while neglecting the fact that ranking is a prediction task on a list of objects. In listwise approach, object lists instead of object pairs are used as instances in learning, and the major task is how to construct a listwise loss function, representing the difference between the ranking list output by a ranking model and the ranking list given as ground truth. Experimental results showed that listwise approach usually outperforms pointwise and pariwise approaches (Cao et al., 2007; Qin et al., 2008). Accordingly, we mainly concentrate on developing listwise learning to rank in our summarization task.

More exactly, taking into account the specific scenario of summarization, it’s better to base our work on a variant of basic listwise training model: ListMLE Top-K presented in (Xia et al., 2009). It’s because that we usually only need to select a small amount of sentences to construct a summary. ListMLE Top-K , a modification of basic listwise algorithm for more suitability in many real ranking problems where the correct ranking of the entire permutation is not needed, could help us to improve the ranking accuracies of top-K sentences. Based on that, our novel RelationListwise function, having absorbed sentence affinity information, is formed to learn the optimal feature weights.

Apparently, how to design appropriate sentence features and measure sentence similarity matter greatly in influencing the system performance. In most existing approaches about feature design, the authors tended to only consider factors that were supposed to reflect the bias of sentences towards a query while neglecting such a possibility: overestimating the relationship with a query might lead to the competitiveness among relevant sentences, which would eventually do harm to the summary quality. For this reason, some extra processing was usually conducted during sentence selection because some top-ranked sentences usually can not be used to construct a high-quality summary directly. For example, (Shen and Li, 2011) defined a total of 20 sentence features for its ranking SVM model. Whereas, those features were produced by paying no attention to avoiding similar sentences to get close scores. Therefore, in order to keep low information redundancy in the finally generated summary, those authors had to apply diversity penalty algorithm to update the sentence orders which resulted from the training function directly. Namely, some previous work had to take two steps to construct a high-quality summary, including initial sentence ranking coming from ranking model

and sentence order adjustment. Hence, a strong motivation comes to our mind: designing sentence features considering the query-biased factors as well as the competitiveness coming from similar sentences, aiming to produce a high-quality summary through directly selecting some top-ranked sentences.

As for sentence similarity, existing literatures have presented various methods to deal with it. Nevertheless, hard matching of words is commonly a primary obstacle in judging whether two sentences are semantically related. For example, while $wonderful$ and $amazing$ are semantically close, they are treated completely different in many existing methods, such as tf-isf (term frequency and inverse sentence frequency) based cosine measure. Motivated by that, we utilize Log-Bilinear Document Model, proposed in (Maas et al., 2011), to achieve the identification of semantically similar words. As a result, sentences with no same words but similar ones could also be considered having a certain degree of semantic similarity. Extensive experiments on DUC2005-2007 standard summarization data sets are performed and their results point out the good performance of RelationListwise in this task.

Since our proposed training model is on the basis of sentence similarity and sentence features, in following sections, after giving related work in Section 2, we first elaborate how to derive sentence similarity in Section 3 and biased features in Section 4, respectively. Then, detailed description of using sentence similarity to improve listMLE top-K is presented in Section 5. Section 6 shows training data generation. Experiments and results are given in Section 7.

2 Related work

We first introduce some supervised learning approaches applied in query-biased summarization. Then, some typical work about feature design and sentence similarity follows.

Supervised learning approaches have been successfully applied to query/topic-biased summarization. (Zhao et al., 2005) applied the Conditional Maximum Entropy, a classification model, on the DUC 2005 query-based summarization task. (Ouyang et al., 2007) used support vector regression (SVR), a pointwise ranking algorithm, to relate the "true" score of the sentence to its features. (Jin et al., 2010) presented a systematic study of comparing different learning to rank algorithms and comparing different selection strategies for multi-document summarization. Whereas, it focused on the simple comparison of some basic models with no optimization. (CHALI and HASAN, 2011) had deeply investigated and compared the effects of using different automatic annotation techniques on different supervised learning approaches, including SVMs, HMMs, CRFs, and MaxEnt, in the domain of query-focused multi-document summarization. (Shen and Li, 2011) explored the use of ranking SVM, a pairwise learning to rank model, for obtaining credible and controllable solutions for feature combinations. Our main contributions not only lie in our unique design of sentence features and sentence similarity measure, more importantly, we integrate sentence relationships with listwise to improve the ranking model while above literatures ignored the relation information among those sentences

With regard to feature design, (Li et al., 2009) treated summarization as a supervised sentence ranking process, where coverage, balance and novelty properties were incorporated. Whereas, it focused on generic summarization rather than query-biased situation. (Wan et al., 2007) gave explicit definitions of biased information richness and novelty, then, it proposed to compute biased information richness using manifold-ranking process (Zhou et al., 2004), and a modified MMR algorithm was applied to keep low information redundancy in generated summaries. In (Wei et al., 2008), authors proposed query-sensitive sentence similarity. Only the

overlapping of topic-relevant contents was penalized when applying MMR algorithm. In addition, clustering techniques were commonly adopted to identify different and novel aspects of documents (Wan and Yang, 2008). The method presented in (Li et al., 2010) is slightly similar with our work for it considered novelty, coverage and balance wholly. However, sentence features of existing literatures were usually acquired asynchronously. For instance, $novelty$ and $balance$ in (Li et al., 2010) were achieved as an optimization process after authors have identified part of high-quality sentences through the effects of other features.

Calculating sentence similarity appears in many applications. tf-isf based cosine measure is widely used to determine the lexical similarity of two sentences. Whereas, high dimensionality and high sparsity usually lead to disappointing performance. (Erkan, 2006) proposed a graph-based sentence ranking model: Biased LexRank, where edge weight or called sentence similarity was acquired using generation probability between two sentences based on a (unigram) language model. (Islam and Inkpen, 2008) determined sentence similarity by combining string similarity, semantic similarity and common-word order similarity with normalization. The similarity between two short text snippets in (Quan et al., 2010) was calculated based on their common terms and their distinguishing terms relationship which was discovered by examining their probabilities under each topic. Some literatures opted to first deal with word similarity calculation, then combine the result with sentence structure information. For example, (Li et al., 2006) first derived word semantic similarity from a lexical knowledge base, modeling common human knowledge about words in a natural language, and a corpus, adapting to the specific application area. Secondly, it considered the impact of word order on sentence meaning. The derived word order similarity measured the number of different words as well as the number of word pairs in a different order. In (Zhang et al., 2011), word similarity only considered the spellings and ignored the semantic meanings of words. Structure information considered the orders of words and the distances between words, and it ignored the syntactic information of sentences. (Yin et al., 2012) used a similar way with (Quan et al., 2010) to determine word relatedness while its structural similarity of sentences was acquired via longest common subsequence (LCS), weighted longest common subsequence (WLCS) and skip-bigram co-occurrence statistics, respectively.

3 New measure of sentence similarity

Hard matching between words has long been an obstacle in determine the relatedness of two sentences. For example, considering following two sentences:

s_1 : employee enjoy happy *holiday* $\quad$ s_2 : employee enjoy happy *vacation*

where words $holiday$ and $vacation$ would be treated with no relation in traditional VSM based cosine measure. Whereas, they are semantically related very much in the real context. Hence, in our perspective, before computing sentence similarity, we should first solve this problem: identifying the semantic relatedness of words.

3.1 Capturing semantic similarities of words

Authors in (Maas et al., 2011) presented an algorithm to acquire word semantic similarity through learning word vectors via an unsupervised probabilistic model of documents. While it is common to represent words as indices in a vocabulary, but this fails to capture the rich relational structure of the lexicon. Vector-based models do much better in this regard. They

encode continuous similarities between words as distance or angle between word vectors in a high-dimensional space. Next, we briefly introduce that algorithm.

For a document (e.g., d), a probabilistic model is constructed using a continuous mixture distribution over words indexed by a multi-dimensional random variable θ, then the probability of d is determined using a joint distribution over d and θ. As many common treatments did, the algorithm also puts an assumption of independence for words given θ. The probability of a document d is as follows

$$p(d) = \int p(d,\theta)d\theta = \int p(\theta)\prod_{i=1}^{N} p(w_i|\theta)d\theta \tag{1}$$

where N is the number of words in d and w_i is the i^{th} word. θ has a Gaussian prior.

Then define the conditional distribution $p(w_i|\theta)$ using a log-bilinear model (Maas and Ng, 2010) with parameters R and b. R is virtually a word representation matrix $R \in \mathbb{R}^{(\beta\times|V|)}$ where the β-dimensional vector representation of each word w in vocabulary V corresponds to that word's column in R, i.e., $\phi_w = R_w$. The random variable θ is also a β-dimensional vector ($\theta \in \mathbb{R}^{\beta}$), indicating the weights of the β dimensions of words' representation vectors. In addition, a bias b_w is introduced for each word to capture differences in overall word frequencies. The energy assigned to a word w, given these model parameters, is

$$E(w;\theta,\phi_w,b_w) = -\theta^T\phi_w - b_w \tag{2}$$

After normalization, we obtain the distribution $p(w|\theta)$,

$$\begin{aligned} p(w|\theta;R,b) &= \frac{\exp(-E(w;\theta,\phi_w,b_w))}{\sum_{w'\in V}\exp(-E(w';\theta,\phi_{w'},b_{w'}))} \\ &= \frac{\exp(\theta^T\phi_w + b_w)}{\sum_{w'\in V}\exp(\theta^T\phi_{w'} + b_{w'})} \end{aligned} \tag{3}$$

Apparently, for a given θ, a word w's occurrence probability is related to how closely its representation vector ϕ_w matches the scaling direction of θ. Finally, maximum likelihood learning is exploited for this model when given a set of unlabeled documents D. In maximum likelihood learning we maximize the probability of the observed data given the model parameters. Here, we omit the learning details[1].

Having obtained vector representations of words, we could determine the semantic relatedness (SR for short) of two terms (e.g., w_1 and w_2):

$$SR(w_1,w_2) = \phi_{w_1}\cdot\phi_{w_2} \tag{4}$$

3.2 Sentence similarity identification

Based on word relatedness, we construct a word connectivity graph, and use PageRank algorithm, with normalized words' term frequencies as prior distribution, to determine words' importance, e.g., the importance score of word w is denoted as $imp(w)$, and importance score of sentence s is: $Imp(s) = \sum_{w\in s} imp(w)\cdot\sqrt{c_s(w)}$, where $c_s(w)$ is the times of w occurring in

[1] For more details, please refer to (Maas et al., 2011)

s. Note that we have filtered out stop words. We use $\sqrt{\{\cdot\}}$ to reduce the influence of repeated words instead of using sentence length to divide the aggregate score of a sentence, because we believe that a sentence with more important words deserves high importance. Based on our algorithm, a sentence with lots of unimportant words will not get a high importance score.

Given two sentences such as s_1 and s_2, our next step is to find for each word a in one sentence the corresponding word a^*, in the other sentence, that maximizes their mutual semantic relatedness (e.g., a in s_1, a^* in s_2 and vice versa).

$$a^* = \arg\max_{b \in s_2} SR(a, b) \tag{5}$$

Then, we average the semantic relevance scores from all terms in sentence s_1, with reference to their best matches in sentence s_2, as shown in Equation 6.

$$\zeta(s_1, s_2) = \frac{\sum_{w_i \in s_1} imp(w_i) \cdot SR(w_i, w_i^*)}{\sum_{w_i \in s_1} imp(w_i)} \tag{6}$$

We do the same for the opposite direction (i.e., from the words of s_2 to the words of s_1) to cover the cases where the two sentences are not equally important or they receive different similarities from each other. Finally, we derive the similarity between sentences s_1 and s_2 as:

$$sim(s_1, s_2) = \frac{Imp(s_1) \cdot \zeta(s_1, s_2) + Imp(s_2) \cdot \zeta(s_2, s_1)}{Imp(s_1) + Imp(s_2)} \tag{7}$$

4 Feature design

In the case of query-sensitive summarization, we conclude that qualified summary sentences should mainly meet the following typical demands: query-biased relevance (Shen and Li, 2011; Otterbacher et al., 2005), biased information richness (Wan et al., 2007) and biased novelty (Wan et al., 2007). Query-biased relevance requires that the sentences in the summary must overlap with the query in terms of topical content. Query-biased information richness denotes the information degree of a sentence with respect to both the sentence collection and the query. Query-biased information novelty is used to measure the content uniqueness of a sentence based on that sentence's capability in differentiating itself from other sentences as well as responding to the demands of the query. According to above definitions, we design multiple sentence features corresponding to them, respectively.

4.1 Four kinds of relevance

Given a sentence s, we exploit following information available in the DUC2005-2007 datasets:

- t_s: Title of the document containing sentence s.
- d_s: The document containing sentence s.
- c_s: The document cluster containing sentence s.
- q_s: Query of the document collection containing sentence s.

Noting that we do not conduct sentence segmentation if the query consists of more than one question, instead we treat it as a single, long sentence. Consequently, we calculate the following four sentence features using similarity measure discussed in Section 3:

- $r_{t,s}$: Relevance between sentence s and the title of the document to which s belongs.
- $r_{d,s}$: Relevance between sentence s and the document to which s belongs.
- $r_{c,s}$: Relevance between sentence s and the document cluster to which s belongs.
- $r_{q,s}$: Relevance between sentence s and query q.

4.2 Biased information richness (BIR)

Given a sentence collection and a query q, the BIR of sentence s is used to indicate the information degree of s with regard to both the sentence set and q, i.e., the richness of information contained in the sentence s biased towards q.

This feature score for each sentence is obtained via a variant version of the manifold-ranking process proposed in (Zhou et al., 2004). Points $\{s_0, s_1, \cdots, s_n\}$ denote the query statement (s_0) and all the sentences in the document collection ($\{s_i | 1 \leq i \leq n\}$) in a manifold space. The ranking function is denoted by $f = [f_0, f_1, ..., f_n]$. (Wan et al., 2007) hypothesized that all the sentences had blank prior knowledge so their initial scores were all set to zero. Whereas in this study, it is rational to treat the query-sentence relevance discussed in Section 4.1 as prior knowledge of sentences. Since s_0 denotes the query description, the initial score vector of these sentences is y $=[y_0, y_1, ..., y_n]$, where $y_0 = 1$ and $y_i = \text{sim}(s_i, s_0)$ (1≤ i≤ n). The manifold ranking can be performed iteratively using the following equation:

$$f(k+1) = \alpha S f(k) + (1-\alpha) y \tag{8}$$

where S is the symmetrically normalized similarity/relevance matrix as for $\{s_0, s_1, \cdots, s_n\}$, trade-off parameter α is set to 0.6, and k indicates the k^{th} iteration. Obviously, modified initial scores will exert a greater influence to sentence scores than the settings in (Wan et al., 2007) at each step of the iteration process. After convergence, let $f_i^\star$ denotes the limit of the sequence $\{f_i(t)\}$, then the BIR of sentence s_i is:

$$BIR(s_i) = f_i^\star \quad (1 \leq i \leq n) \tag{9}$$

4.3 Biased information novelty (BIN)

In our perspective, those sentences, owning relative high BINs and picked out to generate summary, must have information redundancy as low as possible meanwhile meet the user's information need, expressed by a query, as much as possible. Satisfaction of only one of them will certainly be off the original intention of biased novelty. Hence, we employ DivRank, proposed in (Mei et al., 2010), to acquire this sentence property. DivRank uses a *vertex-reinforced random walk* model to rank graph nodes based on a diversity based centrality. The basic assumption in DivRank is that the transition probability from a node to another is reinforced by the number of previous visits to the target node. Let $p_T(u, v)$ be the transition probability from any state u to any state v at time T. We can define a family of time-variant random walk processes in which $p_T(u, v)$ satisfies

$$p_T(u, v) = (1-\lambda) \cdot p^*(v) + \lambda \cdot \frac{p_o(u, v) \cdot N_T(v)}{D_T(u)} \tag{10}$$

where $D_T(u) = \sum_{v \in V} p_o(u, v) N_T(v)$. Here, $N_T(v)$ is the number of times that node v has been visited up to time T and $p^*(v)$ is a distribution which represents the prior preference of

visiting vertex v. In our task, $p^*(v)$ is set to the normalized similarity between sentence v and the query q, i.e., $p^*(v) = \widetilde{sim}(v,q)$. $p_o(u,v)$ is the *organic* transition probability prior to any reinforcement, which can be estimated in a regular time-homogenous random walk, such as

$$p_o(u,v) = \begin{cases} \gamma \cdot \frac{sim(u,v)}{degree(u)} & \text{if } u \neq v; \\ 1-\gamma & \text{otherwise} \end{cases} \tag{11}$$

If the network is ergodic, after a sufficiently large T, the reinforced random walk defined by Equation 10 also converges to a stationary distribution $\pi(v)$. That is

$$\pi(v) = \sum_{u \in V} p_t(u,v)\pi(u), \qquad \forall t \geq T \tag{12}$$

$\pi(v)$ is then used to denote the BIN of sentence v. In experiments, $\lambda = 0.9$ and $\gamma = 0.25$.

5 RelationListwise ranking function construction

Inspired by the work in (Zhou et al., 2011), which described a general ranking function with relationship information among objects, we modify that model specifically for our summarization task. Firstly, we define some notations used in this section. Query q is associated with a sentence collection $S = \{s_1, s_2, \cdots, s_n\}$, and S is associated with a set of judgments $Y = \{y_1, y_2, \cdots, y_n\}$. Here, n denotes the number of sentences in that collection, and y_i is the relevance judgment of sentence s_i with respect to query q. We could also treat y_i to be the position of sentence s_i in ranking list. Exactly, each sentence s_i is represented as a feature vector $\mathbf{x}_i = \Phi(q, s_i)$, where the acquisition of those features is presented in Section 4. In whole, we can see query q corresponds to a set of sentences S, a set of features vectors $X = \{\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n\}$, a set of judgements Y, and R, the affinity matrix among sentences in S.

Let $g(\mathbf{x}_i, \mathbf{w})$ denote the basic ranking function of Listwise method, i.e.,

$$g(\mathbf{x}_i, \mathbf{w}) = < \mathbf{x}_i, \mathbf{w} > = \mathbf{x}_i \cdot \mathbf{w} \tag{13}$$

where vector $\mathbf{w}$ is unknown, and is exactly what we want to learn. In this paper, $g(\mathbf{x}_i, \mathbf{w})$, meaning the content relevance of s_i with regard to query q, is defined as a linear function, namely taking the inner product between vector $\mathbf{x}_i$ and $\mathbf{w}$. Based on this step, we use following formula to derive the final RelationListwise ranking score of sentence s_i ($1 \leq i \leq n$), denoted as $f_{\mathbf{w}}(\mathbf{x}_i, R)$, by integrating its initial Listwise ranking score (i.e., $g(\mathbf{x}_i, \mathbf{w})$) with its neighbors' Listwise scores:

$$f_{\mathbf{w}}(\mathbf{x}_i, R) = (1-\tau) g(\mathbf{x}_i, \mathbf{w}) + \tau \sum_{j \neq i}^{n} g(\mathbf{x}_j, \mathbf{w}) \cdot \tilde{R}^{(i,j)}) \tag{14}$$

where $\tilde{R}^{(i,j)} = \frac{R^{(i,j)}}{\sum_{s \neq i} R^{(i,s)}}$ denotes the normalized similarity between sentence s_i and s_j. The second item of Equation 14 can be interpreted as following: if the relevance score of s_j with query q is high and s_j is very related with s_i , then the relevance value between s_i and q will be increased significantly, and vice versa. In Equation 14 we can find that the prestige of sentence s_i is decided not only by the content of itself, but its neighbors' prestige. The coefficient τ is the weight of relation information (the second item of Equation 14). We can change its value to adjust the contribution of similarity information to the whole ranking value. In our experiment, we set it to 0.5.

5.1 RelationListMLE Top-K probability optimization

Before presenting our training algorithm, it's worth mentioning that a crucial difference between summarization scenario and most ranking problems is that summarization task casts more emphasis on the top-ranked sentences in the final list. Because of the length limit of a summary, most sentences assigned relatively low ranking scores will not be selected to construct a summary. Therefore, the correct ranking of the entire sentence permutation is not needed, our goal is to improve the ranking accuracies of top-K sentences (here we set K to a constant on condition that we are confident that K selected sentences satisfy the demand of summarization task about summary length, e.g., $K = 20$ in our experiments).

There are many training algorithms to learn listwise ranking function, such as Likelihood loss, Cosine loss and Cross entropy loss, among which likelihood loss has been proved to have the most comprehensive properties and its corresponding learning algorithm is called ListMLE (Xia et al., 2008). Accordingly, we integrate K value with listMLE to learn our proposed RelationListwise ranking function. This kind of solution was indicated by (Xia et al., 2009) to be more suitable for some real ranking applications where top-K objects are the focus. For convenience, we name it *RelationListMLE Top-K* probability optimization.

Our proposed optimization method also uses stochastic gradient descent algorithm to search the local minimum of loss functions. The stochastic gradient descent algorithm is described as Algorithm 1.

Algorithm 1: Stochastic Gradient Descent

Input: training data $\{\{X_1, Y_1, R_1\}, \{X_2, Y_2, R_2\}, \cdots, \{X_n, Y_n, R_n\}\}$
Parameter: learning rate η, tolerance rate ε
Initialize parameter **w**
repeat
  for $i = 1$ **to** n **do**
    (1)Compute score of each sentence j with current **w** using Equation 14
    (2)Compute the gradient $\Delta\mathbf{w}$ with current **w** using Equation 15
    (3)Update **w**=**w**-$\eta \times \Delta\mathbf{w}$
  end for
  Compute likelihood loss:

$$L = -\sum_{i=1}^{n} \log \prod_{c=1}^{K} \frac{\exp(f_{\mathbf{w}}(\mathbf{x}_{iy_i^c}, R_i))}{\sum_{t=c}^{n_i} \exp(f_{\mathbf{w}}(\mathbf{x}_{iy_i^t}, R_i))}$$

until change of likelihood loss is below ε times the previous loss
Output: w

In RelationListMLE-Top-K, the gradient of likelihood loss $L(f_{\mathbf{w}}(X_i, R_i), Y_i)$ with respect to w_j can be derived as Equation 15:

$$\Delta w_j = \frac{\partial L(f_{\mathbf{w}}(X_i, R_i), Y_i)}{\partial w_j} \tag{15}$$

$$= \sum_{c=1}^{K} \{ \frac{\sum_{t=c}^{n_i} [\exp(f_{\mathbf{w}}(\mathbf{x}_{iy_i^t}, R_i)) \cdot \frac{\partial f_{\mathbf{w}}(\mathbf{x}_{iy_i^t}, R_i)}{\partial w_j}]}{\sum_{t=c}^{n_i} \exp f_{\mathbf{w}}(\mathbf{x}_{iy_i^t}, R_i)} - \frac{\partial f_{\mathbf{w}}(\mathbf{x}_{iy_i^c}, R_i)}{\partial w_j} \}$$

where

$$\frac{\partial f_{\mathbf{w}}(\mathbf{x}_{ir}, R_i)}{\partial w_j} = (1-\tau)\mathbf{x}_{ir}^j + \tau \sum_{p=1, p\neq r}^{n_i} \mathbf{x}_{ip}^j \tilde{R}_i^{(r,p)} \tag{16}$$

and $\mathbf{x}_{ir}^j$ is the j^{th} element in $\mathbf{x}_{ir}$

6 Training data construction

To apply learning to rank in summarization, we should have a labeled training collection in the form of $(\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_n, y_n)$, where $\mathbf{x}_i$ is a sentence (or sentence feature vector) in sentence set S and y_i is the ranking of the sentences. In addition, the relation information among sentences must be constructed too. To estimate the ranking score of a sentence s given the human summary H, we implement manifold-ranking algorithm to achieve our goal, treating H as a query vertex in graph. The reason for using manifold-ranking algorithm rather than directly calculating the relevance of a sentence towards the query (i.e., H) lies in that manifold-ranking process considers the query-sentence relatedness as well as the inter-sentence affinities. It matches our intention of improving the basic listwise with relationships among sentences.

Whereas, it is worth mentioning that we do not treat the human summary H wholly as a long sentence to participate in the computing of query-sentence similarities. Instead, we treat H as a sentence set and our goal is to find a sentence, from H, that has the relatively maximum similarity with an estimated sentence in S. This is because that if a sentence is similar with a summary sentence, it is also supposed to have the potential to become a summary sentence even though it might have no similarity with other sentences in H at all. So, during the manifold-ranking process, similarity between a pair of sentences is acquired via the method discussed in Section 3 while H-sentence relevance is obtained as follows:

$$rel(s, H) = \max_{r \in H} sim(s, r) \tag{17}$$

We name our method for training data generation $sent\_manifold$. Additionally, biased LexRank (Erkan, 2006) is also a feasible solution to rank sentences for training data construction. Its primary idea is to generate a prior distribution for the objects in traditional random walk to reflect the bias degree of objects towards certain query. We will conduct experiments to compare our approach with some representative alternatives.

7 Experimental study

7.1 Data sets and evaluation metrics

We use the popular query-focused summarization benchmark data sets DUC2005[2], DUC2006[3] and DUC2007[4] for our experiments. Each of them consists of document sets and reference/human summaries. For documents, we use the OpenNLP[5] to detect and tokenize sentences. Stop words are removed and remaining words are stemmed using Porter stemmer[6]. In experiments, DUC2005 is used to train the model tested on DUC2006, and DUC2006 is used to train the model tested on DUC2007. Table 1 gives a short summary of the three data sets.

[4]http://www-nlpir.nist.gov/projects/duc/duc2007/tasks.html
[5]http://opennlp.sourceforge.net/
[6]http://tartarus.org/ martin/PorterStemmer/

	DUC2005	DUC2006	DUC2007
Cluster number	50	50	45
Documents per cluster	25-50	25	25
Summary length limit	250 words	250 words	250words

Table 1: Summary of datasets

We use ROUGE (Lin, 2004) (version 1.5.5) toolkit[7] to measure the summarization performance. In experiments, we report three widely adopted F-measure metrics: ROUGE-1, ROUGE-2 and ROUGE-SU4, among which ROUGE-N means n-gram recall, and ROUGE-SU4 is based on unigram plus skip-bigram match with maximum skip distance of 4.

7.2 Experimental results

7.2.1 Comparison among some typical supervised summarization systems

First, we compare RelationListwise with some competitive and typical supervised summarization algorithms and three top systems of DUC. (1)Ranking-SVM: applying ranking-SVM directly; (2) Ranking-SVM-CSL: Ranking-SVM with Cost Sensitive Loss, proposed in (Shen and Li, 2011) (3)SVR: learning a regression model using SVM, presented in (Ouyang et al., 2007); (4)Listwise: similar to our RelationListwise while taking no account of sentence relationship; (5)top three systems with the highest ROUGE scores that participated in the DUC2006 (S12, S23, S24) and the DUC2007 (S4, S15, S29) for comparison, respectively.

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
SVR	0.41813	0.09492	0.15116
Ranking-SVM	0.42014	0.09713	0.15326
Ranking-SVM-CSL	0.42179	0.10332	0.15377
S23	0.40973	0.09785	0.14562
S12	0.41053	0.09633	0.15074
S24	0.41081	0.09857	0.15248
Listwise	0.42716	0.10387	0.16008
RelationListwise	**0.43066**	**0.10852**	**0.16324**

Table 2: F-measure comparison on DUC2006

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
SVR	0.43821	0.11997	0.16508
Ranking-SVM	0.44514	0.12213	0.17326
Ranking-SVM-CSL	0.44839	0.12332	0.17377
S4	0.43603	0.11785	0.17162
S29	0.43159	0.12048	0.17374
S15	0.44481	0.12907	0.17748
Listwise	0.45283	0.12667	0.17549
RelationListwise	**0.45852**	**0.13091**	**0.17824**

Table 3: F-measure comparison on DUC2007

Tables 2 and 3 present the performance of these systems with the metrics ROUGE-1, ROUGE-2, and ROUGE-SU4. From the results we can observe that in this task, listwise based methods

[7] http://www.isi.edu/licensed-sw/see/rouge/

(RelationListwise and Listwise) generally outperform pairwise methods (Ranking-SVM and Ranking-SVM-CSL), and the latter outperforms SVR, a pointwise learning to ranking. Even through (Shen and Li, 2011) developed cost sensitive loss to improve basic ranking SVM, its results are still inferior to that of Listwise based methods, which indicates the correctness of our choosing Listwise learning to rank as basic training model. More importantly, taking into account the sentence relatedness indeed improves the performance of $Listwise$. As the statistics show, $RelationListwise$ outperforms $Listwise$ over all three metrics.

7.2.2 Validation of feature design

Further, in order to investigate the effectiveness of combining our designed features, we compare our method RelationListwise with some baselines which mainly consider individual features: (1)Rel: a method considering only the sentence relevance towards a query and choosing the most relevant sentences to produce summary until length limit is reached. (2)Rel+MMR: similar with (1) except that we use MMR algorithm to control redundancy. It denotes a system considering query-biased relevance as well as information novelty. (3)Coverage: a baseline clustering-based method. It clusters sentences and selects the most relevant sentences from different clusters. Note that the clustering operation is carried to select sentences that have low degree of information overlap. So this baseline is similar with (2) for considering both relevance and novelty. (4)Manifold: ranking the sentences according to the manifold ranking scores and select top-ranked sentences to construct summary directly, where the parameter $\alpha = 0.5$. It corresponds to feature BIR. (5)Manifold+MMR: similar with (4) except to reduce redundancy via MMR algorithm (Wan et al., 2007). (4)Diversity: selecting sentences according to their query-biased diversity scores acquired using DivRank (Mei et al., 2010). It represents the feature: BIN. Tables 4 and 5 show their comparison results.

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Rel	0.36775	0.07092	0.12777
Rel+MMR	0.37328	0.07109	0.12884
Manifold	0.38827	0.08028	0.13349
Coverage	0.39004	0.08394	0.13705
Diversity	0.39052	0.08814	0.13721
Manifold+MMR	0.39116	0.08741	0.13729
RelationListwise	**0.43066**	**0.10852**	**0.16324**

Table 4: Comparison results of feature design on DUC2006

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Rel	0.38985	0.10075	0.13108
Rel+MMR	0.39938	0.1033	0.14501
Manifold	0.40214	0.10131	0.14833
Coverage	0.41243	0.11196	0.15537
Diversity	0.41440	0.11261	0.15502
Manifold+MMR	0.42015	0.11327	0.15936
RelationListwise	**0.45852**	**0.13091**	**0.17824**

Table 5: Comparison results of feature design on DUC2007

Obviously, the statistics point out the improvement of our approach combining multiple task-specific features over those baselines. While some reference systems involve more than one

information aspect, such as *Rel+MMR* and *Manifold+MMR*, their performances are still limited.

7.2.3 Competitiveness of our similarity measure

In Section 7.2.1, experimental results have validated our proposal that exploiting sentence relation to improve the overall training model. Nevertheless, they could not point out the superiority of our designed measure of sentence similarity. Hence, we keep consistency for our algorithm framework except to replace the part of calculating sentence similarity. Since there are lots of existing sentence similarity measures, and it's hard to compare qualities of them all, we just select following typical alternatives: (1)cosine measure; (2)wordSimi_sentStruct: The measure proposed in (Yin et al., 2012), which determined words semantic similarity by computing the cosine value of the words' distribution representations over latent topics, and identified sentence structure similarity using LCS and etc.; (3)geneProb: Generation probability method presented in (Erkan, 2006). Note that generation probability is not necessarily symmetric, we just average the mutual generation probabilities of two sentences as their final similarity value in experiments. We provide their comparison statistics in Tables 6-7.

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Listwise	0.42716	0.10387	0.16008
cosine measure	0.42906	0.10659	0.16239
geneProb	0.42923	0.10671	0.16246
wordSimi_sentStruct	0.43004	0.10726	0.16307
RelationListwise	**0.43066**	**0.10852**	**0.16324**

Table 6: Comparison results of sentence similarity measures on DUC2006

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Listwise	0.45283	0.12667	0.17549
cosine measure	0.45626	0.12819	0.17634
geneProb	0.45693	0.12873	0.17616
wordSimi_sentStruct	0.45793	0.12956	**0.17833**
RelationListwise	**0.45852**	**0.13091**	0.17824

Table 7: Comparison results of sentence similarity measures on DUC2007

The two tables demonstrate the influence of different sentence similarity measures on our approach. Among the four kinds of measures, $geneProb$ is close with $cosine$ with slight improvement while $wordSimi\_sentStruct$ is more competitive to our proposed similarity measure. Except that $wordSimi\_sentStruct$ performs slightly better than $RelationListwise$ in ROUGE-SU4 over DUC2007, our proposed measure is more superior in other metrics. Note that we also put method $Listwise$ in the tables, and yet its performance is relatively poor compared with ones involving inter-sentence impacts. It further validates that sentence relatedness is worth considering when dealing with sentence ranking problem.

7.2.4 Training data generation comparison

In this section, we empirically investigate the effects of different strategies for training data generation. In Section 6, we have given the reason why choose to compute the similarity of an estimated sentence towards one sentence in H instead of the whole H. Additionally, we also come up with a novel approach for measuring sentence similarity in Section 3. In general, we

could treat reference summary H as (1): a long and single sentence (labeled as *summ*), or (2): a sentence set (labeled as *sent*); meanwhile, ranking methods could be classified into (1): manifold, (2): biased LexRank, and (3)simi: computing the similarities of estimated sentences towards the summary directly. So, we can combine them into 6 kinds of pairs: $summ\_manifold$, $summ\_biasedLexRank$, $summ\_simi$, $sent\_manifold$, $sent\_biasedLexRank$ and $sent\_simi$. Remember that $sent\_manifold$ is our proposed method for training data construction.

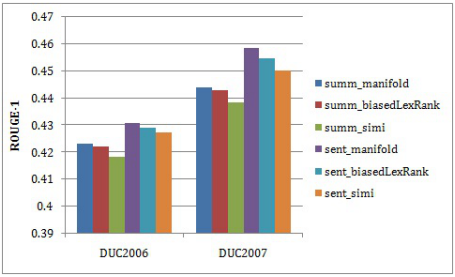

Figure 1: Performance comparison of methods about training data generation.

The comparison results are shown in Figure 1. From the comparison, we observe that:(1)graph-based methods, including $\{\cdot\}\_manifold$ and $\{\cdot\}\_biasedLexRank$, both outperform $\{\cdot\}\_simi$ methods which rank sentences by computing sentences' similarities towards the reference summary directly. It might result from that $\{\cdot\}\_simi$ solution is too simple to take into consideration the prestige of sentences in documents. (2) Using a sentence as the reference is much better than using the whole summary. As the figure shows, all $sent\_\{\cdot\}$ methods outperform $summ\_\{\cdot\}$. This may due to the fact that in constructing training data, we aim to judge the ability of a sentence to be a summary sentence, and it's best to be treated as the ability for the estimated sentence to *replace* certain sentence in H. Therefore, it is more rational to compare our estimated sentence with the sentences in H one by one rather than with the whole H. For example, if a sentence in H (e.g., h_i) has a high similarity (e.g., 0.9) with an estimated sentence s, then s is supposed to be able to replace h_i as a summary sentence. Whereas, if a long sentence s' is also very relevant to the whole H while having very low similarities with sentences in H, it is still not considered to be a good summary sentence.

Conclusion and perspectives

In this work, we propose a novel model named RelationListwise for query-biased multi-document summarization task. More specifically, through defining some unique sentence features and designing a creative measure for sentence relatedness, we integrate sentence relation information with listwise learning to rank to automatically learn feature weights. Experimental results suggest that our modification of basic listwise is considerably in favor of generating high-quality summaries. In future work, we will use more complex features and try some new summarization tasks.

ABSTRACT
Extractive multi-document summarization is mostly treated as a sentence ranking problem. Existing graph-based ranking methods for key-sentence extraction usually attempt to compute a global importance score for each sentence under a single relation. Motivated by the fact that both documents and sentences can be presented by a mixture of semantic topics detected by Latent Dirichlet Allocation (LDA), we propose SentTopic-MultiRank, a novel ranking model for multi-document summarization. It assumes various topics to be heterogeneous relations, then treats sentence connections in multiple topics as a heterogeneous network, where sentences and topics/relations are effectively linked together. Next, the iterative algorithm of MultiRank is carried out to determine the importance of sentences and topics simultaneously. Experimental results demonstrate the effectiveness of our model in promoting the performance of both generic and query-biased multi-document summarization tasks.

KEYWORDS: Multi-document summarization, Topic decomposition, Heterogeneous network.

Proceedings of COLING 2012: Technical Papers, pages 2977–2992,
COLING 2012, Mumbai, December 2012.

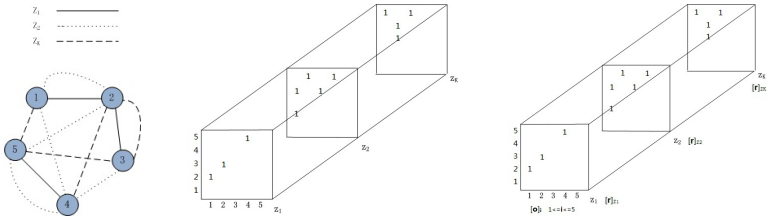
1 Introduction

Multi-document summarization (MDS), having been intensively studied in past decades, is the process of automatically creating a compressed version of a given document collection that provides useful information for a user. It could be mainly classified into two categories: generic MDS and query-focused MDS. The goal of generic MDS is to produce a summary of multiple documents about the same but unspecified topic, while query-focused task requires the generated summary could not only convey the main content of target corpus, but also bias to the information needs of a specific query/topic. Commonly, both of them are treated as a sentence ranking problem.

In most existing summarization systems, sentence ranking was conducted under a single relation assumption. Taking for instance the famous LexPageRank proposed in (Erkan and Radev, 2004). In that model, a sentence connectivity matrix was constructed based on cosine similarity. Then PageRank (Page et al., 1999) algorithm was directly applied to the cosine similarity graph to find the most prestigious sentences in a document. Another compelling example is (Wan et al., 2007), where a weighted network was formed on the sentences by using standard cosine similarity, then authors utilized manifold-ranking algorithm (Zhou et al., 2004) to spread ranking scores from a query to remaining sentences. Apparently, both above literatures were based on the assumption that all sentences existed under a unified relation.

Inspired by some work involving topic decomposition as well as multi-relational data where objects have interactions with others based on different relations, we attempt to map sentence relatedness within multiple topics to heterogeneous relations in this work. More specifically, we assume each topic as a single relation type, and construct an intra-topic sentence network for each relation type. There are many Information Retrieval and Data Mining tasks addressing multi-relational data. For instance, scholars cite other scholars in various conferences, and based on different academic fields, publications cite other publications on the basis of content analysis such as authorship, title, abstract and keywords, web pages link to each other via different anchor texts (Kolda and Bader, 2006). Such a complicated link structure can provide a way of incorporating multiple relations among objects into the derivation of object prestige or popularity. In Figure 1(a), we show an example of multi-relational sentence representation based on our SentTopic-MultiRank model. There are five sentences and K relations among them (K denotes the topic number in LDA, and we only provide three topics z_1, z_2 and z_K as an illustration). We can also represent such multi-relational objects in a tensor shape which is a multi-dimensional array. In the Figure 1(b), a three-way array is provided, where each two-dimensional plane represents an adjacency matrix for one type of relation. The network can be depicted as a tensor of size $5 \times 5 \times K$ where (i, j, k) entry is nonzero if the i^{th} sentence is related to the j^{th} sentence under k^{th} relation.

Then, how to determine the importance of those sentences and relations/topics? (Ng et al., 2011) proposed a general framework named MultiRank to deal with multi-relational data or the corresponding tensor representation for co-ranking purpose. According to that proposal, the MultiRank value of a sentence relies on the number and MultiRank values of all sentences that have multiple relations to this sentence, as well as the MultiRank values of those mutual relations. A sentence, connected via high MultiRank relations by sentences with high MultiRanks, receives a high MultiRank itself. Similarly, the MultiRank of a relation is dependent on which sentences to be linked and their MultiRank scores. A relation, connecting sentences with high MultiRanks, receives a high MultiRank itself. Similar to PageRank, MultiRank's idea



(a) An example of multi-relational sentences in a graph representation

(b) The corresponding tensor representation

(c) The tensor representation with prior

Figure 1: Illustration of SentTopic-MultiRank

is to imagine infinite random surfers in a multi-relational network, and derive a stationary probability distribution of objects and relations as evaluation scores for objects and relations, respectively. We integrate topic decomposition via LDA with MultiRank to produce a novel framework named SentTopic-MultiRank specifically for multi-document summarization.

For generic multi-document summarization, we directly make use of MultiRank algorithm to determine the ranking scores of sentences and topics/relations. While in query-oriented MDS, query bias must be considered. We creatively integrate LDA with generation probability between sentences to design query-oriented prior distributions for sentences and topics, respectively. Motivated by topic-sensitive PageRank (Haveliwala, 2003), as well as HAR (Xutao et al., 2012) which modified MultiRank based on HITS (Kleinberg, 1999) principle for query search, we embed acquired prior distributions into the SentTopic-MultiRank iterative process so that the final ranking results are more desirable for the query statement. Figure 1(c) gives an example for tensor representation of SentTopic-MultiRank with prior knowledge. We apply our approach to generic and query-biased multi-document summarization on standard datasets, experimental results show its good performance in generating high-quality summaries.

The rest of this paper is organized as follows: Section 2 introduces related work. Details of constructing and applying SentTopic-MultiRank model in multi-document summarization task are presented in Section 3. Section 4 gives the process of selecting sentences to generate summary. Finally, experiments and results are showed in Section 5.

2 Related work

In this section, we firstly introduce some representative work about multi-document summarization. Then, some literatures, relevant to topic decomposition, are also presented.

The centroid-based method (Radev et al., 2004) is one of the most popular extractive summarization methods. MEAD is an implementation of the centroid-based method that scores sentences based on features such as cluster centroids, position and TF-IDF. NeATS (Lin and Hovy, 2002) used sentence position, term frequency, topic signature and term clustering to select important content, and used MMR (Goldstein et al., 1999) to remove redundancy. Recently, graph-based methods have been proposed to rank sentences. LexPageRank (Erkan and Radev, 2004) and (Mihalcea and Tarau, 2005) are two such systems using algorithms similar to PageRank and HITS (Kleinberg, 1999) to compute sentence importance. With respect to query-

focused summarization, in (Saggion et al., 2003), a simple query-based scorer by computing the similarity value between each sentence and the query was incorporated into a generic summarizer to produce the query-based summary. (Erkan, 2006) came up with biased LexRank by incorporating prior knowledge into random walk for query summarization task. (Wan et al., 2007) exploited manifold-ranking process proposed in (Zhou et al., 2004) to implement the propagation of ranking scores from the query to remaining sentences, based on a weighted sentence connection network. The spread process was repeated until a global stable state was achieved, and all sentences obtained their final ranking scores. Recently, unsupervised deep learning was first investigated in (Liu et al., 2012) to deal with query summarization.

Furthermore, supervised learning approaches have also been successfully applied in document summarization, where the training data is available or easy to build. The most straightforward way is to regard the sentence extraction task as a binary classification problem. (Kupiec et al., 1995) developed a trainable summarization system which adopted various features and used a Bayesian classifier to learn the feature weights. The system performed better than other systems using only a single feature. (Zhou and Hovy, 2003) applied a HMM-based model and (Shen et al., 2007) proposed a conditional random field based framework. (Ouyang et al., 2007) designed methods for constructing training data based on human summaries and training sentence scoring models based on support vector regression (SVR). (Shen and Li, 2011) introduced a cost sensitive loss to improve ranking SVM, a type of learning-to-rank method, for extractive query-focused multi-document summarization.

Especially, we are mainly inspired by following pioneering work. In recent years, two algorithms were proposed to rank web pages by incorporating topic information within PageRank (Haveliwala, 2003; Nie et al., 2006). The method in (Haveliwala, 2003) decomposed PageRank into various topics, setting the preference values using some conditional probabilities. (Nie et al., 2006) proposed a more complicated ranking framework, where topical PageRanks were performed together. The rationale of (Nie et al., 2006) was, when surfing following a graph link from vertex w_i to w_j, the ranking score on topic z of w_i would have a higher probability to pass to the same topic of w_j and have a lower probability to pass to a different topic of w_j. When the inter-topic jump probability was 0, this method was identical to the approach in (Haveliwala, 2003). (Liu et al., 2010) explicitly defined a new graph-based framework, Topical PageRank, for the task of keyphrase extraction. It first ranked all key-phrases within each latent topic based on a topic-specific phrase graph, then re-ranked them by integrating corpus-topic distribution with intra-topic phrase ranking. Additionally, ToPageRank, a model similar with that of (Liu et al., 2010), was proposed in (Pei et al., 2012) specifically for summarization task. Indeed, a similarity between these literatures with our current idea lies in that we all consider to decompose entire corpus into multiple topics. Whereas, we do not aim to *break up the whole into parts* simply. In their work, there was usually no relation exerted to link each part, so the operation in each part was conducted independently and those objects would not interact with various kinds of relations. Hence, in essence, they still coped with ranking problem under a single relation presupposition, except that having narrowed the scope from a corpus to an individual topic. Differently, in SentTopic-MultiRank, not only are sentences linked with each other by weighted edges, all intra-topic sentence networks are also connected together, though they are considered to be under different relation types, so that we are able to identify the importance of sentences and topics/relations simultaneously. Further, we make full use of sentence-sentence relatedness, sentence-topic interaction and inter-topic impacts to improve the overall ranking performance.

3 SentTopic-MultiRank model

3.1 Topic decomposition of corpus via Latent Dirichlet Allocation (LDA)

In our work, topic model LDA (Blei et al., 2003) is utilized to represent document collection with a mixture of semantic topics. In LDA, it is assumed that observed words in each document are generated by a document-specific mixture of corpus-wide latent topics. We define our corpus of length W with the flat word vector $\mathbf{w} = w_1, \cdots, w_W$. At corpus position i, the element d_i in $\mathbf{d} = d_1, \cdots, d_W$ designates the document containing observed word w_i. Similarly, the vector $\mathbf{z} = z_1, \cdots, z_W$ defines the hidden topic assignments of each observed word. The number of latent topics is fixed to some K, and each topic $z = 1, \cdots, K$ is associated with a topic-word multinomial ϕ_z over the W-word vocabulary. Each ϕ multinomial is generated by a conjugate Dirichlet prior with parameter β. Each document $j = 1, \cdots, D$ is associated with a multinomial θ_j over K topics, which is also generated by a conjugate Dirichlet prior with parameter α. The full generative model is then given by

$$P(\mathbf{w}, \mathbf{z}, \phi, \theta | \alpha, \beta, \mathbf{d}) \propto \left(\prod_{z=1}^{K} p(\phi_z|\beta)\right)\left(\prod_{j=1}^{D} p(\theta_j|\alpha)\right)\left(\prod_{i=1}^{W} \phi_{z_i}(w_i)\theta_{d_i}(z_i)\right)$$

where $\phi_{z_i}(w_i)$ is the w_i-th element in vector ϕ_{z_i}, and $\theta_{d_i}(z_i)$ is the z_i-th element in vector θ_{d_i}. Given an observed corpus $(\mathbf{w}, \mathbf{d})$ and model hyperparameters (α, β), the typical modeling goal is to infer the latent variables $(\mathbf{z}, \phi, \theta)$.

While exact LDA inference is intractable, a variety of approximate schemes have been developed. In this work, we use GibbsLDA++[1], a C/C++ implementation of LDA using Gibbs Sampling, to detect latent topics. This sampling approach iteratively re-samples a new value for each latent topic assignment z_i, conditioned on the current values of all other $\mathbf{z}$ values. After a fixed number of iterations, we estimate the topic-word multinomials ϕ and the document-topic mixture weights θ from the final $\mathbf{z}$ sample, using the means of their posteriors given by

$$\phi_z(w) \propto n_{zw} + \beta$$
$$\theta_j(z) \propto n_{jz} + \alpha$$

where n_{zw} is the number of times word w is assigned to topic z, and n_{jz} is the number of times topic z is used in document j, with both counts being taken with respect to the final sample $\mathbf{z}$. The topic-word multinomials ϕ_z for each topic z are our learned topics; each document-topic multinomial θ_j represents the prevalence of topics within document j.

In experiments, we set $\alpha = 1$ and $\beta = 0.01$. There are already some literatures to study their impacts on LDA performance. Since we pay main attentions to SentTopic-MultiRank model, the influences of LDA hyperparameters α and β are not investigated any more.

3.2 Construction of SentTopic-MultiRank graph

In Section 3.1, we have detected various relation types/topics. The thing left to do in constructing SentTopic-MultiRank is to produce a sentence graph under each relation. Naturally, the sentence similarity should be relation-specific. To capture the similarities of two sentences

[1] GibbsLDA++: http://gibbslda.sourceforge.net

(e.g., x and y) on various latent topics, we represent each sentence as a probability distribution at each topic z ($1 \le z \le K$). Hence, we sample sparse unigram distributions from each ϕ_z using the words in x and y. Their probability distributions given topic-word distribution are denoted as $P_z^x = p(\mathbf{w}_x|z, \phi_z)$ with the word set $\mathbf{w}_x = (w_1, \cdots, w_{|x|})$ in x, and $P_z^y = p(\mathbf{w}_y|z, \phi_z)$ with the word set $\mathbf{w}_y = (w_1, \cdots, w_{|y|})$ in y.

The probability distributions per topic are constructed with only the words in x and y, and the probabilities of remaining words in vocabulary W are set to 0. The W dimensional word probabilities are the expected posteriors obtained from LDA model. Hence, $p_z^x = (\phi_z(w_1), \cdots, \phi_z(w_{|x|}), 0, 0, \cdots) \in (0,1)^W$, $p_z^y = (\phi_z(w_1), \cdots, \phi_z(w_{|y|}), 0, 0, \cdots) \in (0,1)^W$. Given a topic z, the similarity between p_z^x and p_z^y is measured via transformed radius (TR). We first measure the divergence at each topic using TR based on Kullback-Liebler (KL) divergence:

$$TR(p_z^x, p_z^y) = KL(p_z^x || \frac{p_z^x + p_z^y}{2}) + KL(p_z^y || \frac{p_z^x + p_z^y}{2}) \quad (1)$$

where $KL(m||n) = \sum_i m_i \log \frac{m_i}{n_i}$. Then TR is transformed into similarity (Manning et al., 1999):

$$Sim(p_z^x, p_z^y) = 10^{-TR(p_z^x, p_z^y)} \quad (2)$$

Here, we adopt TR rather than the commonly used KL for the reason that with TR there is no problem with infinite values since $\frac{p_z^x + p_z^y}{2} \neq 0$ if either $p_z^x \neq 0$ or $p_z^y \neq 0$, and it is also symmetric, i.e., $TR(x, y) = TR(y, x)$. With the gotten sentence similarities under various topics, we could construct graphs like Figures 1(a) and 1(b) to demonstrate our SentTopic-MultiRank model.

3.3 Sentence ranking using MultiRank algorithm

There are many Data Mining and Machine Learning issues in multi-relational data where objects interact with others under different relations. The work in (Ng et al., 2011) proposed a framework, MultiRank, to determine the importance of both objects and relations simultaneously based on a probability distribution computed from multi-relational data. In our multi-relational sentence network, we apply MultiRank algorithm to derive the importance of sentences and topics. As we analyze sentences under multiple relations and also consider interaction between relations based on sentences, we make use of rectangular tensors to represent them as Figure 1(b). First, we introduce the MultiRank iterative algorithm.

Let R be the real field. We call $\mathscr{A} = (a_{s_1,s_2,z_1})$ where $a_{s_1,s_2,z_1} \in R$, for $s_i = 1, \cdots, n$, $i = 1, 2$ and $z_1 = 1, \cdots, K$, a real (2,1)th order $(n \times K)$-dimensional rectangular tensor. In this setting, we refer (s_1, s_2) to the indices for sentences/objects and z_1 to be the index for topic/relation. For instance, five sentences ($n = 5$) and three relations ($K = 3$) are demonstrated in Figure 1.

First, two transition probability tensors $\mathscr{O} = (o_{s_1,s_2,z_1})$ and $\mathscr{R} = (r_{s_1,s_2,z_1})$ are constructed with respect to sentences and topics by normalizing the entries of $\mathscr{A}$ as follows:

$$o_{s_1,s_2,z_1} = \frac{a_{s_1,s_2,z_1}}{\sum_{i=1}^{m} a_{i,s_2,z_1}}, \quad s_1 = 1, 2, \cdots, n$$

$$r_{s_1,s_2,z_1} = \frac{a_{s_1,s_2,z_1}}{\sum_{j=1}^{K} a_{s_1,s_2,j}}, \quad z_1 = 1, 2, \cdots, K$$

Then we derive the following probabilities:

$$\text{Prob}[X_t = s_1] = \sum_{s_2=1}^{n} \sum_{z_1=1}^{K} o_{s_1,s_2,z_1} \times \text{Prob}[X_{t-1} = s_2, Y_t = z_1] \tag{3}$$

$$\text{Prob}[Y_t = z_1] = \sum_{s_1=1}^{n} \sum_{s_2=1}^{n} r_{s_1,s_2,z_1} \times \text{Prob}[X_t = s_1, X_{t-1} = s_2] \tag{4}$$

where $\text{Prob}[X_{t-1} = s_2, Y_t = z_1]$ is the joint probability distribution of X_{t-1} and Y_t, and $\text{Prob}[X_t = s_1, X_{t-1} = s_2]$ is the joint probability distribution of X_t and X_{t-1}. Suppose our desired equilibrium/stationary distributions of sentences and relations, i.e., the SentTopic-MultiRank values of sentences and relations, are given by

$$\bar{\mathbf{x}} = [\bar{x}_1, \bar{x}_2, \cdots, \bar{x}_n]^T \text{ and } \bar{\mathbf{y}} = [\bar{y}_1, \bar{y}_2, \cdots, \bar{y}_K]^T$$

respectively, with

$$\bar{x}_{s_1} = \lim_{t\to\infty} \text{Prod}[X_t = s_1] \text{ and } \bar{y}_{z_1} = \lim_{t\to\infty} \text{Prod}[Y_t = z_1]$$

for $1 \le s_1 \le n$ and $1 \le z_1 \le K$.

As (3) and (4) are coupled together and they involve two joint probability distributions, a product form of individual probability distributions is employed to replace the joint probability distributions in (3) and (4) by assumption:

$$\text{Prob}[X_{t-1} = s_2, Y_t = z_1] = \text{Prob}[X_{t-1} = s_2]\text{Prod}[Y_t = z_1]$$
$$\text{Prob}[X_t = s_1, X_{t-1} = s_2] = \text{Prob}[X_t = s_1]\text{Prod}[X_{t-1} = s_2]$$

Hence, using the above assumptions and considering t goes to infinity, (3) and (4) becomes

$$\bar{x}_{s_1} = \sum_{s_2=1}^{n} \sum_{z_1=1}^{K} o_{s_1,s_2,z_1} \bar{x}_{s_2} \bar{y}_{z_1}, \quad s_1 = 1, 2, \cdots n \tag{5}$$

$$\bar{y}_{z_1} = \sum_{s_1=1}^{n} \sum_{s_2=1}^{n} r_{s_1,s_2,z_1} \bar{x}_{s_1} \bar{x}_{s_2}, \quad z_1 = 1, 2, \cdots K \tag{6}$$

Under the tensor operation for (5) and (6), we solve the following tensor (multivariate polynomial) equations:

$$\mathscr{O}\bar{\mathbf{x}}\bar{\mathbf{y}} = \bar{\mathbf{x}} \text{ and } \mathscr{R}\bar{\mathbf{x}}^2 = \bar{\mathbf{y}} \tag{7}$$

with

$$\sum_{s_1=1}^{n} \bar{x}_{s_1} = 1 \text{ and } \sum_{z_1=1}^{K} \bar{y}_{z_1} = 1 \tag{8}$$

to obtain the SentTopic-MultiRank values of sentences and relations. An efficient iterative algorithm to solve the tensor equations in (7) is summarized as Algorithm 1. With respect to theoretical analysis of this algorithm, please refer to (Ng et al., 2011) for details.

Algorithm 1: The MultiRank Algorithm

Input: Two tensors $\mathscr{O}$ and $\mathscr{R}$, two initial probability distributions $\mathbf{x}_0$ and $\mathbf{y}_0$ ($\sum_{s_1=1}^{n}[\mathbf{x}_0]_{s_1}=1$ and $\sum_{z_1=1}^{K}[\mathbf{y}_0]_{z_1}=1$) and the tolerance ϵ
Output: Two stationary probability distributions $\bar{\mathbf{x}}$ and $\bar{\mathbf{y}}$
Procedure:

1. Set $t=1$;
2. Compute $\mathbf{x}_t=\mathscr{O}\mathbf{x}_{t-1}\mathbf{y}_{t-1}$;
3. Compute $\mathbf{y}_t=\mathscr{R}\mathbf{x}_t^2$;
4. If $\| \mathbf{x}_t-\mathbf{x}_{t-1} \|+\| \mathbf{y}_t-\mathbf{y}_{t-1} \|<\epsilon$, then stop, otherwise set $t=t+1$ and goto Step 2.

In Algorithm 1, the setting of initial probability distributions does not influence the finally generated stationary probability distributions. We simply set uniform distribution for those sentences while with regard to topics, we set their initial distribution using the topic distribution of the entire corpus. Obviously, above algorithm has nothing to do with any query, so it does not apply to biased summarization task, which is further discussed in subsequent section.

3.4 Prior configuration in query-focused multi-document summarization

Query summarization requires that generated summary could not only express the salient content of target document collection, but also bias to the information needs of query. Then, how to exert the query information to the MultiRank process? Motivated by the idea of topic-sensitive PageRank (Haveliwala, 2003) and random walk with restart (Tong et al., 2008), we consider this issue by assigning desired limiting probability distributions towards sentences and topics, respectively. More specifically, we modify the tensor equations in (7) as follows:

$$(1-\mu)\mathscr{O}\bar{\mathbf{x}}\bar{\mathbf{y}}+\mu\mathbf{o}=\bar{\mathbf{x}} \tag{9}$$

$$(1-\nu)\mathscr{R}\bar{\mathbf{x}}^2+\nu\mathbf{r}=\bar{\mathbf{y}} \tag{10}$$

with Equation 8, where $\mathbf{o}$ and $\mathbf{r}$ are two devised prior probability distributions for sentences and topics/relations, respectively. Here, ($\sum_{i=1}^{n}[\mathbf{o}]_i=1$ and $\sum_{j=1}^{K}[\mathbf{r}]_j=1$), and $0\le\mu,\nu<1$, are two parameters for controlling the influence degree of two prior probability distributions. In experiments, we set $\mu=0.5$ and $\nu=0.9$ simply as (Xutao et al., 2012) indicated. Accordingly, the new iterative algorithm could be presented as Algorithm 2.

Noting that (Xutao et al., 2012) has ever provided a similar solution framework for their proposed HAR model, a modified version of MultiRank on the basis of HITS's principle, to cope with query search. Nonetheless, for one thing, our Algorithm 2 is designed specifically for MultiRank; for another, we further explicitly give the expressions of $\mathbf{o}$ and $\mathbf{r}$ for our summarization application in following sections.

3.4.1 Sentence prior

We try to normalize the relatedness of sentences towards the query description as those sentences' prior distribution. The most commonly used method of computing sentence relatedness is cosine measure. Nevertheless, we opt for an approach that is similar with what adopted by

Algorithm 2: The MultiRank Algorithm Integrated with Prior

Input: Two tensors $\mathscr{O}$ and $\mathscr{R}$, two initial probability distributions $\mathbf{x}_0$ and $\mathbf{y}_0$ ($\sum_{s_1=1}^{n}[\mathbf{x}_0]_{s_1}=1$ and $\sum_{z_1=1}^{K}[\mathbf{y}_0]_{z_1}=1$), two prior distributions of sentences and topics $\mathbf{o}$ and $\mathbf{r}$, two weighting parameters $0\leq\mu,\nu<1$ and the tolerance ϵ
Output: Two stationary probability distributions $\bar{\mathbf{x}}$ and $\bar{\mathbf{y}}$
Procedure:

1. Set $t=1$;
2. Compute $\mathbf{x}_t$=(1-μ)$\mathscr{O}\mathbf{x}_{t-1}\mathbf{y}_{t-1}+\mu\mathbf{o}$;
3. Compute $\mathbf{y}_t$=(1-ν)$\mathscr{R}\mathbf{x}_t^2+\nu\mathbf{r}$;
4. If $\|\mathbf{x}_t-\mathbf{x}_{t-1}\|+\|\mathbf{y}_t-\mathbf{y}_{t-1}\|<\epsilon$, then stop, otherwise set $t=t+1$ and goto Step 2.

(Kurland and Lee, 2010) as well as (Erkan, 2006). They all defined the sentence relatedness (e.g., u and v) as the generation probability of u given v or of v given u. Naturally, sentence-word distribution, as an initial step, must be acquired. They assumed that the weight of a word in certain sentence mainly depends on the word's occurrence frequency in that specific sentence. Given a sentence s, a straightforward way of computing the weights of words contained in s is to normalize their term frequency (TF):

$$P_{TF}(w|s)=c_s(w)/|s| \tag{11}$$

where $c_s(w)$ is times of word w occurring in s, and $|s|$ is the total number of words in s.

However, in our perspectives, it should not be neglected that different words have different degrees of information and instructions, no matter for a document or a sentence. For example, three sentences $s_1=(A,C)$, $s_2=(A:0.9,B:0.1)$ and $s_3=(D,B)$, where A, B, C and D denote 4 discriminative words, and 0.9, 0.1 mean the weights of A and B in the second sentence s_2. Now, if we are asked to distinguish which one of s_1 and s_3 has more similarity with s_2, apparently we should choose s_1. Even though the occurrence frequencies of A and B are the same in sentence s_2 (i.e., their generation probabilities are equal according to Equation 11), they actually have different importance towards s_2. As a result, s_1 is supposed to be more similar with s_2 because it has content s_2 more concerns.

With model LDA, we propose to derive the weight of word w with respect to sentence s where w occurs as follows:

$$P'(w|s)=\frac{P(w|C)}{\sum_{w'\in s}P(w'|C)} \tag{12}$$

where C means the entire corpus, and $P(w|C)$ could be easily acquired by combining corpus-topic distribution and topic-word distribution which are both basic outputs of LDA. To account for the unseen words for s, we smooth the above equation like this:

$$P(w|s)=(1-\lambda)P'(w|s)+\lambda P(w|C) \tag{13}$$

λ is a trade-off parameter and is set to 0.7 in experiments. Consequently, we can talk about

the generation probability of sentence u given another sentence v as:

$$\text{gen}(u|v) = P(u|v)^{\frac{1}{|u|}} = [\prod_{w \in u} P(w|v)]^{\frac{1}{|u|}} \tag{14}$$

We use the length of u (i.e., $|u|$) to conduct normalization so as to avoid the tendency that longer sentences get smaller generation probabilities. Moreover, we use a normalized generation probability to indicate the initial bias of sentences towards the query q, i.e.,

$$[\mathbf{o}]_{s_1} = \frac{\text{gen}(q|s_1)}{\sum_s \text{gen}(q|s)} \quad 1 \le s_1 \le n \tag{15}$$

We mark cosine measure as $cosine-based$, mark Equation 11 based generation probability method as $TF-based$, and label our proposed generation probability approach based on Equation 12 as $weight-based$. In the experimental part, they will be compared with each other to investigate their performance in constructing sentence prior.

3.4.2 Topic prior

When it turns to prior distribution of topics, we must first get the topic distribution of query description, i.e., the conditional probability $P(z_1|q)$, so

$$[\mathbf{r}]_{z_1} = P(z_1|q) = \frac{1}{|q|} \sum_{w \in q} P(z_1|w) \quad 1 \le z_1 \le K \tag{16}$$

where $|q|$ means the word number in q, and $P(z|w)$ is derived via Bayesian rule in LDA.

In experiments, we also set the two initial probability distributions in Algorithm 2 to equal with their corresponding initial distribution in Algorithm 1. Illustration of SentTopic-MultiRank with prior beliefs $\mathbf{o}$ and $\mathbf{r}$ is given as Figure 1(c).

4 Summary generation

After ranking process, sentences usually have close values if they own similar content. Consequently, we perform the modified MMR algorithm, proposed in (Wan et al., 2007), during sentence selection to control the information redundancy of generated summary. The principle of MMR algorithm is to reduce the ranking scores of remaining sentences if they are detected to have a degree of similarities with those sentences having been selected to construct a summary. The algorithm goes as follows:

1. Initiate two sets A=∅, B={s_i|i=1,2, ⋯, n}, and each sentence's initial value is set to its SentTopic-MultiRank score obtained in above section, i.e., $value(s_i)$=$\bar{x}_i$.
2. Sort the sentences in B by their current values in descending order.
3. Suppose s_i is the highest ranked sentence, i.e., the first sentence in B. Move sentence s_i from B to A and update the values of the remaining sentence(s) in B as follows:
   For each sentence s_j in B:
   $$value(s_j) = value(s_j) - \omega \cdot \tilde{S}_{ij} \cdot value(s_i) \tag{17}$$
   where ω is set to 5 in our experiments, $\tilde{S}$ is the normalized sentence similarity matrix.
4. Go to step 2 and iterate until $|B|$=0.

After the final scores are obtained for all sentences, several sentences with highest ranking scores are chosen to produce a summary until length limit is reached.

5 Experiments

5.1 Data sets and evaluation metrics

We validate our algorithm framework in both generic and query-biased multi-document summarization. For generic task, we conduct experiments on the data sets DUC2002[2] and DUC2004[3] in which generic multi-document summarization has been one of the fundamental tasks (i.e., task 2 in DUC2002 and task 2 in DUC2004). For query-related task, experiments are based on the main tasks of DUC2005[4] and DUC2006[5]. Each task has a gold standard data set consisting of document sets and reference summaries. Table 1 gives a short summary of above data sets. Documents are pre-processed by segmenting sentences and splitting words. Stop words are removed and the remaining words are stemmed using Porter stemmer[6].

	DUC2002	DUC2004	DUC2005	DUC2006
Task	Task2	Task2	the only task	the only task
Number of documents	567	500	1593	1250
Number of clusters	59	50	50	50
Data source	TREC	TDT	TREC	TREC
Summary length	200 words	665 bytes	250 words	250 words

Table 1: Summary of data sets

We use the ROUGE (Lin, 2004) (version 1.5.5) toolkit[7] for evaluation, which is officially adopted by DUC for evaluating automatic generated summaries. Here we report the average F-measure scores of ROUGE-1, ROUGE-2 and ROUGE-SU4, which base on Uni-gram match, Bi-gram match, and unigram plus skip-bigram match with maximum skip distance of 4 between the candidate summary and the reference summary, respectively.

5.2 System comparison

5.2.1 Generic multi-document summarization

As for generic multi-document summarization, we compare our proposed method SentTopic-MultiRank with following algorithms. (1)Lead Baseline: The lead baseline takes the first sentences one by one in the last document in a document set, where documents are assumed to be ordered chronologically. (2)Random: The method selects sentences randomly for each document collection. (3)DUC Best: The system with highest ROUGE scores among all the systems submitted. (4)LexPageRank: The method first constructs a sentence connectivity graph based on traditional cosine similarity and then conducts PageRank algorithm to determine global importance scores of sentences (Erkan and Radev, 2004). (5)ToPageRank: The method, proposed in (Pei et al., 2012), decomposes traditional PageRank into multiple PageRank via topic decomposition for generic multi-document summarization.

Tables 2-3 show the experimental results. From those statistics, we observe that ToPageRank is better than LexPageRank while our SentTopic-MultiRank outperforms all the competitors.

[7]http://www.isi.edu/licensed-sw/see/rouge/

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Lead	0.39860	0.16042	0.20315
Random	0.38469	0.11705	0.18007
LexPageRank	0.47473	0.22484	0.25850
DUC Best	0.49869	0.25229	0.28406
ToPageRank	0.49923	0.25735	0.29630
SentTopic-MultiRank	**0.50491**	**0.26714**	**0.30731**

Table 2: *F*-measure comparison on DUC2002

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Lead	0.33182	0.06348	0.10582
Random	0.31857	0.06269	0.11780
LexPageRank	0.37875	0.08354	0.12770
DUC Best	0.38279	0.09216	0.13349
ToPageRank	0.40251	0.09555	0.14027
SentTopic-MultiRank	**0.41016**	**0.09917**	**0.14324**

Table 3: *F*-measure comparison on DUC2004

It suggests that: (1) the decomposition and analysis of topic information indeed benefit the improvement of summary quality, as ToPageRank and SentTopic-MultiRank systems perform. It might result from the fact that not only does target corpus usually involve multiple topics, but a user commonly wishes to obtain information from various aspects by reading a concise text. Analyzing corpus on topic level could deeply and comprehensively identify user desired content. (2)ToPageRank focuses on sentence interaction within a topic's range while SentTopic-MultiRank takes three kinds of relations (sentence-sentence, sentence-topic, topic-topic) into consideration wholly. Hence, propagation of impacts among sentences and topics (noting that topics are treated as relation types) is a bonus to determine the saliency score of sentences.

5.2.2 Query-biased multi-document summarization

To validate SentTopic-MultiRank in query-biased task, following systems are implemented as baselines. (1)Random: The same baseline as that in above generic task. (2)Manifold: ranking the sentences according to the manifold ranking scores. (3)Biased LexRank: A modified version of traditional random walk with prior belief. It was presented in (Erkan, 2006) and the sentence prior knowledge was denoted by sentence's similarity to the query description. (4)top three systems with the highest ROUGE scores that participated in the DUC2005 (S4, S15, S17) and the DUC2006 (S12, S23, S24) for comparison, respectively. Tables 4 and 5 present the performance of these systems on DUC2005 and DUC2006 data sets, respectively.

Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Random	0.30821	0.03976	0.10625
Biased LexRank	0.37324	0.07113	0.12805
Manifold	0.37497	0.07423	0.12907
S17	0.36933	0.07286	0.12937
S4	0.37584	0.07063	0.12868
S15	0.37656	0.07244	0.13248
SentTopic-MultiRank	**0.38803**	**0.07994**	**0.13532**

Table 4: *F*-measure comparison on DUC2005

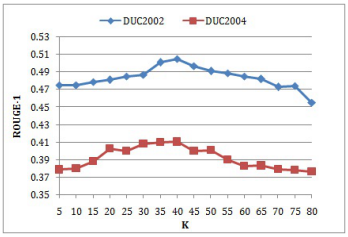
Systems	ROUGE-1	ROUGE-2	ROUGE-SU4
Random	0.34821	0.05297	0.11908
Biased LexRank	0.36814	0.08074	0.12993
Manifold	0.38867	0.08308	0.13307
S23	0.40973	0.09785	0.16162
S12	0.41053	0.09633	0.16074
S24	0.41081	0.09957	0.15248
SentTopic-MultiRank	**0.41567**	**0.10125**	**0.16431**

Table 5: F-measure comparison on DUC2006

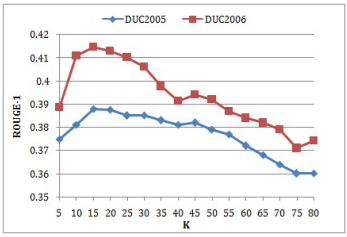
Apparently, our approach SentTopic-MultiRank has the optimal performance, especially outperform the two representative graph-based methods: Biased LexRank and Manifold. Noting that both the sentence networks of Biased LexRank and Manifold are only based on sentence similarity under a single relation type assumption, so the estimation of their sentence ranking scores is limited compared with SentTopic-MultiRank which skillfully considers query-biased information as well as the interactions between sentences and topics.

5.3 Influence of topic number K

LDA is a crucial tool in devising SentTopic-MultiRank and topic number K also denotes the amount of different relation types. In order to investigate how the topic number K exerts influence to system performance, K is varied from 5 to 80. Figures 2(a)-2(b) show the influence of K over ROUGE-1 with respect to generic and query-oriented multi-document summarization, respectively. On the whole, the evaluation scores rise with the increase of K, and reach their respective maximum, then gradually go down when K continues to become larger. Despite some slight fluctuations, they don't matter to the overall conclusion. We could draw the following two meaningful conclusions. (1)It indicates that topic number indeed influences the algorithm result. In fact, our system would be similar with LexPageRank if $K = 1$. (2)Interestingly, two tasks do not reach their optimal situations at an approximate K value, more exactly, generic task requires a relatively large K ($K \approx 40$) while query-biased prefers small K ($K \approx 15$) (here our adoption of an approximation for K is because that we actually vary K every 5 from the start value $K = 5$ in experiments). It may derive from the fact that a query description usually involves few topics, whereas, when applying SentTopic-MultiRank to generic task, we could image the whole corpus as a big query, which concerns about more topics.



(a) ROUGE-1 vs. K for generic multi-document summarization



(b) ROUGE-1 vs. K for query-focused multi-document summarization

Figure 2: Influence of K

5.4 Comparison of three sentence prior methods

In Section 3.4.1, we named *weight-based* for our proposed sentence prior method. In order to confirm its advantage in acquiring more favorable sentence prior distribution, we compare it with two competitors: *cosine-based* and *TF-based* using query-biased summary qualities on DUC2005 and DUC2006. Section 5.3 has indicated that when K is about 15 the quality of query-oriented summary is optimal. For simplicity, we compare the three methods using ROUGE-1 metric under the same condition $K = 15$. Figure 3 gives comparison results. For the space limit, here we give up showing the comparison results on ROUGE-2 and ROUGE-SU4.

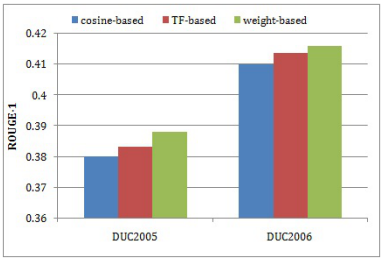


Figure 3: Comparison of three sentence prior methods, $K = 15$.

As Figure 3 shows, generation probability methods, including *TF-based* and *weight-based*, both outperform *cosine-based*. In addition, system using *weight-based* method to generate sentence prior indeed produces summaries with the highest quality. It not only suggests the effectiveness of generation probability methods, but also points out that our method, considering term weights instead of term frequencies to acquire generation probabilities of words given a sentence, is more useful to derive sentence affinity.

Conclusion and perspectives

In this study, we exploit LDA to devise a novel model named SentTopic-MultiRank based on MultiRank algorithm for multi-document summarization. Our intention is to map sentence relatedness over various latent topics to heterogeneous network where multiple topics are treated as various kinds of relations. We apply our approach to both generic and query-biased multi-document summarization. In generic task, we use MultiRank algorithm to directly determine the importance of all sentences, while in query-sensitive task, some query-biased prior beliefs are added to sentences and topics of the SentTopic-MultiRank network, so that some top-ranked sentences are supposed to not only demonstrate the core content of target corpus, but also bias to the information needs of a user's query. Extensive experiments have been performed to prove the effectiveness of our approach in improving the summary quality.

In future work, for one thing, we may apply our model to new summarization task, such as updated summarization; for another, integrating manifold-ranking process with SentTopic-MultiRank might be an interesting idea in some query-related applications.

Language Modeling for Spoken Dialogue System based on Filtering using Predicate-Argument Structures

Koichiro Yoshino[1] *Shinsuke Mori*[1] *Tatsuya Kawahara*[1]

ABSTRACT
We present a novel scheme of language modeling for a spoken dialogue system by effectively filtering query sentences collected via a Web site of wisdom of crowds. Our goal is a speech-based information navigation system by retrieving from backend documents such as Web news. Then, we expect that users make queries that are relevant to the backend documents. The relevance measure can be defined with cross-entropy or perplexity by the language model generated from the documents in a conventional manner. In this article, we propose a novel criteria that considers semantic-level information. It is based on predicate-argument (P-A) pairs and their relevance to the documents (or topic) is defined by a naive Bayes score. Experimental evaluations demonstrate that the proposed relevance measure effectively selects relevant sentences used for a language model, resulting in significant reduction of the word error rate of speech recognition as well as the semantic-level error rate.

COLING 2012, Mumbai, December 2012.

1 Introduction

The tasks of spoken dialogue systems have been extended from simple transactions to general information navigation based upon user requests. Ideally, these systems should handle not only simple, keyword-based queries that current voice search systems respond to but also vague and complex user requests related to, for example, tourist guides or news briefings. This type of application can be achieved through document retrieval in a corresponding domain. For example, we can turn to tourist guidebooks or relevant Wikipedia entries for information on the tourist domain (Misu and Kawahara, 2010). An intelligent dialogue system can be created by restricting the domain and using the knowledge from that domain (Kawahara, 2009). An interactive news navigator that generates dialogues based on news article archives has been developed along this concept (Yoshino et al., 2011).

The automatic speech recognition (ASR) module for spoken dialogue systems (SDSs) needs an appropriate language model (LM) adapted to the task domain and style. Even an ASR system with a very large vocabulary cannot cover all proper nouns or named entities (NEs), which are critical in information retrieval. Ideally, an LM should be trained with a large-scale matched corpus, but in many cases this is not realistic. Therefore, two approaches are commonly adopted. The first involves mixing document texts of the target domain with a dialogue corpus of spoken-style expressions. The other involves collecting relevant texts, possibly from spoken-style sentences, from the Web (Sarikaya et al., 2005; Sethy et al., 2005; Misu and Kawahara, 2006; Bulyko et al., 2007). These approaches try to cover the target domain and style of speech in an indirect way, but the resultant model will inevitably contain a large amount of irrelevant texts.

In general, information navigation systems with speech interfaces have a set of backend documents for retrieval (Schalkwyk et al., 2010). These systems require matching between the backend documents and the user utterance. Based on this assumption, we define a similarity measure of collected sentences from the Web (= expected user utterances) with the backend documents, and select well-matched sentences for LM training.

The overall flow of the proposed method is shown in **Figure 1**. In this paper, we assume two corpora: backend documents (D) and collected sentences (q) from the Web. Superficial matching, in which the method filters sentences based on the similarity in word sequences to the backend documents, is described in Section 2. N-gram model likelihood based on KL divergence is used in this method, and it is equivalent to the conventional perplexity-based method. In Section 3, we propose using deep semantic similarity based on P-A structures. This proposed method provides better filtering, considering not only surface words but also semantic cases. It is suitable forinformation navigation systems that require P-A structures. In Section 4, we propose the combined usage of the two filtering methods mentioned above. The method enables us to take both advantages of the two methods. We evaluate the conventional and proposed methods with ASR accuracy (word error rate (WER)), predicate-argument structure error rate (PAER), and test set perplexity in Section 5.

2 KL Divergence of N-gram Models

We construct an LM for ASR by using a collection of question-style queries (=sentences) from the Web, and matching them with the target backend documents D. For the matching of a question-style sentence q and backend documents D, first, we use KL divergence of LMs for surface word matching. KL divergence is a non-symmetric measurement of the difference

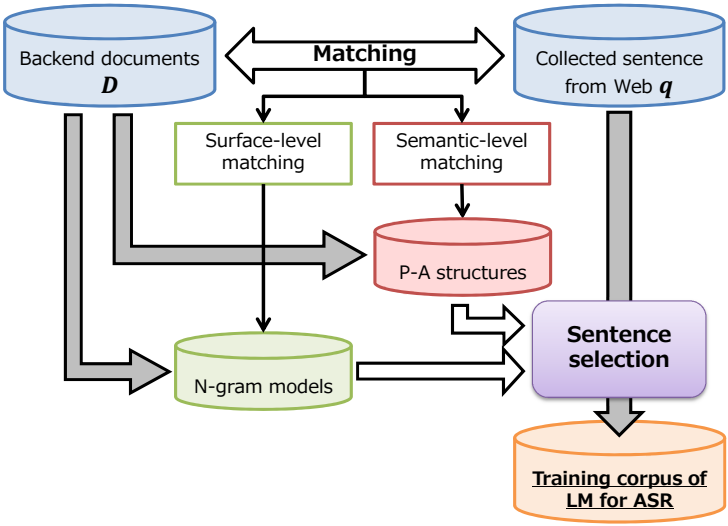

Figure 1: Overview of the proposed method

between two probability distributions (Kullback and Leibler, 1951). KL divergence of sentence q and backend documents D is defined as

$$KL(q||D) = \sum_m P_q(w_m) \log_2 \frac{P_q(w_m)}{P_D(w_m)}, \quad (1)$$

where $w_1 w_2, ..., w_n$ is the word sequence in sentence q. P_D and P_q are the probability distributions of D and q. We define these probability distributions with n-gram (tri-gram) models. We assume that query q consists of one sentence, and most of the time the n-gram distribution trained from only one sentence becomes unique. Then, the probability $P_q(W)$ becomes to 1. We can then make the approximation to KL divergence:

$$KL(q||D) \approx \sum_m \log_2 \frac{1}{P_D(w_m)} \quad (2)$$

$$= -\sum_m \log_2 P_D(w_m). \quad (3)$$

This formulation is equivalent to cross-entropy XE:

$$XE(q,D) = -\sum_m P_q(w_m) \log_2 P_D(w_m) \quad (4)$$

$$\approx -\sum_m \log_2 P_D(w_m). \quad (5)$$

The cross-entropy has two components: self information $P_q(w_m)$ and mutual information $P_D(w_m)$, but the self information $P_q(w_m)$ is equal to 1 as discussed above. These formulations

can be mapped to the definition of perplexity PP.

$$H(q,D) = -\frac{1}{n}\sum_{m=1}^{n}\log_2 P_D(w_m). \quad (6)$$

$$PP(q,D) = 2^{H(q,D)}. \quad (7)$$

There is already a method to filter sentences q based on the perplexity defined with targeted backend documents D (Misu and Kawahara, 2006). In this approach, we construct an n-gram model from the backend documents D and use the perplexity as a superficial similarity measure. This is equivalent to the KL divergence between q and D. We compute the perplexity $PP(q,D)$ to every collected sentence, and then rank them for the filtering.

3 Similarity based on Predicate-Argument Structure

In the conventional filtering method described in the previous section, the matching is performed using word-level similarity measure. However, it is difficult to select sentences that semantically match the backend documents because this method is based on surface information. This is problematic because information navigation systems work based on semantic structures of user utterance (Yoshino et al., 2011). We therefore propose a similarity measure based on P-A structures to select sentences that match the backend documents on the deep semantic level. In this section, our focus is on the semantic structures that are defined with P-A structures.

In the conventional approach, the similarity measure is defined with a generative model $P_D(w_i)$. In this section, we adopt a discriminative approach and calculate $P(D|w_i)$ to predict the significant sentences.

3.1 Predicate-Argument Structure

The P-A structure is automatically generated by a semantic parser (**Figure 2**). This P-A structure has a sub-structure that contains a predicate (w_p), argument (w_a), and its semantic case (w_s) (called a "P-A pair"). The P-A structures consist of various arguments that depend on one predicate with its semantic case. We used the JUMAN/KNP [1] analyzer to parse sentences and obtain the structures automatically. However, not every P-A pair is meaningful in information navigation; actually, only a fraction of the patterns are useful. For example, in the baseball domain, key patterns include "[A (agent) beat B (object)]" and "[A (agent) hit B (object)]", and in the business domain, "[A (agent) sell B (object)]" and "[A (agent) acquire B (object)]". The useful information structure is depending on the domain, and information extraction techniques have been investigated (Grishman, 2003). Conventionally, templates for information extraction have been hand-crafted (Ramshaw and Weischedel, 2005), but this heuristic process is so costly that it cannot be applied to the wide variety of domains on the Web. A method to automatically define domain-dependent templates for information extraction to be used in a flexible information navigation system has been proposed (Yoshino et al., 2011).

3.2 Significance Measure based on P-A structures

We extract important P-A pairs from the backend documents D and create matches between the extracted pairs and a question sentence q to measure the similarity based on the semantic

[1] http://nlp.ist.i.kyoto-u.ac.jp/index.php?JUMAN
http://nlp.ist.i.kyoto-u.ac.jp/index.php?KNP

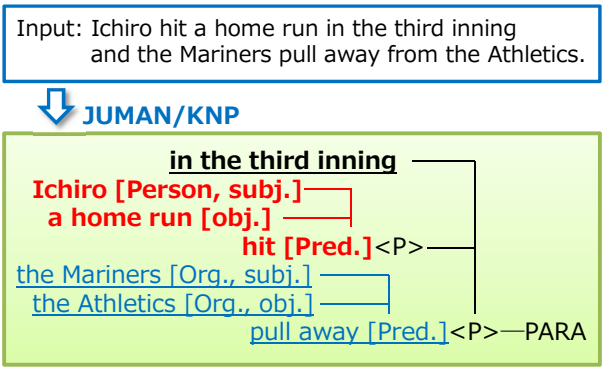

Figure 2: Example of predicate-argument (P-A) structure extraction.

significance. A previous study (Yoshino et al., 2011) has shown that an extraction method based on a Naive Bayes classifier is effective. In this method, the conditional probability of a document D (e.g., baseball) given a word w_i is defined as

$$P(D|w_i) = \frac{C(w_{i,D}) + x_D\gamma}{C(w_i) + \gamma}, \quad (8)$$

where γ is a smoothing factor estimated with a Dirichlet prior (Teh et al., 2006) using the Chinese Restaurant Processes (CRP). To calculate the conditional probabilities, we use sentences $\bar{D}$ of other domains that are extracted at random with the same population of D. x_D, a normalization factor that depends on the size of D, is defined as

$$x_D = \frac{\sum_j C(w_j, D)}{\sum_k C(w_k)}. \quad (9)$$

The P-A structure has a minimum sub-structure P-A pair (PA_i) containing the predicate (w_p), argument (w_a), and its semantic case (w_s). With the above definition, we define the conditional probability $P(D|PA_i)$ as

$$P(D|PA_i) = \sqrt{P(D|w_p, w_s) \times P(D|w_a)}. \quad (10)$$

3.3 Clustering of Named Entities

The statistical method often encounters the problem of data sparseness due to mismatch between the training set and the test set, especially with the named entities (NEs). To solve this problem, we cluster NEs that appear in the training set. NEs are one of the information structures that can be automatically generated by a semantic parser in accordance with a pre-defined category. An example of automatically labeled NEs is shown in the **Figure 2**, in which a labeler assigns person and organization labels to the entities.

We perform clustering to classify P-A structures that have the same trio of predicate, semantic case, and NE. In the example shown in **Figure 3**, two P-A structures that have the same abstract

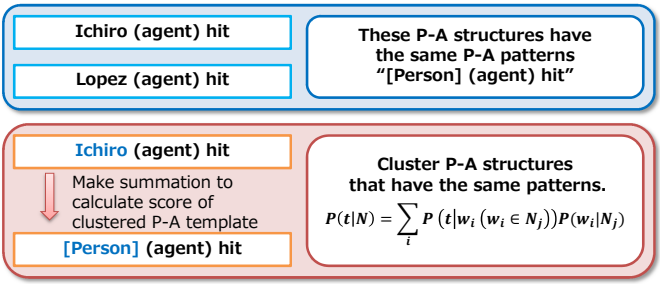

Figure 3: Clustering of named entities (NEs).

P-A pairs are clustered to the same template. We extend the probability of argument $P(w_a)$ as

$$P(D|N_i) = \sum_{k(w_k \in N_i)} P(D|w_k)P(w_k), \quad (11)$$

where N_i is the NE class that is included in arguments w_a. This clustering enables us to reduce lexicon mismatches between the backend documents D and question sentences q, leading to more robust matching.

3.4 Filtering with P-A Templates

For each question sentence q, we calculate the mean of every $P(D|PA_i)$ contained in the sentence q, which is defined as $P(D|q_{PA})$. An example of this scoring is shown in **Figure 4**. The input sentence q has four P-As. We take the mean of their scores to calculate $P(D|q_{PA})$.

Every sentence is ranked with $P(D|q_{PA})$, for selection to be used to train the LM for ASR. With this method, we can select sentences that are more relevant to the backend documents and more likely to be asked by users.

4 Combination of Sentence Selection Methods

We described two similarity measures for the backend documents D and question sentences q in Section 2 and 3. Considering their advantages, we propose a combination of the two methods using ranks and scores.

4.1 Method based on Sentence Rank

In this method, we sort question sentences q with the above-described $PP(q, D)$ and $P(D|q_{PA})$ and rank them as PP_{rank} and PA_{rank}. We then re-sort the sentences by summing the two ranks: $PP_{rank} + PA_{rank}$, for final selection.

4.2 A Method using Normalized Score

We re-define a new score by using $PP(q, D)$ and $P(D|q_{PA})$. The range of $P(D|q_{PA})$ is $0 < P(D|q_{PA}) < 1$, but the range of $PP(q, D)$ is not $0 < PP(q, D) < 1$, so we content it via the

P-A structure

q = "**Ichiro hit a game-winning double when the bases were loaded with two outs in the final inning.**"
PA = ["[Person]/subject/hit",
"a game-winning double/object/hit",
"the bases were loaded with two outs/locative/hit",
"final inning/modifier/hit"]

P-A templates

Score	Argument	case	Predicate	
0.99599	middle relievers		subject	lose
0.99519	relief pitcher		subject	lose
0.98716	final inning		modifier	hit
0.98202	a game-winning double		object	hit
0.98201	the bases were loaded with two outs		locative	hit
0.78062	[Person]		subject	hit
0.09994	share price		subject	slide
0.09994	charge		subject	increase
	...			

Figure 4: An example of $P(D|q_{PA})$ calculation.

sigmoid function.

$$PP' = \frac{1}{1 + e^{-PP}}. \tag{12}$$

A mixing ratio of 3:7 was set after a trial experiment.

5 Experimental Evaluation

We evaluated LMs constructed by the proposed methods with ASR. These LMs were constructed from selected sentences by using the four proposed filtering methods. We compared these models by using three indexes: word error rate (WER), predicate-argument structure error rate (PAER), and adjusted perplexity. PAER is based on the parsing accuracy of recognized sentences. Since the LMs have a different vocabulary size, we used adjusted perplexity, which penalizes smaller-vocabulary LMs.

5.1 Experimental Setting

We prepared an evaluation task using a news navigation system (Yoshino et al., 2011) in the professional baseball domain. Details of the test sets are shown in **Table 1**.

To train $PP(q, D)$ and $P(D|q_{PA})$, we prepared backend documents D of baseball articles from Mainichi newspaper articles (CD-Mainichi newspaper database 2000–2009). To train the LM for ASR, we used question-style sentences q taken from the baseball domain in the Yahoo! QA corpus [2] (a collection of queries on a Web site). The specification of the corpus are shown in **Table 2**. We used Julius[3] (Lee and Kawahara, 2001) as the ASR engine.

[2]This corpus was provided by Yahoo!JAPAN and National Institute of Informatics, Japan.

Table 1: Specification of test sets.

Task	Users	Utterances
News navigation	10	2,747

Table 2: Specification of training sets.

Usage	Corpus	Sentences
Backend documents D	Mainichi newspaper articles	176,852
Pool of sentences q for training	Yahoo!QA entertainment: Baseball	403,602

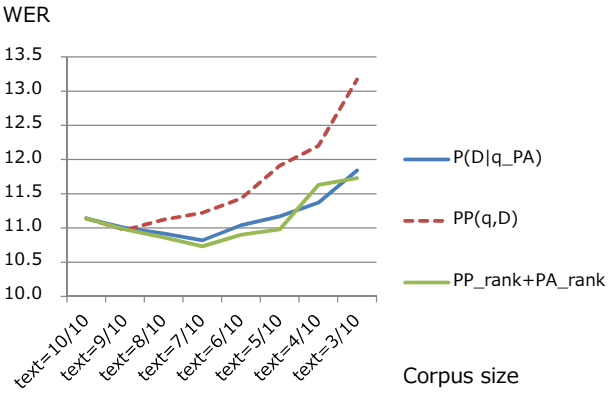

Figure 5: WER on news navigation task.

5.2 Experimental Results

The WER, PAER, and adjusted perplexity results are shown in **Figure 5, 6, and 7**, respectively. The horizontal axes are the relative size of the training set. There was a significant difference between the proposed method ($P(D|q_{PA})$, text $= 7/10$) and the baseline (text $= 10/10$, no filtering), with the significance level of less than 0.05 ($p < 0.05$.) There is no significant difference between the proposed method $P(D|q_{PA})$ and the combined $PP_{rank} + PA_{rank}$ rank or the combined $PP(q, D)$ and $P(D|q_{PA})$ score. Only the combined $PP_{rank} + PA_{rank}$ rank is shown in these graphs because there was not a distinguishable difference between the rank-based method and the normalized score-based method.

The experimental evaluation of WER shows that the similarity measure based on the semantic-level performed better than the conventional surface-level matching using n-gram models. The PAER evaluation also showed that the proposed method using a combination of ranks performed better than the conventional method. This demonstrates that using deep semantic-level similarity can improve the ASR accuracy.

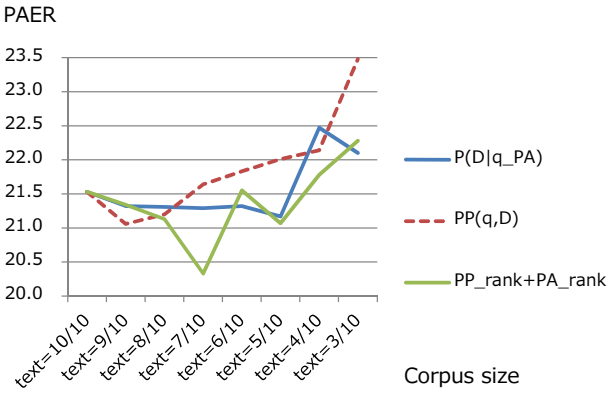

Figure 6: PAER on news navigation task.

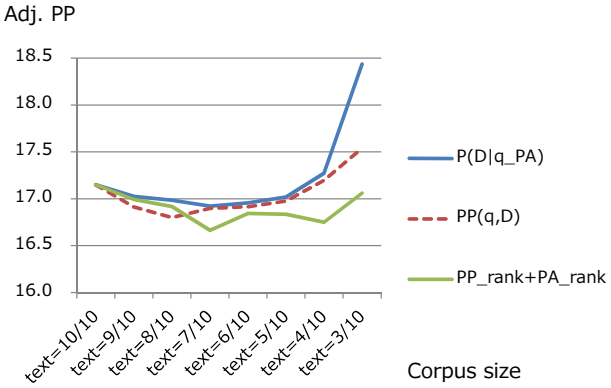

Figure 7: Adjusted perplexity on news navigation task.

6 Conclusion

We have proposed a method of sentence selection for language modeling for information navigation systems. The proposed method features sentence filtering based on semantic-level similarity. Experimental results showed that the proposed method performs better than the conventional method which uses only filtering based on surface-level perplexity. Moreover, the combinational usage of these two measures improve the ASR performance. Especially, filtering based on the P-A structure contributes the improvement of P-A structures accuracy (=reduce the PAER). As a future work, we plan to apply the method to a variety of domains.

ABSTRACT

Automatic detection of sentence errors is an important NLP task and is valuable to assist foreign language learners. In this paper, we investigate the problem of word ordering errors in Chinese sentences and propose classifiers to detect this type of errors. Word n-gram features in Google Chinese Web 5-gram corpus and ClueWeb09 corpus, and POS features in the Chinese POS-tagged ClueWeb09 corpus are adopted in the classifiers. The experimental results show that integrating syntactic features, web corpus features and perturbation features are useful for word ordering error detection, and the proposed classifier achieves 71.64% accuracy in the experimental datasets.

協助非中文母語學習者偵測中文句子語序錯誤

自動偵測句子錯誤是自然語言處理研究一項重要議題，對於協助外語學習者很有價值。在這篇論文中，我們研究中文句子語序錯誤的問題，並提出分類器來偵測這種類型的錯誤。在分類器中我們使用的特徵包括：Google 中文網路 5-gram 語料庫、與 ClueWeb09 語料庫的中文詞彙 n-grams及中文詞性標注特徵。實驗結果顯示，整合語法特徵、網路語料庫特徵、及擾動特徵對偵測中文語序錯誤有幫助。在實驗所用的資料集中，合併使用這些特徵所得的分類器效能可達 71.64%。

1 Introduction

Non-native language learners usually encounter problems in learning a new foreign language and are prone to generate ungrammatical sentences. NLP systems that detect and correct grammatical errors are important and invaluable to language learners. Error detection, which tells if there exists a special type of errors in a given sentence, is the first step for this kind of applications (Leacock, Chodorow, Gamon, & Tetreault, 2010).

Sentences with various types of errors are written by language learners of different backgrounds. The distribution of errors varies across different learner groups. For example, the most frequent error for native English learners is missing comma after introductory element, while the most frequent error for ESL (English as a Second Language) students is comma splice, which joins two sentences by using comma instead of a conjunction (Leacock et al., 2010). In addition, learners may generate sentences with multiple types of errors. This complicates the error detection. To simplify the problem and evaluate the performance of the proposed methods, researchers usually detect one type of error at a time, such as common grammatical errors (Islam & Inkpen, 2011; Wagner, Foster & Genabith, 2007) and prenominal adjective ordering errors (Lin et al., 2009; Malouf, 2000).

A training dataset is indispensable for learning an error detection system. In English, there are many well-established corpora for this purpose such as Cambridge Learner Corpus (CLS). In Chinese, Beijing Language and Culture University built an HSK dynamic composition corpus (动态/dynamic 作文/composition 语料库/corpus) and announced a publicly accessible online system to query this corpus[1]. The HSK corpus contains Chinese compositions written by Chinese language learners in the university. The students' compositions were collected and annotated with different error types. In this paper, we will deal with the word ordering errors in the HSK corpus.

This paper is organized as follows. In Section 2, we survey the related work. In Section 3, we introduce the HSK corpus and specify the type of word ordering errors in Chinese. In Section 4, we describe a web-scale Chinese POS-tagged dataset developed from the ClueWeb09 dataset[2] for this study. In Section 5, we present our feature extraction approaches in detail. Section 6 specifies the experimental setups, and Section 7 presents and analyzes the results. The uses of POS bigrams in the detection of different error types are discussed. Finally, we conclude our study.

2 Related Work

Word ordering errors (WOEs) are defined to be the cases where words are placed in the wrong places in sentences. Word ordering error detection is not only useful for language learning, but also beneficial for many applications such as machine translation. For example, we can use a word ordering error detection module to assess the quality of the machine generated sentences. Lee et al. (2007) employ machine translated sentences as training data to rank the fluency of sentences written by non-native learners in English. Their approaches result in accuracy 76.2%.

[1] http://202.112.195.192:8060/hsk/login.asp ; accessd 2012/08/14.
[2] http://lemurproject.org/clueweb09/ ; accessd 2012/08/14.

Leacock et al. (2010) give thorough surveys in automated grammatical error detection for language learners (native and second language learners). Error types, available corpora, evaluation methods, and approaches for different types of errors are specified in the book.

Several approaches have been proposed to detect English grammatical errors (Chodorow & Leacock, 2000) and Japanese Learners' English Spoken Data (Izumi, Uchimoto, Saiga, Supnithi, & Isahara, 2003). Chodorow and Leacock's approach is tested only on 20 specific English words. Wagner et al. (2007) deal with common grammatical errors in English. They consider frequencies of POS n-grams and the outputs of parsers as features. Their classification accuracy with decision tree is 66.0%. Gamon et al. (2009) identify and correct errors made by non-native English writers. They first detect article and preposition errors, and then apply different techniques to correct each type of errors. Word information such as heads of noun phrases and verb phrases, and POS n-grams in a given context is adopted for error detection. A POS context is defined to be the left and the right of a given preposition. The detection performance varies across different error types. A language model is trained on English Gigaword corpus (Linguistic Data Consortium [LDC], 2003) for error correction. The corrected version whose score is higher than a threshold is proposed as the result.

In addition to newswire text data, a large scale web corpus is also explored. Bergsma, Lin, and Goebel, (2009) adopt Google English Web 1T 5-gram corpus (Brants & Franz, 2006) to compute the frequencies of word n-grams and achieve 95.7% in spelling correction and 75.4% accuracy in preposition selection. Islam and Inkpen (2010) adopt the same corpus for unsupervised preposition error correction. An improved version of Google Web 1T 5-gram corpus called Google N-gram V2 (Lin et al., 2009; Lin et al., 2010) is constructed by adding POS information. Google N-gram V2 contains POS sequence information for each word N-gram pattern. Consider the following unigram example. A word "files" occurs as NNS 611,646 times among all its occurrences:

files 1643568 NNS|611646 VBZ|1031992

Lin et al. (2009) present tools for processing Google N-gram V2 and report tasks that can be benefited by using this corpus, such as base noun phrase parsing and prenominal adjective ordering.

The above research shows that features extracted from English POS-tagged Web corpus are useful. In this paper, we will explore the usefulness of a Chinese POS-tagged web corpus in the application of word ordering error detection for learning Chinese as a foreign language. In addition to the traditional POS and parsing features extracted from this corpus, we will study the effects of different Chinese segmentation methods and perturbation of terms in training the error detector.

The major contributions of this paper cover the following four aspects: (1) application aspect: detecting a common type of Chinese written errors of foreign learners with HSK corpus; (2) language aspect: considering the effects of character-based (without segmentation) and word-based (with segmentation) features in Chinese sentences; (3) resource aspect: exploring the feasibility of using a web-scale word and POS-tagged corpus; and (4) technology aspect: exploring the syntactic features and the web corpus features, and comparing the effects of training corpora by foreign learners and native writers.

3 Word Ordering Errors in Chinese

This section introduces the HSK corpus in our study, and specifies the type of word ordering errors in Chinese.

3.1 HSK Corpus

HSK corpus was built in a project led by Cui Xiliang from 1992 to 2005. This corpus contains 4.24 million characters and 2.83 million words in 11,569 students' compositions. Those students come from different countries to study Chinese in Beijing Language and Culture University. Their compositions are scanned, translated to texts, and annotated with different error types. This corpus also contains students' metadata such as age, country, and language skill level. Since its announcement in 2006, this corpus inspires many research efforts in different fields such as Chinese language teaching and learning.

In the HSK corpus, total 46 error types are labeled. The errors range from character level, word level, sentence level, to discourse level. For some error types, such as missing word error, correct answers are also annotated, so that they can be employed to investigate error detection and correction problems.

3.2 Word Ordering Errors in Chinese

The types of word ordering errors (WOEs) in Chinese are different from that in English. In English, characters are meaningless, while each Chinese character has its own meaning in context. Learners taking Chinese as a foreign language often place character(s) in the wrong places in sentences, and that results in wrong word(s) or ungrammatical sentences. In the HSK corpus, there are 35,884 errors at sentence level, and WOEs are the most frequent type of errors at this level. Table 1 lists the top 10 error types on sentence level in HSK. They belong to different error categories defined in HSK.

#	Error Category	Error Type	Count
1	Other Error Types	Word ordering error	8,515
2	Missing Component	Adverb	3,244
3	Missing Component	Predicate	3,018
4	Grammatical Error	"Is (是)… DE(的)" sentence	2,629
5	Missing Component	Subject	2,405
6	Missing Component	Head Noun	2,364
7	Grammatical Error	"Is (是)" sentence	1,427
8	Redundant Component	Predicate	1,130
9	Other Error Types	Uncompleted sentence	1,052
10	Redundant Component	Adverb	1,051

TABLE 1 – Top 10 types of sentence level errors in HSK

In the HSK website, 8,515 sentences contain WOEs. We collect these sentences and sample a subset of 200 sentences for deep analysis. In this subset, we further classify these WOEs into five categories, including adverb ordering error, subject/verb/object ordering error, prepositional phrase (PP) position error, prenominal adjective ordering error, and others. C*overt error*

sentences (Carl, 1998), which can be interpreted correctly in some specific way, belong to the "others" category. Table 2 lists an example for each category along with its distribution.

Adverb ordering error (35.0%)	也 她 很 关心 also she (is) very concerned (她也很关心)
Subject/verb/object ordering error (32.0%)	就这样 我 休学 大学 来 中国 了 therefore I drop out university (and) come to China (就这样我大学 休学 来中国了)
PP position error (20.5%)	我 留学 在 贵国 I (am) studying in your country (我 在贵国 留学)
Prenominal adjective ordering error (6.0%)	我 遇到了 才貌双全的 一位 女人 I meet beautiful and wise a woman (我遇到了一位 才貌双全的女人)

TABLE 2 – Categories of word ordering errors

The word(s) in an erroneous position are underlined. English words are added to make the examples easy to read. In addition, the correct Chinese sentence is parenthesized below the English one. We can see that adverb ordering and subject/verb/object ordering errors are the two most frequent error categories. Because grammatical error is one category of word ordering errors, parsing may be helpful in this task.

The second and third examples are two interesting examples. In the second example, learner translate "drop out" to 休学 and "university" to 大学 in the same order, but, in Chinese, the reversed order 大学 休学 is more fluent. In the third example, learner translate "am studying" to 留学 and "in your country" to 在贵国, but, in Chinese, changing the position of the PP 在贵国 results in a more fluent sentence.

4 A Web-Scale Chinese POS-Tagged Corpus

We use a publicly available Chinese Web POS 5-gram corpus (CP5g) (Yu, Tang & Chen, 2012) for our experiments. The Chinese POS-tagged corpus has been developed based on the ClueWeb09 dataset, which is a huge web document collection crawled by LTI at CMU. The ClueWeb09 corpus contains documents in ten languages including English, Chinese, and so on. There are 177,489,357 Chinese pages in the ClueWeb09. Although most of the Chinese records are crawled from mainland China, there are still some pages in other languages, such as Japanese. In addition, a Chinese web page may be in different encodings, e.g., Big5, CNS 11643, GBK, GB2312, and Unicode. Thus, the encoding detection and language identification problems have to be dealt with in the development of the CP5g dataset.

After identifying the encoding scheme and the written language, they use the Stanford Chinese word segmenter (Tseng, Chang, Andrew, Jurafsky, & Manning, 2005) to segment the text, and adopt the Stanford POS tagger (Toutanova, Klein, Manning, & Singer, 2003) to tag Chinese sentences. After all n-gram (n=1, 2, 3, 4, 5) patterns are extracted, those patterns that occur less than 40 times are filtered out. The output format is similar to Google N-gram V2.

We also use the Google Chinese Web 5-grams (GC5g) (Liu et al., 2010) corpus for comparison. The size of GC5g is larger than that of CP5g, but GC5g does not contain linguistic information. In addition, GC5g and CP5g are developed by different segmentation systems, i.e., a maximum probability segmenter and a CRF-based segmenter, respectively. That may result in different word patterns and introduce uncertainty into the systems. We will consider these issues when discussing feature extraction of our approaches.

5 Detection of Word Ordering Errors

The detection of word ordering errors (WOEs) is formulated as a binary classification problem. We employ LIBSVM (Chang & Lee, 2011) to build a classifier which detects whether there is a word ordering error in a given Chinese sentence. Different types of features are extracted from various sources in the following sections.

5.1 Syntactic Features

Syntactic features include tagging and parsing results of a sentence. The motivation behind this approach is that the sentence with word ordering errors may result in abnormal POS and parsing patterns, and these linguistic clues are useful for WOE detection.

For the application of tagging features, a sentence is segmented and tagged by using the Stanford segmenter and tagger (Toutanova et al., 2003; Tseng et al., 2005). The performance of POS tagging is 94.13%. The POS *n*-grams (n = 2, 3, 4) in the sentence are extracted, and used as in the bag-of-words approach. In other words, these POS n-grams are treated like words and considered as the features for classification. We use B_2, B_3 and B_4 to refer to the approaches of POS bi-gram, tri-gram, and 4-gram, respectively.

For the applications of parsing features, the Stanford parser is used to analyze the dependency relations in a sentence. Consider the following example.

绿色/JJ 食品/NN 当然/AD 是/VC …
green food definitely is

The Stanford parser generates a set of relations as follows for this example, where the number after each word denotes the word position in the sentence.

amod(*食品-2, 绿色-1*) {*amod*(*food-2,green-1*)}
advmod(*是-4,当然-3*) {*advmod*(*is-4,definitely-3*)}
…

The word in a relation is replaced by its POS tag. For example, *amod*(*食品-2*, *绿色-1*) {*amod*(*food-2*,*green-1*)} is converted into *amod*(*NN*, *JJ*). These kinds of relations are collected, and used as features similar to the bag-of-words approach, in which the relation between two tags is regarded as a word. We use B_p to denote this approach.

Parsing features can be used individually, or integrated with all tagging features to form a larger feature vector B = (B_2, B_3, B_4, B_p) for a sentence. We will explore the effectiveness of all the alternatives in the later experiments.

5.2 Web Corpus Features

Web corpus features are extracted from two reference corpora, i.e., GC5g and CP5g corpora. Intuitively, the sentences with word ordering errors are less likely to occur in the language usages of real world. To measure the probability of a sentence with respect to a reference corpus, we use point-wise mutual information (PMI) (Church & Hanks, 1990). The PMI of a word pair (w_1, w_2) and the score c_g for a sentence that uses GC5g corpus are defined as follows.

$$PMI\ (w_1, w_2) = \log \frac{p(w_1, w_2)}{p(w_1)\,p(w_2)} \quad (1)$$

$$c_g = \frac{1}{L-1} \sum_{l=1}^{L-1} \log \frac{p(w_l, w_{l+1})}{p(w_l)\,p(w_{l+1})} \quad (2)$$

In (2), L is the sentence length in terms of the number of words. We divide the sum of PMIs by sentence length minus 1 for normalization.

To avoid the zero count problems in the above computation, we need some smoothing method. Section 4 specifies that those word pairs occurring less than 40 have been removed from the reference corpora. Thus, there are two cases for an unknown pair: a pair does not appear before, or it occurs, but its total occurrences are less than 40. However, we cannot know which case an unknown pair belongs to. Here, we adopt the same smoothing approach for these two cases. We introduce a $k \in \{1, 10, 20, 30, 39\}$ to replace the zero count, where $k = 1$ means we ignore this unknown word pair, and $k = 39$ is the largest value because the minimum occurrence in the reference corpora is 40.

This approach results in a 5-tuple feature vector $C_g = (c_{g,k})$, $k \in \{1, 10, 20, 30, 39\}$ for a sentence, when the GC5g corpus is regarded as a reference corpus. Similarly, the feature vector $C_b = (c_{b,k})$ is used if the CP5g corpus is adopted to compute the occurrence frequency.

The two feature vectors, C_g and C_b, can be directly input to an SVM classifier. In this way, there is no need to set a fixed threshold. As a usual preprocessing step of SVM training, we also scale each dimension to range [-1, 1].

In addition to word level features, we also consider POS level features. We utilize the tag information in the CP5g corpus to derive a probability of a sentence. The probability is defined as follows.

$$c_{p1} = \frac{1}{L} \sum_{l=1}^{L} \log\ p(t_l \mid w_l) = \frac{1}{L} \sum_{l=1}^{L} \frac{p(t_l, w_l)}{p(w_l)} \quad (3)$$

$$c_{p2} = \frac{1}{L-1} \sum_{l=1}^{L-1} \log \frac{p(t_l, t_{l+1}, w_l, w_{l+1})}{p(w_l, w_{l+1})} \quad (4)$$

where t_l is the POS tag of word w_l, c_{p1} is a normalized probability of a sentence to be tagged as $t_1 t_2 \ldots t_L$ by POS unigrams, and c_{p2} is a normalized probability of a sentence by POS bigrams. Similar to C_g, we have to face the unknown pair problem. Here, we adopt the similar smoothing approach, i.e., let $k \in \{1, 10, 20, 30, 39\}$ be the occurrence count of an unknown pair. We represent a sentence by three alternatives: a 5-tuple vector $C_{p1} = (c_{p1,k})$, a 5-tuple vector $C_{p2} = (c_{p2,k})$, or a 10-tuple vector $C_p = (C_{p1}, C_{p2})$.

5.3 Perturbation of Terms in a Sentence

Motivated by Gamon et al.'s work (2009) that calculates scores derived from a language model to filter out improper correction, we perturb a sentence to see how the features respond to the perturbation. We randomly choose two words and switch their positions to simulate the word ordering errors generated by language learners. After that, we extract different types of features from the perturbed sentences as the procedures described in Sections 5.1 and 5.2.

Let pB_n be a perturbed version of B_n for the perturbed sentence. Similarly, we have all perturbed versions of features. As an alternative to pB_n, we consider the difference to the original sentence and use $\triangle pB_n = pB_n - B_n$ as the features.

5.4 Combining Features

We combine features from different sources to get better models. At first, we cosine-normalize a vector to a unit vector. For example, C_b is normalized by the following formula.

$$\overline{C}_b = \frac{C_b}{\| C_b \|} \tag{5}$$

We then combine normalized vectors for experiments. Here, we equally emphasize different types of features. For example, when combining vectors B_2 and C_b, we normalize B_2 and C_b into $\overline{B}_2$ and $\overline{C}_b$, and combine them to a new vector $(\overline{B}_2, \overline{C}_b)$.

6 Experimental Setups

We collect all 8,515 sentences containing WOEs from the HSK web site. We restrict the sentence length to 6~60 Chinese characters, filter out sentences with multiple error types, and remove duplicate sentences. There are 1,100 error sentences with WOEs for this study.

Considering the ratio of correct sentences, we use balanced datasets in the experiments. The most important reason is that the percentage of WOEs in the real world is relatively small. There are 2.83 million words in HSK. Assume a sentence contains 10 words on average. There are 0.283 million sentences in HSK. If we build an experimental dataset in this ratio, i.e., 8,525 vs. 283,000, the number of correct sentences will dominate the system's performance. Therefore, we build a balanced dataset to prevent this bias and to have a fair examination.

In the study of automatic error detection, collecting linguistic errors in the real world is indispensable, but time-consuming. It needs a lot of efforts to tag the error types and the possible corrections. Therefore, we plan to best utilize the error sentences collected in the HSK corpus to get more results for discussion. From the HSK corpus, we collect 4,400 correct sentences to generate four balanced datasets, each containing 1,100 error sentences and 1,100 correct sentences. These four datasets are called the HSK-HSK datasets.

In addition to using HSK correct sentences as positive sentences, we consider sentences by native Chinese writers as positive sentences to analyze which training set is useful to detect error sentences written by non-native language learners. We collect another 4,400 sentences from Chinese articles written by native Chinese writers, which talk about the same themes as those in HSK corpus, i.e., health, life, job application, classmate and friendship. The sentences from native learners are assumed to be correct. Those 4,400 web sentences are used to generate

another four balanced datasets. The resulting four datasets are named as the NAT-HSK datasets. In total, we have eight datasets in two groups for our experiments.

For each dataset, the corresponding 2,200 sentences are further randomly split into five folds. The experimental results are reported by averaging the 20 folds (4 datasets by 5 folds). In this way, we decrease the variations from the dataset generation, and make more reliable analyses about our approaches. We use RBF kernel and adopt grid search to determine the best SVM parameters in training set.

7 Experimental Results

In this section, we report the average accuracy of HSK-HSK datasets and NAT-HSK datasets. Paired Student's *t*-test is used for significant test. The null hypothesis is reject if $|t| > t_{19,\ 0.975} = 2.093$, where there are 19 degrees of freedom and the probability that *t* is less than 2.093 is 0.975. Because the WOE problem is formulated as a binary classification problem and we use balanced datasets, we adopt accuracy as our evaluation metric, which is more adequate than precision and recall. In addition, we ignore the analysis of confusion matrix in the results because we find that there are no big differences between the results of positive and negative samples.

7.1 Basic Features

Firstly, we want to know the performance of the syntactic features. Table 3 shows the experimental results. B_2, B_3, and B_4 denote feature vectors of POS *n*-grams (*n*=2, 3, 4) and B_p denotes feature vector of dependency relations. (B_2,B_3,B_4,B_p) denotes the combined syntactic feature vectors of POS n-grams (n=2, 3, 4) and parsing feature B_p. The resulting model is named model B.

Features	HSK-HSK		NAT-HSK	
	accuracy (%)	stdev.	accuracy (%)	stdev.
B_2	62.63	2.12	67.61	2.17
B_3	60.81	2.14	65.47	2.24
B_4	57.83	1.98	61.28	2.18
B_p	61.86	2.21	63.17	2.57
B=(B_2,B_3,B_4,B_p)	**63.89**	2.17	**69.61**	2.04

TABLE 3 –Performance of basic features

The accuracy of using POS 2-gram features (i.e., B_2) is better than that of using other individual features significantly except the parsing feature (i.e., B_p) in HSK-HSK datasets. It shows that POS 2-grams are very useful in detecting Chinese word ordering errors.

Another interesting finding is the usefulness of parser. The accuracy of using POS 2-gram features (i.e., B_2) is better than that of using parsing features (i.e., B_p) in NAT-HSK datasets significantly. Its accuracy reaches 67.61%. That reflects the effect of training with native Chinese writers' sentences. Intuitively, the sentences of native Chinese learners are more fluent than those of foreign learners, so that it is easier to detect wrong sentences with POS 2-grams learned from the correct sentences.

Because we use balanced datasets, the trivial baseline is 50% accuracy. Using all the above features outperform the baseline significantly. The combined model $B=(B_2,B_3,B_4,B_p)$ using all syntactic features outperforms the features using only one syntactic feature in both HSK-HSK and NAT-HSK datasets significantly.

7.2 Web Corpus Features

In Chinese, characters are segmented into a sequence of words and then the word frequencies are counted. In the next set of experiments, we aim to know how word segmentation influences the results of error detection. Two issues, including the performance difference without/with segmentation, and the effects of different segmentation systems, are considered.

When calculating $p(w_i,w_{i+1})$ in Equation (2), we use different approaches to get the frequencies of word pairs (w_i,w_{i+1}). The first approach ignores the word boundary between w_i and w_{i+1}, regards them as a single string, and uses string matching to get its count. This is a without-segmentation approach $C_{\bullet W}$, where the subscript character $\bullet$ denotes a reference corpus, i.e., GC5g or CP5g in our experiments. The second approach regards w_i and w_{i+1} as two separate words, and uses exact word matching to count their co-occurrences. This is a with-segmentation approach $C_{\bullet S}$. As a result, when we compute frequencies of word pairs, there are six combinations C_{gS}, C_{gW}, C_{bS}, C_{bW}, C_{p2S}, and C_{p2W}, where the subscript g means the Google Chinese Web 5-gram corpus (GC5g) is adopted, the subscript b means the Chinese Web POS 5-gram corpus (CP5g) is adopted, and the subscript p2 means Equation (4) and CP5g are adopted. We compare the effects of segmentation and the use of different kinds of corpora to see if they are complementary. Table 4 shows the results.

Features	HSK-HSK		NAT-HSK	
	accuracy (%)	stdev.	accuracy (%)	stdev.
C_{gW}	50.84	2.26	63.17	1.54
C_{gS}	52.64	2.01	65.01	2.23
$\overline{\overline{C}}_g=(C_{gW}, C_{gS})$	52.59	2.21	64.77	2.29
C_{bW}	50.90	2.94	63.90	1.81
C_{bS}	51.95	2.67	65.09	1.69
$\overline{\overline{C}}_b=(C_{bW}, C_{bS})$	56.99	1.98	65.93	2.01
C_{p1}	49.33	2.59	53.33	2.16
C_{p2W}	53.19	2.06	60.32	2.19
C_{p2S}	52.10	2.17	59.68	1.53
$\overline{\overline{C}}_p=(C_{p1},C_{p2W},C_{p2S})$	57.01	1.35	61.27	1.68
$(\overline{\overline{C}}_g, \overline{\overline{C}}_b, \overline{\overline{C}}_p)$	59.35	2.48	66.69	1.92
$B=(B_2,B_3,B_4,B_p)$	63.89	2.17	69.61	2.04
$(B, \overline{\overline{C}}_g)$	63.70	1.84	69.82	1.66
$(B, \overline{\overline{C}}_b)$	64.11	2.13	69.85	1.99
$(B, \overline{\overline{C}}_p)$	63.80	2.25	70.23	2.15
$(B, \overline{\overline{C}}_g, \overline{\overline{C}}_b, \overline{\overline{C}}_p)$	**64.34**	2.35	**71.18**	2.29

TABLE 4 –Performance of web corpus features

Comparing the uses of the individual features, i.e., C_{gS}, C_{gW}, C_{bS}, C_{bW}, C_{p1}, C_{p2S}, and C_{p2W}, on the HSK-HSK and NAT-HSK datasets, we find the performance of using NAT-HSK datasets is better than that of using HSK-HSK datasets. That meets our expectation because the correct sentences in NAT-HSK datasets are selected from native Chinese writers' web pages. Thus, we fix the datasets to NAT-HSK in the next discussion.

Because two different segmentation systems are applied in the development of the two reference corpora, we compare C_{gS} and C_{bS} features to see if the segmentation results have different effects on the performance. Their performance, 65.01% vs. 65.09%, does not have a significant difference in NAT-HSK datasets. Thus, we conclude that the two different segmentation systems do not have different effects.

In addition, we compare the performance of C_{gW} (63.17%) vs. C_{gS} (65.01%), and C_{bW} (63.90%) vs. C_{bS} (65.09%) to see if segmentation is necessary. The accuracies using word-based matching (i.e., with segmentation $C_{\cdot S}$) are better than those using string-based matching (i.e., without segmentation $C_{\cdot W}$) significantly. This phenomenon also holds in HSK-HSK datasets. Thus, we conclude that using segmentation systems result in better performance.

Next we analyze the usefulness of individual POS features. Table 4 shows that the performance of using C_{p1} features is 49.33% and 53.33% in HSK-HSK and NAT-HSK datasets, respectively. It seems that POS unigram information does not help. Comparatively, the performance of C_{p2W} shows that POS bigrams are more useful than POS unigrams, but POS-based features (C_{p2W}) cannot compete with word-based features (C_{gW} and C_{bW}). We analyze the eight datasets and find that only 7.9% of the tuple $(t_l,t_{l+1},w_l,w_{l+1})$ in Equation (4) can be found in the CP5g corpus, while 77.9% and 78.6% of the word pair (w_l,w_{l+1}) can be found in the GC5g corpus and the CP5g corpus, respectively. Therefore, we conjecture that with a larger dataset, POS N-grams will make a significant difference in this task.

Finally, we examine the complementary effects of the individual features by different integration. Integrating the individual web corpus features $\overline{\overline{C}}_g$, $\overline{\overline{C}}_b$, and $\overline{\overline{C}}_p$ with all syntactic features B outperforms using only the syntactic features B. The accuracy (71.18%) of the approach integrating all web corpus features ($\overline{\overline{C}}_g$, $\overline{\overline{C}}_b$, $\overline{\overline{C}}_p$) with all syntactic features B is significantly better than the accuracy (69.61%) of the approach using B. This confirms that the web corpus features are useful in WOEs detection.

7.3 Perturbation

Table 5 shows parts of perturbation experiments. The system $B=(B_2,B_3,B_4,B_p)$ significantly outperforms all the perturbation features. It seems that the perturbation does not help in all variations. One possible explanation is that we perturb words, but the word ordering errors usually involve many words such as the example "我 留学 在 贵国" (I am studying in your country) in Table 1. The word-based swapping "在 留学" (in studying) cannot capture the PP "在 贵国" (in your country). A phrase-based swapping should be adopted.

Features	HSK-HSK		NAT-HSK	
	accuracy (%)	stdev.	accuracy (%)	stdev.
B_2	62.63	2.12	67.61	2.17

7.4 Combined Features

We combine all features, including syntactic features (B), web corpus features (C_g, C_b, and C_p), and perturbation features, and report their performance in Table 6. We can see that using all features results in the highest accuracy (71.64%) in NAT-HSK datasets. It is better than the accuracy (69.61%) of the system B significantly. Also, using all features also results in the highest accuracy (64.81%) in HSK-HSK datasets.

Features	HSK-HSK		NAT-HSK	
	accuracy (%)	stdev.	accuracy (%)	stdev.

$B=(B_2,B_3,B_4,B_p)$	63.89	2.17	69.61	2.04

TABLE 6 –Performance of combining features

7.5 Analyses

At first, we want to know the relationship between sentence length and accuracy. We apply the models trained by using all features and one of HSK-HSK datasets, as well as one of NAT-HSK datasets to gather the statistics. These two datasets are denoted as HSK-HSK-1 and NAT-HSK-1, respectively. Figure 1 shows the results. We can see that the average accuracies in both two sets are high when the sentence length is in range [10, 19] characters. Moreover, the performance of using NAT-HSK-1 dataset is better than that of using HSK-HSK-1 dataset in all various lengths. That confirms our conclusion in Section 7.1.

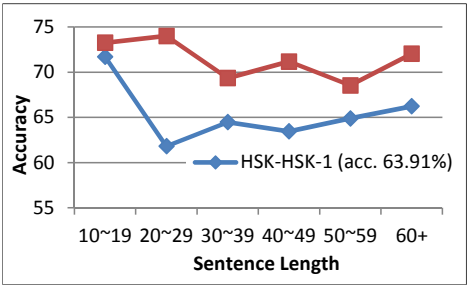

FIGURE 1 – Accuracy analysis by sentence length

Next, we want to know which category of errors is more difficult to detect. Among 200 sentences in Table 1, 197 WOE sentences are used in our experiments. We use HSK-HSK-1 and NAT-HSK-1 to gather the performance in different categories. The overall accuracy of these 197 sentences in HSK-HSK-1 dataset is 74.11% and is 70.56% in NAT-HSK-1 dataset. The detail result is listed in Table 7. The overall average accuracy of HSK-HSK-1 is 63.91% (in Figure 1 and Table 7), which is smaller than the average accuracy 74.11% of 197 sentences. Therefore, the 197 sentences may not be a good representation of HSK-HSK-1 dataset. Comparatively, the overall accuracy of 197 sentences in NAT-HSK-1 dataset is 70.56%, which is near 71.22%. Thus, these 197 sentences may be representative in NAT-HSK-1 dataset. We use the last column to analyze the difficulties of error detection in different categories. Of the former 3 major categories of errors, the accuracy of detecting PP position errors is higher than the overall accuracy. This indicates that the fluent sentences written by native Chinese learners are especially useful for detecting PP position errors in the sentences by non-native learners.

Category	#sentences	HSK-HSK-1	NAT-HSK-1
		accuracy (%)	accuracy (%)
Adverb ordering error	70	77.14	67.14
S/V/O ordering error	65	70.77	67.69
PP position error	41	73.17	**80.49**
Prenominal adjective error	10	**80.00**	80.00
Others	11	72.73	63.64
accuracy (total 197 sentences)		74.11	70.56
accuracy (total 2,200 sentences)		63.91	71.22

TABLE 7 –Performance analysis by category

Finally, we want to know the error detection performance with respect to the students' nationality. We collect the nationality information of the 197 sentences from the HSK website. The results are shown in Table 8. We can find that Korea and Japanese students are the major Chinese learners in the 197 WOE sentences. In HSK-HSK-1 dataset, 77.78% of WOEs from Japanese students can be detected. But this trend is not the same in NAT-HSK-1 dataset. In NAT-HSK-1 dataset, nationality does not make large difference on the error detection performance.

Nationality	#sentences	HSK-HSK-1	NAT-HSK-1
		accuracy (%)	accuracy (%)
Korea	73	69.86	**72.60**
Japan	72	**77.78**	68.06
Other countries	52	75.00	71.15
accuracy (total 197 sentences)		74.11	70.56
accuracy (total 2,200 sentences)		63.91	71.22

TABLE 8 –Performance analysis by nationality

Conclusion

In this paper, we deal with the detection of Chinese word ordering errors for learning Chinese as a foreign language from the application, language, resource and technology aspects. Different categories of word ordering errors in the sentences written by non-native language learners are

analyzed. The experiments show that syntactical features, web corpus features and perturbation features are all useful in detecting word ordering errors. The system using all the features from different sources has the best accuracy, 71.64%, when the native writers' sentences are selected as positive sentences. The proposed system is significantly better than the baseline systems.

In Chinese, word segmentation is inherent in many applications. Even though word ordering errors in Chinese sentences may result in incorrect segmentations, the experiments show that the word-based approach (i.e., with segmentation) is better than the character-based approach (i.e., without segmentation) irrespective of the use of different segmentation systems and reference corpora. On the other hand, although the Chinese Web POS 5-gram corpus is smaller than the Google Chinese Web 5-gram corpus, the experiments show that they have similar performances on the WOE detection. With this important finding, we plan to use linguistic information in the CP5g corpus for other Chinese NLP tasks such as sentiment analysis.

The use of web scale linguistic information provides a solid basis of further error detection and correction. In the future, extending this task to detect other types of errors, using web-scale linguistic corpus to identify the potential error positions and proposing the correct sentences are the works to be investigated.

ABSTRACT

Machine translation aims to generate a target sentence that is semantically equivalent to the source sentence. However, most of current statistical machine translation models do not model the semantics of sentences. In this paper, we propose a novel translation framework based on predicate-argument structure (PAS) for its capacity on grasping the semantics and skeleton structure of sentences. By using PAS, the framework effectively models both semantics of languages and global reordering for translation. In the framework, we divide the translation process into 3 steps: (1) *PAS acquisition*: perform semantic role labeling (SRL) on the input sentences to acquire source-side PASs; (2) *Transformation*: convert source-side PASs to their target counterparts by predicate-aware PAS transformation rules; (3) *Translation*: first translate the predicate and arguments of PAS and then adopt a CKY-style decoding algorithm to translate the entire PAS. Experimental results show that our PAS-based translation framework significantly improves the translation performance.

KEYWORDS: Predicate-argument structure; Semantic role labeling; PAS transformation; PAS-based translation

COLING 2012, Mumbai, December 2012.

1 Introduction

Statistical machine translation (SMT) has made significant progress from word-based models (Brown et al., 1993) to phrase-based models (Koehn et al., 2003; Och and Ney, 2004) and syntax-based models (Galley et al., 2006; Liu et al., 2006; Marcu et al., 2006) over the past decades. However, the existing SMT models are always criticized for not modeling the semantics of languages. Furthermore, reordering is always one of the most difficult and important research problems in SMT. However, although current translation models are much good at local reordering[1], most of them are weak to cope with global reordering[2]. The two weaknesses restrict current translation models a lot, which urges us to seek a new translation framework to model both the semantics of languages and global reordering.

Formally, predicate-argument structure (PAS) is a structure that depicts the relationship between a predicate and its associated arguments, and it always indicates the semantic frame and skeleton structure of a sentence. From the characteristics of PAS, we can see that it provides not only a good semantic representation for modeling semantics, but also a skeleton structure for global reordering. Moreover, Fung et al. (2006) and Wu and Fung (2009b) have shown that PASs of the both sides are more consistent with each other than syntax structures. Considering current syntax-based translation models are always impaired by cross-lingual structure divergence (Eisner, 2003; Zhang et al., 2010), PAS will be a better alternative for building translation models.

Therefore, in this paper, aiming at building a PAS-based translation framework, we propose a novel translation method based on PAS transformation. FIGURE 1 is an overview of our method. Specifically, we divide the entire translation process into 3 steps:

(1) *PAS acquisition*: perform semantic role labeling (SRL) on the input sentences to achieve their PASs, i.e., *source-side PASs*.

(2) *Transformation*: convert source-side PASs to target-side-like PASs by predicate-aware PAS transformation rules, which are extracted from the result of bilingual semantic role labeling (Zhuang and Zong, 2010b). Here, *target-side-like PAS* denotes a list of general non-terminals in target language order, where a non-terminal aligns to a source element. Henceforward, we use source elements to denote the predicate and arguments of source-side PAS (similarly for target elements).

(3) *Translation*: just as FIGURE 1 shows, this step is further divided into two parts: (a) *element translation* is to translate each source element respectively; (b) *translation by global reordering* is to combine the translation candidates of source elements to translate the entire PAS based on the target-side-like PAS.

This method performs translation based on the PASs of sentences. In the transformation step, we model the source-side PAS by PAS transformation rules and convert it to target-side-like PAS. This means that we transform the skeleton structure of source sentence into the skeleton structure of target language. Obviously, this transformation process relates both sides on the skeleton level and would be potential to handle the global reordering problem.

[1] In this paper, global reordering refers to perform reordering based on the entire sentence structure. The other reordering operations are actually all local ones, even for the long-distance reordering without considering the global sentence structure.

[2] Only syntax-based models have tried to model global reordering. However, it needs large translation rules to take the entire sentence structure into account. This requirement always leads to a severe sparsity problem for translation. Therefore, the global reordering problem is not well addressed in these models.

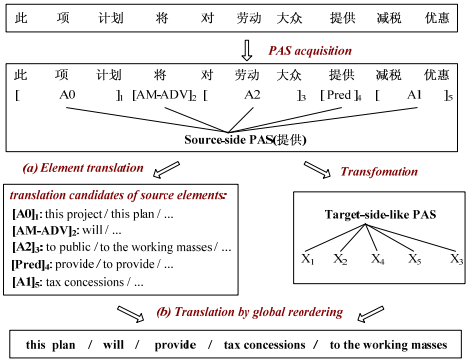

FIGURE 1 Three steps of our PAS-based translation framework: (1) *PAS acquisition*; (2) *Transformation*; (3) *Translation*. In the figure, the same subscript denotes the one-to-one alingment between source elements and non-terminals of target-side-like PAS.

Intuitively, when a human interpreter translates a sentence, he/she segments the sentence according to his/her understanding and translates each part respectively and then he/she translates the entire sentence by combining the partial translation of all parts. From this sense, the translation process of our PAS-based translation framework is similar to human translation to some extent. We believe that this work is a big step towards semantics-based machine translation.

Remainder of the paper is structured as follows. Section 2 elaborates the automatic process of extracting the predicate-aware PAS transformation rules. Section 3 details the translation process of our method. Section 4 describes how to decode the whole sentence with our method. In section 5, we evaluate the effectiveness of our method and in section 6, we introduce the related work. Finally, we end with the conclusion and perspectives.

2 PAS Transformation Rule Extraction

In this section, we introduce the method of bilingual semantic role labeling (SRL) and present how to extract PAS transformation rules based on the bilingual SRL result.

2.1 Bilingual Semantic Role Labeling

Bilingual SRL is to perform SRL on bitext simultaneously. In order to do this, (Zhuang and Zong, 2010b) proposed a method to infer bilingual semantic roles jointly. At first, they looked for aligned bilingual predicates and generated multiple monolingual SRL results by monolingual SRL systems. Then they adopted an integer linear programming method to find the best bilingual SRL result. They not only achieved the start-of-the-art monolingual SRL performance to date, but acquired the mapping between bilingual arguments. Thus, we follow their work to achieve bilingual SRL results for our training set. FIGURE 2(a) shows an example of bilingual SRL.

2.2 Rule Extraction

With the bilingual SRL result in FIGURE 2(a), we can easily generate an *exact transformation rule*, of which the left and right side is the PASs on the two sides, just as FIGURE 2(b) shows. Using the

rule, we can project the translation candidates of source elements to their aligned target elements and then translate the entire PAS by combining these candidates.

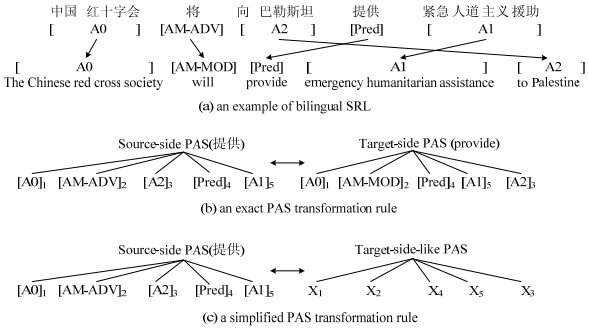

FIGURE 2 – An example of bilingual SRL and the corresponding PAS transformation rules: In (b) and (c), the same subscript at the source and target side denotes the aligned elements in PASs.

Obviously, semantic roles of target elements are not used in the above translation process[3]. Therefore, we can simplify the exact transformation rule by substituting target elements' semantic roles with general non-terminals. We call the achieved target-side PAS as *target-side-like PAS* and name the rule as *simplified transformation rule*, just like the rule in FIGURE 2(c). Basically, a simplified transformation rule $\boldsymbol{r}$ is a triple $< Pred, SP, TP >$:

- *Pred* is the specific source-side predicate where rule $\boldsymbol{r}$ is extracted.
- *SP* denotes the source-side PAS, which is a list of source elements in source language order.
- *TP* is the target-side-like PAS, i.e., a list of general non-terminals in target language order.

For example, the rule in FIGURE 2(c) is a tripe where *Pred* is Chinese verb "提供", *SP* is the source element list $< [A0]_1 [AM\text{-}ADV]_2 [A2]_3 [Pred]_4 [A1]_5 >$, and *TP* is the list of non-terminals $< X_1 X_2 X_4 X_5 X_3 >$. The same subscript in *SP* and *TP* refer to the one-to-one mapping between a source element and a target non-terminal. Obviously, the transformation rule can easily grasp the interrelation of bilingual PASs. Note that the target predicate "provide" in FIGURE 2(b) is ignored because its counterpart predicate "提供" will be translated by the element [Pred] in *SP*.

Virtually, in order to project the translation candidates of source elements to target-side-like PAS, we require that a source argument only aligns to a target argument. However, the result of bilingual SRL usually does not satisfy this requirement. There exist many unaligned source arguments, and sometimes a source argument might align to more than one target argument.

To resolve this problem, we refine the bilingual SRL result via word alignment. We focus on source arguments and refine the corresponding target arguments. For the unaligned source arguments, we look for their target spans via word alignment. If the source argument and its target span are consistent with word alignment[4], and its target span does not overlap with the

[3] Semantic roles of target elements can be used to evaluate the quality of translation candidates. Here we do not consider this point and we take it as our future work.

[4] Two spans are consistent with word alignment means that words in source span only align to words in target span via word alignment, and vice versa.

target span of other source arguments, we take the target span as a virtual target argument for rule extraction. Otherwise, we ignore the source argument.

Towards the source argument aligning to more than one target argument, we check the minimal continuous target span covering all its aligned target arguments. If the span does not overlap with other target arguments, we also take the span as a virtual argument for rule extraction. Otherwise, we discard the source argument. In addition, for the predicate whose multiple arguments align to one or more target arguments (many-to-one/many case), we do not extract rules from that predicate. According to our final statistics, only 6.9% of the aligned predicate pairs are discarded.

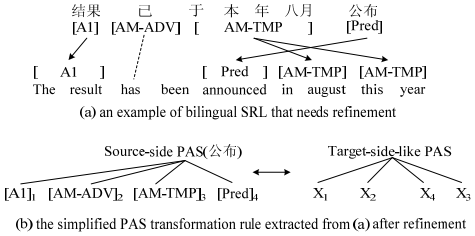

FIGURE 3 – An example for refining the bilingual SRL result.

For example, in FIGURE 3, although the source argument [AM-ADV] is unaligned, we align it to target word *"has"* via word alignment. For source argument [AM-TMP], the minimal span that covers the two target argument [AM-TMP]s does not overlap with other target arguments. We take that span as a big virtual argument for rule extraction. At last, we extract the simplified transformation rule in FIGURE 3(b).

Finally, the transformation rules are organized into a Trie structure. In order to store a rule, we use the rule's *Pred* and *SP* as the key, and *TP* as the value of Trie node. Henceforward, we utilize *TRTrie* to denote the Trie structure encoding all the transformation rules.

2.3 Rule Extension

Basically, some modifier arguments[5] are actually not necessary for the skeleton of sentences. For example, source argument [AM-TMP] in FIGURE 3(a) is a modifier. If we ignore it and its target counterpart, the remaining PAS is still reasonable. Therefore, we extend the PAS transformation rules based on this insight. For a specific PAS transformation rule, we traverse all its modifiers and discard each one in turn, and meanwhile, construct a simplified transformation rule with the remaining arguments of the PAS. For instance, if we ignore the source argument [AM-TMP] in FIGURE 3(a), we can get a simplified transformation rule where *Pred* is verb "公布", *SP* is the source element list $<[\text{A1}]_1\ [\text{AM-ADV}]_2\ [\text{Pred}]_3>$, and *TP* is $<\text{X}_1\ \text{X}_2\ \text{X}_3>$.

2.4 Rule Probabilities

To distinguish different transformation rules during decoding, we design two probabilities for each transformation rule: *predicate-conditioned rule probability* $p_{pred}(r)$ and *source-PAS-conditioned rule probability* $p_{sp}(r)$:

[5] The argument that utilizes AM as its prefix.

$$p_{pred}(r) = \frac{c(r)}{\sum_{r':Pred(r')=Pred(r)} c(r')}$$

$$p_{SP}(r) = \frac{c(TSP(r))}{\sum_{r':SP(r'))=SP(r)} c(TSP(r'))}$$

In the two formulas, $Pred(r)$ and $SP(r)$ denote *Pred* and *SP* of rule ***r*** respectively. $TSP(r)$ refers to the combination of rule ***r***'s *SP* and *TP*. $c(r)$ is the count of rule ***r*** (similarly for $c(TSP(r))$). The two probabilities will serve as features for decoding. Generally, the first feature is mainly used to evaluate which transformation rule is more possible for the specific source predicate. The second feature is used to evaluate which *TP* is more appropriate for the specific *SP*[6]. The two features indicate the distribution of bilingual PASs from two different angles, which will be helpful for the decoder to choose effective PAS transformation rules.

3 PAS-based Translation Framework

In the *PAS acquisition* step, we perform SRL on each test sentence with a monolingual SRL system. To alleviate the negative impact of SRL errors, we use multiple SRL results. We provide the monolingual SRL system with 3-best parse trees of Berkeley parser (Petrov and Klein, 2007), 1-best parse tree of Bikel parser (Bikel, 2004) and Stanford parser (Klein and Manning, 2003). FIGURE 4(a) shows an example of multiple SRL results. In the *transformation* step, we match the multiple SRL results with PAS transformation rules and convert them to target-side-like PASs. Then in the *translation* step, we decode the PAS based on these target-side-like PASs.

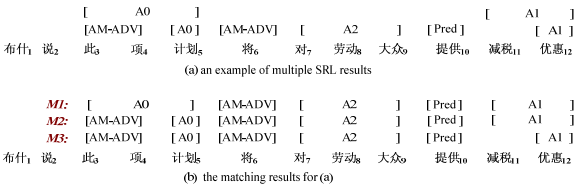

FIGURE 4 – Multiple SRL results and the final mathcing result of the example sentence.

3.1 PAS Transformation

In this section, we describe how to match the multiple SRL results with PAS transformation rules and transform them to target-side-like PASs. We design *Algorithm 1* to achieve our purpose. First, we look for the predicate in *TRTrie* and get the matching Trie node *P_N*. With this node, we continuously match the elements of PAS in order, and meanwhile, expand along *TRTrie*. Finally, we achieve all possible PASs that can match transformation rules. We only preserve the ones covering the largest number of source words or elements. We believe that only the PAS satisfying one of the two conditions is possible to stand for the real skeleton of a sentence and capture a good global reordering operation. For example, FIGURE 4(b) shows the matching result of FIGURE 4(a). The result M1 in FIGURE 4(b) covers the largest number of source words, and M3 carries the largest number of elements, and moreover, M2 satisfies the two conditions. After that,

[6] Actually, this feature should base on the entire rule ***r***, rather than TSP(r). However, this leads to severe data sparseness for rules. Therefore, we pursue the general rules and ignore the predicate here.

we can get target-side-like PASs from the transformation rules. Algorithm 1's complexity is exponential, but its speed is fast in practice because a predicate only carries very few arguments.

Algorithm 1: PAS Transformation Rule Matching

Input: *predicate* ***P****, a list* ***L*** *including all the source elements of* ***P****, and TRTrie*
Output: *a list* ***TPL*** *preserving all the achieved target-side-like PASs*
1: **function** Matching (*P*, *L*, *TRTrie*):
2: sort *L* first by the element's start position and then by its length from small to large
3: find *P* in *TRTrie* and get the Trie node *P_N*, **if** not find *P*, **return** ◁ match the predicate first
4: **for** *c_arg* in *L* **do**: ◁ consider all elements in turn
5: **for** *p_arg* that is before *c_arg* in *L* **do**: ◁ check all partial matching PASs
6: **if** *p_arg* does not overlap with *c_arg*:
7: **for** Trie node *t_n* in *p_arg* **do**:
8: **if** *c_arg* in descendents of *t_n*, **then** store that node into *c_arg* ◁ expand along *TRTrie*
9: find *c_arg* in descendents of ***P_N,*** **if** find, store that node into *c_arg* ◁ PAS might begin with any element
10: check all Trie nodes stored in L's elements, consider the rules covering the largest number of arguments or source words, and save *TP*s of these rules into *TPL* ◁ store the target-side-like PASs
11: return *TPL*

We use *matching score* to evaluate the matching PASs. For a PAS $A_{m1},...,A_{mn}$, such as <[A0][AM-ADV][A2][Pred][A1]> (the matching result M1 in FIGURE 4(b)), its matching score is:

$$p_{MS}(A_{m1},...,A_{mn}) = \frac{\prod_j p(A_{mj} \mid S, pred)}{\sum_{m'} \prod_j p(A_{m'j} \mid S, pred)}$$

where *S* and *pred* denote the test sentence and the predicate respectively. $p(A_{mj} \mid S, pred)$ denotes the probability that the SRL system assigns to element A_{mj}[7]. Additionally, the denominator sums the score of all matching PASs. This matching score will serve as a feature in the final decoder. It is mainly used to reward the good skeleton structure of sentences.

3.2 Gap Word Attachment

In a matching PAS, adjacent source elements might be separated by *gap words* in the sentence. For example, in the matching result M3 of FIGURE 4(b), [Pred] and [A1] are separated by a gap word "减税". For the PAS whose elements are separated by gap words, we cannot translate it only based on the target-side-like PAS because it is not continuous. Therefore, to address this problem, we attach the gap words to their neighbouring left or right elements via parse tree. We look for the lowest common ancestor nodes of the gap word and its left or right neighbouring elements respectively. We compare these two ancestor nodes and attach the gap word to the element whose corresponding ancestor node is lower in the parse tree. For example in FIGURE 5, the common ancestor node of word "减税" and [A1] is node $NP_{11,12}$, while it is node $VP_{10,12}$ for [Pred]. Hence, we attach word "减税" to [A1] and transform the PAS_1 to PAS_2 in FIGURE 5.

In practice, it is common that the neighboring left and right elements get the same ancestor node. This is because a father node can dominate many children nodes in parse trees. To address this problem, we employ the head binarization method (Wang et al., 2007) to binarize the parse trees.

[7] We average the five probabilities given by the 5 parse trees as this probability.

We make the final attachment decision by voting with the abovementioned five parse trees. After attachment, some PASs may be identical to each other, such as the matching result M2 and M3 of FIGURE 4(b). We only retain the one whose matching score is larger.

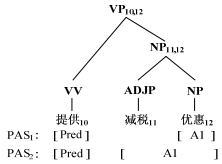

FIGURE 5 – An example of gap word attachment using parse tree.

3.3 PAS Translation

In the *translation* step, we translate each source element by a traditional translation method. Then we combine these candidates to translate the entire PAS based on the target-side-like PAS, just as FIGURE 1 shows. Intuitively, the combination can be operated directly by cube pruning (Chiang, 2007). However, since the source elements are translated independently and many source elements' spans are very short, numerous phrase translation rules are ignored during translation. This fact leads to a narrow decoding space and poor translation accuracy. To alleviate this problem, we design a CKY-style decoding algorithm for each target-side-like PAS.

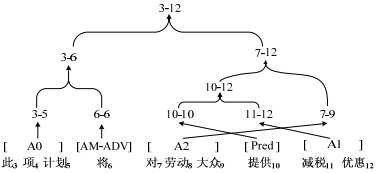

FIGURE 6 – An example of our CKY-style decoding algorithm for target-side-like PAS. In this example, only one path is generated for the final span 3-12. In practice, there can be many paths.

In the CKY-style decoding algorithm, we organize the source elements in target language order based on the target-side-like PAS. For example, in FIGURE 6, we use the rule in FIGURE 2(c) and create the span list [3,5], [6,6], [10,10], [11,12], [7,9]. Then we combine these spans in a bottom-up manner, just like traditional CKY algorithm works. The difference is that we only check all the possible combinations of small spans to form big spans, rather than checking all the split points of a big span. Moreover, if the adjacent spans are not adjacent at the source side, we do not combine them. For instance, in FIGURE 6, span [6,6] and [10,10] are adjacent in target order, but they are not adjacent at the source side. In addition, the translation candidates of newly generated spans, such as span [3,6], come from two parts: combining the translation candidates of its two sub-spans by cube pruning, or using phrase translation rules. These combined spans help to enlarge the search space a lot and yield a good translation performance.

Basically, only when the target-side-like PAS can be binarized, our decoding algorithm can be implemented. According to our statistics, almost all the target-side-like PASs can be binarized. We will detail the statistics in sub-section 5.2. If a target-side-like PAS cannot be binarized, we combine the partial translations of its elements by cube pruning straightforwardly.

4 Decoding with PAS-based Translation Framework

Formally, PAS represents the main structure of a sentence. However, sometimes the sentence cannot be fully covered by a PAS, especially when there are several predicates in the sentence. In order to translate the whole sentence, we design a decoding algorithm in terms of our PAS-based translation framework. The algorithm we adopted here follows the CKY-style framework.

In the decoder, we organize the search space of translation candidates into a hypergraph. For the span covered by PAS (named as *PAS span*), we use a multiple-branch hyperedge to connect that span to the PAS's elements. For the span not covered by PAS (named as *non-PAS span*), we consider all the binary segmentations of that span and use binary hyperedges to link them, just as FIGURE 7 shows. As a realistic example, FIGURE 8(a) shows a sentence and the PAS of its predicate "说(say)". The PASs of another predicate "提供(provide)" in the sentence are shown in FIGURE 4(b). The final decoding hypergraph is shown in FIGURE 8(b).

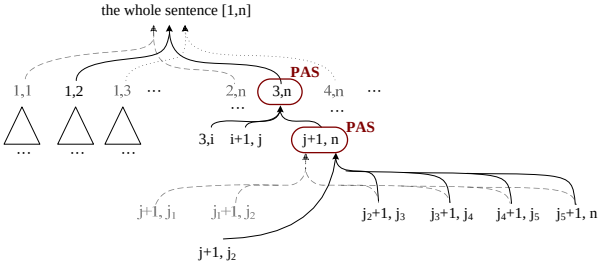

FIGURE 7 – An illustration of the decoding hypergraph. In the FIGURE, *n* refers to the length of sentence. Span [3,n] and [j+1,n] denote PAS spans and their descendent spans are all spans of elements in PAS.

After the hypergraph is constructed, we fill the spans with translation candidates in a bottom-up manner. When we encounter a PAS span, the algorithm described in sub-section 3.3 is used. Otherwise, the traditional translation method is utilized. Obviously, any CKY-based translation method can be used to generate translation candidates, such as BTG translation model and hierarchical phrase-based translation model. In this process, PAS span and non-PAS span are used equally for translating bigger spans. This is because bad PASs might harm the translation accuracy and the competition of PAS spans and non-PAS spans will help to choose good PASs.

For a specific span, we distinguish its translation candidates from different PASs by the two rule probabilities in sub-section 2.4 and the matching score in sub-section 3.1. These probabilities and scores are served as the PAS features for decoding. Their weights are tuned together with other features, such as language model. We call this translation system as *PAS transformation system*.

In the decoder, we can see that the translation candidates of PAS span are generated only by PAS transformation rules, while the traditional translation method also has its own way to translate the same PAS span. We believe that they complement each other because they perform translation from different angles. Thus, to capture this complementation, for the PAS span in the decoding hypergraph, we can use both our PAS-based translation method and the traditional translation method. This leads to a combination system which we call *PAS combination system*.

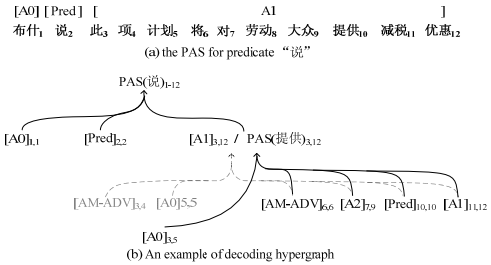

FIGURE 8 – An illustration of the decoding hypergraph. In the FIGURE, the PASs for predicate “提供 (provide)” are the result M1 and M2 in FIGURE 4(b). We omit the non-PAS spans here.

5 Experiment

5.1 Experimental Setup

The experiment is conducted on Chinese-to-English translation. The training data includes 260K bilingual sentence pairs[8]. To guarantee the accuracy of bilingual SRL, the length of each sentence is among 10 and 30 words. We use this data for both bilingual SRL and training the translation system. We first run GIZA++ and employ the *intersection* and *grow-diag-final-and (gdfa)* strategy respectively to produce symmetric word alignments. Then we use the intersection alignment to find the aligned predicates and adopt Zhuang and Zong (2010b)’s method to do bilingual SRL. After that, we refine the result in terms of the gdfa alignment and extract PAS transformation rules as described in section 2.

For machine translation, we train a 5-gram language model with the Xinhua portion of English Gigaword corpus and target part of training data. The development set and test set are the NIST evaluation test data (from 2003 to 2005). To get accurate SRL results, we also only extract sentences whose lengths are among 10 and 30 words. As a result, 595 sentences from NIST MT03 serve as the development set. 1,786 sentences from NIST MT04 and MT05 compose the test set. We perform SRL for the two sets by Zhuang and Zong (2010b)’s method. The translation quality is evaluated by case-insensitive BLEU-4 with shortest length penalty. The statistical significance test is performed by the re-sampling approach (Koehn, 2004). We employ our in-house BTG system used in (Zhang and Zong, 2009) to serve as our baseline translation method. We use PAS(BTG) to denote the PAS transformation system and PAS+BTG to represent the PAS combination system.

5.2 PAS Transformation Rules

In the training data, we acquire 226,968 aligned predicate pairs. From these predicate pairs, we extract 62,597 different simplified PAS transformation rules and then we extend them to 92,278 ones. Among the rules, 99.55% of their TPs can be binarized. Therefore, our decoding algorithm in sub-section 3.3 can be used in almost all cases. To detail our PAS transformation rules, we give the top 5 monotone rules and reordering rules respectively in TABLE 1.

[8] It is extracted from the LDC corpus. The LDC category number : LDC2000T50, LDC2002E18, LDC2003E07, LDC2004T07, LDC2005T06, LDC2002L27, LDC2005T10 and LDC2005T34.

Top 5 monotone rules			Top 5 reordering rules		
Pred	SP	TP	Pred	SP	TP
说(say)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_1\ X_2\ X_3$	提供(provide)	$[A0]_1\ [A2]_2\ [Pred]_3\ [A1]_4$	$X_1\ X_3\ X_4\ X_2$
认为(think)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_1\ X_2\ X_3$	支持(support)	$[A0]_1\ [AM\text{-}ADV]_2\ [Pred]_3\ [A1]_4$	$X_2\ X_1\ X_3\ X_4$
希望(hope)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_1\ X_2\ X_3$	说(say)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_3\ X_1\ X_2$
想(think)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_1\ X_2\ X_3$	表示(express)	$[A0]_1\ [A3]_2\ [Pred]_3\ [A1]_4$	$X_1\ X_3\ X_4\ X_2$
有(have)	$[A0]_1\ [Pred]_2\ [A1]_3$	$X_1\ X_2\ X_3$	举行(hold)	$[A1]_1\ [AM\text{-}LOC]_2\ [Pred]_3$	$X_1\ X_3\ X_2$

TABLE 1 – Top 5 monotone rules and reordering rules. The counts of monotone rules range from 5,101 to 1,745, and the counts of reordering rules range from 339 to 157.

Let us investigate the reordering rules first. The transformation rule for Chinese verb "提供(provide)" moves its argument [A2] behind [Pred] and [A1]. In general, [A2] is usually a prepositional phrase, which begins with a prepositional word, such as "为(for)" or "向(to)". This is reasonable because we always move the prepositional phrase behind verb phrase during Chinese-to-English translation, just as FIGURE 2(a) shows. From the transformation rules, we can see that we reorder the arguments based on the entire PAS. This demonstrates that our PAS-based translation method is good at global reordering.

For the monotone rules, we can see that all top 5 rules focus on [A0], [Pred] and [A1]. This fact demonstrates that Chinese and English are mostly Subject-Verb-Object (SVO) languages. Therefore, during Chinese-to-English translation, we can maintain the main skeleton structure of sentences according to the monotone rules.

5.3 Translation Result

TABLE 2 illustrates the final translation results of our experiments. As we can see, our in-house BTG system outperforms Moses (Koehn et al., 2007) by 0.33 BLEU points, indicating that our BTG system is a strong baseline system. Moreover, from TABLE 2, we can see that system PAS(BTG) only improves the baseline BTG system slightly, by 0.38 BLEU points. However, the PAS+BTG system significantly outperforms the baseline BTG system by 1.14 BLEU points. This comparison means that the PAS can better play its role by combining with BTG model. We will conduct a deep analysis on these results in the next sub-section.

		n-gram precisions			
System	Test Set	1	2	3	4
Moses	32.42	74.91	41.86	24.4	14.43
BTG	32.75	74.39	41.91	24.75	14.91
PAS(BTG)	33.13	75.13	42.55	25.10	15.02
PAS+BTG	**33.89***	74.98	43.17	25.91	15.72

TABLE 2 – Result of BTG system and our PAS-based translation method. The "*" denotes that the result is significantly better than BTG ($p<0.01$).

5.4 Analysis and Discussion

According to our statistics, in the total 1,786 test sentences, there are 1,747 ones have involved in matching PAS transformation rules. However, only 386 sentences in system PAS(BTG) but 1,017 sentences in system PAS+BTG have utilized PASs to generate final translations. Why they have such great difference in the two systems? After analysis, there are two main reasons.

On one hand, decoding space is narrowed and limited by the rigid spans under the PAS-based framework. As we described in sub-section 3.3, we use a CKY-style algorithm to enlarge the decoding space. However, even so, a lot of spans are still ignored during decoding. Moreover, the predetermined spans of arguments also restrict the usage of phrase translation rules.

On the other hand, the accuracy of SRL is not high. To our best knowledge, the F-score of current monolingual Chinese SRL system is only about 80% on the Treebank data. Moreover, this evaluation focuses on arguments, rather than the entire PASs. We can imagine that it would reduce greatly on the non-well-formed training and test data. In addition, according to our statistics, there are 26,809 different matching PASs in the test set in total, in which 16,489 ones (61.5% of all) have a father PAS or child PAS. This means such PAS is an argument of a bigger PAS or carries an argument which is actually a smaller PAS, just as FIGURE 8 shows. This hierarchical structure magnifies the negative impact of bad PASs in system PAS(BTG). Many accurate PASs are thus ignored because of its bad father PAS or child PAS.

Due to the narrow decoding space and bad PASs, the comprehensive translation score of PASs' translation candidates would be too low to be utilized in system PAS(BTG). Therefore, numerous PASs are bypassed by the decoder and only a slight improvement is achieved by system PAS(BTG). To address this problem, we propose system PAS+BTG. It not only combines the decoding space of our PAS-based translation framework and BTG translation model, but also breaks up the close connection between father PAS and child PAS by introducing BTG model's translation candidates for PASs. At last, it achieves significant improvement over BTG system and more PASs in 1,017 sentences are utilized in the system.

	# PAS-Span-Covered-Rate (named as cover-rate)			
PAS(BTG)	[0,50%)	[50%,100%)	100%	total
	181	65	225	471
	# PAS-Span-Covered-Rate (named as cover-rate)			
PAS+BTG	[0,50%)	[50%,100%)	100%	total
	613	775	125	1613

TABLE 3 – Statistics about PAS spans used for generating the final best translations. In the TABLE, for example, column 2 of system PAS(BTG) denotes that 65 PASs covering 50%~100% words of source sentences are utilized in system PAS(BTG).

To verify our above analysis, we further give TABLE 3. As we can see, comparing with PAS(BTG), much more PASs are used in PAS+BTG (471 vs 1613). Moreover, the number of PASs in PAS(BTG) reduces when the *cover-rate* increases[9], while the number for PAS+BTG grows. Just as we discussed above, this is because the big PAS in PAS(BTG) usually depends not only on itself, but also on its child PAS. Once the big PAS carries a bad child PAS, its translation would be also bad due to this child PAS. Therefore, the number of big PASs used in PAS(BTG) reduces. In contrast, the child PAS in PAS+BTG is only a choice but not essential for translating its father PAS. Hence, the number of big PASs used in PAS+BTG increases.

From TABLE 3, we can also see that most of the PASs cover more than 50% words of source sentences. We call these PASs as *sen-wide PAS*. In system PAS+BTG, the number of *sen-wide*

[9] There is an exception when the *cover-rate* is 100% in system PAS(BTG). This is because the 225 test sentences are fully covered by PASs. In system PAS(BTG), the translation of these sentences must be generated by the PAS spans whose *cover-rate* are 100%. Obviously, this is a rigid constraint. We relax this constraint in PAS+BTG system to ignore the bad PASs and 125 ones are kept for the final translation.

PASs is 900 (i.e., 775+125 in TABLE 3) and the number for system PAS(BTG) is 290 (i.e., 225+65 in TABLE 3). Each of these PASs belongs to one individual sentence because they all cover more than 50% words of the sentences. Consequently, 88.5% (900/1,017) sentences in PAS+BTG system and 75% (290/386) sentences in PAS(BTG) system have utilized these *sen-wide PASs*, by which the skeleton structure of sentences are well modeled for translation. Hence, we can conclude that our PAS-based translation method performs global reordering based on these *sen-wide PASs* and achieves improvements over the baseline BTG system.

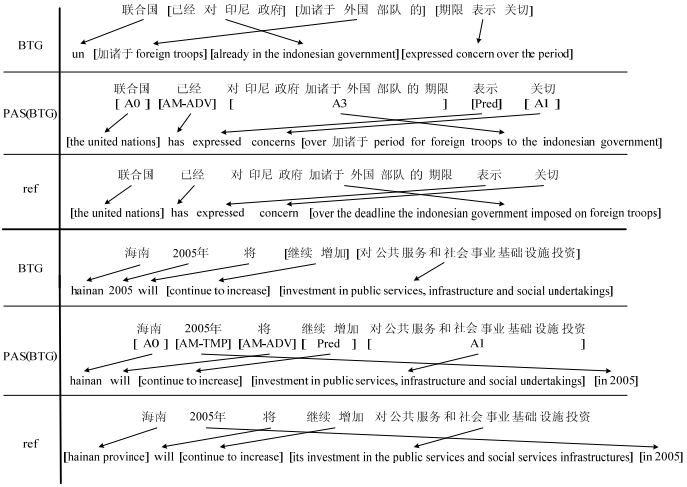

TABLE 4 – Two translation examples of BTG system, PAS(BTG) system, and reference.

We further give two translation examples in TABLE 4 to specially show the effectiveness of our PAS-based translation method. For the first example, BTG system chooses a wrong manner to segment the big prepositional phrase "对 印尼 政府 加诺于 外国 部队 的 期限" into 3 parts. This is because BTG system only tries to get a translation with an average distribution of phrase segmentation. Moreover, since its translation model does not consider any information of sentence structure, it wrongly segments the test sentence and produces a bad translation. Conversely, our PAS(BTG) system segments the sentence based on its PAS. Since a correct PAS denotes the skeleton structure of the sentence, it performs both reasonable sentence segmentation and better global phrase reordering for translation. Furthermore, in the second example, our PAS-based method successfully recognizes the [AM-TMP] argument "2005年" and move it to the end of sentence. However, the BTG system only performs translation without any reordering.

6 Related Work

Previous work utilizing PAS in SMT can be roughly categorized into three directions.

One direction is to do pre-processing or post-processing. Komachi and Matsumoto (2006) and Wu et al. (2011) used PAS-based heuristic rules and automatic rules respectively to pre-order the

input sentences. Wu and Fung (2009b) performed SRL on the outputs of phrase-based system Moses and then reordered the achieved semantic roles to match the roles of input sentences.

Some other works tried to design proper PAS-based features and integrate them into decoder. Liu and Gildea (2010) projected source-side PASs to target side via word alignment and designed a "Semantic Role Re-ordering" feature and a "Deleted Roles" feature for tree-to-string model. Xiong et al. (2012) adopted semantic features to translate verbal predicates and predict the relative position between predicates and arguments.

Some other works focused on utilizing semantic roles to refine the non-terminals of syntax-based translation model. Liu and Gildea (2008) substituted the syntactic labels with semantic roles or combined them together for a tree-to-string model. Aziz et al., (2011) used semantic roles and base-phrase tags to create shallow semantic trees. Gao and Vogel (2011) used target side semantic roles to create SRL-aware non-terminals for hierarchical phrase-based model.

Our work is different from the existing work in the following aspects: (1) we induce PAS transformation rules to model the interrelation between source-side PAS and its target counterpart; (2) we utilize multiple SRL results to alleviate the negative impact of bad PASs; (3) we design a CKY algorithm to translate the entire PAS according to the target-side-like PAS. The algorithm can be easily integrated with any CKY-based decoder to generate better translation hypotheses.

Conclusion and Perspectives

In this paper, we focus on building a PAS-based translation framework for modeling semantic structures in translation model. We first extract PAS transformation rules to model the intrinsic connection between source-side and target-side PASs. Then we perform machine translation in 3 steps: *PAS acquisition*, *transformation* and *translation*. Experimental results demonstrate that our PAS-based translation method improves the translation performance significantly.

Our method improves the translation performance in the following aspects: (1) take advantage of PAS, which keeps consistency well across languages; (2) use PAS transformation rules to perform global reordering in a skeleton scenario; (3) design reasonable strategies to exert the merit of PAS to segment sentences for translation; (4) the PAS-based translation framework can be easily integrated with any CKY-based translation models to generate better translations. In all, the translation process of our PAS-based translation method is similar to human translation to a great extent and it still has much room to improve with the upgrading of SRL performance. We believe it would be a big step towards semantics-based translation model.

In the next step, we will conduct further experiments on other language pairs to demonstrate the effectiveness of our PAS translation method, especially the translation between an SVO language and an SOV language. In addition, we also will utilize the target-side semantic roles to evaluate the quality of translation candidates and the structural integrity of translations.

Acknowledgments

The research work has been funded by the Natural Science Foundation of China under Grant No. 6097 5053 and the Hi-Tech Research and Development Program ("863" Program) of China under Grant No. 2012AA011102 and 2011AA01A207. We would also like to thank Tao Zhuang for the help in generating bilingual SRL results, and the anonymous reviewers for their valuable comments.

ABSTRACT

Parse trees are indispensable to the existing tree-based translation models. However, there exist two major challenges in utilizing parse trees: 1) For most language pairs, it is hard to get parse trees due to the lack of syntactic resources for training. 2) Numerous parse trees are not compatible with word alignment which is generally learned by GIZA++. Therefore, a number of useful translation rules are often excluded. To overcome these two problems, in this paper we make a great effort to bypass the parse trees and induce effective unsupervised trees for tree-based translation models. Our unsupervised trees depend only on the word alignment without utilizing any syntactic resource or linguistic parser. Hence, they are very beneficial for the translation between resource-poor languages. Our experimental results have shown that the string-to-tree translation system using our unsupervised trees significantly outperforms the string-to-tree system using parse trees.

KEYWORDS : Tree-based translation; Unsupervised tree; EM algorithm.

1 Introduction

Recently, ***tree-based models***[1] have been widely studied in statistical machine translation (SMT). The existing tree-based models include ***string-to-tree models*** (Galley et al., 2006; Marcu et al., 2006; Shen et al., 2008), ***tree-to-string models*** (Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006;), and ***tree-to-tree models*** (Eisner, 2003; Ding and Palmer, 2005; Cowan et al., 2006; Zhang et al., 2008; Liu et al., 2009). Due to the effective use of syntactic information, tree-based models have achieved comparable (Liu et al., 2009) and even better performance over phrase-based models (Marcu et al., 2006).

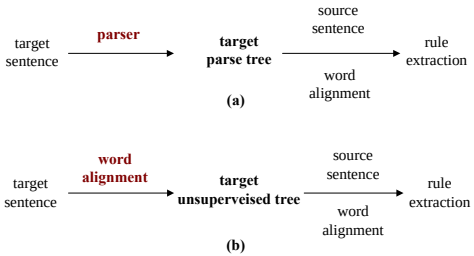

FIGURE 1 – Rule extraction for string-to-tree translation model: (a) using parse trees versus (b) using our unsupervised trees.

In the existing tree-based translation models, parse trees are essential to extracting translation rules. FIGURE 1(a) illustrates the rule extraction process of string-to-tree translation model. The parse tree is usually generated by a linguistic parser which is trained on a manually annotated corpus, such as Treebank. However, the manually annotated corpus is always too inadequate to fully display the strengths of tree-based models. In particular, traditional tree-based systems can not work at all for language pairs without any syntactic resource, which has greatly restricted their application.

From FIGURE 1(a), we can also discover that syntactic parsing is completely independent of word alignment. The separation of parser and alignment leads to a severe incompatibility problem between them. Together with the widely existing parsing errors, numerous useful translation rules are excluded during rule extraction.

To overcome the above two problems of current tree-based models, in this paper, we give up using parse trees and induce better alternatives for tree-based translation models. The alternative tree structures depend only on the word alignment without utilizing any syntactic resource or linguistic parser (see FIGURE 1(b) for illustration). Specifically, the entire process of inducing such tree structures for tree-based translation models is summarized as follows:

1. Based on a word aligned parallel corpus, we first transform those aligned bilingual sentence pairs into packed forests.

[1] The translation models using parse trees on one side or both sides are defined as tree-based models here.

2. Based on the obtained packed forests, we design an EM algorithm to learn an effective synchronous tree substitution grammar (STSG) and then acquire Viterbi tree structures according to the achieved STSG.

In step 1, in order to create a packed forest for a bilingual sentence pair, we first segment the sentence pair into several shorter ones to reduce the huge generation space of tree structures. Then, according to *frontier node assumption*, we compress all the tree structures with the largest number of frontier nodes into a packed forest. We will detail the process of constructing packed forest in Section 3. After all packed forests are generated, we exploit an EM algorithm in step 2 to learn an STSG and then generate Viterbi tree structures for translation. The adopted EM algorithm will be elaborated in Section 4.

Obviously, the above process of inducing tree structures is unsupervised. The syntactic resources and linguistic parsers are not necessary. Hence, comparing with parse trees, the proposed unsupervised trees can be applied to build translation models for more language pairs. Furthermore, by maximizing the number of frontier nodes, the unsupervised trees are compatible with word alignment and thus could achieve a better rule coverage for translation.

Since the existing tree-based translation models are usually restricted by parse trees, using unsupervised trees would be a promising direction for these models. To our best knowledge, this paper is the first effort to introduce effective unsupervised tree structures for tree-based translation models. The most significant contribution of this paper lies in this point. In order to achieve this goal, a series of useful techniques are employed innovatively and meaningfully in the paper. Moreover, the experimental results show that our unsupervised trees significantly outperform the parse trees in the state-of-the-art string-to-tree translation system.

2 Related Work

Our work focuses on inducing effective unsupervised tree structures, and meanwhile, resolving the incompatibility problem between tree structures and word alignment for tree-based translation.

Several researchers have studied unsupervised tree structure induction for different objectives. Blunsom et al. (2008, 2009, 2010) utilized Bayesian methods to learn synchronous context free grammar (SCFG) from a parallel corpus. The obtained SCFG grammar is further used in a phrase-based and hierarchical phrase-based system (Chiang, 2007). Denero and Uszkoreit (2011) adopted a parallel parsing model to induce unlabeled tree structures for syntactic pre-reordering. Different from above works, we concentrate on producing effective and labeled unsupervised trees for tree-based translation models. Moreover, since most of the current tree-based translation models are based on synchronous tree substitution grammar (STSG), our unsupervised trees are thus learned according to STSG, rather than SCFG.

On relieving the incompatibility problem between tree structures and word alignment for translation, previous works mainly focus on two directions:

One direction is to adapt the parse tree structure. Wang et al., (2007) binarized the parse trees and adopted an EM algorithm to select the best binary tree from their parallel binarization forest. Mi et al., (2008b) and Liu et al., (2009) compressed thousands of parse trees into packed forests. Zhang et al. (2011a) applied a CKY binarization method on parse trees to get binary forests for forest-to-string model. Burkett and Klein (2012) adopted a transformation-based method to learn a sequence of monolingual tree transformations for translation. They differ from our work in that

they were all based on parse trees. Compared with them, we construct effective unsupervised tree structures according to the word alignment and do not need any syntactic resource.

The other direction is to integrate the alignment information into parsing. Burkett and Klein (2008) and Burkett et al. (2010) made efforts to do joint parsing and alignment. They utilized the bilingual Treebank to train a joint model and achieved better results on both parsing and word alignment. Liu et al. (2012) re-trained the linguistic parsers bilingually based on word alignment. Our work is different from theirs in that we are pursuing better unsupervised tree structures for better translation performance.

As a whole, compared with previous works, our unsupervised trees are generated fully depending on word alignment. Therefore, by using our tree structures, the incompatibility problem between tree structures and word alignment can be well resolved.

3 Packed Forest Generation

In this section, we introduce how to compress all the reasonable tree structures into a packed forest for the given flat sentence. Packed forest is a compact representation of many tree structures. Generally, it is a pair $<V, E>$ where V is the set of *forest nodes* and E is the set of *hyperedges*. Each hyperedge $e \in E$ is a pair $< h(e), t(e) >$ where *h(e)* is its head node and *t(e)* denotes the vector of its tail nodes. FIGURE 2 illustrates a packed forest that encodes two different tree structures.

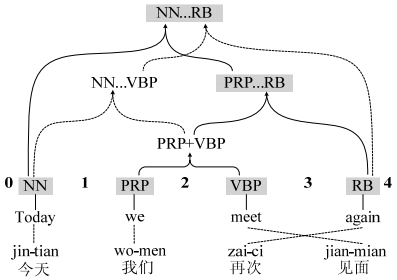

FIGURE 2 – An example of packed forest that encodes two different tree structures. In the FIGURE, shaded nodes denote frontier nodes

3.1 Space Reduction

Basically, there are an exponential number of possible tree structures for a given sentence. These tree structures result in a very huge packed forest. For example, considering a sentence of length L, there will be $0.5L(L+1)$ non-leaf nodes in the forest (each span corresponds to one node). In addition, a forest node covering ***m (m>=2)*** words emits ***m***-1 binary hyperedges[2], leading to $O(L^3)$ hyperedges in total[3]. Consequently, there would be an exponential number of parameters

[2] In our forest, the binary structure serves as the basic unit, which will be demonstrated later.

[3] There are a total of $L + \sum_{i=2}^{L}(L-i+1)\times(i-1) = \frac{1}{6}(L^3+5L)$ edges, including the edges linking to the leaf nodes.

for the STSG achieved from the forests. Such many parameters would cause a difficult estimation problem, especially for the EM algorithm adopted in this paper. Therefore, to reduce the huge generation space of tree structures, we first segment the bilingual sentence pair into several shorter ones and then impose *frontier node assumption* to construct the packed forest.

3.1.1 Bilingual Sentence Segmentation

Bilingual sentence segmentation is to segment a sentence pair into several short sub-sentence pairs whose source sub-sentence and target sub-sentence are translations to each other. Theoretically, in a sub-sentence pair, all included words cannot align to words outside it. However, since many words are wrongly aligned via the automatic word alignment, numerous correct aligned sub-sentence pairs are often excluded under this restriction. Therefore, to relax the restriction, we adopt the following constrains after analyzing the erroneous alignments[4]: (a) the bidirectional length ratios of a sub-sentence pair must be all smaller than 1:3; (b) as a sub-sentence pair, it must contain more than 4 words on each side; (c) in a sub-sentence pair, more than 30% words on each side must be aligned to its counterparts; (d) considering all the alignment links emitted by a sub-sentence, the erroneous ones (align to words outside the sub-sentence pair) account for at most 30% of all links.

To guarantee the segmentation accuracy, we only extract split point candidates based on the punctuations[5] which always denote the boundary of sub-sentences. Complying with the above constraints, we traverse all the split point candidates to search for the optimal split point with minimum number of wrongly aligned words (i.e., minimizing the number of words that align to words outside the sub-sentence pair). Then we segment the sentence pair into two shorter ones at that split point. We recursively segment the newly acquired sub-sentence pairs until no split point candidate is left. FIGURE 3(a) shows the segmentation result of an example sentence pair.

After bilingual sentence segmentation, only the spans inside the sub-sentence pairs are used in the forest. Under this condition, a large amount of useless spans are discarded and the forest is effectively simplified. For example, in FIGURE 3(b), the span “meet again, but” in the English sentence is discarded because it does not belong to any sub-sentence pair.

Note that the method of bilingual sentence segmentation we use here is only a simple segmentation strategy. It can also be substituted by any other segmentation methods. Additionally, after sentence segmentation, we realign words based on the sub-sentence pairs to get a new alignment where all words in a sub-sentence pair align to the words inside it.

3.1.2 Frontier Node Assumption

Bilingual sentence segmentation leads to a great space reduction for constructing packed forests. However, even after sentence segmentation, the generation space of tree structures would be still very large, especially when the sub-sentence is very long. In order to further simplify the space, we take advantage of the following assumption during forest construction:

Frontier Node Assumption*: The more frontier nodes the tree structure has, the more reasonable it is for translation.*

[4] The heuristic values in the constraints are chosen by a series of survey and experiments on a well-aligned corpus.
[5] We use {。 ， ： ； ？ ！} and {. , : ; ? !} as split anchors for Chinese and English, respectively. We take the position before and after the punctuations as split point candidates.

Frontier nodes are utilized to factor a tree structure into several fragments for rule extraction (Galley et al., 2004). Formally, a frontier node is a node that meets the following constraint: the span of the node and its dominated span at the other side are consistent with word alignment[6]. For example, in FIGURE 2, node *PRP…RB*'s span is {we meet again} and it dominates span {*我们 再次 见面*} at the other side. These two spans are consistent with word alignment. Therefore, node *PRP…RB* is a frontier node.

Our *frontier node assumption* makes sense in tree-based translation model. This is because with the purpose of achieving better rule coverage, we tend to extract small minimal rules as many as possible and generate larger rules by composing them. Maximizing the number of frontier nodes supports this goal, while producing many interior (non-frontier) nodes hinders it (DeNero and Klein, 2007). Hence, in the forest constructor, we follow this assumption and only consider the tree structures with the largest number of frontier nodes.

Denero and Uszkoreit (2011) utilized a similar heuristic to construct their unlabeled trees. They required that all spans in their trees must align continuously to the other side. Unlike their heuristic, our *frontier node assumption* only maximizes the number of frontier nodes. The interior nodes are also permitted in the tree structure, which is more flexible and appropriate for constructing forests.

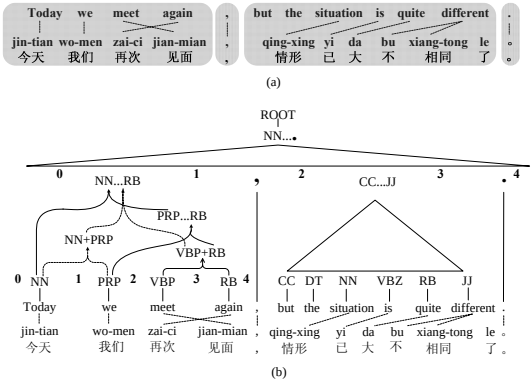

FIGURE 3 – (a) An example of bilingual sentence segmentation. (b) The ultimate packed forest of the example sentence pair in (a).

3.2 Node Labeling

To create packed forests for sentences, a problem that must be resolved is how to label the forest nodes without any syntactic knowledge. Xiong et al. (2006) showed that the boundary word of a phrase is a very effective indicator for phrase reordering. Zollmann and Vogel (2011) labeled hierarchical rules with word classes of boundary words and achieved better translation

[6] A node's dominated span at the other side refers to the minimum continuous span covering all the words that are reachable from the node via word alignment. Two spans are consistent with word alignment means that words in one span only align to words in the other span via word alignment, and vice versa.

performance. Inspired by their work, we combine word classes of boundary words to label forest nodes. We divide the non-leaf forest nodes into three groups: one-word node, dominating only one word in the sentence, and accordingly, two-word node, and multi-word node. Naturally, a one-word node is labeled by the class of its dominating word; a two-word node is labeled by combining the classes of the two words, such as "*C*1+*C*2"; a multi-word node, whose leftmost word's class is *C*1 and rightmost word's class is *C*n, is labeled with "*C*1…*C*n". In this paper, POS tags are employed to serve as the word classes[7]. For example, in FIGURE 3(b), the forest node covering phrase "we meet again" is a multi-word node and is labeled with "*PRP…RB*". Our labeling strategy is similar to (Zollmann and Vogel 2011). The difference is that we are labeling our forest nodes, while they labeled hierarchical rules to substitute the original single non-terminal *X*.

3.3 Forest Constructor

In tree-based translation models, the binary structure has shown its efficiency on improving translation quality (Wang et al., 2007; Zhang et al., 2011a). Inspired by this, we take the binary structure as the basic unit of our forest.

After sentence segmentation, we first build a forest for each sub-sentence pair. Initially, we create a POS node for each word and then perform a CKY-style algorithm to construct forests. FIGURE 4 illustrates the main process of building forest for a sub-sentence pair in FIGURE 3(a). From FIGURE 4 we can see that, the algorithm continuously inspects each span[8] in a bottom-up manner and creates forest nodes to represent the spans.

During the above process, we check every split point in each span and generate an edge[9] for that split point. To comply with the frontier node assumption, we only preserve the edges maximizing $F[i, j]$:

$$F[i, j] = \arg\max_k \{F[i,k] + F[k, j] + Fron[i, j]\} \quad (1)$$

where $F[i, j]$ denotes the number of frontier nodes in the sub-tree whose root node is span $[i, j]$. $k \in (i, j)$ refers to the split point of span $[i, j]$. $Fron[i, j]$ is an indicator function whose value is 1 if the node for span $[i, j]$ is a frontier node and 0 otherwise. Obviously, Equation (1) guarantees that the sub-tree rooted at span $[i, j]$ carries the largest number of fronter nodes. Consequently, in a bottom-up manner, when we arrive at the node covering the whole sentence, we can achieve all the tree structures with the larget number of frontier nodes.

For example, in FIGURE 4(c), span [0,3] (length L=3) has two split points and thus can be composed of span [0,1] and span [1,3], or span [0,2] and span [2,3]. However, just as FIGURE 4(c) shows, there are only 3 frontier nodes in the former case ($F[0,1] + F[1,3] + Fron[0,3] = 3$, here $Fron[0,3] = 0$ because node *NN…VBP[0,3]* is not a frontier node), while there are 4 frontier

[7] Practically, we need a supervised POS tagger, which impairs the unsupervised property of our tree structure to some extent. Actually, the POS tags can be substituted by any unsupervised word classes here. In future, we also plan to design an efficient algorithm to learn the node label automatically, rather than using a heuristic like here.

[8] Here the "span" is based on the POS nodes. For example in FIGURE 4, span 0-2 refers to the span of node sequence "NN PRP".

[9] As each split point corresponds to two adjacent smaller spans, we generate an edge to link these two spans. Therefore, each edge we create here contains a head node and only two tail nodes.

nodes in the latter one ($F[0,2]+F[2,3]+Fron[0,3]=4$). Therefore, we only preserve the edge maximizing $F[0,3]$ for node *NN…VBP[0,3]*, i.e., the edge composed of span [0,2] and span [2,3].

In most cases, a forest node could emit more than one edge with the same largest number of frontier nodes. For example, in FIGURE 4(d), node *NN…RB [0,4]* (length *L*=4) emits two edges with 7 frontier nodes. One links node *NN[0,1]* and *PRP…RB[1,4]*. The other one connects node *NN+PRP[0,2]* and *VPB+RB[2,4]*. We preserve both of these two edges for node *NN…RB [0,4]*. Finally, we achieve the packed forest for the example sub-sentence pair in FIGURE 4(d). In addition, during the forest construction process, the lower nodes and edges not chosen to create upper level nodes will be discarded, such as node *NN…VBP[0,3]* in FIGURE 4(d).

After we create a forest for each sub-sentence pair (named as sub-forest), we combine these sub-forests together to generate a final binary forest for the whole sentence pair. The combination is also performed by a similar CKY-style algorithm. The only difference is that the span in this CKY algorithm is based on the root node of sub-forests. Then we add a goal root node labeled "*ROOT*" to the forest which will be used in the EM algorithm. As an example, FIGURE 3(b) illustrates the final packed forest of the example sentence pair in FIGURE 3(a).

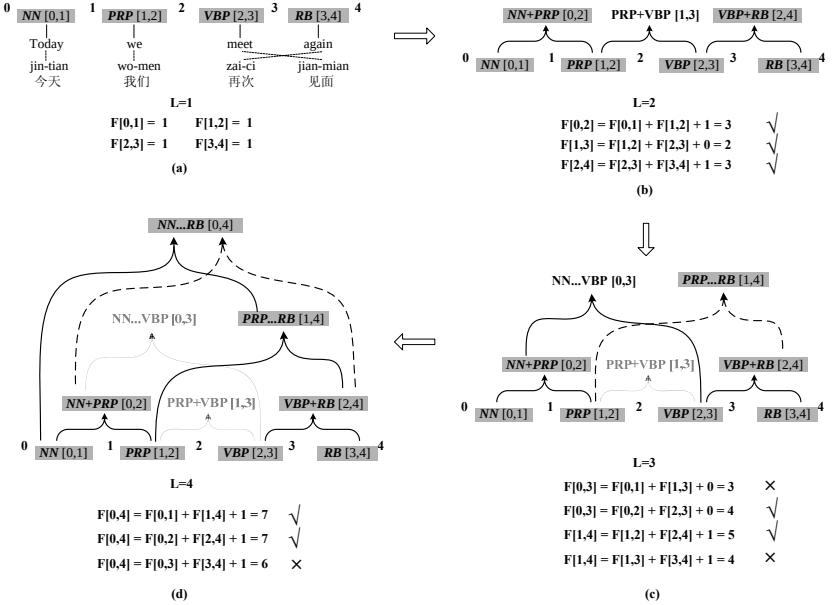

FIGURE 4 – The main process of building forest with the CKY-style algorithm. Here, shaded nodes denote frontier nodes. *L* refers to the length of span. F[i,j] denotes the number of frontier nodes in the sub-tree whose root node is span [i,j]. For example, the sub-tree that roots at span [1,4] in (c) contains 5 frontier nodes. This is because F[1,2] = 1 for node *PRP[1,2]*, and F[2,4] = 3 for node *VBP+RB[2,4]*, and node *PRP…RB [1,4]* is also a frontier node.

4 Learning Viterbi Tree via EM Algorithm

In this section, we design an EM algorithm to learn an effective synchronous tree substitution grammar (STSG) and then acquire Viterbi tree structures based on the STSG. Denero and Uszkoreit (2011) mentioned that their unlabeled tree structures can also be obtained by a similar method. However, their method is based on SCFG. Our work is different from theirs in that the EM algorithm is based on STSG. We use STSG here because most of the current tree-based translation models are based on STSG.

Given a parallel corpus with *n* sentence pairs, and the corresponding packed forest for each target sentence ***e***, we aim to search for a series of trees $(t_{e1}, t_{e2}, ..., t_{en})^*$ that maximize the likelihood of the whole corpus (t_e, f, a) [10], which is formulated as follows:

$$(t_{e1}, t_{e2}, ..., t_{en})^* = \arg\max_{(t_{e1}, t_{e2}, ..., t_{en})} \prod_{i=1}^{n} p(t_{ei}, f_i, a_i)$$

The probability of triple (t_{ei}, f_i, a_i) is further computed by aggregating the rule probabilities $p(r)$ in each derivation *d* in the set of all derivations *D*. That is

$$p(t_{ei}, f_i, a_i) = \sum_{D} \prod_{r \in d} p(r)$$

To get the derivation set *D*, we employ the algorithm of Mi et al., (2008a) to transform our induced packed forests into synchronous derivation forests. Practically, in order to reduce the complexity of the derivation forest, we only utilize the minimal STSG translation rules extracted by the method of Galley et al., (2004) and Mi et al., (2008b) to construct derivation forests[11].

Using the synchronous derivation forests, the rule probabilities are estimated by the inside-outside algorithm (Graehl and Knight, 2004). Here, leaf(***r***) and root(***r***) denote the leaf non-terminals and root node of rule ***r*** respectively. The inside and outside probabilities of forest node ***N*** are defined as follows,

$$p_{IN}(N) = \sum_{r \in R(N)} \left[p(r) \cdot \prod_{N_l \in leaf(r)} p_{IN}(N_l) \right]$$

$$p_{OUT}(N) = \sum_{r:\, N \in leaf(r)} \left[p(r) \cdot p_{OUT}(root(r)) \cdot \prod_{N_l \in leaf(r) - \{N\}} p_{IN}(N_l) \right]$$

where ***R(N)*** denotes the set of matched rules rooted at node ***N***. Therefore, the process of EM algorithm is shown as follows:

[10] In the triple, *te* refers to the target tree structures, *f* denotes the source language sentences, and *a* is the word alignment between them.

[11] We follow the highest attachment strategy in (Galley et al., 2006) to deal with unaligned words.

E-step: the expected count for each occurrence of rule ***r*** in a derivation forest is computed as:

$$p(r) \bullet p_{OUT}(root(r)) \bullet \prod_{N_l \in leaf(r)} p_{IN}(N_l)$$

M-step: the expected counts of rules, *c(r)*, are used to update the probabilities of rules:

$$p(r) = \frac{c(r)}{\sum_{r_a : root(r_a) = root(r)} c(r_a)}$$

After the EM algorithm, we traverse the derivation forest to obtain the Viterbi derivation d^* and its corresponding best tree structure. Then the acquired tree structures can be applied to any traditional tree-based translation system.

5 Experiments

5.1 Experimental Setup

In order to verify the effectiveness of our unsupervised tree structures, we compare them with linguistic parse trees based on string-to-tree translation. Here we experiment on Chinese-to-English translation, for which English parse trees can be easily obtained. Our training data is the FBIS corpus containing about 7.1 million Chinese words and 9.2 million English words. We generate the final symmetric word alignment using GIZA++ and the *grow-diag-final-and* balance strategy. We train a 5-gram language model on the target part of the training corpus and the Xinhua portion of English Gigaword corpus. We use the NIST MT 2003 evaluation data as the development set, and adopt NIST MT04 and MT05 as the test set. The final translation quality is evaluated in terms of case-insensitive BLEU-4 with shortest length penalty. The statistical significance test is performed using the re-sampling approach (Koehn, 2004).

Our baseline system is an in-house string-to-tree system (named ***s2t***) based on Galley et al. (2006) and Marcu et al. (2006). The English side of the training corpus is parsed with Berkeley parser (Petrov et al., 2006). We extract the minimal GHKM rules (Galley et al., 2004) and the rules of SPMT Model 1 (Marcu et al., 2006) with phrases up to length $L=5$ on the source side. Then we extract the composed rules by composing two or three adjacent minimal GHKM rules (Galley et al., 2006). The beam size of the decoder is set as 500. We further implement head binarization on the English parse trees and apply the achieved binary trees to another string-to-tree system (abbreviated as ***s2t-hb***) with the same settings of ***s2t***. In addition, we also run the state-of-the-art hierarchical phrase-based system Joshua (Li et al., 2009) for comparison.

For inducing our unsupervised tree structures, we use Urheen[12] to get the POS tags of the English corpus. Just as we described in section 3.1.1, we reuse GIZA++ and the *grow-diag-final-and* strategy to re-align words based on the sub-sentence pairs and then combine the alignment result together to get a new word alignment for the whole sentence pair. We perform the EM algorithm to capture the final tree structures by 20 iterations. Then we build a string-to-tree system using our induced unsupervised tree structures (abbreviated as ***s2t-IT***). Different from the above

[12] http://www.openpr.org.cn/index.php/NLP-Toolkit-for-Natural-Language-Processing/

baseline system, the beam size of our ***s2t-IT*** system is set as 300 to get a comparable translation speed to the baseline system.

Besides, using the new alignment, we also run the ***s2t*** and ***s2t-hb*** system with the same settings as the abovementioned ***s2t*** and ***s2t-hb*** systems (We mark the systems using the new word alignment as ***re-align*** systems).

5.2 Experimental Results

The translation results of different systems are shown in TABLE 1. As we can see, the performance of the baseline string-to-tree system significantly outperforms the hierarchical phrase-based system *Joshua*, which verifies the superiority of our baseline *s2t* system.

System		MT04	MT05	All
Joshua		30.71	27.86	29.59
s2t (baseline)		33.73*	30.25*	32.75*
s2t-hb		34.09	30.99*	32.92
re-align	***s2t***	33.53	29.30	32.29
	s2t-hb	33.88	30.49*	32.61
	s2t-IT	**34.71#**	**31.55#**	**33.53#**
Number of sentences		1788	1082	2870

TABLE 1 – Results (in case-insensitive BLEU-4 scores) of different systems. The "*" and "#" denote that the result are significantly better than the adjacent above system and all the other systems respectively ($p<0.01$).

TABLE 1 also demonstrates the effectiveness of binary structures. It can be clearly seen that whether we do re-alignment or not, the head binarization approach can always help to improve the *s2t* system (lines 2-5). Besides, as we can see from TABLE 1, the performances of the *re-align s2t* and *s2t-hb* system are slightly worse than the *s2t* and *s2t-hb* system. It indicates that the sentence segmentation method might be harmful to the traditional translation system. We will explore the reason in the next section.

The system using our induced unsupervised trees (*s2t-IT*) achieves the best performance among all the systems. It significantly outperforms the baseline *s2t* system by 0.98 and 1.3 BLEU points on MT04 and MT05 respectively. Furthermore, as shown in TABLE 1, even using the head binarization approach, the performance of the best *s2t-hb* system is still lower than that of our *s2t-IT* system by 0.61 BLEU points on the combined test set. Obviously, the above comparisons strongly demonstrate that our induced unsupervised trees are much more appropriate than parse trees for the string-to-tree translation model.

5.3 Analysis and Discussion

The improvement of translation performance has strongly verified the effectiveness of our induced unsupervised tree structures. We further conduct a series of deep analysis on the result.

We first adopt FIGURE 5, which depicts an example of our unsupervised tree structure and a traditional parse tree structure, to explain the superiority of our unsupervised trees. Comparing these two structures, we can see that our unsupervised tree structure carries more frontier nodes and thus can be factored into more small sub-structures. Consequently, the resulted minimal rules tend to be more general and smaller. For example, in FIGURE 5, rule (c) and (d) are the minimal

rules extracted from the unsupervised tree structure and the parse tree structure respectively to translate Chinese phrase "*有利于* (you-li-yu)". Obviously, rule (c) is much smaller and can be utilized without any limit while rule (d) cannot, since rule (d) requires that the translation after "*is conducive to*" must be dominated by an "***S***" node. Additionally, we can further acquire many big rules by composing several small minimal rules. On the above basis, our induced unsupervised trees are much more conducive to extracting both general enough rules and specific enough rules, which leads to a better rule coverage and translation quality.

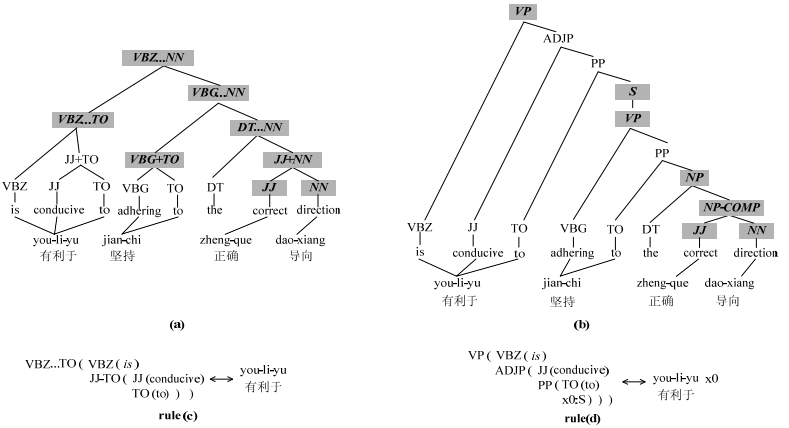

FIGURE 5 – Different tree structures and extracted example rules: (a) the unsupervised tree structures (b) the binary tree structures produced by berkeley parser (The node "NP-COMP" is created by the head binarization approach). The shaded nodes in the FIGURE denote frontier nodes. (c) and (d) are the minimal rules extracted from the structures in (a) and (b) respectively.

To further demonstrate the above analysis, TABLE 2 shows the average number of frontier nodes per tree structure (#Aver-Frontier-Nodes) and the grammar size (#RULES) of different systems. As we can see, the string-to-tree systems using parse trees benefit from the head binarization approach which helps to recall frontier nodes (from 33.9 to 40.4 for *s2t* system and 32.0 to 38.6 for the re-aligned *s2t* system).

System		#Aver-Frontier-Nodes	#RULES
s2t (baseline)		33.9	15.5M
s2t-hb		40.4	28.1M
re-align	***s2t***	32.0	13.8M
	s2t-hb	38.6	26.2M
	s2t-IT	**47.4**	**51.9M**

TABLE 2 – Average number of frontier nodes and grammar size for different string-to-tree systems.

Furthermore, using our induced unsupervised trees, it accounts for 47.4 frontier nodes on average while there are only 33.9 frontier nodes at most in the traditional linguistic parse trees. Obviously,

this comparison indicates that our unsupervised trees are more compatible with the word alignment and are beneficial to extracting more useful translation rules. Just as column "#RULES" shows, our *s2t-IT* system obtains a total of 51.9M rules while the baseline *s2t* system only gets 15.5M rules at most.

We have found that the sentence segmentation method might do harm to the traditional translation system in TABLE 1. TABLE 2 gives a faithful explanation on this phenomenon. As indicated by TABLE 2, after we do re-alignment, the number of frontier nodes decreases (from 33.9 to 32.0 for *s2t*) and the grammar size is reduced at the same time. We believe that the reduced grammar leads to the worse performance of the *re-align s2t* and *s2t-hb* system. Intuitively, the deterioration caused by sentence segmentation would also affect our *s2t-IT* system. However, our *s2t-IT* system still significantly outperforms the baseline *s2t* system. More work would be devoted to alleviate the influence of sentence segmentation.

We further investigate the used tags of tree nodes in our unsupervised trees. According to the statistics, there are a total of 2,862 tags for the non-leaf nodes in the final corpus of our unsupervised trees. With such many tags, a natural question is that does the grammar extracted from these tree structures suffer from a data sparseness problem? TABLE 3 answers this question in detail. In the TABLE, for example, line 2 denotes that the most frequent 143 tags (5% of all tags) account for 76.5% of all frontier nodes and 82.4% of all tree nodes. As illustrated in TABLE 3, 87.0% frontier nodes and 90.3% tree nodes are labeled with the most frequent 286 tags (10% of all tags), indicating that the vast majority of our translation rules are composed of these tags. Compared with the 70 tags[13] used in the linguistic parse trees, we believe our employed tags are both specific enough for distinguishing different rules and general enough for avoiding the data sparseness problem.

#tag num	#percentage of frontier nodes	#percentage of tree nodes
85(3%)	68.0%	75.8%
143(5%)	76.5%	82.4%
228(8%)	83.6%	87.7%
286(10%)	**87.0%**	**90.3%**
429(15%)	92.3%	94.2%
572(20%)	95.2%	96.4%
…	…	…

TABLE 3 – The proportion of frequently appearing tags in our induced tree structures.

Conclusion and Perspectives

In this paper, we propose effective unsupervised trees to substitute parse trees for tree-based translation models. Since current tree-based translation models are all driven by parse trees, this work creates a brand-new direction for them. We first roughly group the words into several sub-sentence pairs by a bilingual sentence segmentation method. After that, we compress all the reasonable tree structures of sentence pairs into packed forests under *frontier node assumption*. Finally, we design an EM algorithm to learn an effective STSG and then select a best tree structure for each sentence pair.

The unsupervised tree structures are constructed depending on the word alignment. Therefore, they are naturally compatible with word alignment and lead to a better rule coverage.

[13] There are 44 POS tags, 5 clausal tags and 21 phrasal tags for labeling the linguistic parse trees.

Experiments on string-to-tree translation system show that our unsupervised trees significantly outperform the parse trees. We believe that our method is quite beneficial for the translation between resource-poor languages.

In the future, we plan to conduct more experiments on other tree-based models, such as tree-to-string model and tree-to-tree model. Furthermore, we also plan to develop unsupervised methods to jointly induce the tree structure and word alignment for tree-based translation models. This issue is more difficult since the search space is much larger and we plan to employ Bayesian methods with sampling approach to fulfil this task.

ABSTRACT
Abbreviation is a common linguistic phenomenon with wide popularity and high rate of growth. Correctly linking full forms to their abbreviations will be helpful in many applications. For example, it can improve the recall of information retrieval systems. An intuition to solve this is to build an abbreviation dictionary in advance. This paper investigates an automatic abbreviation generation method, which uses a stacked approach for Chinese abbreviation generation. We tackle this problem in two stages. First we use a sequence labeling method to generate a list of candidate abbreviations. Then, we try to use search engine to incorporate web data to re-rank the candidates, and finally get the best candidate. We use a Chinese abbreviation corpus which contains 8015 abbreviation pairs to evaluate the performance. Experiments revealed that our method gave better performance than the baseline methods.

1 INTRODUCTION

Abbreviation is defined as a short description of the original long phrase. For example, "ACL" is the abbreviation for the full form "Association for Computational Linguistics". While abbreviation is a common linguistic phenomenon, it causes many problems like spelling variation (Nenadić et al., 2002).The different writing manners make it difficult to identify the terms conveying the same concept, which will hurt the performance of many applications, such as information retrieval (IR) systems.

In IR applications, one simple solution is to expand the original query by adding corresponding abbreviations to a search engine. For example, when using a search engine with an original query of "United States of America", a user will get more relevant results by expanding the query to include the abbreviation "USA." To achieve this we need to have an abbreviation dictionary, which is laborious to manually maintain because the number of abbreviations increases rapidly (Chang and Schutze, 2006). Therefore, it is helpful to automatically generate abbreviation from full forms. This leads to the idea of "abbreviation generation", i.e., finding the correct abbreviation for a full form.

The generation of abbreviations in Chinese differs from that for English. The reason is that Chinese itself lacks many commonly considered features in English abbreviation generation methods (Pakhomov, 2002; Yu et al., 2006; HaCohen-Kerner et al., 2008; Ao and Takagi, 2005). Detailed differences between English abbreviation generation and Chinese abbreviation features are listed in TABLE 1. Due to these differences, specific attention should be paid to Chinese abbreviation generation.

Feature	English	Chinese
Word boundary	YES	NO
Case sensitivity	YES	NO

Table 1: Comparison between Chinese and English abbreviation generation with regards to features.

Most of Chinese abbreviations are generated by selecting representative characters from the full forms[1]. For example, the abbreviation of "北京大学" (Peking University) is "北大" which is generated by selecting the first and third characters, see TABLE 2. This can be tackled from the sequence labeling point of view.

Original	北	京	大	学
Keep/Skip	Keep	Skip	Keep	Skip
Result	北		大	

Table 2: The abbreviation "北大" of "北京大学" (Peking University)

Meanwhile, full forms and abbreviations show linguistic links like co-occurrence in large text materials. If we can find candidate abbreviations and rank them properly, the performance of abbreviation generation can be improved. Web pages can just serve as a large corpus to provide this information. While it is impractical to retrieve and analyze each web page individually, search engine provides an interface to this vast information. When querying a term in a search

[1]A small portion of Chinese abbreviations are not generated from the full form. For example, the abbreviation of "河北省"(He Bei Province) is "冀". However, we can use a look-up table to get this kind of abbreviations.

engine, titles and snippets of pages containing the query terms are returned, which provides a natural corpus for further analysis.

In this paper, we propose a stacked approach to automatically generate Chinese abbreviations. This method consists of a candidate generation phase and a ranking phase. First, we generate a list of candidates for the given full form using sequence labeling method. Then a supervised re-ranking method based on Support Vector Machine (SVM) using web data is applied to find the exact abbreviation.

We evaluate on a Chinese abbreviation corpus and compare it with previous methods. A pure sequence labeling approach by (Sun et al., 2009) and a state-of-art method to incorporate web data by (Jain et al., 2007) are chosen as baseline methods.

The contribution of this paper is that we integrate sequence labeling and web data to create a robust and automatic abbreviation generator. Experiments show that this combination gets better result than existing methods. Using this method we build a Chinese abbreviation dictionary, which later can be used in other NLP applications to help improve performance.

The paper is structured as follows. We first describe our approach. In section 2 we describe the sequence labeling procedure and in section 3 the re-ranking procedure. Experiments are described in section 4. In section 5 we give a detailed analysis of the results. In section 6 related works are introduced, and the paper is concluded in the last section.

2 Candidate Generation

2.1 Sequence Labeling

As mentioned in section 1, the generation of Chinese abbreviations can be formalized as a task of selecting characters from the full form, which can be solved by sequence labeling models. Previous works proved that Conditional Random Fields (CRFs) can outperform other sequence labeling models like MEMMs in abbreviation generation tasks (Sun et al., 2009; Tsuruoka et al., 2005). For this reason we choose CRFs model in the candidate generation stage.

A CRFs model is a type of discriminative probabilistic model most often used for the labeling or parsing of sequential data. Detailed definition of CRF model can be found in (Lafferty et al., 2001; McCallum, 2002; Pinto et al., 2003).

2.2 Labeling strategy

Considering both training efficiency and modeling ability, we use a labeling method which uses four tags, "BIEP". "B" stands for "Beginning character of skipped characters", "I" stands for "Internal character of skipped characters,"E" stands for "End character of skipped characters", and Label "P" means the current character to be preserved in abbreviation. An example is shown in TABLE 3.

2.3 Feature templates

The feature templates we use are as follows. See TABLE 4.

Templates 1 and 2 express uni-grams and bi-grams, which is widely used in abbreviation generation tasks. Template 3 is used to encode the ability of numbers in the generation of Chinese abbreviations. Templates 4 and 5 are designed to detect character duplication, because duplicated characters are often kept only once.

"国家语言文字工作委员会" (National Linguistics Work Committee) The abbreviation is "国家语委" (the 1st, 2nd, 3rd, 9th characters of the full form)	
BIEP	国/P 家/P 语/P 言/B 文/I 字/I 工/I 作/E 委/P 员/B 会/E

Table 3: The abbreviation "国家语委" of " 国家语言文字工作会" (National Linguistics Work Committee)

1. Uni-gram X_i
2. Bigrams (X_i, X_{i+1})
3. Whether X_i is a number
4. Whether character i equals character $i+1$
5. Whether character i equals character $i+2$

Table 4: Feature templates used in our algorithm.

3 Re-ranking

3.1 Re-rank with web data

Many abbreviations simply generated by the CRF model do not actually match the reference abbreviation. The reason is that as a sequence labeling model, CRF gives a most probable abbreviation character sequence by analyzing local information for each character. However, for Chinese abbreviations, local information alone is not adequate.

The full form and its abbreviation naturally co-occur in a large text corpus. This information contributes to the retrieval of an abbreviation given its full form. However, we cannot incorporate this information directly in traditional statistical learning models, because to get this information we first need a list of candidate abbreviations of the full form, which should be obtained in advance. We also observe that although the top-ranked output of the CRF model is not always correct, the true abbreviation very often appears in the top few outputs of the CRF. Therefore we choose to use the output of CRF model as the list of candidates. The remaining job is to find an effective method to re-rank the candidates using some additional information.

The additional information mentioned above can be obtained from search engines. Search engines index huge amount of web pages, providing an efficient interface to such vast information. The results returned by search engines typically contain the total number of related pages, title and snippet for each page. All the above text materials are useful for us to extract "implicit connections" between the full forms and abbreviations to re-rank the candidates generated in the previous phase.

An example of these "implicit connections" is shown in FIGURE 1. In this case we investigate on the search results of the full form "国家语言文字工作委员会" (National Linguistics Work Committee) and its abbreviation "国家语委". From FIGURE 1(a) we can find that the abbreviation "国家语委" appears in the title of the 3rd result when searching the full form. From FIGURE 1(b) we can also find that the full form "国家语言文字工作委员会" co-occurs with the abbreviation in the snippet of the 3rd result when searching the abbreviation. Furthermore, we see that the two queries share the same top-ranked result, which can be inferred from the same URL of the first search result. All of these evidences imply that "国家语委" seems to be the abbreviation for

"国家语言文字工作委员会". Note that the highlighted key words also indicate that the search

(a) Search result of the full form "国家语言文字工作委员会"

(b) Search result of the abbreviation "国家语委"

Figure 1: An example of search results. We can see clearly that the full form and the abbreviation do have implicit connections in search results.

engine itself does not know the correspondence of the two words. In FIGURE 1(a) we can see that in the result containing the abbreviation, the abbreviation itself is not highlighted as a keyword. Instead, it only matches the keyword "国家" (National). Therefore our method just learns to make use of the implicit connections, rather than exploits what the search engine has already learnt.

Besides search results, another appealing source of text corpus that we should mention is Chinese Wikipedia. Wikipedia seems to be more structured, however, we choose not to use Wikipedia in our context because many Chinese abbreviations like coordinate phrases are not collected in wiki-texts. Besides, new abbreviations spring out almost every day, while manually maintained Wikipedia is updated slowly. These shortcomings of Wikipedia make it less competitive than search engines.

For the re-ranking phase, we generate lists of candidates for the training data and label reference abbreviations as positive instances, and the incorrect candidates as negative instances. Then a SVM classifier is trained for its advantage in processing continuous values. The original SVM model itself does not calculate probability, while there are various ways to estimate the probability (Platt et al., 1999). What we use in our approach is the probability a candidate to be labeled as positive. We re-rank these candidates by these probabilities in decreasing order, and choose the first one as the final result.

3.2 Features for re-ranking

The results returned by search engines mainly contain the total number of related pages, title and snippet of each page. Search engines usually automatically highlight the key words in title and snippet by bolding (or red coloring) the keywords. We once considered using the highlighted keywords as counting criterion in our algorithm, but soon we found that this criterion has many deficiencies. Take "清华大学" (Tsinghua University) as an example, one of its false candidate is "清华大", which happens to be the first 3 characters of the full form. When

searching "清华大", many "清华大"s are highlighted, but they are all appears as part of the full form "清华大学". So it will be biased if we choose highlighting as our criterion. All things considered, we use the direct matching schema in our algorithm, instead of only considering the highlighted words given by search engines.

The following are the features we choose.

Factor 1: how often the full form appears in the title when searching for a candidate
We score this factor by taking the first 20 results of searching for the candidate abbreviation form, and counting the number of results for which the title contains the full form. The text containing the abbreviation usually also contains its full form. To avoid misjudge, if the candidate itself does not appear in the search results, its score will be set 0.

Factor 2: how often the candidate form appears in the title when searching for itself
We score this factor by searching for the candidate abbreviation, and counting the number of results whose the title contains the candidate. The popularity of the candidate form to some extent reflects how common it is in daily life. We find that misspellings may have impact on this factor. Therefore, we require the full form to appear in the title of all search results at least once, or the score will be set 0.

Factor 3: how often the full form appears in snippet when searching for a candidate
This factor considers the occurrence of the full form in search result snippets, which is similar to factor 1. The only difference here is that we consider snippets, instead of titles.

Factor 4: how often the candidate form appears in snippet when searching itself
Similar to factor 2, this factor considers the occurrence in search result snippets instead of titles, which serves as a validation for whether the candidate is a legal phrase.

Factor 5 and 6: how often the candidate appears in title and snippet when searching its full form
These factors are represented as factor 5 and 6, corresponding to title and snippet respectively. The two factors are complementary to factor 1 and 3, differing in whether one searches the candidate or the full form. These factors serve as verification for the candidate form in searching full form results, testing whether the candidate is a legal term.

Factor 7: comparing similarity between searching candidate and full form
We first use factor 7 to denote similarity between the titles of the first 20 results of searching a candidate and same amount of titles from searching its full form. For two titles, we say they are same only if they fully match with each other, which indeed is the case in search results.

Factor 8: search results count
This factor is scored by the total number of results returned by searching "full-form AND candidate". As far as we can see, more results when searching the full form and a candidate together indicate a stronger link between these two terms.

Factor 9: the co-occurrence of a candidate and its full form
This factor considers how often a candidate and its full form co-occur in results of searching "full-form candidate". The co-occurrence of the full form and a candidate will increase the probability for this candidate to be the true abbreviation.

Factor 10: matching forward syntactic patterns
We first define syntactic patterns such as "X简称Y" ("Y is short for X"). Then we score this factor by counting how many times the results of searching "full-form candidate" match these patterns.

The word "forward" means the full form appears ahead of the candidate.
Our pattern extraction algorithm is illustrated in TABLE 5. The GetSnippets function returns a list of snippets for the given joint query "full-form + candidate" for each pair (A, B) in S. For each snippet found by GetSnippets function, we replace the full form and the abbreviation with wildcards "X" and "Y". Then we use function GetNgrams to extract character n-grams for n = 2, 3, 4, 5, 6 and 7. The n-grams are guaranteed to contain exactly one X and one Y. We sort the n-grams by their frequency and select the top patterns. We then use these patterns to score candidates in the re-ranking phase. Some of the patterns we use are shown in TABLE 6

Algorithm 1 : ExtractPatterms()
• Initialize: Let S be a "Full form"-"Abbreviation" set. • Begin: • For each full-abbreviation $pairs(A,B) \in S$ Do $D \leftarrow GetSnippets(A,B)$ • For each snippet $d \in D$ Do $N \leftarrow N \cup GetNgrams(A,B,d)$ • $Patterns \leftarrow SortByFreq(N)$ • Return Patterns

Table 5: Algorithm for extract patterns.

• X（Y） • X（简称Y） • X(Y) • X（以下简称Y） • X简称Y，

Table 6: Forward patterns used.

Factor 11: matching backward syntactic patterns
The term "backward", in contrast to the previous "forward", means that the abbreviation appears in front of the full form. The algorithm to extract patterns is the same as factor 10. Some of the patterns we use are shown in TABLE 7.

• Y X • Y-X • Y（X） • Y和X是同义词 • Y是X的简称

Table 7: Backward patterns used.

4 Experiments

We use the abbreviation corpus provided by Institute of Computational Linguistics (ICL) of Peking University in out experiments. The corpus is homogeneous to the corpus used in (Sun et al., 2008, 2009). It contains 8,015 Chinese abbreviations. Various kinds of abbreviation pairs can be found in this corpus, including noun phrases, organization names and some other types. Some examples are presented in TABLE 8. The length distributions of full form and references are shown in FIGURE 2.

Type	Full form	Abbreviation
Noun Phrase	优秀稿件(Excellent articles)	优稿
Organization	作家协会(Writers' Association)	作协
Coordinate phrase	受伤死亡(Injuries and deaths)	伤亡
Proper noun	传播媒介(Media)	传媒

Table 8: Examples of the corpus (Noun Phrase, Organization, Coordinate Phrase, Proper Noun)

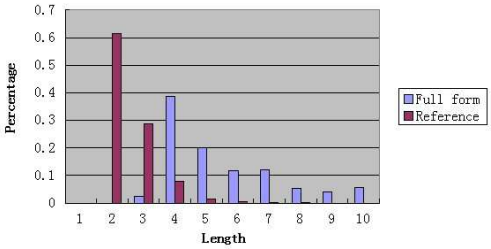

Figure 2: Length distribution of training set.

In some cases a long phrase may contain more than one abbreviation. For these cases, the corpus just keeps their most commonly used abbreviation one for each. Meanwhile to accurately get the results from the search engine that we need in our algorithm, we only keep the pairs with abbreviation containing more than 1 character, because the search results of a single Chinese character are usually ambiguous.

To improve the reliability of the experiment, we use 10 fold cross-validations. The evaluation metric used in our experiment is the top-k accuracy, which is also used by (Tsuruoka et al., 2005) and (Sun et al., 2009). The top-k accuracy measures what percentage of the reference abbreviations are found if we take the top N candidate abbreviations from all the results. In our experiment, top-10 candidates are considered in re-ranking phrase and the measurement used is top-1 accuracy because the final aim of the algorithm is to detect the exact abbreviation, rather than a list of candidates.

CRF++[2] and libsvm[3] , two open source tools, are used, with parameters are kept as default. The kernel function we use in our experiment is RBF kernel. All numeric values in SVM are scaled between 0 and 1. The generation of training examples for re-ranking considers the fact that a full form corresponds to a few candidate abbreviation forms, while only one of them is its reference. During the SVM process, we treat the reference as a positive instance, and treat the other false candidates as negative instances. Take the full form "北京大学" (Peking University) as an example. It corresponds to many candidate abbreviations like "北大", "京学". Only the reference "北大" is regarded as positive instance while the rest are negative. We then normalize the factors described in section 3 and use them together with the CRF score as features for each positive and negative instance in the re-ranking procedure.

The trained SVM classifier is then used in testing to give each candidate a label. For a given

[2]http://crfpp.sourceforge.net/
[3]http://www.csie.ntu.edu.tw/ cjlin/libsvm/

candidate, what we are interested in is not the label, but the probability it will be labeled as positive. In libsvm the probability is calculated based on the vertical distance to the hyper-plane[4] . We follow this schema. This probability is then used as the re-ranking standard and we select the top-ranked candidate as the final result.

For search engine, we use the search engine Baidu[5] in the re-ranking phase, which is the biggest Chinese search engine.

5 Results and Discussion

5.1 Comparison of re-ranking

TABLE 9 shows the top-10 accuracy of the candidate generation stage, which is the first stage of our method. We can see the top-10 candidates include the reference abbreviation for most full forms. The top 10 candidates already cover 92% of the reference abbreviations using BIEP labels. In theory if we can find web data to re-rank the candidates, as high as 92% accuracy can be achieved compared to the original 58% accuracy.

Top-K	1	2	3	5	10
Accuracy	0.5812	0.7293	0.7975	0.8652	0.9240

Table 9: Top-10 Accuracy of CRF-BIEP.

We then use search results to re-rank the top-10 candidates. After re-ranking we select the top-ranked candidate as the final abbreviation of each instance. TABLE 10 shows the results. We can see that the accuracy of our method is 64.25%, which improved by +6% compared to using sequence labeling models alone.

Method	Without re-rank	With re-rank
Top-1 accuracy	0.5812	0.6425

Table 10: Results of Chinese abbreviation generation after re-ranking.

We also compare our method with previous methods. The first two are $CRF + GI$ and $DPLVM + GI$ in (Sun et al., 2009). We compare our approach with another web-based method used in (Jain et al., 2007), which is slightly different from ours. The work in (Jain et al., 2007) focuses on extracting full-abbreviation pairs, rather than generating abbreviations from full forms. However, we think it is meaningful to compare because in both cases the web data is used only to extract the useful information lie between the full form and abbreviation, which is independent of the problem settings. This method is denoted as "$CRF + AEPW$" used point wise mutual information (PMI), popularity of the abbreviation and the pagerank of the URLs in search results as features and integrate these features by multiplying them all. We also compare with another approach denoted as "$CRF + MUL$" which also multiplies all the features described in section 3. We add this comparison to see whether the difference is made by the feature set, not the re-ranking model itself.

TABLE 11 shows the results of the comparisons.

[4]http://www.csie.ntu.edu.tw/ cjlin/libsvm/

[5]http://www.baidu.com

[6]DPLVM is a model that needs multiple random initializations to get closer to the global optimal point. So we did not apply cross-validation for DPLVM+GI.

Method	$CRF + AEPW$	$CRF + MUL$	$CRF + GI$	$DPLVM + GI$[6]	Our method
Top-1 Accuracy	0.5698	0.6039	0.5850	0.5990	0.6425

Table 11: Performance of different method.

While our method outperforms other methods, we surprisingly find that the CRF+AEPW slightly decreases performance compared to the pure CRF approach. The reason is that CRF+AEPW tries to extract information between well-formed full forms and also well-formed abbreviations. However, in the current Chinese abbreviation generation process, some ill-formed candidates may be generated, like include illegal terms and common phrases which are in fact substrings of the full form.

From CRF+MUL we can also find that simply multiplying the scores of each of the features does improve performance, however, the improvement is not as much as our approach. This indicates that our approach can better model the information extracted from search results than the simply treating the features equally. We measure what extent each feature contributes to the re-ranking process by adding one/two feature alone each time. For results see FIGURE3.

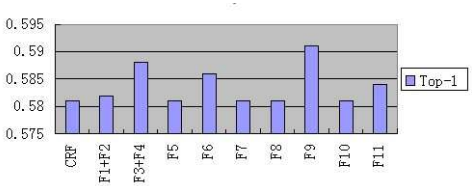

Figure 3: Contribution of each feature. The first column is the original sequence labeling score, which we use as a comparison.

FIGURE3 shows that feature 3+4, and 9 are the top contributing features. From feature 9 we can see that co-occurrence is indeed the most important factor. From feature 3 and 4 we can see that if the full form appears in the search results of a candidate, the candidate tends to be correct. This agrees to our intuition. If a candidate appears in the search results of the full form, it may happen to be a popular word as well as a substring of the full form. However, if the full form appears in the search results of a candidate, it means the full form does have strong link to the candidate.
We find that the re-ranking phase do play an important role in selecting the reference. Some reference abbreviations with low CRF scores can be reordered to the front after re-ranking. TABLE 12 shows the example of the organization name "阿拉伯国家联盟" (Arab League). The CRF score of its reference "阿盟" is low compared to other candidates, while after re-ranking, "阿盟" becomes the top-ranked candidate among all candidates.

TABLE 13, TABLE 14 and TABLE 15 show 3 more examples, which belong to different phrase types: noun phrase, coordinate phrase and proper noun. In all these cases, the references of the full form are picked out from the top 10 candidates. The results indicate that the re-ranking phrase can improve the performance of abbreviation generation.

Candidate	CRF Score	Re-rank Score

5.2 Performance considering length

Long terms contain more characters, which is much easier to make mistakes during the sequence labeling phase. FIGURE 4 shows the top-1 accuracy respect to the term length using BIEP labeling method. The x-axis represents the length of the full form. The y-axis represents top-1 accuracy. We find that the search result based re-ranking method works especially well than pure CRF approach when the full form is long. By re-ranking using web data, additional information is incorporated. Therefore many of these errors can be eliminated. Meanwhile, if the reference

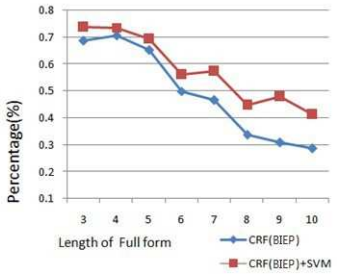

Figure 4: Accuracy grouped by length of full form.

itself is commonly used, the search results tend to contain more information of the relation between the candidate and the full form. With more information at hand, the re-ranking phase can make correct decisions with more confidence.

5.3 Error analysis

Though the accuracy is improved by +6% after we re-rank using search. There are still false candidates generated by the current method. We categorize the remaining errors as follows:

1. Candidates produced in the sequence labeling phase are only a portion of all possible combinations. Considering a full form with length 10, there are $2^{10} - 2 = 1022$ potential

candidates (the original term and empty string are omitted). Note that in our method we only take the top 10 candidates into consideration. If the references do not appear in the top 10 candidates, it is impossible for us to find the reference during the re-ranking phase. This kind of errors usually appears when the full form is very long. We find that this kind of error flourishes when the reference contains a Chinese word as its component. For example, "中央人民政府交通部" (Communication Department of the Central Government) is the full form for "中央交通部". The front "中央" (Central) and end "交通部" (Communication Department) are both Chinese words and appear continuously in the full form. Statistics show that this error makes up 13% of all errors.

2. Besides, character based candidate generation cannot use word level features, like word position. For example, if word "医院"(Hospital) is used in the middle of a full form, it is often abbreviated as "医", while in the end of a full form it will be abbreviated as "院". This is the shortcoming of al character based methods. However, we do not incorporate word information into our framework. As far as we investigate, previous works also seldom involve word information. The reason is that Chinese lacks natural word boundary, which cannot be segmented automatically with perfect accuracy. Current state-of-art Chinese word segmentation tools have at least 5% error rate, which can hurt consequent generation of abbreviations.
3. Search engines may provide biased information when handling location sensitive phrases. Take "香港民主同盟" (Democracy league of Hong Kong) as an example. Its correct abbreviation is "港同盟". Our method choose "民盟" as its abbreviation, which is the abbreviation of "中国民主同盟" (Democracy League of mainland China). Because the search engine we choose is Baidu.com, which is the most prevalent search engine in mainland China. Thus the number of search results related to "民盟" overwhelms that of "港同盟", with "民盟" 5200000 results compared with "港同盟" 13700 results. Besides when the web pages mentioning "民盟" (most of the pages are news pages), the "香港民主同盟" is always mentioned as well because there are homogeneous. Thus it is hard for the algorithm to exclude these interferences using localized search results. However, this kind of errors can be eliminated by using location-independent search engines.
4. Although some false candidates are not the standard reference, they are indeed used colloquially, only not as formally as the reference abbreviations. The reason for this phenomenon lies in the fact that the verification data we use is web search results. Web search results are sometimes colloquial, compared with official documents or other formal materials. Take "丁型病毒性肝炎"(Viral Hepatitis D) as an example, our method generates "丁肝", while the reference is "丁型肝炎". Both of these results are acceptable, while the reference is more formal.

Interestingly, we find that in this kind of errors, the "false" abbreviations are always shorter in length than the standard abbreviations, which is identical to the intuition that these abbreviations are more widely used orally.

6 Related work

Previous research on abbreviations mainly focuses on "abbreviation disambiguation", and machine learning approaches are commonly used (Park and Byrd, 2001; HaCohen-Kerner et al., 2008; Yu et al., 2006; Ao and Takagi, 2005). These ways of linking abbreviation pairs are effective, however, they cannot solve our problem directly because the full form is not always ambiguous. In many cases the full form is definite while we don’ t know the corresponding abbreviation.

To solve this problem, some approaches maintain a database of abbreviations and their corresponding "full form" pairs. The major problem of pure database-building approach is obvious. It is impossible to cover all abbreviations, and the building process is quit laborious. To find these pairs automatically, a powerful approach is to find the reference for a full form given the context, which is referred to as "abbreviation generation".

There is research on heuristic rules for generating abbreviations (Barrett and Grems, 1960; Bourne and Ford, 1961; Taghva and Gilbreth, 1999; Park and Byrd, 2001; Wren et al., 2002; HEARST, 2002). Most of them achieved high performance. However, hand-crafted rules are time consuming to create, and it is not easy to transfer the knowledge of rules from one language to another.

Recent studies of abbreviation generation have focused on the use of machine learning techniques. (Sun et al., 2008) proposed a supervised learning approach by using SVM model. (Tsuruoka et al., 2005; Sun et al., 2009) formalized the process of abbreviation generation as a sequence labeling problem. In (Tsuruoka et al., 2005) each character in the full form is associated with a binary value label y, which takes the value S (Skip) if the character is not in the abbreviation, and value P (Preserve) if the character is in the abbreviation. Then a MEMM model is used to model the generating process. (Sun et al., 2009) followed this schema but used DPLVM model to incorporate both local and global information, which yields better results.

While there are many statistical approaches, there are few approaches using Web as a corpus in machine learning approaches for generating abbreviations. Early examples like (Adar, 2004) proposed methods to detect such pairs from biomedical documents. Related work using web data includes (Liu et al., 2009; Jain et al., 2007). For example (Jain et al., 2007) used web search results as well as search logs to find and rank abbreviates full pairs, which show good result. But in fact search log data is only available in a search engine backend. In contrast, ordinary approach does not have access to search engine internals. Besides, they all use web data to expand the abbreviations to their full form, which is the opposite process of ours.

Conclusion and future work

To build an abbreviation dictionary, we used a stacked method to generate abbreviations from the full forms. We used sequence labeling method with BIEP labels to generate candidates for each full form, and used a SVM classifier which utilizes search results to re-rank the candidates to generate the final result.

The results are promising and outperformed the baseline methods. The accuracy can still be improved. Potential future works may include using semi-supervised methods to incorporate unlabeled data, or use more powerful methods to extract the characters of abbreviations in web data.

{mszhang, car, tliu, lzh}@ir.hit.edu.cn

ABSTRACT
Previous joint models of Chinese part-of-speech (POS) tagging and dependency parsing are extended from either graph- or transition-based dependency models. Our analysis shows that the two models have different error distributions. In addition, integration of graph- and transition-based dependency parsers by *stacked learning* (stacking) has achieved significant improvements. These motivate us to study the problem of stacking graph- and transition-based joint models. We conduct experiments on Chinese Penn Treebank 5.1 (CTB5.1). The results demonstrate that the guided transition-based joint model obtains better performance than the guided graph-based joint model. Further, we introduce a constituent-based joint model which derives the POS tag sequence and dependency tree from the output of PCFG parsers, and then integrate it into the guided transition-based joint model. Finally, we achieve the best performance on CTB5.1, 94.95% in tagging accuracy and 83.98% in parsing accuracy respectively.

TITLE AND ABSTRACT IN CHINESE

采用堆方法融合异种的中文词性和依存句法联合模型

过去的中文词性和依存句法联合模型基本上都根据基于图的依存句法分析模型或者基于转移的依存句法分析模型进行拓展而形成的。我们的分析结果表明这两种不同的模型错误分布并不一样，而且在依存句法中，将基于图的模型和基于转移的模型使用堆方法融合之后，能够显著的提升依存句法的性能，这些促使我们进一步研究采用堆方法去融合基于图的和基于转移的词性依存句法联合模型。我们在中文宾州树库5.1版本（CTB5.1）上进行试验，实验结果表明，相比使用基于图的联合模型为被指导模型，采用转移的联合模型为被指导模型能取得较好的性能。更进一步，我们介绍了基于短语句法结构的联合模型，它从一个句子的概率短语文法分析器输出结果中提取句子的词性序列以及依存树结果，然后我们采用基于短语句法结构的联合模型更进一步指导基于转移的联合模型，最终我们在CTB5.1的数据上取得了最好结果，词性标注准确率达到94.95%，同时，依存句法准确率达到83.98%。

1 Introduction

Part-of-speech (POS) tagging and dependency parsing are two fundamental natural language processing (NLP) tasks. Typically, POS tagging is a preprocessing step for dependency parsing, especially in a pipeline architecture. There are two main problems in a pipeline system: (1) Dependency parsing suffers the problem of error propagation; (2) POS tagging cannot exploit useful, important syntactic information for disambiguation.

For Chinese POS tagging and dependency parsing, a pipeline system seriously suffers these two problems. The study presented in (Li et al., 2011b) demonstrates the error propagation factor. The authors develop a graph-based joint model for Chinese POS tagging and dependency parsing. The most interesting thing they found is that even with lower tagging accuracy, a joint model could achieve higher parsing accuracy. The work presented in (Hatori et al., 2011) also demonstrates a joint model can largely improve the performance of dependency parsing further. They propose a transition-based joint model for Chinese POS tagging and dependency parsing.

Recently, ensemble models have been gained a lot of interests in NLP community. Stacked learning (stacking) (Wolpert, 1992; Breiman, 1996), which is a typical method for ensemble models, has been applied to a number of NLP tasks for its elegance and conciseness, such as Chinese Word segmentation (Sun, 2011), POS tagging (Li et al., 2011a), named entity recognition (Dekai Wu and Carpuat, 2003) and dependency parsing (McDonald, 2006; Nivre and McDonald, 2008; Martins et al., 2008; Søgaard and Rishøj, 2010; McDonald and Nivre, 2011). Especially, (Nivre and McDonald, 2008) demonstrate that the performance of dependency parsing can be largely improved by stacking a graph-based dependency parser and a transition-based dependency parser. Thus it is interesting to investigate the effect of stacked learning when it is applied to joint models.

Graph- and transition-based joint models are extended from graph- and transition-based models of dependency parsing respectively. They are the two mainstream approaches for dependency parsing. It is noteworthy that, the probabilistic context-free grammar (PCFG) parsers, such as Brown parser (Charniak and Johnson, 2005) and Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007), which are traditionally used for constituent parsing, have also been suggested for dependency parsing (Yamada and Matsumoto, 2003; McDonald, 2006; Sun, 2012; Che et al., 2012). We denote these methods by constituent-based models. The precondition of constituent-based models is that the output constituent structure of the PCFG parsers can be transformed into dependency structure by rules adequately. This is satisfied for Chinese. Moreover, the PCFG models can process POS tagging simultaneously in constituent parsing. They treat POS tagging as a submodule of constituent parsing. Thus we can also adopt a PCFG model for joint Chinese POS tagging and dependency parsing. We denote it by constituent-based joint model. (Sun, 2012) proposed to improve the Chinese parsing accuracy by a PCFG parser. Similarly, (Sun and Uszkoreit, 2012) exploited a PCFG parser to enhance Chinese POS tagging. Thus it is reasonable to investigate the performance of constituent-based joint models and to improve the performance of joint Chinese POS tagging and dependency parsing by a constituent-based joint model.

In this paper, first we study the integration of a graph-based joint model (JGraph) and a transition-based joint model (JTrans) by stacked learning. The stacked learning is implemented using a two-level architecture, where the level-0 consists of one or more predictors of which the results are exploited as input to enhance the level-1 predictor. Thus either JGraph or JTrans can be chosen as the level-1 model. We call the stacking model using JGraph as level-1 model

by the guided graph-based joint model and the stacking model using JTrans as level-1 model by the guided transition-based joint model. Further we introduce a constituent-based joint model (JConst) and then integrate this model into the previous better stacking model by further stacking.

We conduct the experiments on Chinese Penn Treebank 5.1 (CTB5.1) data set (Xue et al., 2005). First, we evaluate the performance of stacking models. The guided transition-based joint model gets better performance than the guided graph-based joint model, achieving 94.76% in tagging accuracy and 82.22% in parsing accuracy. Then we evaluate the performance of our constituent-based joint model. The reported accuracies are 93.45% in POS tagging and 81.03% in dependency parsing. Finally, we integrate the constituent-based joint model into the guided transition-based joint model by a further stacking. Our final results are 94.95% in tagging accuracy and 83.98% in parsing accuracy, resulting in further improvements of 0.19% in tagging accuracy and 1.76% in parsing accuracy.

Finally, detailed error analysis is carried out by two aspects: (1) the different error distributions of JGraph, JTrans and JConst are shown in detail to interpret the improvements in stacking and (2) the comparisons between joint models and pipeline approaches are conducted to understand the interaction between Chinese POS tagging and dependency parsing. Through the analysis, we can find several interesting phenomenons. For example, JConst can do better for long distance dependencies, the tagging accuracies of joint models are more fragile facing to wrong dependencies, dependencies with the head on the right are more easily recognized however the corresponding POS tags of the modifiers in these dependencies are more difficult to be handled.

The rest of the paper is organized as follows. Section 2 reviews the related works of our paper. Section 3 describes the graph- and transition-based joint models . Section 4 describes the stacking models including the guided graph-based joint model and the guided transition-based joint model. Section 5 describes our constituent-based model and the further stacking model. Section 6 reports the experimental results. Section 7 gives the systematic analysis of the joint models. Finally, in Section 8 we conclude this paper and point out our future works.

2 Related Works

Related Works on Joint Models of Chinese POS Tagging and Dependency Parsing (Li et al., 2011b) present the first joint model for Chinese POS tagging and dependency parsing. They extend models of graph-based dependency parsing (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010), making them enable to handle POS tagging simultaneously. They conclude that joint models can achieve better performance in dependency parsing and can do much better some certain POS tagging error patterns.

Secondly, (Hatori et al., 2011) and (Bohnet and Nivre, 2012) propose joint models based on transition-based dependency parsing (Nivre, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011). (Hatori et al., 2011) also examine the results of their joint model carefully, demonstrating similar conclusions to that of (Li et al., 2011b). However, their certain error patterns are slightly different with that of (Li et al., 2011b). The differences may be induced by the different manners of modeling the joint task.

Thirdly, the constituent-based joint model processes joint Chinese POS tagging and dependency parsing in an indirectly way. It performs the POS tagging and dependency parsing by a conversion from the initial output of a PCFG parser. In Chinese POS tagging, (Sun and Uszkoreit, 2012) suggest to enhance Chinese POS tagging guided by the output POS tags of

Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007). In Chinese dependency parsing, (Sun, 2012) has proposed to improve the performance of dependency parsing by Berkeley parser. (Che et al., 2012) have compared the performance of several PCFG parsers on Stanford dependencies. This method has also been employed for English dependency parsing (Yamada and Matsumoto, 2003; McDonald, 2006).

In this paper, we study the integration of the three joint models by stacking. Then we discuss these different joint models including the stacking models comprehensively, aiming for two purposes: (1) figure out the benefits from stacking and (2) understand the interaction between Chinese POS tagging and dependency parsing.

Related Works on Stacked Learning *Stacked generalization* is a meta-learning algorithm that is first proposed by (Wolpert, 1992) and (Breiman, 1996). It has been exploited in a number of NLP tasks for integration. We mainly concern the works of stacked learning applied on POS tagging and dependency parsing. The work of (Li et al., 2011a) presented a mostly recent work for stacking POS taggers. They exploit the output of a CRF POS tagger to help a perceptron-based POS tagger with syntactic features. (McDonald, 2006) proposed the first stacking work of dependency parsing. The author incorporated parse decisions of two constituent-based parsers, Collins parser (Collins, 1999; Bikel, 2004) and Charniak parser (Charniak, 2000), into the second-order MST parser. Then (Nivre and McDonald, 2008) suggested integrating graph- and transition-based models by stacking, and more detailed analysis was given in (McDonald and Nivre, 2011). (Martins et al., 2008) also demonstrated that stacking transition- and graph-based parsers can improve parsing performance significantly and meanwhile offer theoretical interpretations for stacking. In our paper, stacked leaning is applied on the joint tasks of Chinese POS tagging and dependency parsing.

3 Two Models for Joint Chinese POS Tagging and Dependency parsing

A dependency tree for an input sentence $\mathbf{x} = w_0 w_1 \cdots w_n$ (where $w_0 = \text{ROOT}$) can be denoted by $\mathbf{d} = \{(h,m) \mid 0 \leq h \leq n, 0 < m \leq n\}$, where (h,m) represents a dependency $w_h \rightarrow w_m$ whose *head* word (or father) is w_h and *modifier* word (or child) is w_m. The task of dependency parsing is to find an optimum dependency tree $\mathbf{d}$ for the input sentence $\mathbf{x}$. Generally, the POS tag sequence of the sentence $\mathbf{t} = t_1 \cdots t_n$ (where $t_i \in T, 1 \leq i \leq n$, T is the POS tag set) is taken as an input for dependency parsing, which is determined by the task of POS tagging, thus forming a pipeline model of the two tasks. POS tagging is a typical sequence labeling problems which can be resolved by algorithms such as maximum-entropy (Ratnaparkhi, 1996), conditional random fields (CRF) (Lafferty et al., 2001) and averaged perceptron (Collins, 2002). The goal of joint models of the two tasks is to find an optimum dependency tree and an optimum POS tag sequence $(\hat{\mathbf{t}}, \hat{\mathbf{d}})$ for $\mathbf{x}$ concurrently.

3.1 Graph-based Joint Model

The graph-based joint model is first proposed by (Li et al., 2011b). Such a model is extended from a graph-based model for dependency parsing (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010). In the model, the score of a dependency tree along with POS tags on each node is factored into scores of small parts.

(Li et al., 2011b) have introduced several different graph-based joint models in term of small parts employed in the models. According to the results they reported, we employ the model Li-11(v1,2nd) in terms of both accuracies and decoding speed. The scoring parts of the model

include dependencies, siblings and grandchilds, as is shown in Figure 1. The score function of Li-11(v1,2nd) can be represented by Equation 1,

$$\begin{aligned}\text{Score}_{\text{joint}}(\mathbf{x},\mathbf{t},\mathbf{d}) = &\sum_{\{(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{pos}}\cdot\mathbf{f}_{\text{pos}}(\mathbf{x},\mathbf{t},m) + \mathbf{w}_{\text{dep}}\cdot\mathbf{f}_{\text{dep}}(\mathbf{x},\mathbf{t},h,m) + \sum_{\{(h,s)(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{sib}}\cdot\mathbf{f}_{\text{sib}}(\mathbf{x},\mathbf{t},h,s,m) \\ &+ \sum_{\{(g,h)(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{grd}}\cdot\mathbf{f}_{\text{grd}}(\mathbf{x},\mathbf{t},g,h,m)\end{aligned} \tag{1}$$

where $\mathbf{w}$ denotes the model parameters and $\mathbf{f}_{\text{pos}}(\cdot), \mathbf{f}_{\text{dep}}(\cdot), \mathbf{f}_{\text{sib}}(\cdot), \mathbf{f}_{\text{grd}}(\cdot)$ denote the features of POS tagging, dependency part, sibling part and grandchild part.

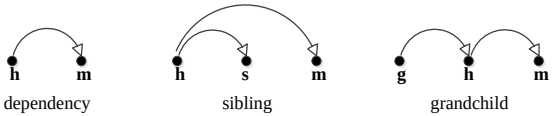

Figure 1: The scoring parts used in our graph-based joint model. Each node in the scoring parts has been tagged with POS already.

For more detailed description, we refer to the original paper. We call this graph-based joint model as JGraph for brevity.

3.2 Transition-based Joint Model

(Hatori et al., 2011) propose the first joint model of Chinese POS tagging and transition-based dependency parsing (Nivre, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011). In a transition-based system, we learn a joint model for scoring the transition A_i from one state ST_i to the next ST_j. As shown in Figure 2, the state ST of the transition system is composed by a stack S and a queue Q, where $S = (\cdots, s_1, s_0)$ is a stack of dependency trees along with POS tags and $Q = (q_0, q_1, \cdots, q_{n-j}) = (w_j, w_{j+1}, \cdots, w_n)$ is the remaining words which have not been processed at the current state.

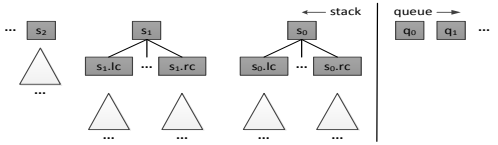

Figure 2: A state in the transition-based joint model. The figure is borrowed from (Huang and Sagae, 2010).

The candidate transition action A at each step is defined as follows:

- SHIFT(t) (SH(t)): move the head word w_j of queue Q into the stack S, assigning the word with the POS tag t.
- REDUCE-RIGHT (RR): merge the top two trees s_0, s_1 into a new subtree $s_0 \overset{\frown}{} s_1$.
- REDUCE-LEFT (RL): merge the top two trees s_0, s_1 into a new subtree $s_0 \overset{\frown}{} s_1$.

Equation 2 describes the score function of the transition-based joint model.

$$\text{Score}_{\text{joint}}(\mathbf{x},\mathbf{t},\mathbf{d}) = \sum_{A_i=\text{SHIFT(t)}} \mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\text{ST}_i, A_i, t) + \sum \mathbf{w}_{\text{syn}} \cdot \mathbf{f}_{\text{syn}}(\text{ST}_i, A_i) \quad (2)$$

where $\mathbf{f}_{\text{pos}}(\cdot)$ refers to the general features exploited in POS tagging and $\mathbf{f}_{\text{syn}}(\cdot)$ is all other features which are syntax related.

In this work, we employ the joint model of Joint-ZN^{-} in (Hatori et al., 2011) after considering the performance. We refer to their paper for more detailed descriptions. We thank the authors for sharing their code with us. We make some changes to make the basic POS tagging features the same with that in JGraph. We call this transition-based joint model as JTrans for brevity.

4 Stacking Joint Models

Stacked learning is a typical approach for model integration. The idea of stacked learning is to include two "level" of predictors : the level-0 includes one or more predictors $g_1, \cdots g_K (K \geq 1) : R^d \rightarrow R$ and the level-1 consists of one single predictor $h : R^{d+k} \rightarrow R$. Each predictor g_k of level 0 receives input $\mathbf{x} \in R^d$ and outputs a prediction$g_k(\mathbf{x})$. The level-1 predictor takes as input $\langle \mathbf{x}, g_1(\mathbf{x}), \cdots, g_K(\mathbf{x}) \rangle$ and outputs a final prediction $h(\mathbf{x}, g_1(\mathbf{x}), \cdots, g_K(\mathbf{x}))$.

In our work, we have two strategies for stacking JGraph and JTrans. The guided graph-based joint model exploits JGraph as the level-1 model and the guided transition-based joint model exploits JTrans as the level-1 model. We will describe them in the following respectively.

4.1 The Guided Graph-based Joint Model

The guided graph-based joint model, which we call JGraph(JTrans), exploits JGraph as the level-1 model and JTrans as level-0 model. As shown in Equation 1, the graph-based joint model computes a dependency tree along with POS tags by factored it into small parts including dependencies, siblings and grandchilds. Correspondingly, assuming the output of JTrans is $(\hat{\mathbf{t}}^{\text{JTrans}} = t_1^{\text{JTrans}} \cdots t_n^{\text{JTrans}}, \hat{\mathbf{d}}^{\text{JTrans}})$, the score function of JGraph(JTrans) becomes:

$$\begin{aligned}\text{Score}_{\text{joint}}(\mathbf{x},\mathbf{t},\mathbf{d}) = &\sum_{\{(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x},\mathbf{t},\hat{\mathbf{t}}^{\text{JTrans}},m) + \mathbf{w}_{\text{dep}} \cdot \mathbf{f}_{\text{dep}}(\mathbf{x},\mathbf{t},h,m,\hat{\mathbf{d}}^{\text{JTrans}}) \\ &+ \sum_{\{(h,s)(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{sib}} \cdot \mathbf{f}_{\text{sib}}(\mathbf{x},\mathbf{t},h,s,m,\hat{\mathbf{d}}^{\text{JTrans}}) + \sum_{\{(g,h)(h,m)\}\subseteq\mathbf{d}} \mathbf{w}_{\text{grd}} \cdot \mathbf{f}_{\text{grd}}(\mathbf{x},\mathbf{t},g,h,m,\hat{\mathbf{d}}^{\text{JTrans}})\end{aligned} \quad (3)$$

We can see that the feature functions are modified to include additional arguments $\hat{\mathbf{t}}^{\text{JTrans}}$ and $\hat{\mathbf{d}}^{\text{JTrans}}$. Thus new features related with the additional arguments will be produced. These new features account for the guided features over the output of JTrans. The specific features used by JGraph(JTrans) are given in Table 1.

4.2 The Guided Transition-based Joint Model

The guided transition-based joint model, which we call JTrans(JGraph), exploits JTrans as the level-1 model and JGraph as level-0 model. As shown in Equation 1, the transition-based joint model computes a dependency tree along with POS tags by the sequence of transition actions of shaping it. Correspondingly, assuming the output of JTrans is $(\hat{\mathbf{t}}^{\text{JGraph}} = t_1^{\text{JGraph}} \cdots t_n^{\text{JoinG}}, \hat{\mathbf{d}}^{\text{JGraph}})$, the score function of JTrans(JGraph) becomes:

$$\text{Score}_{\text{joint}}(\mathbf{x},\mathbf{t},\mathbf{d}) = \sum_{A_i=\text{SHIFT(t)}} \mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\text{ST}_i, A_i, t, \hat{\mathbf{t}}^{\text{JGraph}}) + \sum \mathbf{w}_{\text{syn}} \cdot \mathbf{f}_{\text{syn}}(\text{ST}_i, A_i, \hat{\mathbf{d}}^{\text{JGraph}}) \quad (4)$$

The Guided Graph-based Joint Model: JGraph(JTrans)	
pos	$\{\hat{t}_m^{\text{JTrans}}, \hat{t}_m^{\text{JTrans}} \circ \hat{t}_{m-1}^{\text{JTrans}}, \hat{t}_m^{\text{JTrans}} \circ \hat{t}_{m+1}^{\text{JTrans}}, \hat{t}_{m-1}^{\text{JTrans}} \circ \hat{t}_{m+1}^{\text{JTrans}}\} \otimes \{t_m, w_m \circ t_m\}$
dep	{Whether $h \curvearrowright m$ is in $\hat{\mathbf{d}}^{\text{JTrans}}$?} $\otimes \{t_h, t_m, t_h \circ t_m\}$
sib	{Whether $h \curvearrowright m$ and $h \curvearrowright s$ are in $\hat{\mathbf{d}}^{\text{JTrans}}$?}$\otimes \{t_h, t_m, t_h \circ t_m\}$
grd	{Whether $g \curvearrowright h \curvearrowright m$ is in $\hat{\mathbf{d}}^{\text{JTrans}}$?}$\otimes \{t_h, t_m, t_h \circ t_m\}$
The Guided Transition-based Joint Model: JTrans(JGraph)	
pos	$\{t_m, w_m \circ t_m\} \otimes \{\hat{t}_m^{\text{JGraph}}, \hat{t}_m^{\text{JGraph}} \circ \hat{t}_{m-1}^{\text{JGraph}}, \hat{t}_m^{\text{JGraph}} \circ \hat{t}_{m+1}^{\text{JGraph}}, \hat{t}_{m-1}^{\text{JGraph}} \circ \hat{t}_{m+1}^{\text{JGraph}}\}$
syn	{Whether $s_0 \curvearrowright s_1$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?, Whether $s_0 \curvearrowleft s_1$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?} $\otimes \{s_0.t, s_1.t, s_0.t \circ s_1.t\}$, {Whether $s_0 \curvearrowright s_1$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?, Whether $s_0 \curvearrowleft s_1$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?} $\otimes$ {Whether $s_0 \curvearrowleft (s_0.\text{lc})$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?, Whether $s_0 \curvearrowright (s_0.\text{rc})$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?, Whether $s_1 \curvearrowleft (s_1.\text{lc})$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?, Whether $s_1 \curvearrowleft (s_1.\text{rc})$ is in $\hat{\mathbf{d}}^{\text{JGraph}}$?} $\otimes \{s_0.t, s_1.t, s_0.t \circ s_1.t\}$

Table 1: Guided features for JGraph(JTrans) and JTrans(JGraph). These features are defined by referring to (Li et al., 2011a) for POS related features and (Nivre and McDonald, 2008) for syntax related features. The symbol $\otimes$ denotes a cross join operation, and the symbol $\circ$ denotes a conjoin operation. In features of JTrans(JGraph), the index of m refers to the involved word for tagging, $x.t$ denotes the POS tag of word x, and x.lc and x.rc denote x's leftmost and rightmost child.

We can see that the feature functions are modified to include additional arguments $\hat{\mathbf{t}}^{\text{JGraph}}$ and $\hat{\mathbf{d}}^{\text{JGraph}}$. Thus new features related with the additional arguments will be produced. These new features account for the guided features over the output of JGraph. The specific features used by JTrans(JGraph) are given in Table 1.

5 Constituent-based Joint Model and Further Stacking

5.1 Constituent-based Joint Model

Constituent-based joint models rely on certain PCFG parsers which exploit context-free grammar (CFG) to shape the search space for possible syntactic analysis. POS tagging and syntax analysis are usually processed simultaneously in PCFG parsers. These models have significant differences with the above two models. They model the joint POS tagging and dependency parsing in an indirect way. These models resolve the joint task by a two-step process: (1) constituent parsing and (2) rule-based transformation from constituent structures (CS) to dependency structures (DS). One advantage of constituent-based joint models is that all well-studied PCFG parsers can be used for the joint task. Figure 3 shows an example for this method.

In this work, we choose Berkeley parser[1] (Petrov et al., 2006; Petrov and Klein, 2007) to perform constituent parsing for its high performance in Chinese. We call this constituent-based joint model as JConst for brevity. Berkeley parser is an unlexicalized PCFG parser with latent variables. The observed constituent trees are automatically modeled with fined-grained unobserved constituent trees using latent variables. In Chinese POS tagging, (Sun and Uszkoreit, 2012) have proposed to use the output of Berkeley parser to enhance Chinese POS tagging. In Chinese dependency parsing, (Sun, 2012) has suggested to use Berkeley parser to improve the

(a) Constituent structure with head nodes marked already.

(b) Dependency structure.

Figure 3: An example of constituent-based joint model: 戴相龙说中国经济发展为亚洲作出积极贡献(Dai Xianglong said that Chinese economic development made positive contributions for Asia). The left constituent structure can be converted to the right dependency structure, and the head nodes (marked by [H]) are specified by CS-to-DS rules.

performance of parsing accuracy, and (Che et al., 2012) have demonstrate that Berkeley parser outperforms several other PCFG parsers for Chinese Stanford dependencies.

5.2 Stacking Constituent-based Joint Model as the Second Level-0 Model

As mentioned in Section 4, we have introduced the integration of JGraph and JTrans by stacked learning. Here we concern a more complex case to integrate JConst into the ensemble model of JGraph and JTrans. Actually, it can be carried out very simply by adding the features of JConst similar to the other level-0 model. For example, if we exploit the guided graph-based joint model to integrate JConst, the guided features related with JConst are similar to that related with JTrans, which are produced by replacing the output of JTrans with JConst.

By adding JConst for further stacking, there are two level-0 models in stacking. Besides the independent guided features of the two level-0 models, we suppose that the consistency of the two level-0 models is also an effective indicator. For example, in dependency parsing, if $w_h \frown w_m$ exists in both level-0 models, then the probability of adding such a dependency should be much higher, and if $w_h \frown w_m$ exists in only one of the level-0 models, the probability should be lower but also a positive contribution, and further if $w_h \frown w_m$ doesn't exist in anyone of the level-0 models, the probability should be much lower with a negative impact. We name the features related with the consistency of the two level-0 models as *guided consistent features*. Table 2 lists the guided consistent features used in this work. Both the guided graph-based joint model and the guided transition-based joint model are considered.

6 Experiments

6.1 Experimental Settings

We use CTB5.1 to conduct our experiments. Following the works of (Li et al., 2011b) and (Hatori et al., 2011), we use the standard split of CTB5.1 described in (Duan et al., 2007) and the conversion rules of CS-to-DS in (Zhang and Clark, 2008).

We use the standard tagging accuracy to evaluate POS tagging. For dependency parsing, we use word accuracy (also known as dependency accuracy or UAS), root accuracy and complete

match rate (all excluding punctuation) to evaluate the performance.

The models are trained iteratively and the best one is chosen for final evaluation for each joint model in terms of tagging accuracy and dependency accuracy on development set. The iterative number for graph-based joint models and transition-based joint models are 15 and 50 respectively. The beam size of our transition-based joint models is set to 64. In stacked learning, we split the train data into five folds to get augmented train data for level-1 model.

6.2 Stacking Graph- and Transition-based Joint Models

6.2.1 Baseline Performance

At first, we evaluate the performance of our baseline joint models: JGraph and JTrans. The performance of the pipeline models of JGraph and JTrans are also reported. Table 3 shows the results. The POS tagger of pipeline models is trained using averaged perceptron (Collins, 2002), exploiting the features which are only related with POS tagging. Our POS tagger achieves a tagging accuracy of 94.34% on development set, and 94.11% on test set, which is higher than the pipeline models of (Li et al., 2011b) and (Hatori et al., 2011). PGraph and PTrans denote the pipeline models of JGraph and JTrans respectively.

As shown in Table 3, both JGraph and JTrans achieve higher parsing accuracies than the pipeline models, where JGraph achieves increases of 1.36% and JTrans achieves increases of 1.61%. In tagging accuracy, JGraph achieve increases of 0.4% compared to PGraph, whereas JTrans suffers very little loss compared to PTrans. JGraph has a significant improvement in POS tagging compared to the reported results in their paper as they have enhanced the model before sharing the code for us. We use the code shared by the authors of (Hatori et al., 2011) to train JTrans, meanwhile some modifications have been done to make the basic POS tagging features identical with JGraph. However our parsing accuracy is slightly lower than the reported results in their paper. The work of (Bohnet and Nivre, 2012) is the only one other related work for joint Chinese POS tagging and dependency parsing. They also reported their results on CTB5.1 data set. However we didn't make a comparison as they employed a different conversion method for CS-to-DS.

		Syntactic Metrics			Tagging
		word	root	compl.	Accuracy
Stacking	JGraph(JTrans)	82.04	**78.17**	30.21	94.52
	JTrans(JGraph)	**82.22**	78.03	**30.58**	**94.76**
Graph	JGraph	**80.88**	**75.55**	**28.83**	**94.51**
	PGraph	79.52	75.34	26.70	94.11
	(Li et al., 2011b) (v1,2nd)	80.74	75.80	28.24	93.08
Transition	JTrans	**80.91**	**76.91**	**29.32**	94.07
	PTrans	79.30	75.73	27.80	**94.11**
	(Hatori et al., 2011)(ZN)	81.33	77.93	29.90	93.94

Table 3: The results of baseline models on test corpus. Results of significant test show that the p-value of tagging accuracy is lower than 10^{-3} and the p-value of parsing accuracy is lower than 10^{-5} for both JGraph(JTrans) and JTrans(JGraph).

6.2.2 Stacking Results

Table 3 shows the results of integration JGraph and JConst by stacked learning. We can see both the guided graph-based joint model and the guided transition-based achieve significantly improvements compared to the baseline models. The guided transition-based joint model obtains slightly better performance than the guided graph-based joint model, achieving the tagging accuracy of 94.76% and the parsing accuracy of 82.22%. (Nivre and McDonald, 2008) have done a similar work on dependency parsing. Their result demonstrate that the the guided graph-based model is better than the guided transition-based model in Chinese. Our results are different. This is perhaps caused by our baseline models are more complex, especially the transition-based joint model.

6.3 Stacking Constituent-based Joint Model as the Second Level-0 Model

We have shown that the guided transition-based joint model achieves better performance. Thus we integrate the constituent-based joint model into this guided model in our work.

6.3.1 Performance of the Constituent-based Joint Model

Table 5 shows the performance of JConst. The parsing accuracy of JConst is slightly higher than JGraph and JTrans. This demonstrates that JConst is also an effective method for joint Chinese POS tagging and dependency parsing. However, the tagging accuracy is not good. This may be caused by that Berkeley parser is a generative model, and thus relatively poor POS related features can be used in it.

6.3.2 Effectiveness of Guided Consistent Features

For further stacking JConst, we have suggested the guided consistent features. To test the effect of guided consistent features, we conduct feature ablation experiments. Table 4 shows the results on development set, where the mark {***-GC***} denotes the model without guided consistent features. The ablation of the guided consistent features resulted in 0.2% decreases in tagging accuracy and 0.28% decreases of parsing accuracy for JTrans(JGraph, JConst), showing the effectiveness of these features.

	Syntactic Metrics			Tagging
	word	root	compl.	Accuracy
JTrans(JGraph, JConst)	**84.68**	**80.38**	**34.37**	**95.31**
JTrans(JGraph, JConst){**-GC**}	84.40	79.82	34.12	95.11

Table 4: Feature ablation for guided consistent features.

6.3.3 Final Results

Table 5 shows the final results of stacking JGraph, JTrans and JConst together. The final stacking model JTrans(JGraph, JConst) achieves a tagging accuracy of 94.95% and a dependency accuracy of 83.98%, obtaining further increases of 0.19% in tagging accuracy and 1.76% in parsing accuracy compared to JTrans(JGraph). The improvements of JTrans(JGraph, JConst) compared to JTrans(JGraph) are larger than that of JTrans(JGraph) compared to JGraph or JTrans. In both tagging and parsing performance, JTrans(JGraph, JConst) is better than JTrans(JGraph), and meanwhile JTrans(JGraph) is better than anyone of {JGraph, JTrans, JConst} . It demonstrates that each individual joint model has a positive impact in the stacking.

	Syntactic Metrics			Tagging
	word	root	compl.	Accuracy
JTrans(JGraph, JConst)	**83.98**	**81.29**	**32.15**	**94.95**
JConst	81.03	78.12	28.01	93.45

Table 5: Final results of further stacking for constituent-based joint model.

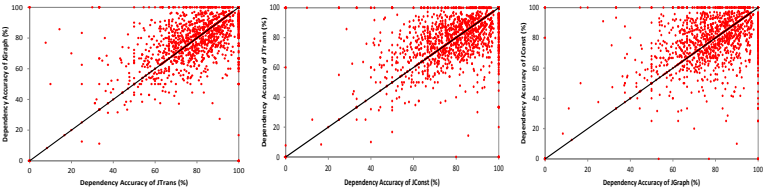
7 Analysis

The analysis is conducted on test corpus of CTB5.1. It includes two aspects. First we carefully examine the error distributions of the joint models, which can help us to figure out how stacked learning helps Chinese POS tagging and dependency parsing. Then we compare the joint models to pipeline models, which can help us to understand the interaction between Chinese POS tagging and dependency parsing.

7.1 Comparisons between Heterogeneous Joint Models

In this section, we mainly concern the performance of dependency parsing. Generally, stacking can perform effectively when the differences between baseline models are very large. For the final stacking model JTrans(JGraph, JConst), the baseline models include JGraph, JTrans, JConst.

First, we display the scatter plots of the parsing accuracies of JGraph against JTrans, JTrans against JConst and JConst against JGraph respectively. Each point (x, y) in the scatter plots denotes a sentence's parsing accuracy in the two joint models. If the point is upper the line $y = x$, it denotes that the joint model represented by vertical axis achieve higher dependency accuracy for the sentence. As is shown in Figure 4, the points seem to be random distributed in the three plots, and the number of points divided by line $y = x$ seems equal. These demonstrates that the error distributions of the three baseline models are rather different. Each model can process better on some sentences, and also may perform worse on some other sentences. By stacking, we can take advantage of the strengths of each model, thus resulting in a better performance.



(a) x:JTrans,y:JGraph (b) x:JConst,y:JTrans (c) x:JGraph,y:JConst

Figure 4: Scatter plots of dependency accuracies of every two baseline models.

Figure 5 shows the performance of dependency parsing in term of dependency length. Dependency length denotes the distance between the head and modifier in a dependency. Generally, dependency accuracies decrease when the distance between the head and modifier become longer. JConst can do better than the other two baseline models. JGraph and JTrans model dependency trees directly, and dependency length is a very important factor when building a dependency to shape the tree, thus JGraph and JTrans can be influenced much by it. However, JConst builds a dependency tree indirectly, the syntax analysis is done under the grammar of CFG, which needn't consider the attributes of a dependency tree. Thus dependency length has smaller influence to JConst. During the stacking, the model can learn that JConst is good at the dependencies with long dependency length. Thus the final stacking model can perform well for long dependency length, which is shown in Figure 5.

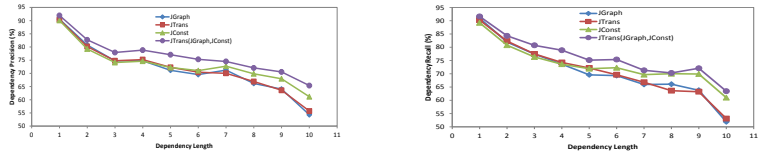


Figure 5: Dependency arc precision/recall relative to predicted/gold dependency length.

7.2 Comparisons between Joint Models and Pipeline Models

Impact on POS tagging : Intuitively, the tagging accuracy should be much higher if the dependency structures are correctly predicted. Table 6 shows the tagging accuracies of the different models with correct dependency heads and wrong heads respectively. The accuracies of words with correct heads are 10% higher than that with wrong heads on average. Joint models are more easily affected by the correctness of dependency head compared to PGraph[2]. This is caused by that we have exploited the syntactic features for POS tagging in joint models.

Next, we investigate which POS tagging error patterns can be influenced greatly in joint models. Figure 6 shows the related high frequency error patterns. The error patterns with rectangles upper the horizontal line are positive error patterns which joint models can do better, and the error patterns with rectangles below are negative error patterns which joint models can

[2]We only choose PGraph for comparison since it achieves better performance than PTrans.

	PGraph	JGraph	JTrans	JConst	JTrans(JGraph, JConst)
Correctly Headed	96.23	96.92↑	96.64↑	96.36↑	97.03↑
Wrongly Headed	86.65	85.34↓	84.16↓	81.79↓	84.7↓

Table 6: POS tagging accuracies with correct dependency heads and wrong dependency heads.

do worse. We can see that the joint models can do significantly better on such error patterns like NN → VV and DEC → DEG, and in contrast joint models can do worse on error patterns for example NR → NN and NN → JJ. Actually, the positive error patterns are important for dependency parsing and the positive error patterns usually needn't to be distinguished in dependency parsing, we will demonstrate it later.

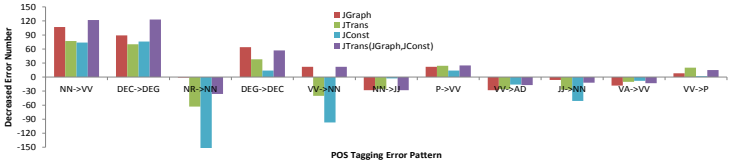

Figure 6: POS tagging error patterns influenced significantly by joint models.

Finally, the arc direction of dependency is also an important factor to influence the POS tagging accuracy. Table 7 shows the POS tagging accuracy of modifier words in term of gold arc direction $w_i \frown w_j$, $w_i \frown w_j$ $(i < j)$[3]. In Chinese, the POS tags such as NN, JJ or AD, which are difficult to be distinguished by dependency parsing, are usually tagged for modifier words in $w_i \frown w_j$, thus we can see that joint models gain little improvements for $w_i \frown w_j$.

	PGraph	JGraph	JTrans	JConst	JTrans(JGraph, JConst)
$w_i \frown w_j$	94.12	94.24	93.78	92.86	94.51
$w_i \frown w_j$	93.95	94.92	94.54	94.54	95.62

Table 7: POS tagging accuracies of modifier words in term of the gold arc direction.

Impact on dependency parsing : We mainly concern how POS tagging errors influence the performance of dependency parsing. In the previous discussion, we have demonstrated that dependency structures can influence some certain POS tagging error patterns significantly. We expect that the parsing accuracies should decrease sharply for the POS error patterns who demonstrate positive influences, because we suppose that these error patterns are harmful for dependency parsing, thus they can be distinguished by dependency parsing. Figure 7 shows the dependency accuracies of these POS tagging error patterns. We can see that the parsing accuracies of joint models for positive error patterns such as NN → VV, DEC → DEG and DEG → DEC drop drastically compared to PGraph. This conforms to our expectation. It demonstrates that joint models can do much better on certain POS tagging errors which are harmful for dependency parsing.

We also look into the impact of dependency arc direction on dependency parsing. Table 8 shows the dependency accuracies in term of gold arc direction. Generally, joint models do much better than PGraph in both $w_i \frown w_j$ and $w_i \frown w_j$. The accuracy of $w_i \frown w_j$ is significantly higher than $w_i \frown w_j$. One interpretation is that the words with POS tags such as NN, JJ or AD are usually

[3]We neglect the ROOT when considering the arc direction.

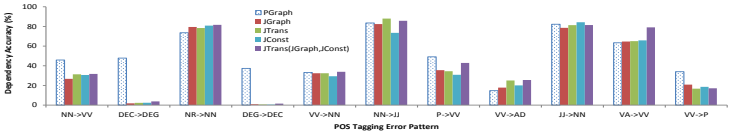

Figure 7: Dependency accuracies of different POS tagging error patterns.

easier to find their dependency head, and the head of such words is always on the right. Further, the accuracy gap of JConst between $w_i \frown w_j$ and $w_i \frown w_j$ is apparently smaller than the JGraph and JConst, which is similar to the phenomenon that dependency length has smaller influence to JConst, as dependency length and arc direction are important factors in JTrans and JConst which process dependency parsing directly.

	PGraph	JGraph	JTrans	JConst	JTrans(JGraph, JConst)
$w_i \frown w_j$	81.03	82.01	82.44	81.75	84.81
$w_i \frown w_j$	76.45	78.92	77.73	79.7	82.35

Table 8: Dependency accuracies in term of the gold arc direction.

Conclusions

In this paper, we present a study to investigate the integration of joint models of Chinese POS tagging and dependency parsing by stacked learning. First we integrate two joint models: JGraph and JTrans. We find that the stacking can improve the performance of joint models significantly. Meanwhile our experimental results demonstrate that the guided transition-based joint model can do better than the guided graph-based joint model. Next, we introduce a constituent-based joint model JConst, which employ a PCFG parser to get the result of constituent structure and then extract the results of POS tagging and dependency parsing from it. To further improve the performance of joint models, we integrate the JConst into the guided transition-based joint model by further stacking. The final stacking joint model achieves a POS tagging accuracy of 94.95% and a parsing accuracy of 83.98% in Chinese, resulting in total error reductions of 8% and 16% respectively compared to the best model of JGraph, JTrans and JConst.

Further, we conduct a detailed analysis aiming to figure out how stacked learning helps dependency parsing and POS tagging, and meanwhile aiming to understand the relationship between Chinese POS tagging and dependency parsing. We can find that JGraph, JTrans and JConst are very different in error distribution, joint models can do much better on certain POS tagging errors which are harmful for dependency parsing.

Acknowledgments

We especially thank Weiwei Sun for her suggestion of stacking constituent-based models in this work. A Lazy Learning Model for Entity Linking Using Query-Specific Information

Abstract

Entity linking disambiguates a mention of an entity in text to a Knowledge Base (KB). Most previous studies disambiguate a mention of a name (e.g.*"AZ"*) based on the distribution knowledge learned from labeled instances, which are related to other names (e.g.*"Hoffman"*,*"Chad Johnson"*, etc.). The gaps among the distributions of the instances related to different names hinder the further improvement of the previous approaches. This paper proposes a lazy learning model, which allows us to improve the learning process with the distribution information specific to the queried name (e.g.*"AZ"*). To obtain this distribution information, we automatically label some relevant instances for the queried name leveraging its unambiguous synonyms. Besides, another advantage is that our approach still can benefit from the labeled data related to other names (e.g.*"Hoffman"*,*"Chad Johnson"*, etc.), because our model is trained on both the labeled data sets of queried and other names by mining their shared predictive structure.

Keywords: Entity Linking, Lazy Learning, Query-Specific Information.

Proceedings of COLING 2012: Technical Papers, pages 3089–3104,
COLING 2012, Mumbai, December 2012.

1 Introduction

Recently, more and more knowledge bases (KB) which contain rich knowledge about the world's entities such as Wikipedia [1], OpenCyc [2] and KIM [3] (Popov et al., 2004) have become available. These knowledge bases have been shown to form a valuable component for many natural language processing tasks such as knowledge base population (Ji and Grishman, 2011), text classification (Wang and Domeniconi, 2008), and cross-document coreference (Finin et al., 2009). However, to be able to utilize or enrich these KB resources, the applications usually require linking the mentions of entities in text to their corresponding entries in the knowledge bases, which is called entity linking task and has been proposed and studied in Text Analysis Conference (*TAC*) since 2009 (McNamee and Dang, 2009).

Given a mention of an entity in text and a KB, entity linking is to link the mention to its corresponding entry in KB. The major challenges of this task are name variation and name ambiguity. Name variation refers to the case that more than one name variation such as *alias, misspelling* and *acronym* refers to the same entity. For example, both *"48th State"* and *"The Grand Canyon State"* refer to *state of Arizona, U.S.*. Name ambiguity refers to the case that more than one entity shares the same name. For example, *"AZ"* may refer to *state of Arizona*, the Italian airline *Alitalia*, the country *Azerbaijan*, or other entries in KB that have the same name.

Most previous studies on entity linking used annotated data to learn a classifier or ranker (Dredze et al., 2010; Lehmann et al., 2010; Zheng et al., 2010; Zhang et al., 2010; Ploch, 2011; Ratinov et al., 2011) or to estimate parameters (Gottipati and Jiang, 2011; Han and Sun, 2011). Besides, from the analysis by Ji et al. (2011), all of the top systems from the participants in the shared task of *TAC-11*[4] used supervised learning approaches to solve this disambiguation problem.

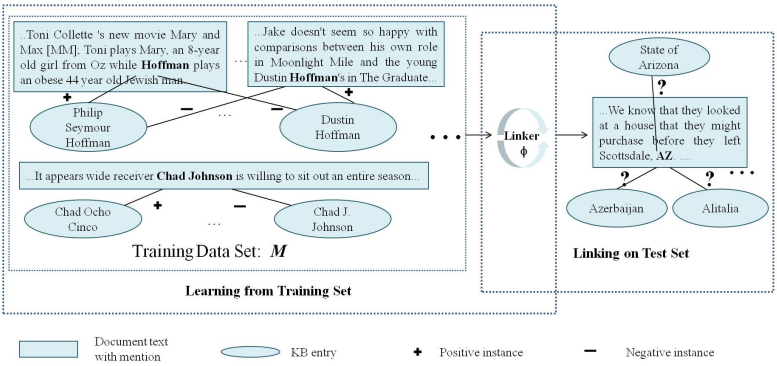

Figure 1: The System Architecture for Traditional Approaches. (*M* contains a certain number of names. *"Hoffman"* and *"Chad Johnson"* are two examples of them.)

However, as there are infinite number of entity names, it is impossible to manually create the labeled

[1] http://www.wikipedia.org/
[2] http://www.opencyc.org/
[3] http://www.ontotext.com/kim
[4] http://nlp.cs.qc.cuny.edu/kbp/2011/

data set for each name. The available labeled data for entity linking is only for a certain number of names. Thus, as shown in Figure 1, the previous approaches disambiguate a mention of the name (e.g.*"AZ"*) based on the distribution knowledge learned from the labeled mention-KB_entry pairs in the training set ***M*** related to other names (e.g.*"Hoffman"*,*"Chad Johnson"*, etc.). Given the query, the previous systems are static at evaluation time and their training does not depend on the input query. However, Figure 2 illustrates the distribution of the labeled instances related to the three names in a feature space (*Bag of Words*, *Named Entities* and *Edit Distance*, the popular features used in previous work). We can see that the width and location of the gap to separate positive and negative instances for different names vary widely. Moreover, the positive-negative instance ratio of each name is also very different from others. Thus, the entity linker generalized beyond labeled names (*"Hoffman"*, *"Chad Johnson"*, etc.) without considering the knowledge of the queried name (*"AZ"*) suffers from this distribution problem.

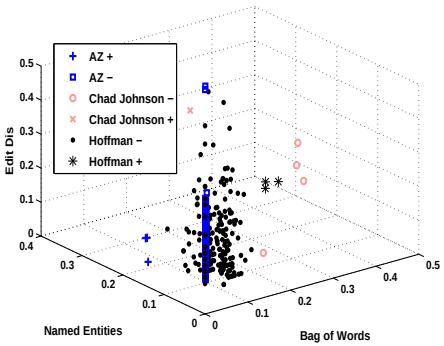

Figure 2: Instances Illustration in 3D Feature Space (Feature detail is in Table 2)

To narrow down the gap between the instance distributions related to labeled and queried names, this paper proposes a lazy learning model, in which generalization on the labeled data is delayed until a query is made. This allows the distribution information specific to queried name to be incorporated into the learning process. To obtain this distribution information, our lazy learning model automatically labels some relevant instances for the queried name leveraging its unambiguous synonyms.

In addition to the new notion of benefiting from the auto-generated instances related with the queried name, our approach further benefits from the manually labeled data related to other names. Specifically, the learned linker generalizes on the labeled data sets related to both queried and other names by exploiting the inherent predictive structure shared by these two data sets. We conduct evaluation on *TAC* data. Our experiments show that our proposed lazy learning model significantly improves entity linking over the state-of-the-art systems.

The remaining of this paper is organized as follows. In Section 2, we review the related work for entity linking. Section 3 elaborates the pre-processing stage to retrieve the possible KB entries

for a given mention. Section 4 presents our lazy learning for entity linking with query-specific information. Section 5 discusses a special case - NIL mentions . The experiments are shown in Section 6. Section 7 concludes the paper.

2 Related Work

As we have discussed, most of the previous entity linking work (Dredze et al., 2010; Lehmann et al., 2010; Zheng et al., 2010; Zhang et al., 2010; Ploch, 2011; Gottipati and Jiang, 2011; Han and Sun, 2011) fall into the traditional entity linking framework shown in Figure 1. Besides, the collaborative approach (Chen and Ji, 2011) tried to search similar queries as their query collaboration group by clustering texts. This differs from our method where we use the selective knowledge from unlabeled data.

In some other work, entity linking is also called *named entity disambiguation using Wikipedia* (Bunescu and Pasca, 2006; Cucerzan, 2007) or *Wikification* (Mihalcea and Csomai, 2007; Milne and Witten, 2008; Ratinov et al., 2011). These two similar tasks link expressions in text to their referent Wikipedia pages. However, since Bunescu and Pasca (2006) used Wikipedia hyperlinks to train the SVM kernel, Cucerzan (2007) used Wikipedia collection and news stories as the development data, and all of the three *Wikification* work (Mihalcea and Csomai, 2007; Milne and Witten, 2008; Ratinov et al., 2011) generalized their ranker on the data generated from Wikipedia without considering the knowledge of the queried name, they also fall into the traditional entity linking framework and suffer from the distribution problem in the previous entity linking systems. Thus, we believe that our proposed lazy learning approach also can benefit these two tasks.

In WePS-3 [5], a task of *Online Reputation Management* was proposed (Amigo et al., 2010; Spina et al., 2011), which is the same with entity linking when KB only has one entry. Given a set of Twitter entries containing an ambiguous company name, and given the home page of the company, the task is to filter out Twitter entries that do not refer the company. Amigo et al. (2010) concluded that it was not viable to train separate system for each of the companies, as the system must immediately react to any imaginable company name. Thus, in this benchmark, the set of company names in the training and test corpora are different. However, the lazy learning approach proposed in this paper demonstrates that it is feasible to train separate system for each company, and the system can immediately react to any company name without manually labeling new corpora.

More generally, resolving ambiguous names in Web People Search (WePS) (Artiles et al., 2007) and Cross-document Coreference (Bagga and Baldwin, 1998) disambiguates names by clustering the articles according to the entity mentioned. This differs significantly from entity linking, which has a given entity list (i.e. the KB) to which we disambiguate the mentions.

3 Candidate Generation

Because the knowledge base usually contains millions of entries, it is time-consuming to apply the disambiguation algorithm to the entire knowledge base. Thus, the following pre-processing process is conducted to filter out irrelevant KB entries and select only a set of candidates that are potentially the correct match to the given query (a query consists of a name mention and its associated document text).

Because of name variation problem, it is ineffective to retrieve entity candidates by comparing the name strings of mention and KB entry. Thus, we need to use external world knowledge to build the name variation list for each KB entry. Since our experiment used a KB derived from Wikipedia, and

[5] http://nlp.uned.es/weps/

other KBs such as *KIM* and *OpenCyc* usually can be mapped to Wikipedia (Nguyen and Cao, 2008), we find the variations for the entries in KB by leveraging name variation sources in Wikipedia: *"titles of entity pages"*, *"disambiguation pages* [6]*"*, *"redirect pages* [7]*"* and *"anchor texts"*. Then, the candidates can be selected by comparing the name string of the mention with the name strings in the variation list of each KB entry. The KB entry with a name string which matches the name of the mention is considered as a candidate. In addition, as a pre-processing step, we prefer a candidate set with high recall. Thus, to increase the recall, we find more candidates by selecting the KB entry if its name string contains the name string of the mention (e.g. *"Cambridge, Massachusetts"* contains *"Cambridge"*).

4 Lazy Learning for Linking

We formalize the disambiguation task as follows. We are given a query q (i.e. a document d_q with a mention m_q) and its associated KB candidates C_q={c_1,..,c_N} generated in Section 3, and our goal is to select the correct KB entry e from the set C_q. Specifically, let $\phi_q(q,c_i)$ be a score function reflecting the likelihood that the candidate c_i is the correct KB entry for q. Then, a disambiguation model is to solve the following optimization problem:

$$e = \arg\max_{c_i \in C_q} \phi_q(q, c_i) \tag{1}$$

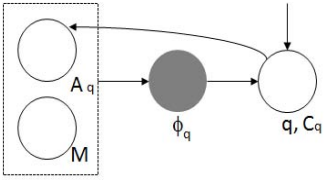

Figure 3: Lazy Learning Framework

In this section, we present our lazy learning model to solve this optimization problem. As shown in Figure 3, our process of the resolution is as follows:

1: Automatically label an instance set A_q based on the query q and candidates C_q.

2: Generalize a function ϕ_q on the data set A_q related with the queried name and a manually labeled data set M related with other names.

3: Select the correct KB entry e from the candidates using the function ϕ_q.

As shown in Figure 1, previous approaches generalize a universal linker ϕ for all of the queries on a labeled data set $\boldsymbol{M}$ related to irrelevant names (*"Hoffman"*, *"Chad Johnson"*, etc.), and they suffer from the distribution problem shown in Figure 2. In contrast, our lazy learning approach delays the model generalization until receiving the query. It can generalize a separate function ϕ_q for each query leveraging the distribution knowledge learned from the instances in A_q. As A_q is

[6] http://en.wikipedia.org/wiki/Wikipedia:Disambiguation
[7] http://en.wikipedia.org/wiki/Wikipedia:Redirect

automatically labeled for the queried name, it can be used to narrow down the gap of the instance distributions related to different names shown in Figure 2. Besides, ϕ_q also benefits from $\boldsymbol{M}$ in our model by mining its predictive information shared with A_q. Now, let us elaborate the method for generating A_q, and the generalization of ϕ_q, respectively.

4.1 Distribution Information A_q for Queried Name

In this section, we propose to obtain the distribution information for the queried name by automatically labeling some instances A_q for it. Following our work Zhang et al. (2010), which automatically generates training data for entity linking, we automatically label the instances related to the queried name based on its unambiguous synonyms.

Given a document d_q with a mention m_q and its associated KB candidates C_q, for example,

$\boldsymbol{d_q}$ *(*$\boldsymbol{m_q}$***="AZ")****: ...We know that they looked at a house that they might purchase before they left Scottsdale,* ***AZ****. ...*;

$\boldsymbol{C_q}$*: {*c_1*: state of Arizona,* c_2*: Azerbaijan, ...,* c_N*: Alitalia}*,

automatically creating the labeled set A_q for the name *"AZ"* requires automatically linking some mentions of *"AZ"* in text with the KB candidates in C_q. Our approach performs this linking based on two facts: (a) the title of the KB entry is unambiguous (e.g. *"state of Arizona"*). (b) The name variations of KB entry derived from *"redirect pages"* of Wikipedia in Section 3 are unambiguous (e.g. *"The Grand Canyon State"*). Then, we can generate the unambiguous name variation list for each candidate in C_q (see Table 1).

c_1	*state of Arizona; The Grand Canyon State; US-AZ; 48th State; AZ (U.S. state); The Copper State; Arizona, United States; ...*
c_2	*Azerbaijan; Azerbaidzhan; Republic of Azerbaijan; Azerbaijan Republic; Azerbaijani independence; Azerbaijan (Republic); ...*
...	
c_N	*Alitalia; Alitalia Airlines; Alitalia airways; Alitalia.it; Alitalia S.p.A.; ...*

Table 1: Unambiguous Variations for the Candidates of *"AZ"*

Because the unambiguous name only refers to one KB entry, we can link unambiguous name appearing in a document with the correct KB entry directly without human labor. Thus, we search the documents with these unambiguous name variations from a large document collection. Two examples of the retrieved documents are as below:

d_1 *(*m_1*="The Grand Canyon State"): ...* ***The Grand Canyon State*** *will get its shot to host the big game a year from now, ...*

d_2 *(*m_2*="Azerbaijan Republic"): ... It is located 30 km east of Ardebil and on the borderline with* ***Azerbaijan Republic****. ...*

We denote the labeled instance as a 4-tuple *(d,m,e,+1/-1)*, which means mention *m* in document *d* can/cannot be linked with KB entry *e*. Then, the two unambiguous examples above can be labeled as *(*d_1*,* m_1*,* c_1*, +1)* and *(*d_2*,* m_2*,* c_2*, +1)* automatically.

As we need to label the instances related to the name *"AZ"*, we further replace the unambiguous names in the documents with their ambiguous synonyms *"AZ"*. Then d_1 and d_2 are converted to:

d_1' *(m_q="AZ"): ...**AZ** will get its shot to host the big game a year from now, ...*

d_2' *(m_q="AZ"): ...It is located 30 km east of Ardebil and on the borderline with **AZ**. ...*

Finally, the labeled data set A_q for the queried name *"AZ"* is generated, where A_q=*{(d_1', m_q, c_1, +1),(d_1', m_q, c_2, -1), ...,(d_1', m_q, c_N, -1),(d_2', m_q, c_1, -1),(d_2', m_q, c_2, +1), ...,(d_2', m_q, c_N, -1) ...}*.

The data set A_q contains the query-specific information and such kind of information is not available in the training data M, such as the query-specific context features: words "*Airlines*" and "*State*" learned from A_q will be helpful for the disambiguation of "*AZ*"

4.2 Linear Function ϕ_q

In this section, we formulate the disambiguation function ϕ_q in Eq. 1 as follows,

$$\phi_q(q, c_i) = u^T \mathbf{X}_i \tag{2}$$

where the document d_q with a mention m_q and the candidate c_i in C_q are represented as a feature vector $\boldsymbol{X}_i \in \chi$, and u is a weight vector.

Estimate u on A_q. A popular method for finding u is *empirical risk minimization* with *least square regularization*. In this work, given a training set A_q=*{(d_i, m_q, e_i, Y_i)}*$_{i=1,...,n^{(q)}}$ ($Y \in$ *{+1,-1}*) related to the queried name m_q, firstly we transfer the instance *(d_i, m_q, e_i)* to the feature vector $\boldsymbol{X}_i^q$. Then, A_q=*{($\boldsymbol{X}_i^q$, Y_i^q)}*$_{i=1,...,n^{(q)}}$, ($\boldsymbol{X} \in \chi$, $Y \in$ *{+1,-1}*). Finally, we aim to find the weigh vector u that minimizes the empirical loss on the training data,

$$\hat{u} = \arg\min_u \left(\frac{1}{n^{(q)}} \sum_{i=1}^{n^{(q)}} L(u^T \mathbf{X}_i^q, Y_i^q) + \lambda \|u\|^2 \right) \tag{3}$$

where L is a loss function. We use a modification of the Huber's robust loss function: $L(p, y) = (max(0, 1 - py))^2$, if $py \geq$ *-1*; and *-4py* otherwise. We fix the regularization parameter λ to 10^{-4}.

Transfer *(q,c_i)* to Feature Vector $\boldsymbol{X}$. The features we adopted to construct $\boldsymbol{X}_i$ from *(q,c_i)* include 13 typical feature types used in *TAC* (Lehmann et al., 2010; Ji and Grishman, 2011), and the features are divided into four groups, contextual features (**CF**), semantic features (**SeF**), surface features (**SuF**) and generation source (**GS**) (see Table 2).

4.3 Incorporate M to u Estimation

A practical issue that arises in estimating u only on A_q is the paucity of labeled instances for some queries. This is because we automatically label the instances A_q leveraging its unambiguous synonyms (see Section 4.1). However, for some queried names, it is hard to find a sufficient number of unambiguous synonyms or the related documents containing these synonyms. On the other hand, the total number of available manually labeled instances M for other irrelevant names is relatively large. To illustrate the role of M in learning, consider the disambiguation of the two mentions "CPC" and "NY" in two documents. If the first mention "CPC" refers to entity "Communist Party

Name	Description
*Contextual Features (**CF**)*	
Bag of Words	The cosine similarity (tf.idf weighting) between query document and text of the candidate.
Similarity Rank	The inverted cosine similarity rank of the candidate in the candidate set.
Co-occurring NEs	Number of the same named entities appearing in query document and the text of the candidate.
*Semantic Features (**SeF**)*	
NE type	True if NE type (i.e. Person, GPE, Organization) of the query and the candidate is consistent.
Topic Similarity	Topic similarity between query document and text of candidate obtained by LDA (Blei et al., 2003)
*Surface Features (**SuF**)*	
Surface Match	True if the query matches the title of the candidate
Substring Match	True if the title of the candidate begins with the query (e.g. *"Beijing China"* and *"Beijing"*)
Acronym	True if the query is an acronym for the title of the candidate (e.g. *"NY"* and *"New York"*)
Word Match	Number of the same words between the title of the candidate and the query
Word Miss	Number of the different words between the title of the candidate and the query
Edit Distance	Levenshtein distance between name strings of the query and the candidate's title
*Generation Source (**GS**)*	
Wikipedia Source	True for each Wikipedia source (i.e. "entity pages", "disambiguation pages", "redirect pages" and "anchor texts" (Section 3)) which generates the candidate
String Match	For the candidate not generated from Wikipedia source, true if it is generated from full match.

Table 2: Feature Set for Disambiguation.

of China" and the second mention "NY" refers to entity "the city of New York", they have similar surface features (e.g. feature "acronym" is true), certain surface features effective for linking to "Communist Party of China" may be also effective for disambiguating "NY", and vice versa

However, with the gap in other aspects between the distributions of A_q and M shown in Section 1, directly adding M to our training set will produce a lot of noise with respect to the queried name. Thus, instead of using all the distribution knowledge in M, we propose to only incorporate the shared knowledge with A_q from M into u estimation based on *structural learning*.

The Structural Learning Algorithm. *Structural learning* (Ando and Zhang, 2005b) is a multi-task learning algorithm that takes advantage of the low-dimensional predictive structure shared by multiple related problems. Let us assume that we have K prediction problems indexed by $l \in \{1,..,K\}$, each with $n^{(l)}$ instances $(\mathbf{X}_i^l, \mathrm{Y}_i^l)$. Each $\boldsymbol{X}_i^l$ is a feature vector of dimension p. Let Θ be an orthonormal $h \times p$ (h is a parameter) matrix, that captures the predictive structure shared by all the

K problems. Then, we decompose the weight vector $\boldsymbol{u}_l$ for problem l into two parts: one part that models the distribution knowledge specific to each problem l and one part that models the common predictive structure,

$$\mathbf{u}_l = \mathbf{w}_l + \Theta^T \mathbf{v}_l \tag{4}$$

where $\mathbf{w}_l$ and $\mathbf{v}_l$ are weight vectors specific to each prediction problem l. Then, the parameters Θ, $\mathbf{w}_l$ and $\mathbf{v}_l$ can be learned by *joint empirical risk minimization*, i.e., by minimizing the joint empirical loss of the predictors for the K problems on the training instances as Eq. 5,

$$\underset{\Theta,\mathbf{w}_l,\mathbf{v}_l}{\arg\min} \sum_{l=1}^{K} \left(\frac{1}{n^{(l)}} \sum_{i=1}^{n^{(l)}} L\left(\left(w_l + \Theta^T v_l \right)^T \mathbf{X}_i^{(l)}, Y_i^{(l)} \right) + \lambda \|w_l\|^2 \right) \tag{5}$$

It shows that $\mathbf{w}_l$ and $\mathbf{v}_l$ are estimated on $n^{(l)}$ training instances of problem l. In contrast, Θ is estimated on all the training instances of the K problems. This is the key reason why structural learning is effective for learning the predictive structure shared by multiple prediction problems.

Alternating Structure Optimization. The Θ optimization problem in Eq. 5 can be approximately solved by the following alternating structure optimization procedure (Ando and Zhang, 2005a),

> 1: Learn K weight vectors u_l' for all the K problems on their corresponding instances independently using *empirical risk minimization* (similar with Eq. 3).
>
> 2: Let $U' = [u'_1, \ldots u'_K]$ be the $p \times K$ matrix formed from the K weight vectors.
>
> 3: Perform Singular Value Decomposition on U':$U' = V_1 D V_2^T$. The first h column vectors of V_1 are stored as rows of $\hat{\Theta}$

Structural Learning for Entity Linking: Incorporate *M* to *u* Estimation. As previous entity linking systems do not consider the information of the queried name, they usually use all the instances in M without any difference to train the linker. However, in data set M, some instances related with some particular names may share more predictive information with the queried name than other instances. Thus, in this work, we group the instances in M based on the "name", and then learn the shared information from the "name" group instead of individual instance. As shown in Figure 1, the data set M for entity linking usually has a certain number of names (e.g. *"Hoffman"*, *"Chad Johnson"*, etc.), each with some labeled instances. Then, we treat each "name" and its associated instances in M as a prediction problem of *structural learning*. Besides, the queried name (e.g. *"AZ"* in Figure 1) with auto-labeled instances A_q is our target prediction problem, which is the problem we are aiming to solve.

According to the applications of *structural learning* in other tasks, such as WSD (Ando, 2006), *structural learning* assumes that there exists a predictive structure shared by multiple related problems. In order to learn the predictive structure Θ shared by M and A_q, we need to (a) select relevant prediction problems (i.e. relevant names) from M. That is, they should share a certain predictive structure with the target problem; (b) select useful features from the feature set shown in Table 2. The relevant prediction problems may only has shared structure with target problem over certain features. In this paper, we use a set of experiments including feature split and data set M

partitioning to perform these two selection processes. This empirical method for selection will be elaborated in Section 6.3.

Let us assume that we have selected relevant names from data set M, which together with the queried name can be used as the K related prediction problems in *structural learning*. Applying *structural learning* to the K problems, we can obtain the shared structure $\hat{\Theta}$ by *alternating structure optimization*. Then, the weight vector $\boldsymbol{u}$ for the queried name in Eq. 2 can be approximately solved by the following procedure:

1: Learn $\hat{w}$ and $\hat{v}$ for the queried name by minimizing the empirical risk on data set A_q:

$$\arg\min_{w,v} \left(\frac{1}{n^{(q)}} \sum_{i=1}^{n^{(q)}} L\left((w + \hat{\Theta}^T v)\mathbf{X}_i^q, Y_i^q \right) + \lambda \|w\|^2 \right)$$

2: The estimated weight vector u for the queried name is:

$$\hat{u} = \hat{w} + \hat{\Theta}^T \hat{v}$$

The $\hat{\Theta}^T \hat{v}$ part is learned from the selected names in M and all the instances in A_q, and therefore it can model the shared predictive structure between M and A_q, and remove the noises in M as we expected. The $\hat{w}$ part is learned from the data set A_q, which can tackle the distribution problem (see Figure 2) in the previous work only using M.

5 Predicting NIL Mentions

So far we have assumed that each mention has a correct KB entry; however, when we run over a large corpus, a significant number of entities will not appear in the KB. In this situation, the document d_q with mention m_q should be linked to NIL. Traditional approaches usually need an additional classification step to resolve this problem (Zheng et al., 2010; Lehmann et al., 2010). In contrast, our approach seamlessly takes into account the NIL prediction problem. As we define $Y \in \{+1,-1\}$ to denote whether the pair of the mention and KB entry can be linked together, the median 0 can be assigned to $\phi_q(q,NIL)$. Then Eq. 1 is extended to:

$$e = \arg\max_{c_i \in C_q \cup NIL} \phi_q(q, c_i) \tag{6}$$

6 Experiments and Discussions

6.1 Experimental Setup

In our study, we use *TAC-10*[8] KB and document collection to evaluate our approach for entity linking. The KB is derived from Wikipedia, which contains 818,741 different entries and the document collection contains 1.7 million documents from newswire and blog text. Each KB entry consists of the Wikipedia Infobox [9] and the corresponding Wikipedia page text.

[8] http://nlp.cs.qc.cuny.edu/kbp/2010/

[9] http://en.wikipedia.org/wiki/Template:Infobox

The test set of *TAC-10* has 2,250 mentions across three named entity (**NE**) types: Person (**PER**), Geo-Political Entity (**GPE**) and Organization (**ORG**). The documents containing these mentions are from the document collection above. The training set of *TAC-10* consists of 5,404 mentions. Among them, 3,404 mentions are used as the data set M in our approach and the remaining 2,000 mentions are used as development set in our experiments.

We adopt micro-averaged accuracy officially used in *TAC-10* evaluation for our experiments, i.e. the number of correct links (including *NIL*) divided by the total number of the mentions.

6.2 Statistics of Data Set A_q

To minimize the distribution gap discussed in Section 1, we incorporate the distribution knowledge learned from A_q to the learning process. Thus, one of the key factors for the success of our lazy learning model is whether we can obtain A_q for the queries.

Therefore, firstly we investigate the amount of the labeled instances created for each query. When our model runs over the test data set, we find that 359 queries are assigned empty candidate sets (i.e. $C_q = \emptyset$) by the process described in Section 3. For these queries, we can directly link them with *NIL* without disambiguation. Thus, we only need to create A_q for the remaining 1,891 queries.

Figure 4 compares the proportions of the queries in different A_q size ranges. It shows that we have successfully created non-empty A_q for 96% of the 1,891 queries. This proves that our approach learning the distribution knowledge for the queried name from the automatically labeled instances A_q is feasible in practice. This also supports our assumption about the existence of the document with unambiguous synonyms in the document collection.

We also note that 49% of the queries have 10 to 99 labeled instances in A_q and 37% have 100 to 999 instances for each linker . In contrast, previous approaches usually trained their model on thousands of labeled instances. Thus, it suggests that we need more labeled instances for some queries and it is necessary to still leverage the manually labeled data set M in our learning process.

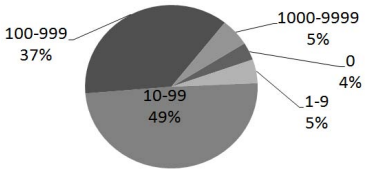

Figure 4: Proportions of the Queries Based on the Sizes of their Corresponding A_q

6.3 Exploring Θ Configuration

Because our lazy learning model generalizes on both the distribution knowledge learned from A_q and the predictive structure Θ shared by A_q and M, the effectiveness of such shared structure Θ is another key factor for the success of our lazy learning model. Thus, inspired by the work (Ando, 2006) for WSD, we design a set of experiments to investigate the configuration of Θ.

Consider the disambiguation of the two mentions *"CPC"* and *"NY"* in two documents again. They have similar surface features (e.g. feature *"acronym"* is true). The surface features effective for linking to *"Communist Party of China"* may be also effective for disambiguating *"NY"* to "the

city of New York", and vice versa. However, with respect to the semantic features, these two disambiguation problems may not have much in common. This is because *"Communist Party of China"* is likely related with the topic "politics", but *"the city of New York"* does not have such particular topic. That is, shared structure Θ between different names may depend on feature types, and in that case, seeking Θ for each of feature groups (*CF, SeF, SuF* and *GS* in Table 2) separately may be more effective. Hence, we experimented with both Θ configuration in Eq. 5 and Θ configuration, learning a Θ_j for each feature group j separately in Eq. 7.

$$\sum_{l=1}^{K}\left(\frac{1}{n^{(l)}}\sum_{i=1}^{n^{(l)}}L\left(w_l^T\mathbf{X}_i^{(l)}+\sum_{j\in F}v_l^{(j)\,T}\Theta_j\mathbf{X}_i^{(l,j)},Y_i^{(l)}\right)+\lambda\|w_l\|^2\right) \tag{7}$$

where F is a set of disjoint feature groups, and $\boldsymbol{X}^{(j)}$ (or $v^{(j)}$) is a portion of the feature vector $\boldsymbol{X}$ (or weight vector v) corresponding to feature group j, respectively.

The NE types of the instances in A_q and M are *PER, GPE* and *ORG*. Intuitively, the predictive structures of the names with the same NE type may be more similar than those of cross-NE-type names. Therefore, except for the feature split discussed above, we explore another two Θ configurations. One learns Θ from A_q and the whole M for each query. The other learns Θ from A_q and the subset of M, where the instances have the same NE type with the query.

Thus, we experimented on our development data set with the combinations of the two types of Θ configuration, i.e. configuration of feature split F and configuration for partitioning of data set M.

Figure 5 compares the performance using the various Θ configurations, and the results are in line with our expectation. *F={CF+SeF+SuF+GS}* treats the features of these four types as one group. It is equivalent to the Θ configuration without feature split in Eq. 5. Comparison of *F={CF, SeF, SuF, GS}* (learning Θ_j for these four feature groups separately by Eq. 7) and *F={CF+SeF+SuF+GS}* indicates that use of the feature split indeed improves disambiguation performance. We are also interested in whether all the feature groups are suitable for learning Θ_j. Thus, we further experimented with *F={SeF, SuF, GS}*, *F={CF, SuF, GS}*, *F={CF, SeF, GS}* and *F={CF, SeF, SuF}*. Figure 5 shows that these different subsets of feature groups do not improve the performance over using all the feature groups, and it proves that all the feature groups contribute to the learning of Θ. Besides, this figure also shows that learning Θ from A_q and the subset of M (i.e. instances have the same NE type with the query) usually performs better than learning it from A_q and the whole M. At last, as Θ has one parameter - its dimensionality h, the performance shown in this figure is the ceiling performance on the development set obtained at the best dimensionality (in {10, 50, 100,...}).

6.4 Evaluation Results for Lazy Learning

The experiments in this section evaluate our lazy learning model on the test data set of *TAC-10*. Our experiments used the best dimensionality $h = 150$ of Θ tuned on the development set in Section 6.3.

Table 3 shows the performances of three baseline methods and our approach with overall accuracy as well as accuracy on five subsets of the test set.

The second row (*M (Eq.3)*) used *empirical risk minimization* to estimate the weight vector u on the data set M (similar with Eq. 3). The third row (*M(SVM)*) used *SVM* classifier (Herbrich et al., 2000) to estimate the model on M. These two methods are similar with most of the previous work for disambiguation, because all of them disambiguate a mention of a name based on the distribution

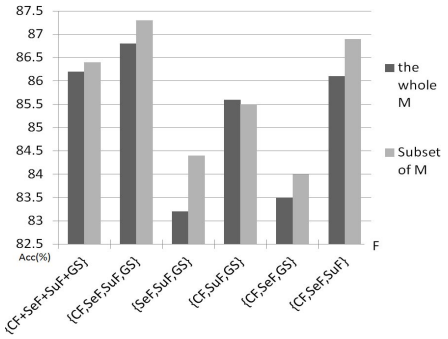

Figure 5: Accuracy on Development Set (As Θ has one parameter - its dimensionality h, the performance here is the ceiling performance obtained on the development set at the best dimensionality in {10, 50, 100,...})

knowledge learned from other labeled names. Row 5 (or 6) A_q+Θ *(or* Θ_j*)* shows the accuracy of our lazy learning model, which generalized the linker on both the distribution knowledge learned from A_q and the predictive structure Θ shared by A_q and M. Row 5 does not use feature split or data set M partitioning for learning Θ, but Row 6 uses them. Comparison of Row 6 and Row 2, 3 indicates our lazy learning model achieves significant improvements of 4.1% and 3.8%, respectively ($\rho < 0.05$, χ^2 statistical significance test). This significant improvement obtained by our approach is from solving the distribution problem (see Section 1) of previous methods.

Besides, Row 4 (M+A_q) used *empirical risk minimization* to estimate u on the data set M and A_q directly. Comparing it with our lazy learning model, the idea to learn the shared predictive information Θ achieves significant ($\rho < 0.05$) gain. This is because, rather than directly using M with a lot of noise, we only incorporate the useful information in M shared with A_q to our learning process.

	ALL	inKB	NIL	PER	ORG	GPE
M(Eq.3)	83.7	81.1	85.9	92.0	82.1	76.9
M(SVM)	84.0	78.5	88.6	92.1	84.0	76.0
M+A_q	84.5	81.4	87.1	92.7	82.7	78.1
A_q+Θ	86.6	84.5	88.3	94.8	85.2	79.7
A_q+Θ_j	**87.8**	85.5	90.0	96.1	86.3	80.9

Table 3: Micro-averaged Accuracy on Test Set

6.5 Comparison with State-of-the-Art Performance

We also compare our approach with the top systems in *TAC-10*. As shown in Figure 6, our lazy learning model achieves a 2% (or 5.9%) improvement over the best (or second best) system in *TAC-10*. The best system "lcc" used a state-of-the-art machine learning algorithm (i.e., logistic classifier) for disambiguation. However, same with other previous work, they only trained their model on data set M without considering the knowledge related to the queried name. Comparing it with our approach, it proves that our lazy learning model has effectively tackled the distribution

problem in the previous work and indeed improved the disambiguation systems. On the *TAC-11* data set, we obtain the similar result. We apply our method in this paper to our system in *TAC-11* (Zhang et al., 2011), which achieves 87.6% with a 1.3% improvement.

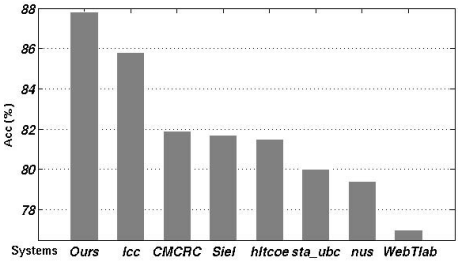

Figure 6: A Comparison with *TAC-10* Systems

6.6 Response Time

Our lazy learning delays the generalization on the labeled data until receiving the query. Hence, comparing with previous work, it increases the response time of the system for each query. However, many of the entity linking applications such as *knowledge base population* do not require real-time user interaction, and therefore they are time-insensitive applications. For those potential time-sensitive applications, we can calculate u_i' (i=1,...,K) in the optimization procedure of Eq. 5 before receiving the query and extract the features from the candidates in parallel. In our experiment, when using 8 *CPUs* (*1.86GHz*) for the multi-thread configuration and using Lemur/Indri[10] to index and search document for generating A_q, our approach can disambiguate the mentions in an article as fast as the baseline method (*M (Eq.3)*) using a single *CPU*.

7 Conclusions and Future Work

With the goal of achieving higher disambiguation performance, our focus was to solve the distribution problem in previous approaches. We have presented a lazy learning model, which can incorporate the distribution knowledge of the queried name to the learning process. To obtain this distribution knowledge, we proposed to automatically label relevant instances A_q for the queried name. Besides, instead of using or combining labeled data set M directly to train the linker, we proposed to use the predictive structure Θ shared by M and A_q. Our experiment showed that the best configuration of Θ was to use feature split over all the feature groups and use data set M partitioning according to NE type. Finally, our experiments also proved that previous approaches for entity linking can be significantly improved.

In the future, to further improve the disambiguation performance, we would like to explore more methods to learn the knowledge from M and A_q.

ABSTRACT
With the emergence of community-based question answering (cQA) services, question retrieval has become an integral part of information and knowledge acquisition. Though existing information retrieval (IR) technologies have been found to be successful for document retrieval, they are less effective for question retrieval due to the inherent characteristics of questions, which have shorter texts. One of the major common drawbacks for the term weighting-based question retrieval models is that they overlook the relations between term pairs when computing their weights. To tackle this problem, we propose a novel term weighting scheme by incorporating the dependency relation cues between term pairs. Given a question, we first construct a dependency graph and compute the relation strength between each term pairs. Next, based on the dependency relation scores, we refine the initial term weights estimated by conventional term weighting approaches. We demonstrate that the proposed term weighting scheme can be seamlessly integrated with popular question retrieval models. Comprehensive experiments well validate our proposed scheme and show that it achieves promising performance as compared to the state-of-the-art methods.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (CHINESE)

利用依存句法关系图改进问句检索中的词项赋权

随着社区型问答服务的出现，问句检索成为了信息及知识获取的重要途径。尽管已有的信息检索模型在文档检索方面取得成功，但是由于问句检索的短文本特性，使得已有检索模型很难适用于问句检索。对于已有的基于词项赋权的问句检索模型而言，一个主要的问题是在计算词项权重时忽略了词项之间的关系。为了解决这个问题，我们提出了一种新的利用词项间的依存句法关系作为线索的词项赋权机制。对于给定问句，我们首先构建依存关系图来计算每个词项对的关联强度，进而我们根据依存关联度来更新常规的词项权重。我们验证了所提出的词项赋权机制能够有效地整合到现有的问句检索模型中，且实验结果相比于当前最优问句检索模型有了较大提升。

1 Introduction

With the proliferation and growth of Web 2.0, cQA services, such as Yahoo! Answers[1], Quora[2] and WikiAnswer[3], have emerged as extremely popular alternatives to acquire information online. They permit information seekers to post their specific questions on any topic and obtain answers provided by other participants. Meanwhile, the blooming social networking technologies quickly link the questions to the experts with first hand experiences and propagate well-answered questions among public who also have similar or relevant questions. Over times, a tremendous number of high quality QA pairs devoted by human intelligence has been accumulated as comprehensive knowledge bases, which greatly facilitate general users to seek information by querying in natural languages (Park and Croft, 2010; Ming et al., 2010; Park et al., 2011). As cQA services contain large scale question and answer (Q&A) archives, they offer an invaluable information resource on the Web, to provide answers to new questions posed by the users (Jeon et al., 2005b).

However, question retrieval is not a trivial task (Wang et al., 2009) due to the following problems. First, compared to other indexed documents, the archived questions in current cQA forums are usually very short, which are hard to be matched by lexicon and statistics based approaches such as okapi BM25 (Robertson et al., 1994) model etc. Similar situation happens to twitter search which also deals with short text. It was pointed out in (Teevan et al., 2011; Kwak et al., 2010) that traditional IR technologies can not be directly applied to such applications. Second, the queries are frequently depicted in natural language form that often includes various sophisticated syntactic and semantic features; they can not be easily handled by the simple key word matching models employed by current dominant web search engines.

It is worth mentioning that there already exist several efforts dedicated to research on question match. For example, Xue et al. (Xue et al., 2008) have exploited the translation-based language model (TLM) for question retrieval in large QA database and achieved significant retrieval effectiveness. A syntactic tree kernel approach to tackling the similar question matching problem was proposed by Wang et al. (Wang et al., 2009). Cui et al. (Cui et al., 2005) have tried to measure term dependencies by using different dependency parsing relation paths between the same term pairs. However, they didn't consider how the dependency parsing relation path similarities between term pairs influence the term weights. Despite their success, literature regarding question retrieval is still relatively sparse. Most of the existing work overlook the term relations by assuming that the terms in questions are independent. However, term relations, which reflect the semantic closeness between term pairs, have potentially great impacts on term weighting tasks. Table 1 shows the searching result by TLM which is the state-of-the-art question retrieval model. Though both questions are relevant to the search query, one is ranked at the top, while the other is ranked at 31st. This example demonstrates that the ability to capture term relevance among different dependency parsing relation paths is a key problem in question retrieval.

In this paper, we propose a novel term weighting scheme by exploiting the dependency relations between term pairs, which assumes that strongly dependent terms should be assigned closer weights. Given a question, we first construct a dependency graph and compute the corresponding dependency relevance matrix. Next, based on the dependency relations, a general approach

Query	How do you **charge** a farad **capacitor**?	Rank
Correct Position	How do you **charge** a 1 farad **capacitor**?	1
Wrong Position	5 farad **capacitor** for my audio system.. how to **charge** / install?.	31

Table 1: An example of question retrieval result which shows the relevant questions in both correct and wrong ranking position.

is employed to recover the "true weights" from the initial "basic" ones estimated using the traditional methods, such as maximum-likelihood (Xue et al., 2008). Finally, we integrate our term weighting scheme with classic IR model and the state-of-the-art TLM for question retrieval.

The contributions of this work are two-fold:

- First, we propose a novel term weighting scheme that models the closeness in term weights between word pairs in a sentence based on its overall grammatical dependency graph. To the best of our knowledge, this is the first work that tries to enhance term weighting based on dependency relation.
- Second, we seamlessly integrate the novel dependency graph based term weights as an orthogonal factor into the state-of-the-art retrieval models, and produce promising results on real-world data.

The remainder of this paper is organized as follows. Section 2 introduces our term weighting scheme. Sections 3 and 4 present the improved question retrieval model and our experimental results, respectively. Related works are briefly reviewed in Section 5, followed by the conclusions and future work in the last Section.

2 Proposed Term Weighting Scheme

As a key component in question retrieval models, we will first introduce our proposed term weighting scheme based on dependency relation modeling, before we proceed to integrate the model into a unified question retrieval.

2.1 Dependency Relation Detection

As mentioned earlier, dependency relations in the grammatical sense may exist between term pairs and may have certain effects on quantifying term importance. To further study the dependency strength given a question, we first perform dependency parsing utilizing the popular Stanford parser tool (de Marneffe et al., 2006). An illustrating example of parsing result for the question "How do you charge a farad capacitor?" is shown in Figure 1(a). The labels in red font represent dependency relations between term pairs. We note that dependency relations only exist between two terms which are syntactic related. It is also observed that the result of dependency parsing for a sentence is usually represented as a tree. We next remove the pseudo root node from the generated tree and ignore the directions of arcs as well as the labels, we then obtain the undirected dependency graph $G = (V, E)$, for $V = w_1, w_2, ..., w_n$, $E = e_1, e_2, ..., e_m$. where w_i represents the term in query, and e_j represents the undirect relation between terms.

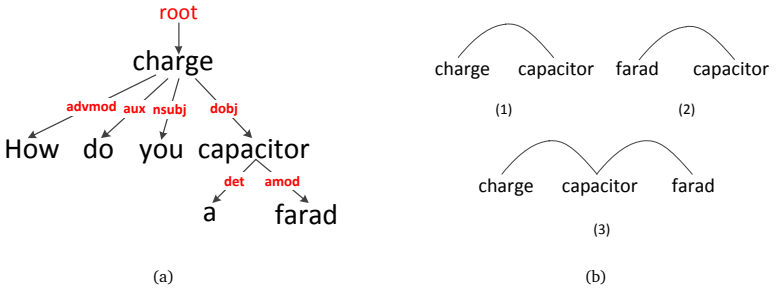

Figure 1: Illustration of the dependency relations for the question "How do you charge a farad capacitor?": (a) dependency parsing tree and (b) dependency relation path.

The undirected graph ensures that every term pair in a given question has a dependency relation path, with shorter paths reflect stronger relations. Figure 1(b) shows the representative length of the dependency relation paths from dependency relation graph. From Figure 1(b), it is obvious that the term "charge" is the direct neighbour of term "capacitor", hence, the dependency relation path length dr_path_len equals to 1 as shown in Figure 1(b) (1). However, "charge" is a bit farther away from the term "farad" as the dr_path_len between term "charge" and "farad" equals to 2 as shown in Figure 1(b) (3). This implies that "charge" should be weighted more closely with "capacitor" than with "farad".

2.2 Dependency based Closeness Estimation for Pairwise Terms

Several existing methods can be employed to compute the closeness between pairwise terms, such as pointwise mutual information (pmi), Chi and mutual information (Gao et al., 2004; Terra and Clarke, 2003). However, few of them take the syntactic dependency into consideration. Instead our approach estimates the dependency relevance of term pairs by linearly integrating multi-faceted cues, i.e., dependency relation path analysis as well as probabilistic analysis.

First, from the perspective of dependency relation path, we denote $dr\_path\_len(t_i, t_j)$ as the length of dependency relation path between term t_i and t_j. The dependency relevance can be defined as:

$$Dep(t_i, t_j) = \frac{1}{b^{dr\_path\_len(t_i,t_j)}} \quad (1)$$

where b is a constant larger than 1, which is selected based on a development set comprising 28 questions, which are randomly sampled from our querying collection. We tune b to the value that optimize the MAP. We name this metric as term dependency metric.

Second, we perform statistical analysis to capture the closeness of term pairs by pmi (Terra and Clarke, 2003) which directly capture the statistical relevance or independence between two terms, share many characteristics as mutual information. It can be formally formulated as:

$$Close_{pmi}(t_i, t_j) = \log \frac{p(t_i, t_j)}{p(t_i)p(t_j)} \quad (2)$$

where $p(t_i, t_j) = \frac{N_d(t_i,t_j)}{N_D}$ represents the probability of co-occurrence between terms t_i and t_j. $p(t_i) = \frac{N_d(t_i)}{N_D}$ and $p(t_j) = \frac{N_d(t_j)}{N_D}$ are respectively the probability of t_i and t_j occur in the whole data collection, where $N_d(t_i, t_j)$ represents the number of documents that contain both t_i and t_j. N_D represents the total number of documents. Meanwhile, $N_d(t_i)$ and $N_d(t_j)$ represent the number of documents that contain terms t_i and t_j respectively. This metric is referred to as term closeness metric.

Finally, we linearly combine the above two metrics by metric combination as:

$$w_{rel(i,j)} = \lambda Dep(t_i, t_j) + (1 - \lambda) Close_{pmi}(t_i, t_j) \tag{3}$$

where λ is a trade-off parameter.

2.3 Reallocation of Relation-based Term Weights

In the above section, we introduce the dependency relevance between two terms. Through capturing the strength of relevance, we expect to optimize the term weights. In this section, we will introduce the method which we use to reallocate term weights using dependency relevance.

First, for a given question q, we compute the dependency relevance among terms in q. If there are n terms in question q, we can construct a $n \times n$ matrix M, which we call the dependency relevance matrix. The element in M, m_{ij}, represents the dependency relevance between terms t_i and t_j computed using Equation 3. Note that as the dependency relevance graph is undirected, M is a symmetric matrix.

Second, we use orthogonal transformation to transform matrix M into a random matrix E so that we can ensure that there must be an analytical solution for the equations of which coefficient matrix equals E, where each elements in E is in range $[0, 1)$, and the sum of elements in the same row equals to 1. Hence, E has an eigenvalue that equals to 1. The solution vector of E exists and the vector with eigenvalue 1 corresponds to the solution vector. In addition, $E = D^{-1}M$, where D^{-1} is the orthogonal matrix which is used to transform the matrix M to E. Moreover, when matrix E and B are written as $E = D^{-\frac{1}{2}}BD^{\frac{1}{2}}$ and $B = D^{-\frac{1}{2}}MD^{-\frac{1}{2}}$, we can see that E is similar in structure with matrix B. Therefore, E and B will have the same eigenvalues. In fact, after solving the eigenvalues of matrix B, we get the eigenvalues of E.

Third, once we transform the dependency relevance matrix into a random matrix, we can obtain the analytical solution as term weights. However, we can also see that the analytical solution is not dependent on the initial term weight vector W_q^0. In our method, the initial term weight vector is estimated using the traditional IR models, such as VSM, BM25 and LM, and the translation-based language model (TLM) (Xue et al., 2008). Although, these models are term independent models, their term weighting schemes can also reflect the relevance between the query and documents. Hence, we linearly combine the initial term weight vector into our term weighting scheme and the analytical solution is the final optimized term weight vector W_q^*, which is derived as shown in Algorithm 1.

Term weight reassignment can be regarded as recovering the "true" weights from the initial one by using dependency relation information. The initial term weights provide a baseline for the "true" weights. Though noisy, they still reflect partial facts of the "true" weights and thus need to be preserved to some extent. Therefore, we introduce the trade-off parameter α. A small α means that the initial term weights play important role. When $\alpha = 0$, the new term weights will be the same as the initial weights.

Algorithm 1: The term weighting reallocation algorithm

Input: W_q^0, M
Output: W_q^*
Compute: $E = D^{-1}M$
Given: α
$W_q = \alpha E W_q + (1-\alpha)W_q^0$
Solution:
$W_q^* = (1-\alpha)(1-\alpha E)^{-1}W_q^0$

3 Unified Question Retrieval Model

To demonstrate that our term weighting scheme can be seamlessly integrated with the current popular question retrieval models without any underlying change, we first introduce the classic IR models and describe ways that our proposed term weighting scheme can be integrated.

3.1 Classic IR Models (VSM, BM25, LM)

The VSM model has been widely used in question retrieval. We consider a popular variation of this model, given query q, the ranking score S_{q,q^c} of the question q^c can be computed as follows:

$$S_{q,q^c} = \frac{\sum_{t \in q \bigcap q^c} w_{t,q} w_{t,q^c}}{\sqrt{\sum_t w_{t,q}^2}\sqrt{\sum_t w_{t,q^c}^2}}, \tag{4}$$
$$\text{where } w_{t,q} = \ln(1 + \frac{N}{f_t}), w_{t,q^c} = 1 + \ln(tf_{t,q^c}).$$

Here, given the query question q, S_{q,q^c} represents the ranking score of candidate question q^c. N is the number of questions in the collection, f_t is the number of questions that contain term t, and tf_{t,q^c} is the frequency of term t in q^c.

While the VSM model favors short questions, the BM25 model takes into account the question length to overcome this problem. Given a query q, the ranking score S_{q,q^c} of the question q^c can be computed as follows:

$$S_{q,q^c} = \sum_{t \in q \bigcap q^c} w_{t,q} w_{t,q^c}, \tag{5}$$
$$\text{where } w_{t,q} = \ln(\frac{N + f_t + 0.5}{f_t + 0.5}),$$
$$w_{t,q^c} = \frac{(k+1)tf_{t,q^c}}{k(1-\mathbb{b}) + \mathbb{b}\frac{W_{q^c}}{W_A} + tf_{t,q^c}}.$$

Here, k and $\mathbb{b}$ are two empirical parameters. W_{q^c} is the question length of q^c and W_A is the average question length in the whole question set.

The LM model is widely used in information retrieval, and also in question retrieval. The basic idea of the LM model is to estimate a language model for each question, and then rank questions by the likelihood of the query according to the estimated model for questions. Here, we use

Dirichlet smoothing for LM model. Given a query q, the ranking score S_{q,q^c} of the question q^c can be computed as follows:

$$\begin{aligned} S_{q,q^c} &= \prod_{t \in q} P(t|q^c) \\ &= \sum_{t \in q} P(t|M_q) \times \log P(t|M_{q^c}) \\ &= \sum_{t \in q \bigcap q^c} w_{t,q} w_{t,q^c}, \\ &\text{where } P(t|M_q) = tf_{t,q^c}, \\ P(t|M_{q^c}) &= \frac{|q^c|}{|q^c|+\delta} \times \frac{tf_{t,q^c}}{|q^c|} + \frac{\delta}{|q^c|+\delta} \times \frac{tf_{t,C}}{|C|} \end{aligned} \tag{6}$$

Here, C is the collection which contains about 20 millions question and answer pairs. $tf_{t,C}$ is the frequency of term t in C and δ is a smoothing parameter. Dirichlet smoothing is used in language model.

Integrating New Term Weights with Classic IR Models

From the aforementioned classic IR models, we find that they can be generalized to the following format:

$$S_{q,q^c} = \sum_{t \in q \bigcap q^c} w^0_{t,q} w_{t,q^c} \tag{7}$$

where t is term in question query q and $w^0_{t,q}$ represents the weight of term t in q. Note that language model can be transformed into the general form by logarithmic transformation. To replace the original term weights into dependency relevance term weight, we derive the updated form of IR models as follows:

$$S_{q,q^c} = \sum_{t \in q \bigcap q^c} w^{dr}_{t,q} w_{t,q^c} \tag{8}$$

where $w^{dr}_{t,q}$ is the updated weights explored by our proposed term weighting scheme.

3.2 Translation-based Language Model (TLM)

The TLM model, which is the state-of-the-art model in question retrieval, can be formally stated as:

$$p(q|q^c) = \prod_{w \in q} p(w|q^c) \tag{9}$$

where $p(w|q^c)$ is written as:

$$p(w|q^c) = \beta p_{ml}(w|q^c) + (1-\beta) \sum_{t \in q^c} p(w|t) p(t|q^c) \tag{10}$$

Here, given query question q, q^c indicates the candidate question for retrieval. $p(w|q^c)$ and $p(w|t)$ denote the language model and translation model, respectively; and β is the parameter to balance the two models.

Integrating New Term Weights with TLM

It is worth emphasizing that $p_{ml}(w|q^c)$ is the term weighting component in TLM. We further accomplish the unified question retrieval by simply replacing it with our term weighting scheme, and restate it as:

$$p(w|q^c) = \gamma p_{dr}(w|q^c) + (1-\gamma)\sum_{t \in q^c} p(w|t)p(t|q^c) \quad (11)$$

where dr indicates the dependency relevance.

4 Experiments

4.1 Experimental Settings

We collected a large real-world data set from Yahoo! Answers, that contains $1,123,034$ questions as our searching corpora, covering a wide range of topics, including health, internet, etc. From this dataset, we randomly selected 140 questions as our searching queries and 28 as the development set to tune all the involved parameters.

To obtain the relevance ground truth of each question query, we pool the top 20 results from various methods, such as vector space model, okapi BM25 model, language model and our proposed methods. We then asked two annotators, who are not involved in the design of the proposed methods, to independently annotate whether the candidate question is relevant (score 1) with the query question or not (score 0). When conflicts occur, a third annotator was involved in making the final decision.

For evaluation, we use precision at position n ($p@n$)($n = 1, 5, 10$), mean average precision (MAP) and mean reciprocal rank (MRR).

4.2 On Performance Comparison

We evaluate the effectiveness of our proposed term weighting scheme, with several question retrieval approaches.

First, we introduce several baselines, which includes three classic IR models, namely the Vector Space Model (VSM), okapi BM25 model (BM25) and Language model (LM).

- **VSM**: The Vector Space Model is used for question retrieval as baseline-1.
- **BM25**: The okapi BM25 model is used for question retrieval as baseline-2.
- **LM**: The language model based IR model is used for question retrieval as baseline-3.

The reason we use the classic IR models as baselines is that the classical IR models are easy to develop and tractable to operate. They capture the evidences from the whole corpus and perform well in tradition IR (Robertson et al., 1994) and cQA question and answer retrieval (Jeon et al., 2005b) tasks. The parameters in the above methods are tuned using development queries. The smoothing parameter δ of language model is set to 600; the k in BM25 model is set to 1.2 and $\mathbb{b}$ is set to 0.75 by following (Robertson et al., 1994).

Correspondingly, we derive three models which are integrated with our dependency relevance term weighting scheme, namely, **drVSM**, **drBM25** and **drLM**, respectively.

	p@1	p@5	p@10	MAP	MRR
VSM	0.1714	0.1691	0.1297	0.1980	0.1598
%chg	+18.4%	+18.2%	+17.5%	+4.5%	+16.9%
drVSM	**0.2029**	**0.1999***	**0.1523***	**0.2069***	**0.1868***
BM25	0.1857	0.1866	0.1418	0.2133	0.1716
%chg	+15.4%	+14.2%	+15.1%	+3.5%	+15.9%
drBM25	**0.2143**	**0.2131***	**0.1632***	**0.2208***	**0.1989***
LM	0.2071	0.2064	0.1603	0.2635	0.1929
%chg	+13.6%	+13.1%	+13.4%	+3.0%	+10.1%
drLM	**0.2353**	**0.2334***	**0.1818***	**0.2714***	**0.2124***

Table 2: Experiment results of classic IR models and the corresponding enhanced models that are integrated with the proposed dependency relevance term weights. $*$ indicates statistical significance over the respective baselines at 0.95 confidence interval using the t-test. %chg denotes the performance improvement in percent of dependency relevance based term weighting scheme enhanced model over the corresponding baseline.

Table 2 summarizes the experimental results in the five evaluation metrics using the three retrieval models and the three baselines. We can observe that the performances of all the three retrieval models are enhanced by dependency relevance-based term weighting scheme. Meanwhile, they obtain significant improvements over their baselines respectively. It indicates that, on the one hand, the proposed term weighting scheme is effective in question retrieval task. On the other hand, the proposed term weighting scheme provides orthogonal information about term weights when combined with the three classic IR models.

Through the experimental results, we can also see that the three classic IR models benefit differently from the dependency graph-based term weights. We conjecture the reason may be that, first, the LM has the collection smoothing scheme, so the original term weighting scheme is more rational than VSM and BM25. Second, the BM25 term weighting scheme considers question length feature so that it is unbiased in questions with different length, while the VSM favors short questions. Therefore, VSM benefits most from the term weighting scheme, followed by BM25 and LM.

Next, we introduce the state-of-the-art dependency relation-based question retrieval models as follow.

- **PRM**: Dependency relation-based passage retrieval model (PRM), which is proposed by Cui et al. (Cui et al., 2005) for question retrieval as baseline-4.

We use PRM[4] as baseline to check that whether our method is more effective than the previous dependency based IR model in question retrieval.

Next, we introduce the state-of-the-art question retrieval model TLM as another baseline, as we use two metrics to capture the term relevances, we introduce tcmTLM and tdmTLM to check the performances of each metric in question retrieval. Finally, we combine the above two metrics in

[4]We ran PRM under the setting of baseline-5 as described in (Cui et al., 2005)

form of Equation 3 and get the dependency relevance-based question retrieval model (**drTLM**). We describe the above four models as follows.

- **TLM**: Translation-based language model (TLM) which is proposed by Xue et al. (Xue et al., 2008), we implement it as baseline-5.
- **tcmTLM**: TLM integrated with our term weighting scheme where only term closeness metric is utilized to estimate the term relations.
- **tdmTLM**: TLM integrated with our term weighting scheme where only term dependency metric is utilized to estimate the term relations.
- **drTLM**: TLM integrated with our term weighting scheme where both term closeness metric and term dependency metric are combined to estimate the term relations.

For each method mentioned above, the involved parameters are carefully tuned, and the parameters with the best performances are used to report the final comparison results.

	p@1	p@5	p@10	MAP	MRR
PRM	0.2429	0.2397	0.1974	0.3595	0.2174
%chg	+14.1%	+10.6%	+7.4%	+16.0%	+18.8%
TLM	0.1928	0.1976	0.1759	0.2889	0.1889
%chg	+37.5%	+34.2%	+20.5%	+44.3%	+36.7%
tcmTLM	0.2084	0.2036	0.1903	0.3123	0.2145
%chg	+33.0%	+30.2%	+11.4%	+33.5%	+20.4%
tdmTLM	0.2675	0.2590	0.2086	0.4014	0.2495
%chg	+3.6%	+2.4%	+1.6%	+3.9%	+3.5%
drTLM	$\mathbf{0.2771}^{*}_{\dagger}$	$\mathbf{0.2651}^{*}_{\dagger}$	$\mathbf{0.2120}^{*}_{\dagger}$	$\mathbf{0.4170}^{*}_{\dagger}$	$\mathbf{0.2583}^{*}_{\dagger}$

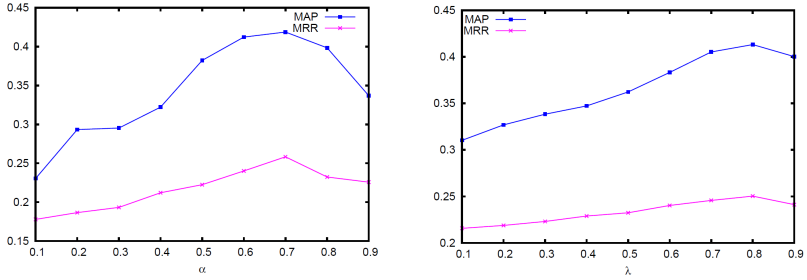
Table 3: Performance comparison among different question retrieval methods. $*$ and † indicate that the statistical significance over baseline and tcmTLM respectively is distributed within 0.95 confidence interval using the t-test. %chg denotes the boosted performance by **drTLM** in percentage. The results of our method are in bold font.

It can be observed that the performance of TLM can be enhanced by our term weighting scheme. This is due to the fact that our term weighting scheme captures the relations between term pairs and get better term weighting allocation. Compared with the existing dependency relation-based question answering passage retrieval model PRM, our method outperforms PRM in the above five evaluation methods. In particular, we only use dependency path length as a bridge to capture the relevance between two terms, which is a simple, stable and efficient way to use deep parsing, and get better performance. From this table, we can also observe that TLM integrated with tdm outperforms itself integrated with tcm. This is because tdm characterize more intrinsic dependency relations rather than the simple co-occurrences captured by tcm. Furthermore, the TLM incorporated with both tcm and tdm achieves the best performance. It worth noting that the performance of TLM is lower than that in the original paper, it is because that we use different data set and the answer evidence is not considered here.

4.3 On Parameter Sensitivity

In this section, we present how the parameters influence on question retrieval performance. In our experiments, grid search is performed to obtain the optimal values for parameters on the development set under the results of **drTLM** model.

As discussed before, smaller α in Algorithm 1 means initial term weighting scores dominate the term reassignment task, and ignore the dependency relations at all when α trends to zero. While a larger α means that our term weighting scheme will play a major role. The curve of MAP and MRR with different α value is presented in Figure 2(a) with other parameters fixed. We can see that the MAP and MRR increase with α growing and arrive at the peak when $\alpha = 0.7$ on our real dataset (development set); the performance then decrease sharply after that.



(a) (b)

Figure 2: The performance of **drTLM** with different α (a) and λ (b), when other parameters are fixed.

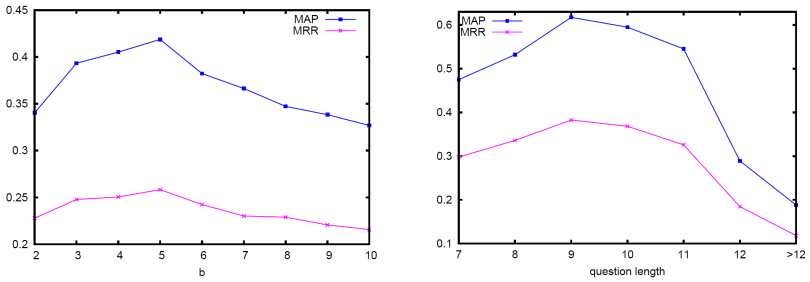
From Figure 2(a), we can infer that in our term weighting scheme, the improvement is mainly depended on term dependency relevance weighting scheme, meanwhile, the original term weights can somewhat influence the performance.

In our term weighting scheme, we introduce two relevance metrics between term pairs for term weighting reallocation as represents in Equation 3, the parameter λ is used to balance the two relevance metrics. Figure 2(b) shows the variation of MAP and MRR when λ is changing from 0.1 to 0.9.

From Figure 2(b), we can see that the MAP and MRR increase with λ growing and arrive at peak when $\lambda = 0.8$. It indicates that comparing with term closeness metric, the term dependency metric play the dominant role in the proposed term weighting scheme. Furthermore, it also illustrates that the term dependency relevance metric can effectively capture the strength of relations between two terms and influence the reallocation of term weights.

To further check the influence of parameter b in Equation 1 on the performance of question retrieval, Figure 3(a) presents the curve of MAP and MRR with different b value. From Figure 3(a), we can see that the performance arrive at the peak when $b = 5$.

In addition, we also consider the influence of question length, which indicates the number of words in one question, on the performance of question retrieval. Figure 3(b) shows the curve



(a) (b)

Figure 3: The performance of **drTLM** with different b (a) and question length (b), when other parameters are fixed.

of MAP and MRR with different question length. Through Figure 3(b), we actually check the ability of our proposed method on handling queries in different length as well as in different complexities. From Figure 3(b), we can see that the proposed method can adapt queries in wide range of length, which is from 7 to 11, and get well performance on question retrieval. Meanwhile, we also see that in question retrieval, neither shorter nor longer queries, can get better performance. It also reveals that natural language question queries can better represent users' searching intent than key words queries as they contain plentiful lexical information, as well they may introduce more noise. The parameter γ in Equation 11 equals 0.8, which also illustrates that in the dependency relevance-based TLM (**drTLM**) model, the proposed term weighting scheme contributes more in question retrieval. The improvement of searching results mainly depend on the reallocated term weights.

4.4 On Efficiency Analysis

For our proposed approach, we can see that the computational cost mainly comes from two parts: (1) question dependency parsing; (2) graph-based term weighting. Assume the question length is n, it can be analyzed that the computational cost scales as $O(n^3)$. In our data collection, n is averaged as 10.8, which leads to very low computational cost. In our experiments, we compare the time of process for each search round between the proposed **drTLM** model and PRM model which is also a dependency relation-based model that we use as baseline-5. The average search rounds that **drTLM** complete at one second is 14, while PRM is 17 (with a pc of 72G memory and Intel(R) Xeon(R) CPU E5620@2.40GHz). It means that the above two methods are comparable in efficiency. However, our proposed method doesn't need to training models, which leads to more efficient. Meanwhile, for further efficiency, we can also use iterative methods to get the numerical solution instead of analytical solution in graph-based term weighting.

4.5 Case Study

Table 4 representatively illustrates the top 5 search results for the query "How do you charge a farad capacitor?" by TLM and **drTLM** which is our dependency graph enhanced TLM. Clearly, our proposed model returns more relevant questions at top positions, mainly due to the adjusted weights for term "charge", "farad", and "capacitor".

Rank No.	TLM	**drTLM**
1	**How do you charge a 1 farad capacitor**?	**How to charge a farad capacitor**?
2	**How do you charge a 5 farad capacitor**?	**How do you charge a 1 farad capacitor**?
3	What resistor do you use to charge a 1 farad capacitor?	**How do you charge a 5 farad capacitor**?
4	How do you install a farad amp capacitor?	How do you install a 1 farad capacitor?
5	How do you hook up a 3 farad capacitor to two amps?	**5 farad capacitor for my audio system.. how to charge / install**?

Table 4: Search results comparison between TLM and **drTLM** for query "How do you charge a farad capacitor?".Questions in bold font are relevant ones.

5 Related Work

The existing IR technologies are frequently based on Bag-of-Words models and regard both the query and documents in collections as composition of individual and independent words. For example, Ponte et al. (Ponte and Croft, 1998) utilized unigram language model for information retrieval. Jones et al. (Jones et al., 2000) proposed the binary independent retrieval (BIR) model to capture the relevance between queries and documents. Duan et al. (Duan et al., 2008) proposed a new language model to capture the relation between question topic and focus. They may not be directly applicable in the question retrieval domain due to at least two reasons. First, compared to the simple keywords based search, the querying questions are usually represented in natural language and depict some concepts linked by intrinsic semantic relationships. Second, the to be searched documents are also questions, which are far shorter than the verbose documents in traditional search approaches.

Jeon et al. (Jeon et al., 2005a,b), moving forward one step, provided comparison of four different retrieval models, i.e., vector space model, okapi, language model and translation model for question retrieval in archived cQA data, experimental results revealed that the translation model outperforms the other models. Later, Xue et al. (Xue et al., 2008) combined the language model and translation model to a translation-based language model and observed better performance in question retrieval. Following that, Ming et al. (Ming et al., 2010) utilized three domain specific metrics to explore term weights and integrated them into existing IR models. However, most of these term weighting based retrieval models ignore the dependency relations between term pairs.

Researchers never stop to capture the term dependencies for IR models. For instance, (Song and Croft, 1999; Srikanth and Srihari, 2002) replaced the unigram to bigram and bi-term in language model. Gao et al. (Gao et al., 2004) proposed a dependency language model

to capture term dependencies through dependency parsing relations. Park et al. (Park and Croft, 2010) explore dependency features for term ranking in verbose query. Moreover, they proposed a quasi-synchronous IR model (Park et al., 2011) to integrate dependency information. Cui et al. (Cui et al., 2005) have tried to measure the terms dependencies by using different dependency parsing relation paths between same term pairs. Sun et al. (Sun et al., 2006, 2005) explored dependency relations for query expansion and answer extraction in question passage retrieval and answering retrieval. However, they only estimated term dependencies or syntactics between adjacent term and overlooked the nonadjacent cases. To tackle this issue, in this paper, we proposed a term weighting approach by incorporating global dependency relevance.

Conclusions

In this paper, we explored the dependency relations between question terms to enhance the question retrieval in cQA. Given a question, we first automatically constructed a dependency graph, and then estimated the relation strength between vertex pairs. Based on the quantified dependency relations, we proposed a novel term weighting scheme to refine the initial term weights estimated by traditional technologies. Further, we demonstrated that our term weighting approach can be unified with the state-of-the-art question retrieval models. By conducting experiments on real-world data, we demonstrated that our proposed scheme yields significant gains in retrieval effectiveness.

This work begins a new research direction for weighting question terms by incorporating dependency relation cues. In future work, we will further study the dependency relation based term weights by differentiating the importance of relation types and assigning relation-aware weights.

Long-tail Distributions and Unsupervised Learning of Morphology

Qiuye Zhao[1] *Mitch Marcus*[1]

Abstract

In previous work on unsupervised learning of morphology, the long-tail pattern in the rank-frequency distribution of words, as well as of morphological units, is usually considered as following Zipf's law (power-law). We argue that these long-tail distributions can also be considered as lognormal. Since we know the conjugate prior distribution for a lognormal likelihood, we propose to generate morphology data from lognormal distributions. When the performance is evaluated by a token-based criterion, giving more weights to the results of frequent words, the proposed model preforms significantly better than other models in discussion. Moreover, we capture the statistical properties of morphological units with a Bayesian approach, other than a rule-based approach as studied in (Chan, 2008) and (Zhao and Marcus, 2011). Given the multiplicative property of lognormal distributions, we can directly capture the long-tail distribution of word frequency, without the need of an additional generative process as studied in (Goldwater et al., 2006).

Keywords: Morphological Learning, Zipf's law, Lognormal distribution, Long tail distribution, Gibbs Sampling, Bayesian approach.

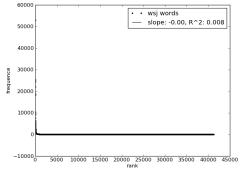
1 Introduction

Unsupervised learning of morphology is an active research area. In this work, we will focus on learning segmentations of words[1]. A segmentation of word w can be denoted as $w = t.f$, which means that concatenating stem t and suffix f gives word w.

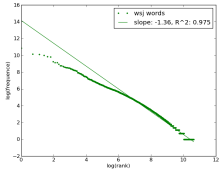
Assuming that stems and suffixes are independently distributed, a baseline generative morphology model is like this,

$$
\begin{aligned}
k^T, k^F &= \text{number of distinct stem types, number of distinct suffix types} \\
\alpha^T, \alpha^F &= \text{constant hyper-parameters} \\
\theta^T, \theta^F &\sim \text{Symmetric-Dirichlet}_{k^T}(\alpha^T), \text{Symmetric-Dirichlet}_{k^F}(\alpha^F) \\
t_{i=1...N}, f_{i=1...N} &\sim \text{Multinomial}(\theta^T), \text{Multinomial}(\theta^F) \\
w_{i=1...N} &\sim I(w = t.f)P(t|\theta^T)P(f|\theta^F)
\end{aligned}
$$

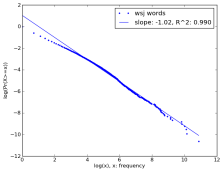
where N is the number of words and $I(w = t.f)$ is the indicator function taking on value 1 when concatenating stem t and suffix f gives word w and 0 otherwise.



(a) The rank-frequency plot of words.



(b) The log-log rank-frequency plot.



(c) The CCDF plot of words.

Figure 1: Observing long-tail distributions of word frequency in WSJ Penn Treebank.

In the above baseline model, there no special statistical property of word frequency is captured, nor of morphological units (e.g. stems or suffixes). As depicted in Figure 1-a, it is well-known that given a large corpus, a rank-frequency plot of words generally exhibits a long tail that is distinctively heavier than in normal (Gaussian) distributions. An alternative way to show this long-tail pattern is by plotting the corresponding Complementary Cumulative Distribution Function (CCDF) on logistic scales. As depicted in Figure 1-c, the CCDF plot behaves like a straight line and is smoother than the corresponding log-log rank-frequency plot in Figure 1-b, which also approaches a straight line for long-tail distributions. When words are segmented into stems and suffixes, distributions of these units can also be examined.

As we are going to show in Section 2.3, the rank-frequency distributions of morphological units also show up as straight lines in log-log rank-frequency plots and CCDF plots. In previous work on morphological learning, such as (Chan, 2008), (Zhao and Marcus, 2011) and (Goldwater et al., 2006, 2011), the straight lines on logistic scales are usually interpreted as following Zipf's law (Zipf, 1949). On the other hand, lognormal distributions with large variance also yield straight lines on both the log-log rank-frequency plot and the CCDF plot. In Section 2, we are going to discuss

[1] A segmentation model may not be well-defined for morphology, especially when morph-rich languages are considered; however, different forms of morphological analyses may be compared as simple segmentation analyses.

more about the long-tail distributions and argue that the signature straight lines may suggest either power-law or lognormal.

So as to take advantage of the special statistical property of morphological units, which is considered as following the Zipf's law in (Chan, 2008), Chan proposes a rule-based bootstrapping algorithm for morphology learning, which is revised in (Zhao and Marcus, 2011) for acquiring functional elements. Even though Zipf's law is discussed in both works, its specific definition does not really matter in the design of the algorithms. For the sake of comparison with other models, we implement a reduced version of the bootstrapping algorithm as described in (Zhao and Marcus, 2011), eliminating all ad-hoc linguistic assumptions encoded in the original algorithm. With this rule-based algorithm, the acquired segmentation model performs rather well when evaluated with the type-based criterion, but notably bad with the token-based evaluation, which gives more weights to the results of frequent words than the type-based evaluation. We will describe this algorithm in Section 3.1 with more details.

The rule-based bootstrapping algorithm utilizes type frequencies only, no matter what form of input is given. On the other hand, as shown in (Goldwater et al., 2006), when Dirichlet-multinomial model is assumed, the option of utilizing token frequency in generative model doesn't help, and in the contrast it hurts the inference of the generative model. Goldwater et al. (2006) argued that this morphology model doesn't capture the special statistical property of word frequency, therefore, an addition generative process is introduced to transform the word frequencies to exhibit the desired distribution. Since the long-tail pattern in word frequency is considered as following Zipf's law, a generalized Chinese restaurant process, Pitman-Yor process (Pitman and Yor, 1997), is exploited for producing power-law distributions. For the sake of comparison, we re-implement the morphology model in (Goldwater et al., 2006), and conduct more experiments with different configurations.

We propose to compute lognormal likelihood, instead of multinomial likelihood, for both stems and suffixes, in the generative morphology model. With this lognormal model, the option of utilizing token frequency, i.e. taking input of the unprocessed text data, dose help the inference of the generative model, especially when the token-based evaluation is preformed. When evaluated by the token-based criterion, which gives more weights to the results of frequent words, the proposed model performs significantly better than other models in discussion, no matter what form of input is fed to the multinomial model or the rule-based algorithm.

With the proposed model, the particular statistical properties of stems and suffixes are utilized in a Bayesian model instead of a rule-based model. Furthermore, as we will discuss in Section 2.3, given the multiplicative property of lognormal distributions, the word frequency distribution can also be predicted as lognormal. Therefore, we can directly capture the statistical property of word frequencies without the need of an additional generative process. Especially, the proposed generative model is more accurate with the token-based evaluation when utilizing token frequency, and more accurate with the type-based evaluation when utilizing type-frequency. This result pattern suggests that the proposed model is able to adapt to real data distribution by itself, therefore, we do not need to concern with justifying the appearance of type frequencies in morphology learning, as pursued in (Goldwater et al., 2006).

We are going to use Gibbs sampling, a standard Markov Chain Monte Carlo (MCMC) method for the inference of generative models. In each iteration, the morphological analysis of each word is sequentially re-sampled from its conditional posterior given morphological analyses of all other words. Since the sampling process is much more complex and time-consuming for the lognormal model than the multinomial model, we propose to constrain the learning of generative models with

the acquisition outputs of the rule-based model. Since the rule-based bootstrapping algorithm takes input of raw corpora only and so the generative models, the combination of these two processes results in a totally unsupervised learning process as well. Even though this method is motivated by the concern of training efficiency, the proposed use of acquisition outputs from a rule-based model also significantly improves the performance of generative models, consistently for both the lognormal and the multinomial model.

2 Long-tail distributions

2.1 The long-tail pattern

Given a large corpus, we can compute the word frequency of each word type by counting its occurrences in the corpus. When we plot word frequency against its rank, such as in Figure 1-a, there is a long tail of the curve composed of the large number of words that occur in low frequency. When plotted on a logistic scale, as in Figure 1-b, the rank-frequency plot behaves like a straight line. An equivalent form of the rank-frequency approach is to plot the corresponding Complementary Cumulative Distribution Function (CCDF). Instead of plotting a function of rank, we can also plot $P(F >= f)$ as a function of frequency f. As shown in Figure 1-c, the CCDF plot also behaves like a straight line on the logistic scale, which is smoother than the log-log rank-frequency plot.

We generally refer this kind of distributions as long-tail distributions, observing that a large portion of its population are composed of low-frequency events, which form a longer tail than normal (Gaussian) distributions. Long-tail patterns have been widely observed in various fields, but they may be studied as different distributions. For example, economists may be familiar with this pattern as Pareto distribution, which is also known as '80-20' rule. In Pareto's original study (Pareto, 1896), the long-tail pattern is shown on CCDF plots, so it took a while for people to understand that it is a power-law distribution and is synonymous with 'Zipf's law' (Newman, 2005). Zipf's law is proposed by linguist George Kingsley Zipf in his study of vocabulary distribution, and is widely used to interpret the straight lines on logistic scales in the study of language. In more recent works, the convention of treating long-tail patterns as power-law distributions has been challenged. For example, Downey (Downey, 2001) argues that many networks metrics, such as file sizes and transfer times, should be modeled as lognormal distributions. Lognormal distributions with large variance also yield straight lines on the log-log rank-frequency plot and the CCDF plot.

2.2 Generating Zipf's law and lognormal distributions

Based on the idea of preferential attachment, i.e. a 'richer-get-richer' process, if we generate new word occurrences more likely of popular word types than of rarely seen word types in previous process, then word frequency of the generated corpus may follow Zipf's law or be lognormal, depending on subtle differences in the generative processes.

More specifically, suppose that we are given i words for a start, $i \geq 1$. Let n_k^i denote the number of occurrences of all the words that occur exactly k times in the previous i words. Let $P(w_{i+1} = k)$ denote the probability that the $i + 1_{\text{th}}$ occurrence is a word that has already appeared k times in the previous i words. Consider the following process as described in (Simon, 1955),

$$P(w_{i+1} = k) = \alpha n_0 + F_i n_k^i,$$

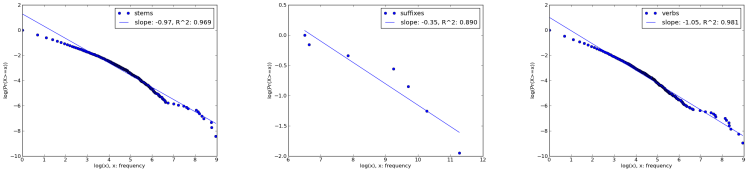
where n_0 and α are constants. If $F_i = \frac{(1-\alpha)}{i}$, then asymptotically, $P(w_i = k)$ will approach a power-law distribution. On the other hand, if the constant item is removed from the above process,

$$P(w_{i+1} = k) = F_i n_k^i,$$

and F_i are independent and identically distributed variables with finite mean and variance, then asymptotically, $P(w_i = k)$ will approach a lognormal distribution.

A even more naive generative model for Zipf's law is Miller's monkey (Miller, 1957), who can not only type with a keyboard, but also distinguish space bar from other keys. If Miller's monkey manages to hit the space bar with a constant probability and never hits the space bar twice subsequently, then the word frequency in the monkey's output follows a power law. One crucial assumption in Miller's demonstration is that all non-space letters are hit with equal probabilities. However, for the case that any two letters are hit with different probabilities, Perline (1996) argues that for all words of length up to a constant, their rank-frequency distribution converges to a lognormal distribution.

After reviewing a brief history of generative models for power-law and lognormal distributions, Mitzenmacher (2004) suggests that *"It might be reasonable to use which ever distribution makes it easier to obtain results."* [2]



(a) The CCDF plot of stems. (b) The CCDF plot of suffixes. (c) The CCDF plot of verbs.

Figure 2: Observing long-tail distributions for morphological units.

2.3 Lognormal distributions

One advantage of modeling long-tail patterns as lognormal is so that the multiplicative property holds, i.e. the product of independent lognormally-distributed random variables is itself lognormally distributed. For example, consider the baseline generative morphology model as described in the introduction, $P(w) = P(t)P(f)$. If both stems and suffixes are lognormally distributed, then word frequency is also lognormally distributed.

So as to examine the distributions of morphological units, with the help of the gold part-of-speech annotations, we segment all verbs into stems and suffixes in WSJ Penn Treebank (Marcus et al., 1993). As shown in Figure 2-a and b, the signature straight lines on CCDF plots suggest that both stems and suffixes of verbs can be modeled as lognormal. Then, given the multiplicative property of lognormal distributions, verbs should also be lognormally distributed, which is confirmed by its CCDF plot in Figure 2-c.

Another reason for one to consider modeling long-tail patterns as lognormal distributions is that we know the conjugate prior distribution for a lognormal likelihood, but not for power-law likelihood. Considering the generative model $P(w) = P(t)P(f)$, if we assume that t and f are lognormal, their mean μ and variance σ^2 can be drawn from Normal priors and Inverse-Gamma priors respectively.

[2] As also pointed out in (Mitzenmacher, 2004), if a power law distribution can have infinite mean and variance, then it is inaccurate to analyze it as lognormal. In present examples, we assume the exponent of power-law distributions is greater than 0, thus it is safe for us to experiment with either distribution.

3 A rule-based model

Given a set of stems $\mathbb{T}$ and a set of suffixes $\mathbb{F}$, we can divide a word w into stem t and suffix f, if $t \in \mathbb{T}$, $f \in \mathbb{F}$ and $w = t.f$. For example, if $\mathbb{T} = \{$*'laugh-'*, *'analyz-'*$\}$, and $\mathbb{F} = \{$*'-ed'*, *'-s'*$\}$, then *'analyzed'* can be segmented into *'analyz-'* and *'-ed'*, but *'red'* won't be segmented. So as to learn such a rule-based morphology model, we need to acquire a set of stems and a set of suffixes.

3.1 A bootstrapping algorithm for acquiring morph units

In this section, we are going to describe a bootstrapping algorithm, adapted from the algorithm for acquiring functional elements in (Zhao and Marcus, 2011). This line of algorithms is especially designed to account for the long-tail pattern observed for stems and suffixes, but not specific to either Zipf's law or lognormal distributions. As stated in (Chan, 2008), in which a bootstrapping algorithm is originally proposed for acquiring transformation-based morphological rules, *"what matters, though, is that the number of types per inflection decreases rapidly, ..., there are few highly frequent inflections, and many more infrequent ones."*

Following (Zhao and Marcus, 2011), our algorithm is built upon a distributional property of 'functional elements': they occur in diverse contexts. In the case of learning morphological segmentations, 'functional elements' are suffixes in context of stems. For example, an inflectional ending *'-ed'* can be concatenated to most verb stems to derive past tense forms, in contrast to which a non-sense suffix *'-roached'* can only be seen in few particular word types.

If all prefixes in all possible divisions of a word count as stems, then as computed from the WSJ corpus, the top three suffixes with the highest contextual diversity will be *'-s'*, *'-d'* and *'-e'*, two of which do not comply with common sense of morphological suffixes in English. In other words, for acquiring suffixes, we want to compute their contextual diversity according to properly justified stems only. The most simple way of justifying stems as proper contexts for suffixes is to check whether it serve as context of more than one type of suffixes. For example, stem *'laughin-'* should not be justified, because except for a particular suffix *'-g'*, it cannot be concatenated with other suffixes to form legal words.

Given a set of properly justified stems T, we measure the contextual diversity of a suffix f as

$$div(f, \mathbb{T}) = \sum_{t \in \mathbb{T}} \delta(t.f),$$

where $\delta(t.f)$ is set to 1 if $t.f$ forms any word, otherwise 0. For example, if we are given a set of properly justified stems, including *'laugh-'* but not *'b-'*, the diversity measurement of *'-ing'* will increase by one given the existence of word *'laughing'* but not word *'bing'*.

Algorithm 1 The bootstrapping algorithm for acquiring stems and suffixes

Require: A corpus $\mathbb{C}$ containing raw text only.
  Initialize set $\mathbb{F}_0$ to be empty and set $\mathbb{T}_0$ to contain all possible prefixes
  for $k = 1...K$ iterations **do**
    Let $\mathbb{F}_k$ contain the top k suffixes with the highest diversities measured by $div(f, \mathbb{T}_{k-1})$.
    Let $\mathbb{T}_k$ contain stems that form legal words with suffixes in $\mathbb{F}_k$
  end for
  return $\mathbb{F}_K$ and $\mathbb{T}_K$

We implement a reduced version of the bootstrapping algorithm in (Zhao and Marcus, 2011),

eliminating all ad-hoc linguistic assumptions encoded in the original algorithm. As depicted in Algorithm 1, the algorithm generates two sets of acquisition outputs during the bootstrapping process, both of which justify the proper set for measuring contextual diversity for each other. As the two sets alternately update during the bootstrapping process, the diversity measurement of either set is expected to be more and more accurate.

The only required input to this algorithm is a corpus $\mathbb{C}$ of raw text without any form of annotation. Set $\mathbb{F}_0$ is initialized to be empty and set $\mathbb{T}_0$ is initialized to contain all prefixes in all possible divisions of all words in corpus $\mathbb{C}$. At the k_{th} bootstrapping iteration, $k > 0$, we compute set $\mathbb{F}_k$ as the top k suffixes of the highest contextual diversity according to set $\mathbb{T}_{k-1}$. And set $\mathbb{T}_k$ contain stems that can form legal words with suffixes in $\mathbb{F}_k$. Since the diversity measurement of suffixes varies over iterations with respect to updated set of stems, a suffix that is selected to output at some iteration, is not guaranteed to be selected in the following iterations.

kth iter.	set $\mathbb{F}$	size of set $\mathbb{T}$
1th	*-s*	668
5th	*-ed, -ing, -s,* ***-e****, -es*	2274

Fix set $\mathbb{T}$ with all prefixes in all possible divistions of words.		
k=20	*-s,* ***-d****,* ***-e****, -ed,* ***-g****, -n,* ***-ng****, -y, -ing,* ***-t****,* ***-r****, -es, -er, -on,* ***-l****,* ***-rs****,* ***-a****, -ly, -ion,* ***-0***	7091

Table 1: The acquisition outputs by Algorithm 1 over WSJ Penn Treebank.

We run this bootstrapping algorithm for acquiring stems and suffixes from the WSJ corpus. For the sake of comparison, we also experiment without updating set $\mathbb{T}$ during the bootstrapping. With the unchanged set $\mathbb{T}$, which is initialized to contain all prefixes in all possible divisions of all words in corpus $\mathbb{C}$, the bootstrapping algorithm is degenerated to a simple counting function, which, for a given k, returns the top k frequent suffixes. So as to compare with other models more fairly, we didn't implement the mechanisms in the original algorithm for removing complex suffixes such as *-ers*, *-ings* and *-ors*, neither the trick for removing the most noisy suffix *-e*.

4 A generative model with multinomial likelihood

In this section, we are going to describe a generative morphology model that involves one more random variable than the baseline model we sketched in the introduction. In the baseline generative model, we assume without any condition that both stems and suffixes are independently and multinomially distributed. For the current model, stems and suffixes are independently and multinomially distributed in each inflectional class. A morphological analysis of word w can be denoted as (c, t, f), which means that $w = t.f$ and this analysis belongs to inflectional class c.

Assume a multinomial distribution over k^C inflectional classes, with parameters θ^C. To make predictions about new classes, we take symmetric Dirichlet priors α^Con parameters θ^C, which means that the way each inflectional class is used has little variation. When k^C is set as 1 in this model, it degenerates to the baseline generative model that assumes stems and suffixes are independently distributed. Again, let N be the number of words and $I(w = t.f)$ denote the indicator function taking on value 1 when concatenating stem t and suffix f gives word w and 0 otherwise.

Our generative morphology model is like this,

$$
\begin{aligned}
k^C &= \text{number of inflectional classes} \\
\alpha^C, \alpha^T, \alpha^F &= \text{constant hyper-parameters} \\
\theta^C &\sim \text{Symmetric-Dirichlet}(\alpha^C) \\
\theta^T_{i=1...k^C}, \theta^F_{i=1...k^C} &\sim \text{Symmetric-Dirichlet}(\alpha^T), \text{Symmetric-Dirichlet}(\alpha^F) \\
c_{i=1...N} &\sim \text{Multinomial}(\theta^C) \\
t_{i=1...N}, f_{i=1...N} &\sim \text{Multinomial}(\theta^T_{c_i}), \text{Multinomial}(\theta^F_{c_i}) \\
w_{i=1...N} &\sim I(w_i = t.f)P(c_i = c|\theta^C)P(t|c, \theta^T)P(f|c, \theta^F)
\end{aligned}
$$

This is the morphology model of choice in (Goldwater et al., 2011), following which we also use Gibbs sampler, a simple and widely-used Markov Chain Monte Carlo method, for inference. Assume the exchangeability of morphological analyses. The finite set of morphological analyses $\{a_1, ..., a_N\}$ is exchangeable, if for a permutation, π, of the integers from 1 to N,

$$P(a_1, ..., a_N) = P(a_{\pi(1)}, ..., a_{\pi(N)}).$$

At each iteration, from $\mathbf{a} = \{a_1, ..., a_N\}$, sample a'_1 given morphological analyses of all other words, i.e. $A_{-1} = \{a_2, ..., a_N\}$, then go to $\{a'_1, a'_2, ..., a_N\}$ and so on until $\{a'_1, a'_2, ..., a'_N\} = \mathbf{a}'$. It can be shown that this sampling process defines a Markov chain on $\mathbf{a}, \mathbf{a}', \mathbf{a}'', ...$ After a sufficient amount of time, the probability values are independent of the starting values and tend towards the stationary distribution $P(\mathbf{a})$. More about Gibbs sampling will be discussed in Section 5.2, where sampling processes for two generative models are compared.

Related work

The Dirichlet-multinomial model is not able to capture neither the particular statistical property of word frequencies, as studied in (Goldwater et al., 2006), nor the particular statistical property of morphological units, as studied in (Chan, 2008) and (Zhao and Marcus, 2011). As described in Section 3.1, a rule-based bootstrapping algorithm can be designed to take advantage of long-tail distributions of both stems and suffixes. However, as we will show with experimental results in Section 6, the rule-based model performs notably bad with the token-based evaluation, which gives more weights to the results of frequent words than the type-based evaluation.

In a two-stage learning framework proposed in (Goldwater et al., 2006), the morphology model as introduced above is used as a 'generator' for producing words. Word frequencies are then transformed to exhibit power-law by an additional generative process, called 'adaptor'. Especially, a two-parameter generalization of Chinese Restaurant Process (Pitman and Yor, 1997) is used as an adaptor. The Pitman-Yor process implements the principle of preferential attachment and guarantees the exchangability of its outputs. As we will also show in Section 6, the generator, i.e. the Dirichlet-multinomial model, learns reasonably well from the input of distinct word types, i.e. type-based input; however, the multinomial model itself cannot adapt to the input of unprocessed text data, i.e. the token-based input. Augmented with an adaptor, the generator may achieve its best performance with all forms of input; however, the introduction of such an adaptor does not improve the overall performance of the generator. In the following section, we will propose a generative model that learns well from both forms of input: type-based or token-based, without the need of an adaptor. The proposed model is able to utilize token frequency by itself, therefore, we do not need

to concern with justifying the appearance of type frequency in morphology learning, as pursued in (Goldwater et al., 2006).

5 A generative model with lognormal likelihood

We propose to compute lognormal likelihood, instead of multinomial likelihood, for both stems t and suffixes f. In this way, the particular statistical property of stems and suffixes is utilized in a Bayesian model other than a rule-based model. Furthermore, as we discussed in Section 2, given the multiplicative property of lognormal distributions, for each inflectional class, the generated word distribution is also lognormal. Therefore, with the proposed model, we can directly capture the statistical property of word frequencies without the need of an additional generative process.

5.1 The probability model

Again, assume that stems and suffixes are independent given inflectional classes. We still have a multinomial distribution over k^C classes, with parameters θ^C, and take symmetric Dirichlet priors α^C on θ^C. Now, in each inflectional class c, we assume a lognormal distribution of frequency for both stems and suffixes. It is equivalent to assume that the logarithms of stem/suffix frequency are normally distributed over the rank. For example, if the logarithms of stem frequency, $\mathfrak{L}(t)$, is normally distributed with mean μ^T and variance $(\sigma^T)^2$, then stem frequency t is lognormally distributed with mean e^{μ^T} and variance $(\sigma^T)^2$.

For a random variable X that is normally distributed, if both its mean μ and variance σ^2 are random, we will use the following distribution for priors, which can be shown to be conjugate to normal likelihood. Assume μ_0, γ_0, α, and β as the constant hyper-parameters, then we have

$$\begin{aligned}\sigma^2 &\sim \text{Inverse-Gamma}(\alpha, \beta)\\ \mu|\sigma^2 &\sim \text{Normal}(\mu_0, \gamma_0/\sigma^2)\\ x|\mu, \sigma^2 &\sim \text{Normal}(\mu, \sigma^2).\end{aligned}$$

In our case, we construct the probability distributions as follows:

$$\begin{aligned}\theta^C &\sim \text{Dirichlet}(\alpha^C)\\ c_{i=1\ldots N} &\sim \text{Multinomial}(\theta^C)\\ (\sigma^T_{i=1\ldots k^C})^2, (\sigma^F_{i=1\ldots k^C})^2 &\sim \text{Inverse-Gamma}(\alpha^T, \beta^T), \text{Inverse-Gamma}(\alpha^F, \beta^F)\\ \mu^T_{i=1\ldots k^C}, \mu^F_{i=1\ldots k^C} &\sim \text{Normal}(\mu^T_0, \gamma^T_0/(\sigma^T_i)^2), \text{Normal}(\mu^F_0, \gamma^F_0/(\sigma^F_i)^2)\\ t_{i=1\ldots N}, f_{i=1\ldots N} &\sim \text{Log-Normal}(e^{\mu^T_{c_i}}, (\sigma^T_{c_i})^2), \text{Log-Normal}(e^{\mu^F_{c_i}}, (\sigma^F_{c_i})^2)\\ w_{i=1\ldots N} &\sim I(w_i = t.f) P(t|c_i, \mu^T_{c_i}, (\sigma^T_{c_i})^2) P(f|c_i, \mu^F_{c_i}, (\sigma^F_{c_i})^2)\end{aligned}$$

where $\alpha^C, \mu^T_0, \gamma^T_0, \alpha^T, \beta^T, \mu^F_0, \gamma^F_0, \alpha^F$ and β^F are constant hyper-parameters .

5.2 Gibbs Sampling

As discussed in Sect 4, we use Gibbs sampler for the inference of generative models. At each iteration, we need to sample a morphological analysis for each word given the morphological analyses of all other words. For example, at initialization, each word receives a random analysis, then we proceed by sampling a morphological analysis a'_1 of the first word, w_1, given the random

Multinomial	$(c,t,f)\|w_i,\mathbf{A}_{-i} \sim I(w_i = t.f)\frac{\alpha^C+m_c}{k^C\alpha^C+N}\frac{\alpha^T+m_{c,t}}{k^T\alpha^T+m_c}\frac{\alpha^F+m_{c,f}}{k^F\alpha^F+m_c}$
Lognormal	$c\|\mathrm{A}_{-i} \sim \frac{\alpha^C+m_c}{k^C\alpha^C+m_c}$ $(\sigma_c^T)^2\|\mathrm{A}_{-i} \sim IG(\alpha^T+\frac{m_{c,t}}{2},\beta^T+\frac{\sum(\mathfrak{L}(t_i)-\overline{\mathfrak{L}(t)})^2}{2}+\frac{m_{c,t}\gamma_0^T(\overline{\mathfrak{L}(t)}-\mu_0^T)^2}{2(\gamma_0^T+m_{c,t})})$ $\mu_c^T\|(\sigma_c^T)^2,\mathrm{A}_{-i} \sim N(\frac{m_{c,t}\overline{\mathfrak{L}(t)}+\gamma_0^T\mu_0}{m_{c,t}+\gamma_0^T},\frac{\sigma_c^T}{m_{c,t}+\gamma_0^T})$ $(\sigma_c^F)^2\|\mathrm{A}_{-i} \sim IG(\alpha^F+\frac{m_{c,f}}{2},\beta^F+\frac{\sum(\mathfrak{L}(f_i)-\overline{\mathfrak{L}(f)})^2}{2}+\frac{m_{c,f}\gamma_0^F(\overline{\mathfrak{L}(f)}-\mu_0^F)^2}{2(\gamma_0^F+m_{c,f})})$ $\mu_c^F\|(\sigma_c^F)^2,\mathrm{A}_{-i} \sim N(\frac{m_{c,f}\overline{\mathfrak{L}(f)}+\gamma_0^F\mu_0}{m_{c,f}+\gamma_0^F},\frac{\sigma_c^F}{m_{c,f}+\gamma_0^F})$ $(t,f)\|w_i,\mathrm{A}_{-i} \sim I(w_i = t.f)\mathtt{lognormal}(e^{\mu_c^T},(\sigma_c^T)^2)\mathtt{lognormal}(e^{\mu_c^F},(\sigma_c^F)^2).$

Table 2: Sample a morphological analysis of the word w_i.

analyses of all other words, $A_{-1} = \{a_2, a_3, ..., a_N\}$. Then we sample a morphological analysis a_2' of word w_2, given $A_{-2} = \{a_1', a_3, ..., a_N\}$, and so on until it stabilizes.

For the multinomial model, we sample (c,t,f) together, with the following posterior conditional probability, $P((c,t,f)|w_i,A_{-i}) \propto I(w_i = t.f)P(c_i = c|\theta^C,A_{-i})P(t|c,\theta^T,A_{-i})P(f|c,\theta^F,A_{-i})$. Take the second term of the above equation as an example. As a result of our choice of conjugate priors, the posterior distribution, $P(t|c,\theta^T,A_{-i})$, is also multinomial but with a different parameter $\alpha' \sim \text{Dirichlet}(\alpha^F + m_{c,f})$, where $m_{c,f}$ is the number of analyses that contain both inflectional class c and suffix f. Therefore, the second term can be reduced to a form with θ^T integrated out, $P(t_i = t|\mathbf{A}_{-i},c) = \frac{\alpha^T+m_{c,t}}{\alpha_+^T+m_c}$. Similarly reductions can be done to other terms as well and putting together the results, we obtain the conditional probability for sampling (c,t,f) given the current word and morphological analyses of all other words, which is shown at the first row of Table 5.2.

For the lognormal model, we sample the inflection class c first, from the posterior distribution as discussed above. Then we sample (t,f) from its posterior distribution given the sampled c and morphological analyses of all other words. Again, given our choice of conjugate priors, the posterior distributions of stem t and suffix f are still lognormal with updated mean and variance. For the lognormal model, so as to update these parameters, we need to alternatively sample variance and mean from their own posterior distributions respectively. In practice, the updated mean and variance are sampled regarding the normal distribution of stem/suffix frequency's logarithms, $\mathfrak{L}(t/f)$. The specific sampling process is depicted in the second row of Table 5.2, for a comparison with the multinomial model[3]. We won't go into details of computing the updated parameters for sampling new mean and variance[4], but it is worth noticing that the data samples are logarithms of frequencies.

The sampling of lognormal distributions is obviously much more complex and time-consuming than multinomial distributions. We are motivated to constrain the learning of generative models

[3] Table 5.2 is constructed based on one of our reviewers' suggestion.
[4] A detailed discussion can be seen in (Jordan, 2010)

with the acquisition outputs from the rule-based model, which runs very fast by itself. As we will show by experimental results in Section 6, the constrained learning is not only much faster but also significantly improves the performance.

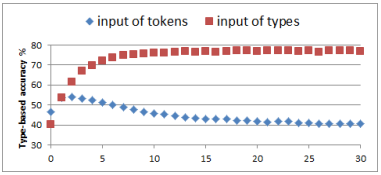
6 Experiments

In this section, we run experiments on unsupervised learning of morphology and compare the approaches we describe in Section 3, 4 and 5. Following (Goldwater et al., 2011), we will learn morphological segmentations for verbs in the WSJ corpus with the input of raw text only. Given the Penn Treebank guidelines, we consider words associated with tags of 'VB', 'VBP', 'VBZ', 'VBD', 'VBN' or 'VBG' as verbs. Using the gold part-of-speech annotations, we extracted 137,899 verbs from the whole WSJ corpus which belong to 7,728 distinct word types. With heuristics based on part-of-speech tags and spellings, we automatically segment each verb into a stem, which cannot be empty, and a suffix, which may be empty, and use these segmentations as gold standards for evaluation.

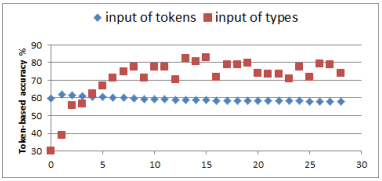
Given the gold analysis of each word, the accuracy of a morphology model can be evaluated in two ways. For a type-based evaluation, we compute the accuracy as the percentage of correctly analyzed word types out of all distinct word types that are ever seen in the corpus. For a token-based evaluation, we compute the accuracy as the percentage of correctly analyzed tokens out of all occurrences of words in the whole corpus. In most previous work on unsupervised learning of morphology, only the type-based evaluation is reported. However, we agree with Goldwater et al. (2006) that the token-based evaluation gives more weights to the results of frequent words, thus reflects better the performance of each approach as applied to real text data.

Different forms of input

In formal study of morphology, the acquisition input is usually taken as the list of distinct word types. For example, as shown in Section 3.1, the bootstrapping algorithm measures contextual diversity with type frequency only. On the other hand, natural text data typically use most types of words more than once. Furthermore, when a model is trained with the input of distinct types only, each word occurrence of the same type will always receive the same analysis by the model. However, if a model is trained with real text data, then with a generative model, a word may receive different analyses on different occurrences.



(a) Type-based evaluation.

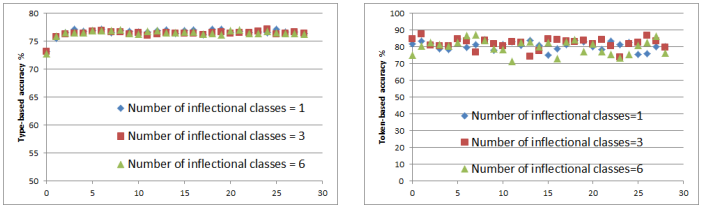


(b) Token-based evaluation.

Figure 3: Experiment with different forms of input.

First, we replicate the experiments in (Goldwater et al., 2006). The morphology model is multinomial as discussed in Section 4. As shown in Figure 3, the multinomial model learns well with the input of distinct word types, but poorly with the token-based input.

Inflectional classes



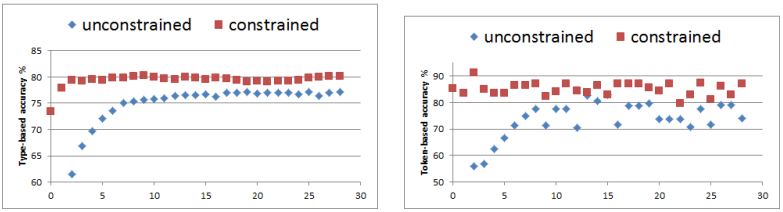
(a) Type-based evaluation. (b) Token-based evaluation.

Figure 4: Experiment with different numbers of inflectional classes.

In the above experiment, the number of inflectional classes is set as 6 following (Goldwater et al., 2006). However, this choice of the number of inflectional classes is rather arbitrary. Therefore, we experiment with different settings of this parameter. As shown in Figure 4, different choices of inflectional classes do not make significant differences in training results.

Constrained Learning

As we described in Section 5, the sampling of the lognormal model is much more complex and time-consuming than the sampling of the multinomial model. Motivated by the concern of training efficiency, we propose to constrain the learning of generative models with the acquisition outputs from the rule-based model that we described in Section 3.1. Since the rule-based model takes input of raw text only and so the generative models, the combination of these two processes results in a totally unsupervised learning process as well. More specifically, suppose that we have acquired a set of suffixes containing *-es* and *-s* only. With constrained learning, the only possible segmentations we need to consider for word *porches* are *porch+es*, *porche+s*, and *porches+""*, instead of all the 7 possible segmentations of this 7-character word. In practice, we constrain the learning of generative models with 20 suffixes acquired by the bootstrapping algorithm.



(a) Type-based evaluation. (b) Token-based evaluation.

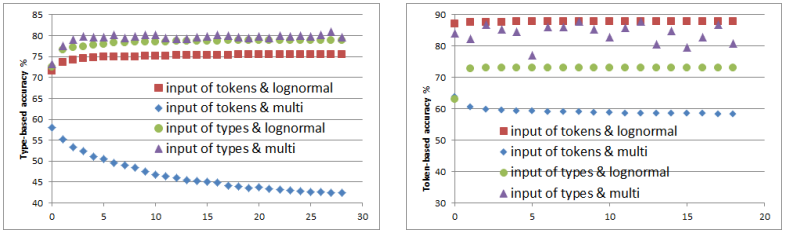
Figure 5: Experiment with constrained learning of multinomial models.

As shown in Figure 5, the constrained learning converges much faster than its unconstrained counterpart. Since the bootstrapping algorithm is very fast by itself, taking almost no time compared to the training of generative models, the total training time is saved a lot. Moreover, even though

this method is motivated by the concern of training efficiency, it also significantly improves the performance. As clearly shown in Figure 5, the constrained learning achieves notably higher performance by both the type-based and token-based evaluations.

The generative model with lognormal likelihood

As discussed in Section 5, by replacing the multinomial likelihood with lognormal likelihood, we can take advantage of the particular statistical property of morphological units with a Bayesian approach; moreover, we can capture the statistical property of word frequency without the need of an additional generating process. We experiment with the lognormal model over different forms of input, and evaluate it by different criteria. Based on the above experimental results, in this experiment, we set the number of inflectional class as 1, and apply the constrained learning with 20 suffixes acquired by the bootstrapping algorithm.



(a) Type-based evaluation.

(b) Token-based evaluation.

Figure 6: Experiment with generative models of multinomial or lognormal distributoins.

Overall, the proposed model performs significantly better than the multinomial model, especially when trained with unprocessed text data. As shown in Figure 6-a, when they are both given the input of distinct types, the results of the lognormal and multinomial models are not distinguishable by the type-based evaluation. However, in contrast to the multinomial model, the lognormal model is able to learn from unprocessed text data as well. As shown in Figure 6-b, by the token-based evaluation, the proposed lognormal model achieves its best performance with the input of text data, which is much more accurate than the best of the multinomial model. It is interesting to observe that the proposed lognormal model is more accurate with the token-based evaluation when trained with token-based learning, but more accurate with the type-based evaluation when trained with type-based learning. This result pattern suggests that the proposed model is able to adapt to real data distributions by itself, without the need of an additional generative process.

Compare all three models

We have shown the acquisition outputs of the bootstrapping algorithm in Table 1, upon which we can build a rule-based segmentation model. In contrast to the learning progress of generative models, which will converge to a relatively steady state, we stop the acquisition process after 20 bootstrapping iterations following previous experiments. Furthermore, so as to compare the generative models with the rule-based model, for each generative model, we compute the average accuracy of its last 5 training iterations.

	input form	type-based evaluation	token-based evaluatoin
bootstrapping	either	**83.59**%	64.04%
multinomial	type-based	79.98%	81.06%
lognormal	type-based	78.85%	73.10%
multinomial	token-based	42.36%	58.06%
lognormal	token-based	75.46%	**87.79**%

Table 3: Compare all three models with different forms of input.

As shown in Table 3, the rule-based model achieves a type-based accuracy as high as 83.59%, significantly higher than any other generative model. However, by the token-based evaluation, the rule-based model performs rather bad. The highest token-based accuracy, 87.79%, is achieved by the lognormal generative model. No matter what form of input is fed to the multinomial model, this level of token-based accuracy cannot be achieved.

7 Conclusion and future work

In previous work on unsupervised learning of morphology, the long-tail pattern observed for the rank-frequency distribution of words, as well as of morphological units, is usually considered as following Zipf's law (power-law). We argue that the signature straight lines on logistic scales may suggest either power-law or lognormal. We have also discussed that both based on the idea of preferential attachment, the generative processes for generating Zipf's law and lognormal distributions have only subtle differences. The advantage of considering the long-tail distributions of morphological units as lognormal is so that we can utilize the statistical property in a Bayesian model. Moreover, given the multiplicative property of lognormal distributions, we can directly capture the long-tail distribution of word frequency without the need of an adaptor.

The experimental results show that the proposed model performs significantly better than other models in discussion, especially when it is evaluated by a token-based criterion that respects more of the real distribution of text data. Moreover, the proposed model can not only learn from the list of distinct word types, which can be handled by other models as well, but also from the unprocessed text data, which cannot be handled by other models. Especially, the proposed generative model is more accurate with the token-based evaluation when trained by token-based learning, and more accurate with the type-based evaluation when trained by type-based learning. This result pattern suggests that the proposed model is able to adapt to real data distribution by itself.

In this work, our primary goal is to provide an alternative perspective on modeling the long-tail distributions for morphology learning, rather than to develop a state-of-the-art morphology learning system. We are aware of recent work on morphology learning that utilize more extra information and achieve good results on more data. Extra information that has been shown to be useful for morphology model includes syntactic context (Lee et al., 2011), document boundaries (Moon et al., 2009) and so on. The proposed model has a potential to be developed as a more complex learning system, thus, in future work, we plan to extend our model to integrate these extra information and compare with more benchmark systems.

ABSTRACT
Search log sessions contain a large number of paraphrases contributed by users during query rewriting. However, it is a big challenge to distinguish paraphrases from the simply related queries in the sessions. This paper addresses this problem by making innovative use of user behavior information embodied in query sessions. Specifically, we learn paraphrase patterns from the search log sessions with a classification framework, in which three types of user behavior features are exploited besides the conventional features. We evaluate the method using a query log of a commercial search engine. Experimental results demonstrate the effectiveness of our method, especially the significant contribution of the user behavior features. We extract over 250,000 pairs of paraphrase patterns from the used search log, with a precision over 76%.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (CHINESE)

基于用户行为特征从搜索会话中挖掘复述查询模板

搜索引擎用户在搜索时经常会对查询进行同义改写，以获得更好的搜索结果，因此搜索日志的查询会话中包含大量的复述资源。然而一个困难的问题是如何区分查询会话中哪些查询是复述关系，哪些则仅仅是语义相关而已。本文通过更好地利用查询会话中隐含的用户行为特征来解决这一问题。具体地，我们基于分类的方法从查询会话资源中挖掘复述查询模板。在分类模型中，我们不仅使用了传统的复述识别特征，还尝试了三种用户行为特征。我们使用一个商业搜索引擎的用户搜索日志来评估本文提出的方法。评估结果证明了本文方法的有效性，尤其是用户行为特征起到的明显作用。我们从所使用的用户日志中共抽取出了超过250,000对的复述模板，其准确率超过76%。

1 Introduction

Paraphrases have been shown to be useful in plenty of areas, such as machine translation (MT) (Callison-Burch et al., 2006; Madnani et al., 2007; Marton et al., 2009), question answering (QA) (Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Duboue and Chu-Carroll, 2006; Riezler et al., 2007), and web search (Zukerman and Raskutti, 2002). In particular, the capability of paraphrasing is essential in web search, since in many cases the user queries need to be paraphrased so as to improve the quality of the search results.

This paper focuses on learning paraphrase query patterns from search log sessions, which could be useful in various applications, especially in query paraphrasing. Although search log sessions have been extensively exploited for mining related queries, this is the first work, as far as we know, to learn paraphrases from this data source. Mining paraphrase query patterns and related queries are both useful for search engines, but in different aspects. On the one hand, related queries can be used for query suggestion and recommendation, using which the users can extend their search interest and get some related information. However, the related queries are not suitable for direct query rewriting with the purpose of retrieving more and better results exactly reflecting the user's requirement, since the related queries often have different meanings from the original user query. On the other hand, the paraphrase query patterns are mined for query paraphrasing, which is to directly rewrite user queries during search. This is useful especially in the cases where the original user queries contain some uncommon words that need to be rewritten into more common expressions with the same meaning. The following examples show the difference between them:

Related queries:
q_1: 凯文 杜兰特 的 身高 是 多少 *(what is the height of Kevin Durant)*
q_2: 凯文 杜兰特 的 体重 是 多少 *(what is the weight of Kevin Durant)*
Paraphrase queries:
q_1: 凯文 杜兰特 的 身高 是 多少 *(what is the height of Kevin Durant)*
q_2: 凯文 杜兰特 的 真实 身高 *(true height of Kevin Durant)*

In a nutshell, our method involves two steps. In the first step, we induce candidate pattern pairs from query pairs co-occurring within the same query sessions, while in the second step, we recognize paraphrase patterns from the candidates using a classifier. We investigate comprehensive features in paraphrase recognition, including not only conventional features based on string similarities, but also novel features based on user behaviors. In detail, we design three types of user behavior features, namely, (1) the frequency based features for measuring the co-occurrence frequency between two patterns within sessions, (2) the lexical score features for estimating the lexical level paraphrasing likelihood, and (3) the distance based features for measuring the separation distance between queries in sessions.

We conduct experiments using a Chinese query log from Baidu[1], a commercial search engine. The results show that the classification based approach is effective in paraphrase recognition. Particularly, the user behavior features can significantly enhance the classification performance. More than 250,000 pairs of paraphrase patterns are learned from the used search log with a precision over 76%, which suggests that the search log sessions are rich in high-quality paraphrases. Furthermore, we find that our method is complementary to a previous method learning paraphrases from query-click pairs of query logs, which inspires us to integrate them in our future research.

[1] www.baidu.com

In what follows, we first review related studies in Section 2. We then introduce the pattern pair induction method in Section 3. The paraphrase pattern recognition method is proposed in Section 4, in which the user behavior features are described in detail. We present the experiment results in Section 5 and conclude the paper in Section 6.

2 Related Work

2.1 Paraphrase Learning

Plenty of methods have been proposed to extract paraphrases from various data sources. In (Barzilay and McKeown, 2001), the authors viewed multiple translation versions of the same literary works as monolingual parallel corpora and extracted paraphrases with a co-training algorithm. In (Barzilay and Lee, 2003; Dolan et al., 2004), researchers collected comparable news articles reporting on the same event, and further extracted parallel sentences for learning paraphrase phrases and patterns. There are also studies focusing on extracting paraphrases from large-scale monolingual corpora based on distributional hypothesis (Lin and Pantel, 2001; Bhagat and Ravichandran, 2008). The basic idea is that phrases or patterns appearing in similar contexts tend to have the same meaning.

Besides monolingual corpora, bilingual corpora have also been exploited for paraphrase extraction. Bannard and Callison-Burch (2005) first presented the method to learn paraphrase phrases from a bilingual phrase table. The key idea is that phrases aligned with the same foreign phrase could be paraphrases. Callison-Burch (2008) then improved the method by imposing syntax constraints to filter paraphrases with different syntactic structures. In addition, Zhao et al. (2008) extended this method to paraphrase pattern extraction.

To our knowledge, few studies have been conducted on learning paraphrases from query logs. Zhao et al. (2010)'s study might be the closest to our work. Their method is motivated by the assumption that user queries and the clicked titles are potential paraphrases. Accordingly, they train a classifier to recognize paraphrases from query-title pairs. They further extract query-query and title-title paraphrases from the query-title paraphrases based on the assumption that queries clicking on the same title and titles clicked on for the same query are also likely to be paraphrases. Additionally, they induce paraphrase patterns from the mined paraphrases. Our work differs from Zhao et al.'s mainly in that we learn paraphrase patterns from query sessions instead of query-click pairs. We compare these two methods in the experiments (Section 5.3).

2.2 Search Log Mining

Search engine query logs have been extensively exploited. Especially, there is a large body of research focusing on mining related queries from search logs and applying them in query rewriting and recommendation. Such research can be classified into three groups. The first group of methods utilizes user clicks when computing query similarity. The underlying assumption is that if users tend to click on similar documents for two queries, then the meanings of the queries should be similar (Wen et al., 2002; Baeza-Yates and Tiberi, 2007). In the second group of methods, researchers mine query rewriting terms directly from user clicked documents. Their basic idea is that terms from queries and user clicked documents are related (Cui et al., 2002; Riezler et al., 2008). The third group of methods learns related queries from query sessions. The assumption is that queries submitted by the same user within a short time might be related in meaning (Fonseca et al., 2005; Jones et al., 2006; Zhang and Nasraoui, 2006; Szpektor et al., 2011). Our work is close to the third group. However, what we learn are

paraphrase patterns rather than related queries or patterns.

3 Pattern Pair Induction

3.1 Concepts

Query. In this work, we collect user queries and other useful information from the used search logs and represent a query q as a triplet:

$$q = \langle qc, qt, cn \rangle,$$

where qc denotes the query content, qt is the time when qc is searched, and cn ($\geq$0) denotes the number of results clicked by the user. All queries in the search log are first preprocessed, including word segmentation, Part-of-Speech (POS) tagging, and Named Entity (NE) recognition.

Session. A query session (QS) is a sequence of queries submitted by the same user within a short time. We represent a query session with n queries as:

$$QS = q_1 ... q_i ... q_n,$$

where q_i is a query described above. Note that the order of queries in a session does matter, which records the sequence of user actions.

Pattern. A pattern is composed of two parts, i.e., pattern words and slots. Pattern slots can be instantiated with different words that meet certain constraints. We represent pattern slots as POS tags, which means that each slot can be instantiated by words with the specified POS. In our experiments, words with five kinds of POSes are allowed to form slots, including *noun* (n), *verb* (v), *adjective* (a), *numeral* (m), and *time* (t).

3.2 Induce Pattern Pairs

The reason why we learn paraphrase query patterns rather than directly extracting paraphrase queries is that paraphrase patterns usually achieve a higher coverage in applications than paraphrase instances. In addition, query patterns are much less sparse than queries. This work induces pattern pairs from query pairs co-occurring within the same query sessions. In detail, from a session $QS = q_1 ... q_i ... q_n$, we first extract all query pairs $\langle q_i, q_j \rangle$ ($1 \leq i < j \leq n$) in which q_i and q_j share at least one identical word. We then replace one or more shared identical word with their POS tags (slots), and thereby generate pattern pairs. It is obvious that we may induce more than one pattern pair from a query pair by selecting different slots. In addition, we assign a unique number to each pair of aligned slots in a pattern pair to distinguish slots with identical POS tags.

Figure 1 shows an example of pattern pair induced from a query pair. The slot $[n-1]$ denotes that the slot is the first slot in the pattern and the POS of fillers should be noun (n). In practice, we constrain that each pattern contains at least one content word besides slots, so as to filter meaningless patterns. In addition, since queries are mostly short, we constrain that each pattern contains at most two slots. We aggregate pattern pairs induced from all sessions in the search log and sum up the frequencies for each pair. Pattern pairs satisfying the following requirement are retained: (1) the frequency of the pattern pair exceeds a threshold T_1, (2) the number of unique fillers for each slot exceeds a threshold T_2.

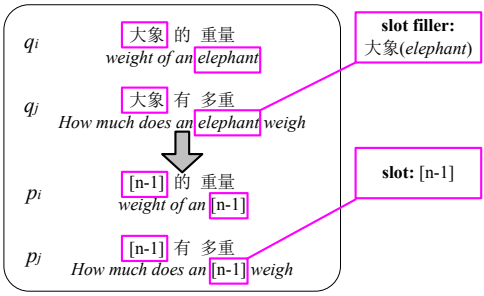

Figure 1: Example of pattern pair induction.

4 Paraphrase Pattern Recognition

Following the previous studies (Brockett and Dolan, 2005; Finch et al., 2005; Malakasiotis, 2009), we recast paraphrase pattern recognition as a classification problem. Each induced pattern pair is classified into one of the two classes, i.e., *paraphrase* and *non-paraphrase*. A Support Vector Machines (SVM) classifier is used in our experiments, since it has proven effective in this task (Brockett and Dolan, 2005; Finch et al., 2005). Our classification features can be divided into two groups: the baseline features examined in previous studies (Section 4.1) and user behavior based features proposed in this work (Section 4.2).

4.1 Baseline Features (F_{BL})

Conventional features for paraphrase recognition include three classes, i.e., lexical features, syntactic features, and semantic features. The lexical features measure the surface similarity between word sequences. Syntactic features compute the structural similarity between parse trees. Semantic features measure deep semantic relatedness based on some external knowledge base, such as WordNet in English. Our baseline features are mostly lexical features. In detail, given a pair of candidate patterns p_1 and p_2, our baseline features include: (1) length ratio feature, computed as the length of the shorter pattern divided by that of the longer one, (2) edit distance feature, computed as described in (Zhao et al., 2010), (3) cosine similarity feature, in which the words are weighted based on tf-idf, (4) word overlap rate feature, (5) character overlap rate feature[2], and (6) named entity feature, a boolean feature indicating whether p_1 and p_2 contain identical named entities.

We do not use syntactic features because most of user queries are not well-formed sentences but short n-grams, which cannot be parsed. We do not employ semantic features, either, since the underlying semantic knowledge bases are language-dependent.

4.2 User Behavior Features (F_{UB})

The most distinguishing characteristic of the query log, compared with other data sources, is that it contains rich information about users' searching and browsing behaviors, which could be

[2]Chinese words are composed of characters and words with the same meaning often contain similar characters.

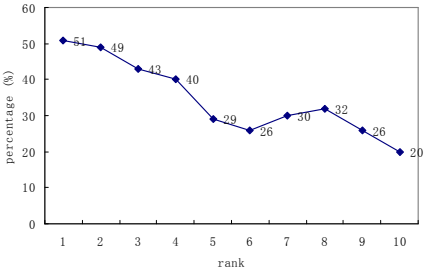

Figure 2: Percentage of paraphrases at each rank.

useful features for recognizing paraphrases. In this work, we design three types of user behavior features based on the observation and analysis of user behaviors from different aspects, which are detailed as follows.

Frequency based Features (F_{fr}). According to our observation, pattern pairs that frequently co-occur within sessions are more likely to be paraphrases. We substantiate our observation with an experiment, in which we randomly sampled 100 patterns with at least 10 candidate paraphrase patterns. We ranked all candidates according to their co-occurrence frequency with the target pattern and kept top-10. The 1000 pattern pairs are manually evaluated and the percentage of paraphrases at each rank is depicted in Figure 2. As can be seen, the percentage of paraphrases decreases as the rank gets lower. We therefore design the frequency based feature as:

$$F_{fr}(p_1, p_2) = \frac{freq(p_1, p_2)}{\sum_p freq(p_1, p) + C_1}, \tag{1}$$

where $freq(p_1, p_2)$ is the frequency of $\langle p_1, p_2 \rangle$ on the whole set of pattern pairs, C_1 is a constant parameter used to avoid overestimating the feature value when p_1 is too infrequent. We also compute the frequency based feature in the other direction, i.e., $F_{fr}(p_2, p_1)$ in the same way.

Lexical Score Features (F_{ls}). Inspired by lexical weight features used to measure phrase pair quality in machine translation (Koehn et al., 2003), we introduce lexical score features to measure the lexical level paraphrase likelihood of each pattern pair. We design a lexical scoring approach based on the observation that many words keep unchanged when users rewrite their queries within sessions. It is reasonable to assume that those unchanged words across queries should exclusively align with themselves, while the changed words may likely form paraphrase word pairs. Accordingly, given a pair of related queries $q_1 = w_{11}...w_{1m}$ and $q_2 = w_{21}...w_{2n}$ extracted from the same session, we compute two scores for any word pair $\langle w_{1i}, w_{2j} \rangle$ $(1 \le i \le m, 1 \le j \le n, w_{1i} \ne w_{2j})$ from them, namely, a *positive* score $a_+(w_{1i}, w_{2j})$ and a *negative* score $a\_(w_{1i}, w_{2j})$. Suppose W is the set of identical words shared by q_1 and q_2, and $l = |W|$, we compute $a_+(w_{1i}, w_{2j})$ and $a\_(w_{1i}, w_{2j})$ as:

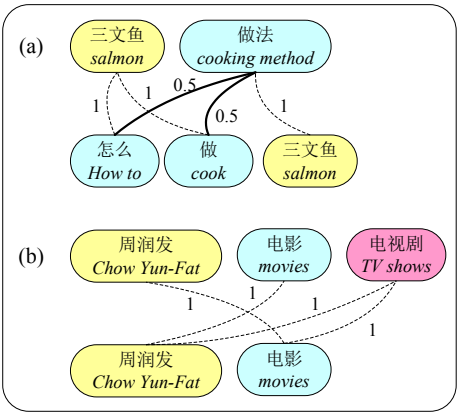

Figure 3: Examples of lexical scoring.

$$a_+(w_{1i}, w_{2j}) = \begin{cases} 0 & if\ w_{1i} \in W \vee w_{2j} \in W \\ \frac{1}{(m-l)*(n-l)} & otherwise \end{cases}$$

$$a_-(w_{1i}, w_{2j}) = \begin{cases} 1 & if\ w_{1i} \in W \vee w_{2j} \in W \\ 0 & otherwise \end{cases}$$

It can be interpreted that, if a word w in q_1 also appears in the other q_2, then w cannot *align* with other words in q_2 (i.e., such alignment gets a negative score). Otherwise, w will get an equal likelihood to *align* with each word in q_2 (i.e., gets a positive score). Examples in Figure 3 illustrate the lexical scoring process. A solid line denotes a positive alignment (a_+), whereas a dashed line denotes a negative alignment (a_-). The a_+ and a_- scores are also given in the figure. As can be seen, the lexical scoring approach assigns a_+ scores to the potential paraphrases (e.g., *cooking method* and *how to cook*) and a_- scores to the incorrectly aligned pairs (e.g., *movies* and *TV shows*).

We sum up a_+ and a_- scores for each word pair w_{1i} and w_{2j} over all the extracted query pairs and compute the lexical score $LS(w_{1i}, w_{2j})$ as follows:

$$LS(w_{1i}, w_{2j}) = \frac{\sum a_+(w_{1i}, w_{2j})}{\sum a_+(w_{1i}, w_{2j}) + \sum a_-(w_{1i}, w_{2j}) + C_2}, \quad (2)$$

where C_2 is a smoothing parameter. At run time, for a pattern pair $\langle p_1, p_2 \rangle$, we ignore slots, stop words, and the shared identical words from two patterns. Suppose the left words are

$p_1' = w_{11}...w_{1m}$ and $p_2' = w_{21}...w_{2n}$, we define the lexical score feature $F_{ls}(p_1, p_2)$ as follows:

$$F_{ls}(p_1, p_2) = \frac{1}{n}\sum_{j=1}^{n} \max_{1 \le i \le m} LS(w_{1i}, w_{2j}). \quad (3)$$

We compute feature $F_{ls}(p_2, p_1)$ in the same way.

Distance based Features (F_{dis}). It is obvious that we should not treat all query pairs from a session equally. Our observation of the user behaviors reveals that queries close to each other in a session are more likely to be paraphrases than those far apart. Therefore, given a pair of related queries $\langle q_i, q_j \rangle$ from a session QS, we measure the distance between two queries from three aspects:

- Query based distance dq. dq is defined as the number of queries between q_i and q_j in the session QS:
$$dq(q_i, q_j) = j - i - 1. \quad (4)$$
- Click based distance dc. The motivation here is that if a user clicks on a few retrieved results, it is likely that the user finds related information from the current results, and it is therefore less likely for her to further paraphrase the query. Given the number of clicks cn_k for query q_k, dc is defined as the sum of clicks between q_i and q_j:
$$dc(q_i, q_j) = \sum_{k=i}^{j-1} cn_k. \quad (5)$$
- Search time based distance dt. Given the timestamps qt_i and qt_j for queries q_i and q_j, dt is defined as the search time interval between q_i and q_j in the session QS:
$$dt(q_i, q_j) = qt_j - qt_i. \quad (6)$$

The distance of a pattern pair $\langle p_1, p_2 \rangle$ is defined as the average distance between query pairs from which $\langle p_1, p_2 \rangle$ is induced. Let $dx(p_1, p_2)$ be the distance between two patterns, we define the distance based feature as: $F_{dx}(p_1, p_2) = exp\{-dx(p_1, p_2)\}$, which guarantees that: (1) the smaller the distance, the larger the feature value, and (2) the feature values vary in the range (0,1].

5 Experiments

In our experiments, we used a query log from Baidu, a Chinese commercial search engine for extracting paraphrase query patterns. The queries were first segmented into sessions using an algorithm based on both time interval and content relatedness. A total of 87,744,130 sessions, containing 362,994,092 queries, were collected from the used query log after removing sessions with only one query. Query preprocessing, including word segmentation, POS tagging, and NE recognition[3], was performed using toolkits implemented based on the state-of-the-art models.

[3]Our NE classes include not only conventional classes like *person*, *location*, *organization*, *numeral*, and *time*, but also some classes frequently occur in user queries, including *movie*, *tv show*, *song*, *novel*, *brand*, *video game*, and *software*.

Table 1: P/R/F under different feature combinations. "*" indicates that the improvement is significant ($p < 0.05$) compared with the classifier using only baseline features.

We induced 868,243 pattern pairs from the sessions as described in Section 3. Note that, in practice, we eliminated pattern pairs in which one pattern subsumes the other, i.e., the case of expansion or reduction, as well as the pairs in which two patterns only have some trivial differences, such as inserting or deleting a stop word. The libsvm toolkit[4] was used as the classifier, with its default parameter settings. Some other parameters used in our method were set empirically: $T_1 = 5$, $T_2 = 3$, $C_1 = 20$, $C_2 = 10$.

5.1 Evaluation of the Classifier

We randomly sampled 5115 candidate pattern pairs to form the experimental data set. Two Chinese native speakers were asked to annotate the pattern pairs separately. A pattern pair should be annotated as *positive* (correct paraphrase patterns) or *negative* (otherwise). We follow the instance-based evaluation approach proposed by Szpektor et al. (2007). Particularly, we provide pattern slot fillers to the annotators along with the pattern pairs. A pattern pair is judged as paraphrase only when most of the instances generated by filling the slots with the provided fillers are paraphrases. We calculated the annotation agreement between two annotators. The result shows that the observed agreement is 0.96 and the Kappa value is 0.90. We believe that the high annotation agreement is due to the careful training of the annotators and the instance-based evaluation approach. A third annotator was asked to decide the final annotation for the disagreed pattern pairs.

To evaluate the classifier, we ran 5-fold cross validation with the human annotated data, in which we used 4/5 of the data for training and the rest 1/5 for testing in each run. The evaluation criteria are precision (P), recall (R), and f-measure (F) with regard to the positive class. The average P, R, and F of the classifier under different feature combinations over five runs are reported in Table 1.

The first line of table 1 shows the classification performance when we only use the baseline features. Lines 2-4 summarize the performance when we add each type of user behavior features separately. As can be seen, all the user behavior features can significantly improve the recall and f-measure. This is not surprising, since many paraphrase patterns are not similar enough at the surface level. The user behavior features supply additional evidences for measuring the semantic closeness between patterns, which help to recognize more paraphrase patterns with larger surface difference. Furthermore, lines 5-6 show that the classification performance keeps improving when the user behavior features are added one by one. We achieve the highest P, R, and F when all three types of user behavior features are used. This result indicates that the

Table 2: Analysis of the distance based features. "*" indicates that the degradation is significant ($p < 0.05$) compared with the classifier using all features.

user behavior features improve the performance from different aspects, it is thus necessary to combine them together.

We can find from line 3 of Table 1 that the lexical score features also significantly improve the precision of the classifier, which implies that this type of features is useful for filtering noise. We find after analyzing the data that, query pairs like "贾斯汀比伯 身高 (*Justin Bieber height*)" and "贾斯汀比伯 身高 体重 (*Justin Bieber height and weight*)" are quite common in users' search sessions, in which a query is expanded by adding a word closely related to the original query words. As a result, many closely related non-paraphrase word pairs, like 身高 (*height*) and 体重 (*weight*), get large $a\_$ scores and thereby penalized by the lexical score features. That's the main reason why the precision can be enhanced using this type of features.

People may wonder if our lexical score features can outperform the lexical weight features used in MT. For comparison, we implemented the latter on our data set. In detail, we conducted word alignment on the candidate pattern pairs and computed lexical weights in two directions as proposed in (Koehn et al., 2003). We then replaced our lexical score features with the lexical weights and evaluated the classifier via 5-fold cross validation. The average performance is: P=74.78%, R=67.30%, F=70.76%. As can be seen, the performance is lower than the current result (See the last line of Table 1), especially in precision. This result suggests that the lexical weighting approach in MT is unsuitable in paraphrase recognition. The main reason, we believe, is that it is unable to penalize the closely related non-paraphrases as our approach does.

In addition, since the distance based features are defined from three different aspects, we need to evaluate the individual contributions of these features. To this end, we omitted one or two distance based features from several runs and analyzed the influence. The results are given in Table 2. It is interesting to find from lines 2-4 of the table that, there is no degradation in performance when we omitted each distance based feature separately, which suggests that the features may not be independent of each other. Further results can be found from lines 5-7, where we omitted two features together each time. We can see that eliminating the click based and search time based distance features together (F_{dc}+F_{dt}) leads to an obvious degradation in recall and f-measure, while the query based distance feature (F_{dq}) seems helpless. It also implies that the F_{dc} and F_{dt} features follow the same trend. Actually, it is likely that the user's requirement has already been satisfied by the current search results if she spends a long time clicking on and browsing the results. It is therefore less possible for her to paraphrase the query any more. In other words, users' clicking and browsing behaviors are good indicators for recognizing paraphrases.

Table 3: Examples of the extracted paraphrase patterns under different types.

5.2 Evaluation of the Paraphrase Patterns

We used all the 5115 pairs of human annotated patterns to train a classifier, which was then applied to recognize paraphrase patterns from the candidate pattern pairs. A total of 252,963 pairs of paraphrase patterns were extracted in this way. Our statistics show that the average length of the patterns is 2.78 (words), which is mainly because the user queries are mostly short. One may argue that the short paraphrase patterns cannot cover long queries in applications such as query paraphrasing. We believe this problem can be alleviated by allowing partial match of patterns when applying them on long queries. Further statistics show that, over 77% of the paraphrase patterns contain only one slot, and over 90% slots are noun slots.

We randomly sampled 1000 pairs of paraphrase patterns for human assessment. The result shows that the precision is 76.4%. Typological analysis shows that the correct paraphrase patterns can be classified into four groups, including (1) phrase substitution, (2) adding or removing (+/-) information that does not change the meaning, (3) spelling correction, and (4) complex paraphrases, involving both word replacement and structural transformation. The distributions and examples are depicted in Table 3.

As can be seen, phrase substitution is the most represented class, with over 42% of all paraphrase patterns. This is consistent with the statistics reported in (Zhao et al., 2008). There are also quite a few paraphrase patterns in the class "information +/-", reflecting that many users tend to add or remove information to refine their queries while preserving the meaning. The third class, i.e., spelling correction was not conventionally regarded as a type of paraphrase. However, pattern pairs of this class actually convey the same requirement of users and are useful in applications such as query correction. Complex paraphrases are scarce compared with the other

three classes, suggesting that users do not often dramatically transform their queries if their requirement does not change. Note that, paraphrase patterns of the type *spelling correction* can only be applied in one direction, namely, to paraphrase the incorrect queries to the correct forms, while the other three types are not sensitive to the direction. Our method is not likely to learn paraphrase patterns with wrong direction, as people seldom paraphrase a correct query to an incorrect one in the search sessions.

It is interesting to find out to what extent the paraphrase patterns are dependent on the slot fillers. Our analysis shows that more than 76% of the paraphrase patterns are context-independent, which means that the pattern pairs convey the same meaning no matter what words instantiate the slots. For the other 24% of paraphrase patterns, the paraphrase relationship holds only under certain contexts. For example, the pattern pair "什么 [n-1] 好 (*what [n-1] is good*)" and "什么 [n-1] 好吃 (*what [n-1] is delicious*)" can be viewed as paraphrases only when the slot is filled with a food name. Judging in what context the paraphrase patterns can be applied is important in applications, which will be left in our future work.

5.3 Comparison Experiments

In this section, we compare our method with the method proposed in (Zhao et al., 2010), which is referred to as Zhao-10 hereafter. As mentioned above, Zhao-10 makes use of the click-through relationship between queries and clicked document titles from query logs. In particular, Zhao-10 learns paraphrase patterns in two steps. In the first one, it extracts candidate paraphrases from three sources, namely, pairs of queries and clicked titles, pairs of queries clicking on the same title, and pairs of titles clicked on for the same query. A classifier is employed to filter the candidates from each source. Then in the second step, it induces paraphrase patterns from each pair of paraphrases $\langle p_1, p_2 \rangle$ by abstracting one word shared by p_1 and p_2 as slot [X].

We ran Zhao-10 on our search log data and extracted 53,198 pairs of paraphrase patterns after removing the ones with only trivial differences between each other. We randomly selected 1000 pairs for manual annotation, and the result shows that the precision is 82.6%. Comparing this result with that reported in Section 5.2, we can find that the paraphrase patterns extracted with Zhao-10 are more precise than those extracted with the method proposed in this paper, but the quantity is smaller. We also analyze the types of the extracted correct paraphrase patterns as we do in section 5.2. The analysis result suggests that the paraphrase patterns extracted with Zhao-10 can also be classified into the four types as mentioned above, but the distribution is quite different: (1) phrase substitution: 82.13%, (2) information +/-: 9.79%, (3) spelling correction: 2.20%, (4) complex paraphrase: 5.88%.

Furthermore, we examined the intersection between paraphrase patterns extracted with our method and Zhao-10[5]. The result shows that the intersection is extremely small. Only 707 pairs of paraphrase patterns were extracted with both methods. This result implies that our method and Zhao-10 are quite complementary. It is promising to integrate these two methods for paraphrase extraction, whereby we can make full use of the search log information, including queries, clicks, and sessions.

[5]Since the pattern slots are not specified with POS tags in Zhao-10, we did not consider POS mismatch when counting the intersection of two sets of paraphrase patterns.

5.4 Analysis of Portability

People may wonder whether the proposed method can be extended to other languages or other applications. Here we analyze the portability of the method from two aspects:

Language portability. In our experiments, we used preprocessing tools to process Chinese query logs, which include word segmentation, POS tagging, and NE recognition (NER). Although these modules were implemented to process Chinese, the underlying algorithms and models can be language independent. However, please note that the models should be trained with annotated query data, since models trained with normal sentences or texts usually do not work well if they are directly applied on query corpora. Especially, in the NER module, we automatically mine new candidate NEs from the query logs everyday and update the NE dictionary, so as to handle the emerging NEs in user queries. To summarize, the preprocessing modules can be implemented based on language-independent models, but they should be specially trained and adapted for query data.

Application portability. The method is designed for mining paraphrase queries, which could then be used in query rewriting. However, the mined paraphrase patterns can also be used in other applications, especially the paraphrases with the type "phrase substitution", which we believe can be used in sentence rewriting and sentence similarity computation (i.e., matching paraphrases from two sentences when computing their similarity). We will examine the usefulness of the mined paraphrases in other applications in our future experiments.

6 Conclusions and Future Work

This paper proposes a classification-based method for learning paraphrase query patterns from search log sessions. The following conclusions can be drawn from the experiment results. Firstly, we for the first time demonstrate that search log session data is a rich source for extracting paraphrase patterns. Secondly, the classification-based method is effective in paraphrase pattern extraction. Especially, the proposed user behavior features evidently improve the classification performance. Thirdly, our method and the click-through based method (Zhao et al., 2010) are complementary. In our future work, we will improve our paraphrase extraction model by taking advantages of both the query session and click-through knowledge from search logs. In addition, we will try to automatically classify the extracted paraphrase patterns into different types (see Table 3), so as to suit different applications.

ABSTRACT
Community-based question answering (CQA) has become an important issue due to the popularity of CQA archives on the web. This paper is concerned with the problem of question retrieval. Question retrieval in CQA archives aims to find historical questions that are semantically equivalent or relevant to the queried questions. However, question retrieval is challenging partly due to the word ambiguity and lexical gap between the queried questions and the historical questions in the archives. To deal with these problems, we propose the use of translated words to enrich the question representation, going beyond the words in the original language to represent a question. In this paper, each original language question (e.g., English) is automatically translated into an foreign language (e.g., Chinese) by machine translation services, and the resulting translated questions serves as a semantically enhanced representation for supplementing the original bag of words. Experiments conducted on real CQA data set demonstrate that our proposed approach significantly outperforms several baseline methods and achieves the state-of-the-art performance.

利用双语翻译对社区问答进行问题检索

由于互联网上社区问答数据集的流行，使得社区问答的研究变得越来越流行。本文关注的是问题检索。 问题检索的目的是从历史问题数据集中查找与查询问题语义等价或相关的历史问题。然而，问题检索的挑战主要是词汇歧义和查询问题与历史问题 之间的词汇鸿沟。为了解决这些问题，我们提出利用翻译词来丰富问题的表示，而不单纯利用原始语言的词来表示问题。 在本文中，通过机器翻译，每个原始语言（例如：英语）的问题都被自动翻译成另一种外国语言（例如：汉语）， 经过翻译后的问题可以作为一种增强的语义表示来辅助原始的基于词袋的表示方法。在真实社区问答数据集上的实验表明，我们的方法可以极大提升基线系统的方法 并取得了最好的性能。

1 引言

在过去的若干年中，大规模的问答数据集成了互联网上的重要信息资源。 这些资源包括传统的由专家或公司为他们的产品提供的常见问题解答集以及新出现的基于社区的在线服务，例如Yahoo! Answers和Live QnA，在这些在线社区上，人们可以回答他人提出的问题。这种在线社区称为基于社区的问答服务。 在这些社区中，任何人都可以提问和回答关于任何主题的问题，寻找信息的人与那些知道答案的人就联系起来了。 由于社区问答上的答案通常以显式的形式由人们提供，它们对回答真实问题起到了很好的作用 (Wang et al., 2009)。

为了更好地利用大规模的问答对，具备帮助用户检索先前答案的功能非常必要 (Duan et al., 2008)。因此， 检索与查询问题语义等价或相关的问题是一件非常有意义的任务。然而，问题检索的挑战主要是词汇歧义和查询问题与历史问题 之间的词汇鸿沟。词汇歧义通常会引发问题检索模型检索出许多与用户查询意图不匹配的历史问题。这也是由问题和用户的高度多样化造成的。例如，依据不同的用户，词"interest"既可以指"curiosity"也可以指"a charge for borrowing money"。另外一个挑战是查询问题与历史问题的词汇鸿沟。查询问题中的词不同于历史问题中的词但是它们之间是相关的词。 词汇鸿沟问题对社区问答的问题检索而言更加严重，主要是问答对通常很短，查找相同的内容表达往往使用不同的词(Xue et al., 2008)。

为了解决词汇鸿沟问题，大多数学者将问题检索任务看作是一个统计机器翻译的问题，并利用IBM模型1(Brown et al., 1993)来学习词与词之间的翻译概率(Berger et al., 2000; Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009)。 实验结果一致表明基于词的翻译模型取得了比传统检索方法更好的性能。 最近，Riezler et al. (2007)和Zhou et al. (2011)提出了基于统计短语翻译的问题和答案检索方法。基于短语的翻译模型可以刻画上下文信息，在翻译的过程中对整个短语建模， 从而在某种程度上降低了词汇歧义的问题。然而，目前公开发表的工作都是基于单语的方法，仅仅利用了原始语言的信息， 而没有利用来自其它语言潜在的丰富的语义信息。通过其它语言，可以利用各种方法增加原始问题的语义信息，从而提高仅仅利用原始语言方法的性能。

通过利用外国语言，我们提出利用翻译表示通过外国语言词汇来替换原始语言中的词，其中外国语言是指不同于原始语言的。 利用双语信息进行问题检索的基本思想如下：（1）从一种语言翻译成另一种语言的过程中可以利用上下文信息，如表1所示，英文单词"interest"和 "bank"在不同的上下文中有多种意思，在利用**Google Translate** (Google-Trans)翻译的过程中正确的意思可以得到纠正。因此，问题中词的歧义在翻译的过程中可以根据上下文信息得到解决。（2）多个语言相关的词在某种语言中可以被翻成另外一种语言的唯一表示。如表1所示，英文单词例如"company"和"firm"可以被翻译成中文单词"公司 (gōngsī)"，"rheum"和"catarrh"可以被翻译成中文单词"感冒(gǎnmào)"。

在本文中，通过机器翻译，每个原始语言（例如：英语）的问题都被自动翻译成另一种外国语言（例如：汉语）， 经过翻译后的问题可以作为一种增强的语义表示来辅助原始的基于词袋的表示方法。具体来说， 原始语言与外国语言的词汇之间通过翻译联系起来，对解决上述两个问题的解决起到重要的作用。 首先，每个原始语言句子中的词可以被翻译成另一种语言中的多个词，因此在给定原始语言中词的上下文的情况下， 词汇歧义在翻译的过程中可以得到解决。同时，语义相关的多个词可以被翻译成另一外国语言中的一个词。 因此，原始语言中的词汇鸿沟在某种程度上可以通过另一种外国语言中的翻译词来解决。

我们利用来自Yahoo! Answers的大规模数据集做实验。采用两种商业翻译服务（例如，Google Translate和Yahoo Babel Fish和一种基于词典的基线翻译将大规模的英文问题翻译成中文问题。 实验表明，我们的方法可以极大提升基线系统的方法并取得了最好的

	英语	汉语

2 Introduction

Over the past few years, large-scale question and answer archives have become an important information resource on the Web. These include the traditional FAQ archives constructed by the experts or companies for their products and the emerging community-based online services, such as Yahoo! Answers[1] and Live QnA[2], where people answer questions posed by other people. This is referred as the community-based question answering services. In these communities, anyone can ask and answer questions on any topic, and people seeking information are connected to those who know the answers. As answers are usually explicitly provided by human, they can be helpful in answering real world questions (Wang et al., 2009).

To make use of the large-scale archives of question-answer pairs, it is critical to have functionality of helping users to retrieve previous answers (Duan et al., 2008). Therefore, it is a meaningful task to retrieve the semantically equivalent or relevant questions to the queried questions. However, question retrieval is challenging partly due to the **word ambiguity** and **lexical gap** between the queried questions and the historical questions in the archives. **Word ambiguity** often causes a question retrieval model to retrieve many historical questions that do not match the user's intent. This problem is also amplified by the high diversity of questions and users. For example, depending on different users, the word "interest" may refer to "curiosity", or "a charge for borrowing money". Another challenge is **lexical gap** between the queried questions and the historical questions. The queried questions may contain words that are different from, but related to, the words in the relevant historical questions. The lexical gap is substantially bigger for question retrieval in CQA largely due to the fact that the question-answer pairs are usually short and there is little chance of finding the same content expressed using different wording (Xue et al., 2008).

To solve the lexical gap problem, most researchers regarded the question retrieval task as a statistical machine translation problem by using IBM model 1 (Brown et al., 1993) to learn the word-to-word translation probabilities (Berger et al., 2000; Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009). Experiments consistently reported that the word-based translation models could yield better performance than the traditional methods. Recently, Riezler et al. (2007) and Zhou et al. (2011) proposed a phrase-based translation model for question and answer retrieval. The phrase-based translation model can capture some contextual information in modeling the translation of phrases as a whole, thus the word ambiguity problem is somewhat alleviated. However, most existing studies in the literature are basically *monolingual approaches* which are restricted to the use of original language of questions, without taking advantage of potentially rich semantic information drawn from other languages. Through other languages, various ways of adding semantic information to a question could be available, thereby leading to potentially more improvements than using the original language only.

Taking a step toward using other languages, we propose the use of *translated representation* by alternatively presenting the original questions with the words of a foreign language, one that is different from the original language of questions. The idea of exploiting bilingual information for question retrieval is based on the following observations: (1) Contextual information is exploited during the translation from one language to another. As shown in Table 2, English words "interest" and "bank" that have multiple meanings under different contexts are correctly

	English	Chinese
Word ambiguity	How do I get a loan from a **bank**?	我(wǒ) 如何(rúhé) 从(cóng) **银行(yínháng)** 贷款(dàikuǎn) ?
	How to reach the **bank** of the river?	如何(rúhé) 前往(qiánwǎng) **河岸(héàn)** ?
Lexical gap	company firm	公司(gōngsī) 公司(gōngsī)
	rheum catarrh	感冒(gǎnmào) 感冒(gǎnmào)

Table 2: Google translate: some illustrative examples.

addressed by **Google Translate**[3] (GoogleTrans). Thus, word ambiguity based on contextual information is naturally involved when questions are translated. (2) Multiple words that are semantically similar in one language may be translated into unique words or a few words in a foreign language. For example in Table 2, English words such as "company" and "firm" are translated into "公司 (gōngsī)", "rheum" and "catarrh" are translated into "感冒(gǎnmào)" in Chinese.

In this paper, each original question is automatically translated into a foreign language by machine translation services, and the resulting translated questions serve as a semantically enhanced representation for supplementing the original bag of words. Specially, the vocabularies of the original and foreign languages are connected via translation, which could bring about important benefits in dealing with the two addressed problems. First, an original language word can be translated into multiple candidate words in a foreign language. Therefore, the word ambiguity problem can be resolved during the translation in a given context of an original language word. Conversely, various different original language words that refer to similar meanings are translated into a single word or a few words in a foreign language. Thus, the lexical gap problem in the original language is to some extent ameliorated by using the translated words in a foreign language.

We conduct experiments on a large-scale data set from Yahoo! Answers. Two commercial machine translation services (e.g., Google Translate and Yahoo Babel Fish[4]) and a baseline dictionary-based system are used for translating English questions into Chinese questions. Experimental results show that our proposed method significantly outperforms several baseline methods and achieves state-of-the-art performance.

The remainder of this paper is organized as follows. Section 3 introduces the framework of the proposed method. Section 4 describes our proposed method in detail. Section 5 presents the experimental results. In Section 6, we conclude with ideas for future research.

3 Framework of the Proposed Approach

The framework of the proposed approach for question retrieval is summarized in Figure 1. Each historical question in original language (e.g., English) is translated into the corresponding foreign language (e.g., Chinese) via machine translation services. Note that in the framework, different machine translation services can be used to obtain different translation. When a queried question is given, the queried question is translated using the same machine translator. Next, question retrieval on both representations (e.g., English representation and Chinese

[3]http://translate.google.com/translate_t
[4]http://babelfish.yahoo.com/translte_txt

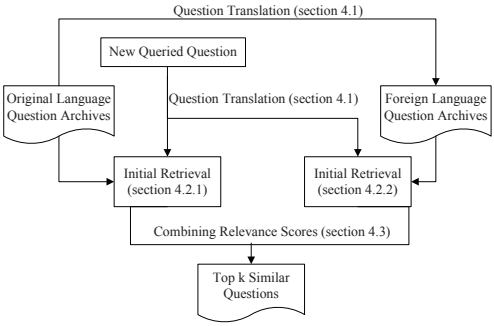

Figure 1: Framework of our approach by using question translated representation.

representation) is performed, and the two resulting relevance scores are combined to produce a final ranked list of semantically similar questions.

4 Our Approach

4.1 Question Translation

Translating historical questions in original language (e.g., English) into the corresponding foreign language is the first step of the proposed approach. Manual translation is time-consuming and labor-intensive, and it is not feasible to manually translate a large amount of questions in original language in real applications. Fortunately, machine translation techniques have been well developed in the NLP filed, though the translation quality is far from satisfactory. A few commercial machine translation services can be publicly accessed. In this paper, the following two commercial machine translation services and one baseline system are used to translate English questions into Chinese questions.

Google Translate (GoogleTrans): Google Translate is one of the state-of-the-art commercial machine translation systems used today. Google Translate employs statistical machine learning methods to build a translation model based on large-scale bilingual parallel corpus. Contextual information is utilized during the translation from one language text to the aligned text in anther language.

Yahoo Babel Fish (YahooTrans): Different from Google Translate, Yahoo Babel Fish uses SYSTRAN's rule-based translation engine. SYSTRAN is one of the earliest developers of machine translation software. SYSTRAN employs complex sets of specific rules defined by linguists to analyze and then transfer the grammatical structure of the source language into the target language. During the translation, word ambiguity can be resolved based on the contextual information.

Baseline Translate (DicTran): We simply develop a translation method based only on one-to-one word translation using an English to Chinese lexicon in StarDict[5].

[5]StarDict is an open source dictionary software, available at http://stardict.sourceforge.net/.

4.2 Bilingual Retrieval Method

4.2.1 Retrieval model

Language models have been performed quite well empirically in many information retrieval tasks (Zhai and Lafferty, 2001), and also have performed very well in question retrieval (Jeon et al., 2005; Cao et al., 2009, 2010). In this paper, we use the language modeling approach for question retrieval. In the language modeling approach to question retrieval, language models are constructed for each queried question $\mathbf{q}$ and each historical question $\mathbf{d}$ in CQA archives C. The historical questions in C are ranked by the distance to a given queried question $\mathbf{d}$ according to the language models. The most commonly used language model in question retrieval is the unigram model, in which words are assumed to be independent of each other.

One of the commonly used measures of the similarity between query model and historical question model is negative Kullback-Leibler (KL) divergence (Zhai and Lafferty, 2001). With unigram model, the negative KL-divergence between model $\theta_{\mathbf{q}}$ of query $\mathbf{q}$ and model $\theta_{\mathbf{d}}$ of historical question $\mathbf{d}$ is computed as follows:

$$\begin{aligned} Score(\mathbf{q},\mathbf{d}) &= -\sum_{w\in V} p(w|\theta_{\mathbf{q}}) \log \frac{p(w|\theta_{\mathbf{q}})}{p(w|\theta_{\mathbf{d}})} \\ &= \sum_{w\in V} p(w|\theta_{\mathbf{q}}) \log p(w|\theta_{\mathbf{d}}) - \sum_{w\in V} p(w|\theta_{\mathbf{q}}) \log p(w|\theta_{\mathbf{q}}) \\ &= \sum_{w\in V} p(w|\theta_{\mathbf{q}}) \log p(w|\theta_{\mathbf{d}}) + E(\theta_{\mathbf{q}}) \end{aligned} \tag{1}$$

where $p(w|\theta_{\mathbf{q}})$ and $p(w|\theta_{\mathbf{d}})$ are the generative probabilities of a word w from the models $\theta_{\mathbf{q}}$ and $\theta_{\mathbf{d}}$, V is the vocabulary of C, and $E(\theta_{\mathbf{q}})$ is the entropy of $\mathbf{q}$.

Let $tf(w,\mathbf{q})$ and $tf(w,\mathbf{d})$ as the frequencies of w in $\mathbf{q}$ and $\mathbf{d}$, respectively. Generally, $p(w|\theta_{\mathbf{q}})$ is calculated with maximum likelihood estimation (MLE):

$$p(w|\theta_{\mathbf{q}}) = \frac{tf(w,\mathbf{q})}{\sum_{w'\in\mathbf{q}} tf(w',\mathbf{q})} \tag{2}$$

To calculate $p(w|\theta_{\mathbf{d}})$, several smoothing methods have been proposed to overcome the data sparseness problem of a language model constructed from one historical question (Zhai and Lafferty, 2001). Therefore, $p(w|\theta_{\mathbf{d}})$ with the Dirichlet prior smoothing can be calculated as follows:

$$p(w|\theta_{\mathbf{d}}) = \frac{tf(w,\mathbf{d}) + \lambda p(w|\theta_C)}{\sum_{w'\in V} tf(w',\mathbf{d}) + \lambda} \tag{3}$$

where λ is the prior parameter in the Dirichlet prior smoothing method, and $p(w|\theta_{\mathbf{C}})$ is the probability of w in C, which is often computed with MLE:

$$p(w|\theta_C) = \frac{\sum_{\mathbf{d}\in C} tf(w,\mathbf{d})}{\sum_{\mathbf{d}\in C}\sum_{w'\in V} tf(w',\mathbf{d})} \tag{4}$$

4.2.2 Retrieval model for translated representation

We now extend the retrieval model described in subsection 4.2.1 in order to support translated representation. Let $\pi(\mathbf{d})$ be the translated representation result by using the machine translation service π (e.g., Google Translate) for a given historical question $\mathbf{d}$, and $\pi(\mathbf{q})$ be the translated representation result by using the machine translation service π for a queried question $\mathbf{q}$. Therefore, the query language model $p(w|\theta_{\pi(\mathbf{q})})$ based on the translated representation can be calculated as follows:

$$p(w|\theta_{\pi(\mathbf{q})}) = \frac{tf(w, \pi(\mathbf{q}))}{\sum_{w' \in \pi(\mathbf{q})} tf(w', \pi(\mathbf{q}))} \tag{5}$$

Similarly, by replacing $tf(w, \mathbf{d})$ in equation (3) with $tf(w, \pi(\mathbf{d}))$, we obtain the following smoothed model $p(w|\theta_{\pi(\mathbf{d})})$:

$$p(w|\theta_{\pi(\mathbf{d})}) = \frac{tf(w, \pi(\mathbf{d})) + \lambda p(w|\theta_{\pi(C)})}{\sum_{w' \in V_F} tf(w', \pi(\mathbf{d})) + \lambda} \tag{6}$$

where V_F is vocabulary of the translated foreign language, and $p(w|\theta_{\pi(\mathbf{C})})$ is defined by

$$p(w|\theta_{\pi(C)}) = \frac{\sum_{\mathbf{d} \in C} tf(w, \pi(\mathbf{d}))}{\sum_{\mathbf{d} \in C} \sum_{w' \in V_F} tf(w', \pi(\mathbf{d}))} \tag{7}$$

Finally, we calculate the relevance score of the historical question $\mathbf{d}$ with respect to the queried question $\mathbf{q}$ using $Score(\pi(\mathbf{q}), \pi(\mathbf{d}))$ based on their translated representation.

4.3 Combining Relevance Score for Bilingual Representation

After obtaining the two relevance scores from the original and translated representation perspective, we can rank the final similar historical questions based on the linear combination and refined ranking approach, respectively.

4.3.1 Linear combination

To produce a single ranked list from the two relevance scores using equation (1) on the original and translated representation, we use the following linear combination:

$$Score_{E+F}(\mathbf{q}, \mathbf{d}) = \alpha Score(\mathbf{q}, \mathbf{d}) + (1 - \alpha) Score(\pi(\mathbf{q}), \pi(\mathbf{d})) \tag{8}$$

In equation (8), the importance of relevance scores on the original and translated representation is adjusted through α. When $\alpha = 1$, the final retrieval model is based on the original representation. When $\alpha = 0$, the final retrieval model is based on the translated representation.

4.3.2 Refined ranking approach

Based on the original and translated representation, we can obtain two kinds of ranked lists $\vec{R}_E(\mathbf{q})$ and $\vec{R}_F(\pi(\mathbf{q}))$, which reflect the similarity between a queried question and a historical

questions from two different perspectives. If the retrieval model based on the original representation cannot capture the similarity due to the word ambiguity and lexical gap, then the retrieval model based on the translated representation should be good for dealing with the word ambiguity and lexical gap problems. Therefore, we consider a refined ranking approach to boost the question retrieval performance.

In order to measure the similarity between the two ranked results, we utilize a measurement, similar to Jaccard coefficient, which is defined as the size of the intersection divided by the size of the union of these two top k ranked results,

$$J = \frac{|\vec{R}_E(\mathbf{q}) \bigcap \vec{R}_F(\pi(\mathbf{q}))|}{|\vec{R}_E(\mathbf{q}) \bigcup \vec{R}_F(\pi(\mathbf{q}))|} \tag{9}$$

This measurement implies the following meaning: a large value is reached if the retrieval model based on the translated representation could retrieve many common relevant historical questions within the top-k results. Based on this scheme, we adopt a measurement for an adaptive ranking refinement. Let $R_E(\mathbf{q}, \mathbf{d})$ be the rank of historical question $\mathbf{d}$ for a given queried question $\mathbf{q}$, and let $R_F(\pi(\mathbf{q}), \pi(\mathbf{d}))$ be the rank of translated representation $\pi(\mathbf{d})$ for a given translated queried question $\pi(\mathbf{q})$. Therefore, we define a refined score $Score(\mathbf{q}, \mathbf{d})$ based on the following function:

$$Score(\mathbf{q}, \mathbf{d}) = \frac{1}{R_E(\mathbf{q}, \mathbf{d})} + \varphi(\mathbf{d}) \cdot J \cdot \frac{1}{\hat{R}_F(\pi(\mathbf{q}), \pi(\mathbf{d}))} \tag{10}$$

where $\varphi(\mathbf{d}) = 1$ if $\mathbf{d} \in \vec{R}_E(\mathbf{q})$ and $\pi(\mathbf{d}) \in \vec{R}_F(\pi(\mathbf{q}))$, otherwise $\varphi(\mathbf{d}) = 0$. By applying the refined ranking strategy, we obtain the refined ranking model shown in Algorithm 1.

Algorithm 1 Refined Model for Question Retrieval

Input: Given a queried question $\mathbf{q}$;

Step1: Retrieve the top-k most relevant historical questions based on the original representation using equations (1) to (4), and then obtain the ranked results $\vec{R}_E(\mathbf{q})$;

Step2: Retrieve the top-k most relevant historical questions based on the translated representation using equations (5) to (7), and then obtain the ranked results $\vec{R}_F(\pi(\mathbf{q}))$;

Step3: Refine with equation (10) and get the final ranked results.

Output: Return the ranked historical questions $\{\mathbf{d}_1, \mathbf{d}_2, \cdots, \mathbf{d}_k\}$.

4.4 Category-Sensitive Language Model for Bilingual Representation

In CQA, when a user asks a question, the user typically needs to choose a category for the question from a predefined hierarchy of categories. Hence, each question in CQA archive has a category label and questions in CQA services are organized into hierarchies of categories (Cao et al., 2009, 2010). Based on these observations, it is naturally to employ the category information for bilingual representation. Let $c(\mathbf{d})$ be the leaf category of historical question $\mathbf{d}$, then *category-term frequency* of $\mathbf{d}$ for word w is defined as follows:

$$tf(w, \mathbf{d} \cup c(\mathbf{d})) = tf(w, \mathbf{d}) + \mu \cdot tf(w, c(\mathbf{d})) \tag{11}$$

where μ is the weight of category frequency, and $tf(w, c(\mathbf{d}))$ is frequency of word w in $c(\mathbf{d})$. Finally, model $\theta_{\mathbf{d}}$ defined in equation (3) is written as:

$$\begin{aligned} p(w|\theta_{\mathbf{d},c(\mathbf{d})}) &= \frac{tf(w, \mathbf{d} \cup c(\mathbf{d})) + \lambda p(w|\theta_C)}{\sum_{w' \in V} tf(w', \mathbf{d} \cup c(\mathbf{d})) + \lambda} \\ &= \frac{tf(w, \mathbf{d}) + \mu \cdot tf(w, c(\mathbf{d})) + \lambda p(w|\theta_C)}{\sum_{w' \in V} tf(w', \mathbf{d}) + \sum_{w' \in V} tf(w', c(\mathbf{d})) + \lambda} \end{aligned} \tag{12}$$

Similarly, we could define the translated representation for model $p(w|\theta_{\pi(\mathbf{d})})$ as follows:

$$p(w|\theta_{\pi(\mathbf{d}),\pi(c(\mathbf{d}))}) = \frac{tf(w, \pi(\mathbf{d})) + \mu \cdot tf(w, \pi(c(\mathbf{d}))) + \lambda p(w|\theta_{\pi(C)})}{\sum_{w' \in V} tf(w', \pi(\mathbf{d})) + \sum_{w' \in V} tf(w', \pi(c(\mathbf{d}))) + \lambda} \tag{13}$$

Given the bilingual representation, we again combine the two category-sensitive relevance scores with the above linear combination and refined ranking approach, respectively.

5 Experiments

5.1 Data Set and Evaluation Metrics

We collect the data set from Yahoo! Answers and use the *getByCategory* function provided in Yahoo! Answers API[6] to obtain CQA threads from the Yahoo! site. More specifically, we utilize the *resolved* questions and the resulting question repository that we use for question retrieval contains 2,288,607 questions. Each resolved question consists of four parts: "question title", "question description", "question answers" and "question category". For question retrieval, we only use the "question title" part. It is assumed that the titles of the questions already provide enough semantic information for understanding the users' information needs (Duan et al., 2008). There are 26 categories at the first level and 1,262 categories at the leaf level. Each question belongs to a unique leaf category. Table 3 shows the distribution across first-level categories of the questions in the archives.

Category	#Size	Category	# Size
Arts & Humanities	86,744	Home & Garden	35,029
Business & Finance	105,453	Beauty & Style	37,350
Cars & Transportation	145,515	Pet	54,158
Education & Reference	80,782	Travel	305,283
Entertainment & Music	152,769	Health	132,716
Family & Relationships	34,743	Sports	214,317
Politics & Government	59,787	Social Science	46,415
Pregnancy & Parenting	43,103	Ding out	46,933
Science & Mathematics	89,856	Food & Drink	45,055
Computers & Internet	90,546	News & Events	20,300
Games & Recreation	53,458	Environment	21,276
Consumer Electronics	90,553	Local Businesses	51,551
Society & Culture	94,470	Yahoo! Products	150,445

Table 3: Number of questions in each first-level category

We use the same test set in previous work (Cao et al., 2009, 2010). This set contains 252 queried questions and can be freely downloaded for research communities.[7] For each method, the top 20 retrieval results are kept. Given a returned result for each queried question, an

[6] http://developer.yahoo.com/answers

[7] The data set is available at http://homepages.inf.ed.ac.uk/gcong/qa/

annotator is asked to label it with "relevant" or "irrelevant". If a returned result is considered semantically equivalent to the queried question, the annotator will label it as "relevant"; otherwise, the annotator will label it as "irrelevant". Two annotators are involved in the annotation process. If a conflict happens, a third person will make judgement for the final result. In the process of manually judging questions, the annotators are presented only the questions.

Evaluation Metrics: We evaluate the performance of question retrieval using the following metrics: **Mean Average Precision** (MAP) and **Precision@N** (P@N). MAP rewards methods that return relevant questions early and also rewards correct ranking of the results. P@N reports the fraction of the top-N questions retrieved that are relevant. We perform a significant test, i.e., a t-test with a default significant level of 0.05.

Parameter Selection: We tune the parameters on a small development set of 50 questions. This development set is also extracted from Yahoo! Answers, and it is not included in the test set. For the smoothing parameter λ, we set $\lambda = 2000$ empirically in the language modeling approach for both English representation and Chinese translated representation. For parameter μ used in equation (11), we set $\mu = 0.8$ empirically. For parameter α, we do an experiment on the development set to determine the optimal values among 0.1, 0.2, $\cdots$, 0.9 in terms of MAP. As a result, we set $\alpha = 0.6$ in the experiments empirically as this setting yields the best performance. For parameter k described in Algorithm 1, we try several different values on the development set. Finally, we set $k = 30$ empirically as this setting gives the better performance.

5.2 Question Retrieval Results using Language Model

Table 4 shows a comparison of the results obtained using monolingual and bilingual representation using language model (LM) defined in subsection 4.2.1 and subsection 4.2.2 for question retrieval. In Table 4, **E** denotes the baseline LM using English representation (queried questions and historical questions). **C** denotes the run of LM using Chinese representation via English-Chinese translation (queried questions and historical questions). **E + C** denotes the run of LM with the combination of English and Chinese representation, where **Linear E + C** denotes the linear combination using equation 8, and **Refined E + C** denotes the refined ranking approach using equations 9 and 10. There are some clear trends in the results of Table 4:

Translation tools	#	Methods	MAP	P@10
-	1	E	0.385	0.242
GoogleTrans	2	C	0.350	0.234
	3	Linear E + C	0.468†	0.269†
	4	Refined E + C	**0.483**†	**0.275**†
YahooTrans	5	C	0.327	0.214
	6	Linear E + C	0.441†	0.258†
	7	Refined E + C	0.465†	0.267†
DicTran	8	C	0.246	0.178
	9	Linear E + C	0.398	0.246
	10	Refined E + C	0.414†	0.249

Table 4: Comparison of bilingual and monolingual representation using language model (LM) for question retrieval. The mark † indicates statistical significance over E.

(1) Using the bilingual translated representation, question retrieval performance can be significantly improved (row 1 vs. row 3 and row 4; row 1 vs. row 6 and row 7; row 1 vs. row 9 and

row 10). The reason is that various different words in English that refer to similar meanings can be translated into only a few words or a single word in Chinese. Thus, the lexical gap problem in English is to some extent ameliorated by using translated words in Chinese.

(2) We can see that question retrieval performance relies positively on the translated bilingual representation, and **GoogleTrans** performs the best while **DicTran** performs the worst (row 3 vs. row 9; row 4 vs. row 10), which is consistent with the fact **GoogleTrans** is deemed the best of the three machine translation systems, while **DicTran** is the weakest one. Moreover, **DicTran** performs translation without taking into account the surrounding words as contextual information, while **GoogleTrans** and YahooTrans are context-dependent and thus produce different translated Chinese words depending on the context of an English word. Therefore, the word ambiguity problem can be resolved during the English-Chinese translation in a given context of an English word.

(3) Comparing the two combination strategies **Linear** and **Refined**, it is seen that the refined ranking strategy (Refined E + C) gives the better results than linear combination regarding the different translation tools (row 3 vs. row 4; row 6 vs. row 7; row 9 vs. row 10).

5.3 Question Retrieval Results using Category-Sensitive Language Model

Table 5 shows the comparison results of monolingual and bilingual representation using category-sensitive language model (CSLM) for question retrieval. In Table 5, **E** denotes the baseline CSLM using the English representation only, and **E + C** denotes the run of CSLM based on the English and Chinese representation.

Translation tools	#	Methods	MAP	P@10
-	1	E	0.441	0.258
GoogleTrans	2	C	0.396	0.247
	3	Linear E + C	0.493†	0.282†
	4	Refined E + C	**0.525**†	**0.290**†
YahooTrans	5	C	0.358	0.237
	6	Linear E + C	0.476†	0.272†
	7	Refined E + C	0.492†	0.281†
DicTran	8	C	0.283	0.191
	9	Linear E + C	0.455	0.263
	10	Refined E + C	0.470†	0.270†

Table 5: Comparison of bilingual and monolingual representation using category-sensitive language model (CSLM) for question retrieval. The mark † indicates statistical significance over E.

Category-sensitive language model (CSLM) without considering the translated representation (e.g., row 1 in Table 5) is highly effective for question retrieval, achieving about 5.6% MAP increase over the baseline LM (e.g., row 1 in Table 4), with statistical significance. Similar findings have also been found by Cao et al. (2009) and Cao et al. (2010). Additionally, using the bilingual translated representation (E + C) achieves further improvements over CSLM (e.g., row 1 vs. row 3 and row 4). Specially, our refined ranking approach (Refined E + C) using GoogleTrans achieves about 8.4% further increase of MAP over the baseline CSLM (E) for question retrieval, finally leading to a noticeable increase of 14% MAP over the baseline LM.

5.4 Comparison with Different Methods

The motivation of this paper is to solve the lexical gap and word ambiguity problems for question retrieval. Jeon et al. (2005) proposed a word-based translation model for automatically fixing the lexical gap problem. Experimental results demonstrated that the word-based translation model significantly outperformed the traditional methods (i.e., VSM, BM25, LM). Xue et al. (2008) proposed a word-based translation language model for question retrieval. The results indicated that word-based translation language model further improved the retrieval results and obtained the state-of-the-art performance. Zhou et al. (2011) proposed a monolingual phrase-based translation model for question retrieval. This method can capture some contextual information in modeling the translation of phrases as a whole. To implement the word-based translation models, we use the GIZA++ alignment toolkit[8] trained on one million question-answer pairs from another data set[9] to learn the word-to-word translation probabilities. For phrase-based translation model described in (Zhou et al., 2011), we employ Moses toolkit[10] to extract the phrase translation and set the maximum length of phrases to 5. Recently, Singh (2012) extended the word-based translation model and explored strategies to learn the translation probabilities between words and the concepts using the CQA archives and a popular entity catalog. However, these existing studies in the literature are basically monolingual translation, which are restricted to the use of the original language of the CQA archives, without taking advantage of potentially rich semantic information drawn from other languages. In this paper, we propose the use of translated words to enrich question representation, going beyond the words in original language to represent the questions.

#	Methods	MAP	P@10
1	Jeon et al. (2005)	0.405	0.247
2	Xue et al. (2008)	0.436	0.261
3	Zhou et al. (2011)	0.452	0.268
4	Singh (2012)	0.450	0.267
5	**Refined E + C (LM, GoogleTrans)**	**0.483**†	**0.275**†

Table 6: Comparison with different methods for question retrieval without considering the category information. The mark † indicates statistical significance over previous work.

The comparisons with different methods for question retrieval are shown in Table 6. The results in Table 6 show that we propose the use of translated words to enrich question representation is much better than traditional monolingual approaches (row 1, row 2, row 3 and row 4 vs. row 5). Significant tests using t-test show the difference between our proposed approach and traditional monolingual approaches for cases marked in the table are statistically significant.

To further analyze why traditional monolingual approaches fail to give the satisfactory results for solving the word ambiguity and lexical gap problems, we identify two key challenges in adapting traditional monolingual translation approaches for question retrieval(Jeon et al., 2005; Xue et al., 2008; Zhou et al., 2011). First, unlike bilingual text, question-answer pairs are not semantically equivalent, leading to a wider range of possible phrases for a given phrase.

[8] http://www-i6.informatik.rwth-aachen.de/Colleagues/och/software/GIZA++.html

[9] The Yahoo! Webscope dataset Yahoo answers comprehensive questions and answers version 1.0, available at http://reseach.yahoo.com/Academic_Relations.

[10] http://www.statmt.org/moses/

Furthermore, both sides of question-answer parallel text are written in the same language (e.g., English). Thus, the most strongly associated word or phrase pairs found by the off-the-shelf word alignment and phrase extraction tools are identical pairs. Second, in question-answer pairs, there are far more unaligned words than in bilingual pairs. Also, there are more large phrase pairs that cannot be easily decomposed. These difficult cases confuse the IBM word alignment models. To the best of our knowledge, it is the first work to give a thorough analysis the key challenges in adapting traditional monolingual translation approaches for question retrieval.

Besides, we are aware of only two published studies (Cao et al., 2009) and (Cao et al., 2010) on utilizing category information for question retrieval. Now we compare our proposed category-sensitive language model (CSLM) for bilingual representation with these two studies. Cao et al. (2009) employed classifiers to compute the probability of a queried question belonging to different categories, and then incorporated the classified categories into language model for question retrieval. Cao et al. (2010) introduced the different combinations to compute the global relevance and local relevance, the combination VSM + TRLM showed the superior performance than others. In this paper, we compare the proposed method with the combination VSM + TRLM. To implement these two methods, we employ the same parameter settings with Cao et al. (2009) and Cao et al. (2010). Table 7 shows the comparison. From this table, we can see that our proposed category-sensitive language model (CSLM) for bilingual representation can significantly improve the performance. The results also validate the effectiveness of the proposed method.

#	Methods	MAP	P@10
1	Cao et al. (2009)	0.408	0.247
2	Cao et al. (2010)	0.456	0.269
3	**Refined E + C (CSLM, GoogleTrans)**	**0.525**†	**0.290**†

Table 7: Comparison with previous work for question retrieval by considering the category information. The mark † indicates statistical significance over previous work.

5.5 Parameter Sensitivity of Combination

To combine the relevance scores for question retrieval, we propose to use the linear combination and the refined ranking approach to rank the final similar questions. In linear combination, we use parameter α to control the relative importance of original question representation and translated representation. In refined ranking approach, we retrieve the top-k similar questions from two perspectives for each queried question. To investigate the effect of these two parameters, we design the following experiments.

To examine the effect of α, we choose the best translation service GoogleTrans and evaluate α with different values among 0, 0.1, $\cdots$, 0.9 in terms of MAP on a small development set of 50 questions. This development set is also extracted from Yahoo! Answers data, and it is not included in the test set. The experimental results for different α are illustrated in Figure 2. Monolingual baselines E and C are used for reference. Figure 2(Left) shows that, for MAP, **E + C** performs better than baselines E and C when $\alpha \in (0.2, 0.9)$. Therefore, a relative broad set of good parameter value is observed. When $\alpha = 0.6$, **E + C** gives the best performance.

To investigate the effect of parameter k, we also choose the best translation service GoogleTrans with several different values from 10 to 50 in terms of MAP on this development set.

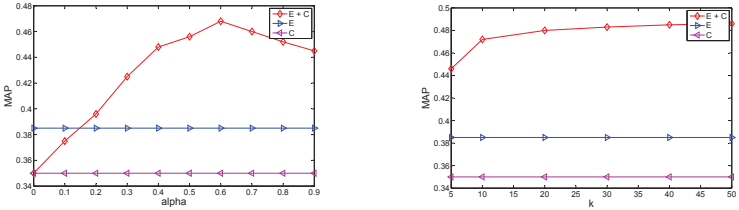

Figure 2: Left: The effect of parameter α for the linear combination using MAP metric; Right: The effect of parameter k for the refined ranking using MAP metric.

The experimental results for different k are illustrated in Figure 2(Right). We can see the performance becomes better for greater k used in the refined ranking approach. We believe the reason is that more historical questions may contain more similar questions. However, a larger k may result in longer processing time. Therefore, a good tradeoff is to set $k = 30$.

6 Related Work

6.1 Question Retrieval in CQA

The research of question retrieval has been further extended to the CQA data. The major challenge for question retrieval in CQA is the word ambiguity and lexical gap problems. Jeon et al. (2005) proposed a word-based translation model for automatically fixing the lexical gap problem. Xue et al. (2008) proposed a word-based translation language model for question retrieval. The results indicated that word-based translation language model further improved the retrieval results and obtained the state-of-the-art performance. Subsequent work on word-based translation models focused on providing suitable parallel data to learn the translation probabilities. Lee et al. (2008) tried to further improve the translation probabilities based on question-answer pairs by selecting the most important terms to build compact translation models. Bernhard and Gurevych (2009) proposed to use as a parallel training data set the definitions and glosses provided for the same term by different lexical semantic resources. Cao et al. (2010) explored the category information into the word-based translation model for question retrieval.

Recently, Riezler et al. (2007) and Zhou et al. (2011) proposed a phrase-based translation model for question and answer retrieval. The phrase-based translation model can capture some contextual information in modeling the translation of phrases as a whole, thus the word ambiguity and lexical gap problems are somewhat alleviated. Singh (2012) addressed the lexical gap issues by extending the lexical word-based translation model to incorporate semantic information (entities).

However, most existing works in the literature are basically monolingual approaches which are restricted to the use of the original language of the CQA archives, without taking advantage of potentially rich semantic information drawn from other languages. In this paper, we intend to address two fundamental issues in question retrieval: word ambiguity and lexical gap. To solve these problems, we enrich the question representation via bilingual translation. Compared to the traditional monolingual approaches, our proposed bilingual translation is much more effective due to the recent advance in statistical machine translation. To the best of our knowledge, it is the first work to improve question retrieval in CQA via bilingual translation.

6.2 WSD and Query Expansion for Monolingual Information Retrieval

Besides in CQA, word ambiguity and lexical gap have been investigated in information retrieval (IR). Zhong and Ng (2012) proposed a novel approach to incorporate word senses into the language modeling approach to IR. Experimental results showed that word sense disambiguation (WSD) can significantly improve a state-of-the-art IR system. Query expansion has been one of the most effective approaches to resolve the lexical gap problem, which enrich the original query by adding some additional words (Lv and Zhai, 2010; Xu et al., 2009). Recently, Trieschnigg et al. (2010) enriched the original word-based representation with a concept-based representation, thereby proposing the translation of the original word language to a concept language. However, their translation models are based solely on the use of translation at the lexical level (e.g., word-to-concept), and thus their method is very different from our context-dependent style of translation. Na and Ng (2011) also applied automatic translation for monolingual retrieval. However, they used the expected frequency of a word computed from all possible translated representations, while we use the state-of-the-art commercial machine translation service (e.g., Google Tranlate), which is much simpler than their translation strategies.

6.3 Machine Translation for Cross-Lingual Information Retrieval

Cross-lingual retrieval information retrieval (CLIR) addresses the problem of retrieving documents written in a language different from the query language. The common approach in CLIR is to perform query translation or document translation using a machine translation system(Chen and Gey, 2004; Kraaij et al., 2003). However, the major difference is that our goal is to improve monolingual question retrieval and not CLIR. Moreover, these studies performed translation without taking into account the context information of an original word(Chen and Gey, 2004; Kraaij et al., 2003). On the contrary, our approach is context-dependent and thus produces different translated words depending on the context of a word in original language.

Conclusion and Future Work

In this paper, we intend to address two fundamental issues in question retrieval: word ambiguity and lexical gap. To solve these problems, we propose the use of bilingual question representation, encouraged by the fact that a translated word in a foreign language can be used to enrich the original question representation. We employ the statistical machine translation services to automatically translate all questions, producing bilingual representations. Then, the relevance score between a queried question and a historical question is computed by combining two evidences derived from the bilingual perspectives. Experimental results conducted on large-scale CQA data set from Yahoo! Answers show that by using English-Chinese translation, our approach achieves improvements over monolingual approaches, and the improvements are in many cases statistically significant.

There are some ways in which this research could be continued. First, we would like to extend the current experiments by considering other languages (e.g., English-French, Chinese-English, etc.). We want to see how strongly the linguistic diversity between original and foreign languages affects question retrieval performance. Second, we will try to investigate the use of the proposed approach for other kinds of data set, such as categorized questions from forum sites and FAQ sites.

Exploiting Lexical Dependencies from Large-Scale Data for Better Shift-Reduce Constituency Parsing

Abstract

This paper proposes a method to improve shift-reduce constituency parsing by using lexical dependencies. The lexical dependency information is obtained from a large amount of auto-parsed data that is generated by a baseline shift-reduce parser on unlabeled data. We then incorporate a set of novel features defined on this information into the shift-reduce parsing model. The features can help to disambiguate action conflicts during decoding. Experimental results show that the new features achieve absolute improvements over a strong baseline by 0.9% and 1.1% on English and Chinese respectively. Moreover, the improved parser outperforms all previously reported shift-reduce constituency parsers.

Title and Abstract in Chinese

利用大规模数据词汇依存关系改进移进－归约成分句法分析

本文提出了一种利用词汇依存关系改进移进－归约成分句法分析的方法。首先，我们利用基准系统在大规模无标注数据上进行自动句法分析并从分析结果中抽取词汇依存关系。其后，我们在词汇依存信息的基础上定义了一组新特征并将这些特征整合到移进－归约句法分析模型 中。新特征用于帮助消除移进－归约过程中的动作歧义。实验结果表明，新特征在英文和中文数据上分别取得了0.9% 和1.1%的性能改进。最终得到的句法分析器的性能优于相关研究工作中所报告的移进－归约句法分析器的性能。

1 Introduction

Due to the simplicity and running efficiency, shift-reduce parsing has been studied extensively for a variety of grammars, ranging from constituency parsing (Sagae and Lavie, 2005, 2006; Zhang and Clark, 2009) through dependency parsing (Nivre, 2004; Yamada and Matsumoto, 2003; Zhang and Clark, 2008) to CCG parsing (Zhang and Clark, 2011). In dependency and CCG parsing, shift-reduce parsing is among the best-performing algorithms (Huang and Sagae, 2010; Zhang and Clark, 2011). However, compared to commonly-used statistical parsers available on the web such as Charniak-Johnson (Charniak and Johnson, 2005) and Petrov-Klein (Petrov and Klein, 2007), shift-reduce constituency parsers still have room left for further improvements on parsing accuracy.

There exist at least two major directions to advance shift-reduce constituency parsing. One direction is to design better training and decoding algorithms. For example, in the respect of decoding, Sagae and Lavie (2006) proposed a best-first search strategy to expand the search space. In the respect of training, Zhang and Clark (2009) replaced local classifiers with a global learning algorithm. The other direction is to enrich feature representations for better shift-reduce constituency parsing, which will be the focus of this paper. In this direction, previous work has extensively studied a variety of features, all in the framework of supervised learning (Sagae and Lavie, 2005, 2006; Wang et al., 2006; Zhang and Clark, 2009).

How to further enrich feature representations for better shift-reduce constituency parsing becomes a very challenging problem. In this paper, we solve this issue by using the information of lexical head-modifier[1] relations (a.k.a. lexical dependencies) (Collins, 1996). Previous work on other constituency parsers have shown the effectiveness of lexical dependency information on disambiguating syntactic structures (Collins, 1996, 1997; Eisner and Satta, 1999). But in shift-reduce constituency parsing, such information is not fully used. For instance, Zhang and Clark (2009) completely neglected lexical dependency information. Sagae and Lavie (2005) and Wang et al. (2006) only incorporated as features the most recently recognized (left and right) modifiers of some designated words. Unlike previous work on shift-reduce constituency parsing, this paper aims to incorporate features that encode the information of whether words in an input sentence tend to have head-modifier relations. In addition, although it is feasible to get lexical dependency information from human-labeled treebank data by using head-finding rules (Collins, 1999), we find that lexical dependencies obtained from this source suffer from data sparseness (Section 5.1). We propose to solve this problem by utilizing additional large-scale unlabeled data.

The basic idea of our approach is to provide shift-reduce parsers with lexical dependency information that is obtained from large-scale auto-parsed data. To this end, we first parse unlabeled data with a baseline parser and afterwards extract bigram and trigram lexical dependencies from automatically parsed trees. Based on the extracted lexical dependencies, we finally design a set of features to enhance the baseline parser. The experiments in Section 5 show that new features can improve a strong baseline parser by 0.9% and 1.1% on English and Chinese data sets respectively. Moreover, our parser outperforms previously reported shift-reduce constituency parsers while maintaining efficiency.

Specifically, we make the following contributions in this paper:

- We propose a set of novel features for better shift-reduce constituency parsing that is based on lexical dependencies obtained from large-scale auto-parsed data;

[1] By 'head-modifier' we mean the linguistic notion that a word (*modifier*) modifies another word (*head*).

- We empirically compare two different sources for obtaining lexical dependencies: human-labeled treebank data and large-scale auto-parsed data respectively, and show the superiority of using auto-parsed data (Section 5.1);
- We empirically analyze major sources of shift-reduce parsing errors (Section 3.1) and verify the effectiveness of new features in resolving shift-reduce action conflicts (Section 5.6.2);

2 Baseline Parser

We use the beam-search shift-reduce parser (Zhang and Clark, 2009) as the baseline system in this paper. [2] In what follows, we describe the parser in brief.

2.1 The Shift-Reduce Parsing Process

The shift-reduce process in the baseline parser assumes binary-branching trees, so binarization and debinarization are required for transforming training data and parsing output, respectively (Zhang and Clark, 2009). Given an input sentence (words and POS tags), any possible parse tree yielding the sentence corresponds *exactly* to one sequence of states. Formally, each state in the sequence is denoted by a tuple $\langle S, Q \rangle$, where S is a stack containing partial parses and Q is a queue of word-POS pairs that remain unprocessed. In particular, the initial state is $\langle \phi, w_1 \dots w_n \rangle$ where S is empty and Q contains the entire input sentence. The final state is $\langle S, \phi \rangle$ where S contains a single parse tree with a pre-designated root label and Q is empty. Thus, the shift-reduce parsing process is a transition process from the initial state to the final state by performing a sequence of the following actions.

1. shift, which moves a pair of word and POS tag from the head of the queue to the stack. Here the queue is required to be non-empty.
2. reduce-unary-X, which extends the top item on the stack by applying a unary rule and then replaces the top item with the newly generated constituent. Here X represents a treebank phrase label, such as *NP*, which is to be used as the root label of the new constituent.
3. reduce-binary-{L/R}-X, which moves top two items out of the stack and pushes a new item onto the stack. The new item has X as its root label and consists of two children with the first popped item becoming the right child and the second popped item becoming the left child. The switch L/R indicates whether the left (L) or the right (R) child becomes the head child.
4. terminate, which pops the root node off the stack and ends parsing. This action is applicable only when the stack contains a single parse and the queue is empty.

2.2 Beam Search Extension

The shift-reduce parsing process described above can be extended with beam search, as presented in Algorithm 1. The algorithm starts by initializing a beam of size K with the initial state. In each iteration after the initialization, states are popped in turn out of the beam. For each popped state, all applicable actions are then evaluated with respect to the state. Scored action-state pairs are sorted in a temporary priority queue. When the beam gets empty, top K highest-scored action-state pairs are fetched from the priority queue and next states corresponding to the action-state pairs are inserted back into the beam. If the highest-scored state in the beam is a final state, it will be returned as the parsing result; else the iteration continues. The algorithm has time complexity of $O(nK)$, where n is the sentence length and K is the beam size.

[2] www.cl.cam.ac.uk/~yz360/zpar.html

Algorithm 1 Beam-search shift-reduce parsing

Input: a POS-tagged word sequence $w_1 \dots w_n$
beam size K and *action set*

```
1: B ← {⟨ϕ, w_1 ... w_n⟩}        // initialize beam
2: loop
3:     priority queue P = []
4:     while B not empty do
5:         state ← pop(B)
6:         for all act ∈ action set do
7:             score ← evaluate act for state
8:             P·insert (⟨score, act, state⟩)
9:     for i = 0 to K do
10:        ⟨score, act, state⟩ ← Pop-Top (P)
11:        next ← apply act to state
12:        insert next to B
13:    best ← highest-scored state in B
14:    if best is complete then
15:        return best
```

2.3 Model and Learning Algorithm

To score an action A with respect to a state $Y = \langle S, Q \rangle$, we use a linear model as defined by

$$Score(\langle A, Y \rangle) = \vec{w} \cdot \Phi(\langle A, Y \rangle) = \sum_i \lambda_i f_i(\langle A, Y \rangle)$$

where $f_i(\langle A, Y \rangle)$ are features extracted jointly from the action A and state Y. To learn parameters λ_i, we use the generalized perceptron algorithm proposed in Collins (2002).

Generalized perceptron is an online learning algorithm that learns one instance at a time. The basic procedure is to use the beam-search parsing algorithm (Algorithm 1) to parse the yield of a gold parse tree. Whenever the gold partial parse is pruned from the beam, parameters will be updated immediately and the learner moves to the next training instance. Such a strategy is known as "early-update" (Collins and Roark, 2004). Finally, model parameters are set to be an average of the weight vectors obtained during the online learning.

2.4 Baseline Features

Features used in the baseline parser are similar as those used in Zhang and Clark (2009). For convenience of reference, we repeat the features in Table 1, where the symbol S_i represents the i_{th} item from the top of the stack S and the symbol Q_i denotes the i_{th} item from the front end of the queue Q. The symbol w represents the lexical head for an item; c represents the label for an item; and t denotes POS of a lexical head. Note that Zhang and Clark (2009) also used bracket-related and separator features for Chinese parsing, which have been removed in the latest release of their parser. So in this article we choose to ignore such language specific features.

3 Our Approach

3.1 Motivation

We first empirically analyze major sources of shift-reduce parsing errors with the parsing results of the baseline parser on the English development set. The baseline parser is trained on human-labeled training data. Regarding the parsing results, we are especially concerned with *first mistakes* that the baseline parser makes because future mistakes are often caused by previous ones. There are

Description	Templates
Unigrams	$S_0tc, S_0wc, S_1tc, S_1wc, S_2tc, S_2wc, S_3tc, S_3wc,$ $Q_0wt, Q_1wt, Q_2wt, Q_3wt,$ $S_0lwc, S_0rwc, S_0uwc, S_1lwc, S_1rwc, S_1uwc$
Bigrams	$S_0wS_1w, S_0wS_1c, S_0cS_1w, S_0cS_1c,$ $S_0wQ_0w, S_0wQ_0t, S_0cQ_0w, S_0cQ_0t,$ $Q_0wQ_1w, Q_0wQ_1t, Q_0tQ_1w, Q_0tQ_1t,$ $S_1wQ_0w, S_1wQ_0t, S_1cQ_0w, S_1cQ_0t$
Trigrams	$S_0cS_1cS_2c, S_0wS_1cS_2c, S_0cS_1wQ_0t, S_0cS_1cS_2w,$ $S_0cS_1cQ_0t, S_0wS_1cQ_0t, S_0cS_1wQ_0t, S_0cS_1cQ_0w$

Table 1: A summary of baseline feature templates, where S_i represents the i_{th} item in stack S and Q_i denotes the i_{th} item in the queue Q from the front end.

ID	Mistake Type	Ratio (Count)
1	shift vs. red-binary	47.8% (451)
2	shift vs. red-unary	18.1% (171)
3	red-binary vs. red-unary	5.4% (92)
4	red-binary-L/R-{X vs. X*}	16.5% (156)
5	red-unary-{X_1 vs. X_2}	5.7% (54)

Table 2: Types and ratios of first mistakes made by the baseline parser on the English development set with auto-assigned POS.

944 first mistakes in total in the parsing results. Table 2 shows the types and ratios of the top 5 most frequent first mistakes. Cases 1-2 consist of conflicts between shift and reduce actions. Case 3 is comprised of conflicts between reduce-binary and reduce-unary actions. Mistakes in cases 4-5 are caused by wrong choices of labels where the symbols X, X_1, and X_2 refer to treebank phrase labels and the symbol X* denotes a temporary label which is introduced when a constituent with label *X* is binarized. From the table we notice that action conflicts between shift and reduce-binary are the largest source of parsing errors, which cover nearly half of first mistakes.

Intuitively, lexical dependency information is beneficial to resolving shift and reduce-binary conflicts. In the following, we use a real example to make clear the intuition. Figure 1 illustrates the shift-reduce parsing process of the baseline parser on a sentence with auto-assigned POS tags. The baseline parser proceeds correctly until it reaches the state in Figure 1-(a). At that point, there is a conflict between reduce-binary (Figure 1-(b)) and shift (Figure 1-(c)) actions. We find that the baseline parser wrongly chooses the reduce-binary action because the word *bore* is (incorrectly) tagged as a verb.[3] The baseline parser tends to group the words preceding a verb as a constituent. However, if the parser is informed that the words *a* and *bore* have a lexical dependency relationship, the parser may correct its choice and switch to the shift action. In addition, we find that the human-labeled data used to train the baseline parser does not contain lexical dependencies between *a* and *bore*. We can see that extracting lexical dependencies solely from human-labeled training data has a data sparseness problem. This motivates us to utilize unlabeled data as an additional source for lexical dependency extraction.

[3]All the occurrences of *bore* in the training data of the POS tagger have the POS tag *VBD*.

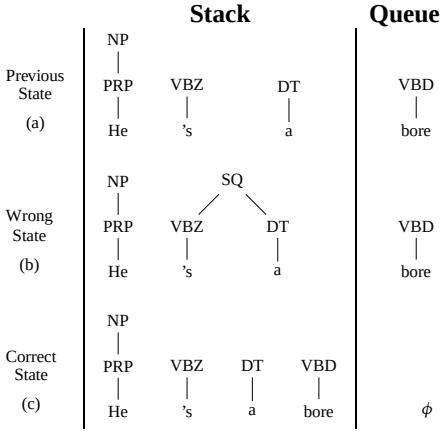

Figure 1: An example of shift-reduce conflicts, illustrating how lexical dependency information helps to disambiguate the conflicts.

3.2 Data Preprocessing

Before conducting lexical dependency extraction, we use the baseline parser to generate constituency parse trees from unlabeled data. Since shift-reduce parsers require POS tags as input, automatical POS tagging should be performed on unlabeled data before performing syntactic parsing. For unspaced languages such as Chinese, automatical word segmentation is also needed. To simplify the extraction process, we convert automatically parsed constituency trees into dependency trees with Penn2Malt (or other conversion tools).[4]

3.3 Extraction of Lexical Dependencies

After the tree conversion, the following lexical dependencies are read off from dependency trees. Here we restrict the dependencies to those between two words (bigram lexical dependencies) and those between three words (trigram lexical dependencies).

Bigram Lexical Dependencies

If two words are connected by an arc in a dependency tree, we claim these two words maintain a bigram lexical dependency. For pairs of words that have dependencies, we make a record of the words as well as their head-modifier relations. Formally, bigram lexical dependencies are denoted as $\langle w_1, w_2, L/R \rangle$ where L/R indicates the direction of the dependency arc that connects w_1 and w_2. Moreover, lexical dependencies are word-order sensitive, that is, $\langle w_1, w_2, L \rangle$ is regarded to be different from $\langle w_2, w_1, R \rangle$.

Trigram Lexical Dependencies

Trigram lexical dependencies encode a head-modifier relationship among three words. As with bigram lexical dependencies, trigram lexical dependencies are also word-order sensitive. In this

Bigram Dependency Features			
$f_L(s_1w, s_0w)$	$f_L(s_1w, s_0w) \circ s_1t \circ s_0t$	$f_R(s_1w, s_0w)$	$f_R(s_1w, s_0w) \circ s_1t \circ s_0t$
$f_L(s_1w, q_0w)$	$f_L(s_1w, q_0w) \circ s_1t \circ q_0t$	$f_R(s_1w, q_0w)$	$f_R(s_1w, q_0w) \circ s_1t \circ q_0t$
$f_L(s_0w, q_0w)$	$f_L(s_0w, q_0w) \circ s_0t \circ q_0t$	$f_R(s_0w, q_0w)$	$f_R(s_0w, q_0w) \circ s_0t \circ q_0t$
Trigram Dependency Features			
$f_L(s_1w, s_1rdw, s_0w)$	$f_L(s_1w, s_1rdw, s_0w) \circ s_1t \circ s_0t$	$f_R(s_1w, s_0ldw, s_0w)$	$f_R(s_1w, s_0ldw, s_0w) \circ s_1t \circ s_0t$
$f_L(s_0w, s_0rdw, q_0w)$	$f_L(s_0w, s_0rdw, q_0w) \circ s_0t \circ q_0t$	$f_R(s_0w, NONE, q_0w)$	$f_R(s_0w, NONE, q_0w) \circ s_0t \circ q_0t$

Table 3: New features designed on the basis of lexical dependencies. Here the symbol w represents a word and the symbol t represents a POS tag.

paper, we only consider the type of trigram lexical dependencies that have the first or the last word be the head and that require the other two words to be siblings among all the modifiers of the head. Such lexical dependencies can be represented formally as $\langle w_1, w_2, w_3, L/R \rangle$. Here the switch L/R indicates the head among the three words. Specifically, the symbol L specifies w_1 to be the head and the symbol R designates w_3 to be the head. In addition, we also consider the special case that w_2 is *NONE*, which indicates that w_1 (w_3) is the rightmost (leftmost) modifier of w_3 (w_1).

3.4 Proposed Features

After extracting all lexical dependencies, we group bigram and trigram lexical dependencies *separately* into three categories according to their frequencies. Specifically, if a dependency relation is among top-10% most frequent records, then it receives the group tag *High Frequency (HF)*; else if it is in top-20%, then we use the tag *Middle Frequency (MF)*; else we use the tag *Low Frequency (LF)*. Although such a grouping strategy is heuristic in some sense, it has been proven effective in Chen et al. (2009). After the grouping, we finally get two lists, containing bigram and trigram lexical dependencies respectively.

Based on the bigram and trigram lexical dependency lists, we propose a set of dependency features which is described in detail in the following. Here s_i denotes the i_{th} item from the top of the stack S, and q_i the i_{th} item from the front end of the queue Q. In addition, s_iw (s_it) refers to the head word (POS) of s_i and q_iw (q_it) refers to the word (POS) of q_i.

3.4.1 Bigram Dependency Features

Bigram dependency features have a generic form of $f_{L/R}(w_1, w_2)$ which returns a group tag (HF, MF, or LF) if the lexical dependency $\langle w_1, w_2, L/R \rangle$ is found in the bigram lexical dependency list; else it returns *NULL*. The above feature template is instantiated into three pairs of features: $\{f_L(s_1w, s_0w), f_R(s_1w, s_0w)\}$, $\{f_L(s_0w, q_0w), f_R(s_0w, q_0w)\}$, and $\{f_L(s_1w, q_0w), f_R(s_1w, q_0w)\}$.

We also combine the above features with POS tags of w_1 and w_2. Thus we have three more pairs of features in the generic form of $f_{L/R}(w_1, w_2) \circ t(w_1) \circ t(w_2)$, where $t(w_i)$ represents the POS tag of the word w_i. All the bigram dependency features are listed in Table 3.

3.4.2 Trigram Dependency Features

Trigram dependency features have the generic form of $f_{L/R}(w_1, w_2, w_3)$. In this paper, this feature template is instantiated into two pairs of features. The feature function $f_L(s_1w, s_1rdw, s_0w)$ returns a group tag if $\langle s_1w, s_1rdw, s_0w, L \rangle$ is found in the trigram lexical dependency list, where s_1rdw denotes the rightmost modifier of s_1w that has been recognized so far during the shift-reduce parsing process. Note that s_1rdw might be *NONE* if no right modifiers have been recognized for s_1w. The

other trigram dependency features, $f_R(s_1w, s_0ldw, s_0w)$, $f_L(s_0w, s_0rdw, q_0w)$, and $f_R(s_0w$, *NONE*, $q_0w)$ can be explained in a similar way. As with bigram dependency features, POS tags are combined with above features to obtain richer feature representations. Trigram dependency features used in the paper are summarized in Table 3.

3.5 Parsing with Proposed Features

To use the proposed dependency features, we only need to update the scoring function defined in Section 2.3. The new scoring function is shown in the following.

$$Score'(\langle A, Y\rangle) = \sum_i \lambda_i f_i(\langle A, Y\rangle) + \sum_j \lambda_j^d f_j^d$$

where $f_i(\langle A, Y\rangle)$ are the baseline features listed in Table 1 and f_j^d refer to the dependency features defined above.

4 Experimental Setup

4.1 Data Preparation

For English experiments, our labeled data came from the Wall Street Journal (WSJ) corpus of the Penn Treebank (Marcus et al., 1993). We used the standard divisions: sections 2-21 were used as training data, section 24 was used for system development, and section 23 was held out for performance evaluation. In terms of English unlabeled data, we used the TIPSTER corpus (LDC93T3A) which contains news articles from various sources, though in this paper we only used Wall Street Journal articles. In addition, we did not remove the sentences of the WSJ portion of the Penn Treebank from the TIPSTER corpus.

For Chinese experiments, we used Chinese Treebank (CTB) version 5.1 (Xue et al., 2005) as labeled data. Specifically, articles 001-270 and 440-1151 were used as training data, articles 271-300 were held out for performance evaluation, and articles 301-325 were used as development data. In the respect of Chinese unlabeled data, we utilized the corpus of Chinese Gigaword (LDC2003T09) after some basic cleanups.

We conducted necessary preprocessing on English and Chinese unlabeled data before they were fed to the baseline parser for automatic parsing. Specifically, we applied OpenNLP for English sentence boundary detection and tokenization.[5] For English POS tagging, SVMTool was used which achieves a per-token accuracy of 97.1% on section 23 of the WSJ corpus.[6] For the Chinese unlabeled data, we conducted sentence boundary detection simply according to sentence ending punctuations, including question marks, full stop marks, and exclamation marks. Raw sentences were automatically segmented with a CRF-based word segmenter which achieves a segmentation accuracy of 97.2% on the testing data of CTB 5.1. For automatic Chinese POS tagging, we utilized the Stanford POS tagger. [7] We trained the tagger on the CTB 5.1 training data and achieved a tagging accuracy of 95.4% on the CTB 5.1 testing data.

Table 4 contains detailed data statistics of all the above corpora.

Combined	89.3	89.5	89.4	85.3	85.2	85.2

Table 5: Comparative results on English and Chinese developments sets with lexical dependencies extracted from diverse sources.

4.2 Performance Scoring

For performance evaluation in all the following experiments, we used *EVALB* to provide bracket scoring as well as complete match scoring.[8] For significance tests, we adopted the comparator developed by Daniel Bikel to compute *p-value*.[9]

4.3 Running Parameters

We set the beam size to 16 in both training and decoding which maintains a good trade-off between parsing efficiency and accuracy (Zhang and Clark, 2009). With respect to the iteration number of perceptron learning, we tuned the parameter on the English and Chinese development sets and finally set the value to 21 for both English and Chinese experiments.

5 Experimental Results

5.1 Comparison of Different Sources

Table 5 shows the comparative results on English and Chinese development sets with lexical dependencies obtained from different sources. We experimented with four different settings: no lexical dependency information was used (Baseline), lexical dependencies were solely from human-labeled training data (Human-Labeled), lexical dependencies were solely from auto-parsed data (Auto-Parsed), and lexical dependencies were from the combination of human-labeled and auto-parsed data (Combined). For the latter three settings, all the dependency features listed in Table 3 were incorporated. In the data combination, we simply gave our human-labeled training data a relative weight of one.

From the results we can see that, although lexical dependency information from human-labeled training data can improve the performance on both English and Chinese, the improvement on Chi-

nese is marginal (+0.1% in F1-score). One reason is that lexical dependencies from human-labeled training data have a data sparseness problem. By contrast, the use of large-scale auto-parsed data brings on much bigger improvements (+1.1% in F1-score on both English and Chinese). In addition, we find that data combination has trivial effect on the performance. One possible reason is that lexical dependencies form human-labeled training data are overwhelmed by those from auto-parsed data. We will leave further discussions on data combination to our future work and focus on the setting of obtaining lexical dependencies from auto-parsed data.

5.2 Main Results on English Data

Table 6 shows the main results on the English test set, where the two types of dependency features were added incrementally to the baseline parser. As the results show, both bigram and trigram dependency features have positive effect on the parsing accuracy. Specifically, on the whole test set the overall improvement over the baseline parser is +0.9% in F1-score, where bigram dependency features contribute an absolute 0.6% improvement and trigram dependency features further improve the performance by 0.3% over the results of using bigram dependency features. Significance tests show that the overall improvement on the whole test set is statistically significant on the level of $p < 10^{-4}$.

5.3 Comparative Results on English

Table 7 shows the comparison of our parser with a large body of representative related work. For fair comparison, here we disregarded parsers that are based on combination methods such as Petrov (2010) and Zhang et al. (2009). Following the taxonomy adopted in Huang et al. (2010), we grouped the related work into single parsers (SINGLE), discriminative reranking approaches (RE), and self-training (SELF). Note that our parser belongs to the category of self-training. From the results we can see that our parser outperforms all the single parsers listed in the table except Carreras et al. (2008). However, compared with Carreras et al. (2008), our parser has much smaller time-complexity: $O(nK)$ vs. $O(n^3G)$, where K is the beam size used in our parser and G is a grammar constant in Carreras et al. (2008). Compared with reranking and self-training parsers, our parser has relatively low parsing accuracy. But the reranking technique is actually complementary with our approach, so we might enhance our parser with this technique in the future.

Table 8: Main results on the CTB 5.1 test set, using automatically assigned POS tags and lexical dependencies extracted from auto-parsed data. Two types of dependency features are added **incrementally**.

5.4 Main Results on Chinese Data

In parallel to the results on the English test set, Table 8 shows the main results on the Chinese test set, using auto-assigned POS tags and lexical dependencies extracted from auto-parsed data. From the results on the whole test set we can see that dependency features contribute a bigger absolute improvement on Chinese than that on English ($+1.1\%$ vs. $+0.9\%$). One possible reason is that the size of Chinese unlabeled data used in the paper is much bigger. Significance tests show that the overall improvement induced by bigram and trigram dependency features on the whole test is statistically significant on the level of $p < 10^{-3}$. These results indicate that the new features are very effective.

5.5 Comparative Results on Chinese

Comparing Chinese constituency parsers is difficult in the sense that previously reported results were achieved frequently on different versions of CTB and/or with different data split standards. Zhang and Clark (2009) presented a detailed comparison between the baseline parser of this paper and a large body of related work on CTB 2.0. Here we only compared our parser with the parsers available on the web for Chinese parsing, as shown in Table 9. From the results we can see

Type	Parser		LP	LR	F1
SINGLE	Charniak (2000)*		79.6	82.1	80.8
	Bikel (2004)†		79.3	82.0	80.6
	Petrov and Klein (2007)		81.9	84.8	83.3
RE	Charniak and Johnson (2005)*		80.8	83.8	82.3
	This Paper	Baseline	79.5	80.7	80.1
		Auto-Parsed	80.6	81.9	81.2

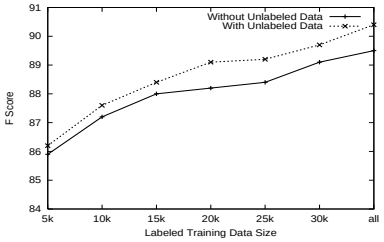
that, on Chinese parsing our parser outperforms Bikel (2004) and Charniak (2000) by 0.6% and 0.4%, respectively. However, our parser lags behind Petrov and Klein (2007) and the reranking parser (Charniak and Johnson, 2005).

5.6 Additional Analysis

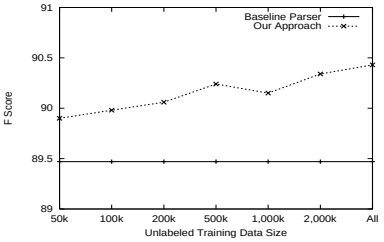
We performed several types of analysis, focusing on English, to investigate the effect of different sizes of human-labeled training data and auto-parsed data, as well as how lexical dependency information changes the distribution of first mistakes made by the baseline parser.

5.6.1 Effect of Different Sizes of Labeled and Unlabeled Data

We studied the effect of varying sizes of human-labeled training data by a randomly sampling from sections 2-21. Meanwhile, we always used the whole set of auto-parsed data. The results are depicted in Figure 2-(a). As the results show, auto-parsed data improves parsing accuracy even when the human-labeled training data is small in size. In addition, by using our approach, a fraction of sections 2-21 plus the whole set of auto-parsed data is sufficient to achieve the F1-scores obtained by the parser trained solely on the whole sections 2-21.



(a) varying labeled training data



(b) varying unlabeled data

Figure 2: Results with varying sizes of human-labeled training data and unlabeled data.

We also examined the effect of varying sizes of unlabeled data. In this experiment, we used sections 2-21 as human-labeled training data and changed the size of unlabeled data through random sampling. The results are depicted in Figure 2-(b). From the results we can see that improvements

achieved by using unlabeled data are enlarged with the increment of the size of unlabeled data until the performance finally levels off.

5.6.2 Reduction on First Mistakes

The baseline parser made 1,522 first mistakes on the English test set. We analyzed how our approach changed the first mistakes. We grouped the changes into four cases. *No-Change* (1,090) refers to the case that the baseline and our parser make the same first mistakes at the same positions. In the case of *Correct* (249), first mistakes made by the baseline parser are corrected by our parser. *Wrong* (121) means that our parser makes first mistakes earlier than the baseline parser. Finally, *Others* (47) refers to the case that our parser and the baseline parser make first mistakes of different types at the same positions. In addition, we are especially interested in how our approach reduces first mistakes of the type *shift vs. reduce-binary*. So we compared the numbers of first mistakes of this type in the *Correct* and *Wrong* cases, which are 168 and 78 respectively.

6 Related Work

Shift-reduce parsing has been widely studied for constituency parsing. Sagae and Lavie (2005) proposed a classifier-based shift-reduce parsing algorithm which was extended with a best-first search strategy in Sagae and Lavie (2006). Wang et al. (2006) adapted the parser in Sagae and Lavie (2005) to Chinese parsing and compared some representative classifiers. Zhang and Clark (2009) proposed a global learning algorithm to replace local classifiers. Shift-reduce parsing has also widely applied to parsing with other grammars (Nivre, 2004; Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Clark, 2011). In this paper we focus on improving Zhang and Clark (2009) with a set of novel features defined on lexical dependencies obtained from auto-parsed data. To the best of our knowledge, semi-supervised approaches to shift-reduce constituency parsing have not been widely studied before.

The approach used in this paper belongs to the category of semi-supervised learning. In the respect of semi-supervised learning for constituency parsing, self-training has been extensively studied (McClosky et al., 2006; Huang and Harper, 2009; Huang et al., 2010). The difference is that we use partial information derived from auto-parsed data instead of entire automatically parsed trees. Chen et al. (2009) and Noord (2007) exploited lexical dependencies from unlabeled data for dependency and HPSG parsing, respectively. In this paper we for the first time use lexical dependency information for advancing the state-of-the-art shift-reduce constituency parsers. It is noteworthy that, although Chen et al. (2009) and our work use the same strategy to extract lexical dependencies, features defined on lexical dependencies are distinct. Specifically, Chen et al. (2009) proposed features for a graph-based dependency parser while this paper focuses on a transition-based constituency parser. More recently, Bansal and Klein (2011) proposed features for both dependency and constituency parsing based on Web counts from the Google n-grams corpus. By contrast, lexical dependency information used in this paper is derived from auto-parsed data. Moreover, Web counts from the Google n-grams corpus represent surface evidence of lexical affinities while lexical dependencies are able to encode information on deep syntactic structures.

7 Conclusion

We have presented a method to utilize lexical dependency information to improve shift-reduce constituency parsing. A set of new features was proposed based on the lexical dependency information and integrated into the shift-reduce parser. Our method well addressed the action conflict problem. We evaluated the proposed method on English and Chinese data. The results show that our

new parsers provide comparable accuracies with state-of-the-part parsers while maintaining the advantage in parsing speed.

Acknowledgments

We would like to thank Wenliang Chen for his help in extracting lexical dependencies and discussions on designing features.
