ABSTRACT
Information structure, i.e the way speakers construct sentences to present new information in the context of old, can capture rich linguistic information about the discourse structure of scientific documents. Information structure has been found useful for important Natural Language Processing (NLP) tasks, such as information retrieval and extraction. Since scientific articles typically follow a certain discourse structure describing the prior work, problem being solved, methods used, and so forth, it could also be useful for summarization of these articles. In this work we focus on a scheme of information structure called Argumentative Zoning (AZ), and investigate whether its categories could support extractive text summarization in a scientific domain. We develop a summarization system that uses AZ categories (i) as features and (ii) in the final sentence selection process. We evaluate the system directly as well as using task-based evaluation. The results show that AZ can support both full document and customized summarization. We report a statistically significant improvement in summarization performance against a competitive baseline that uses journal section labels instead of AZ information.

TITLE AND ABSTRACT IN MANDARIN

一种根据“论证结构”自动摘录科技文献的方法

信息结构是指作者组织语句陈述信息的方式。信息结构例如科技文献的篇章结构包含丰富的语言信息，有助于解决自然语言处理领域的一些重要问题例如信息检索和信息提取等。科技文献通常使用特定的篇章结构来陈述以往的研究，阐述研究问题以及研究方法等等，这些篇章结构可以被用于文献的自动摘录。本文着眼于一类特定的信息结构 — “论证结构”，研究其是否有助于更好地摘录科技文献。在本文开发的摘录系统中，“论证结构”有两种用途：一是作为特征供机器学习，二是用于最终的语句筛选过程。本文对该系统进行了直接和间接的评测，测试结果显示“论证结构”有助于更好地对全文或指定信息进行摘录。基于“论证结构”的摘录系统显著性优于基于章节标题的摘录系统。

KEYWORDS: discourse, information structure, argumentative zones, summarization, document summarization, information access.

KEYWORDS IN MANDARIN: 篇章，信息结构，论证结构，文本摘要，信息获取.

COLING 2012, Mumbai, December 2012.

1 Introduction

Information structure is the study of how writers package information into a sentence and convey new information (e.g. new methods, results and conclusions) in the context of old information (e.g. previous or related work) within a document. A number of frameworks capturing different aspects of information structure (including e.g. discourse, rhetorical, argumentative and conceptual) have been proposed, many of which focus on scientific documents (Teufel and Moens, 2002; Shatkay et al., 2008; Teufel et al., 2009; Liakata et al., 2010). Scientific documents are highly structured in nature, and knowledge about their information structure can support important Natural Language Processing (NLP) systems aimed at improving information access to scientific literature.

To date, information structure has proven useful for different information retrieval and extraction tasks, as well as for manual literature review (Tbahriti et al., 2006; Ruch et al., 2007; Guo et al., 2011b). One NLP task which is highly important for the scientific domain and which might similarly benefit from information structure is document summarization. Scientific articles are well structured containing sections such as "Prior work", "Method", "Experiments" etc, and also contain a rich network of citations. While section and citation based features have been exploited extensively in prior summarization works (see section 2), categories of information structure have received little attention. A good summarization system should be able to identify the "key" concepts in an article and generate a summary that has good coverage over the ideas expressed in the article. In the case of scientific documents, information structure can capture rich linguistic characteristics defined by eg. the discourse status of sentences, and therefore could help a summarization system select the right mix of sentences to be used from the document.

(Teufel and Moens, 2002) introduced a scheme of information structure called Argumentative Zoning (AZ) which classifies sentences in scientific text into categories (such as Aim, Background, Own, Contrast and Basis) on the basis of their rhetorical status in scientific discourse. They performed experiments which show that AZ can be used to identify and summarize novel contributions as well as background information in a scientific article. However, they did not investigate integrating AZ in an automatic summarization system.

In this paper we focus on this topic and explore whether knowledge about information structure could be used to support an actual summarization system performing extractive summarization in the scientific domain. Like (Teufel and Moens, 2002), we focus on AZ because this scheme has aided many other NLP tasks and has shown wide applicability across different scientific domains (including e.g. computational linguistics, chemistry, biology). Experimenting on biomedical corpus data, we use the version of AZ adapted for biology by (Mizuta et al., 2006).

We develop a simple summarization system for evaluation purposes and use it as a framework when investigating two approaches to integrating both manually and automatically obtained AZ categories into summarization: (i) including them as features in a classification task for selecting sentences that should be part of a summary, along with other features that have traditionally been found useful in such a classification task, and (ii) using them as a selection mechanism for identifying the final set of sentences that should be made part of the summaries.

We evaluate these approaches via two task-based evaluations - extractive summarization of complete articles as well as generation of customized summaries based on user requirements. We also compare their performance against a competitive baseline that makes use of section labels (instead of AZ labels) in biomedical articles. To the best of our knowledge, this is

the first work that compares the use of section labels against AZ in summarization. The results are promising. They demonstrate that AZ can be an effective feature to include in summarization systems and can improve the quality of summaries generated for scientific papers. Both manually and automatically obtained AZ labels prove useful. In the future, the approach could be optimised for integration in state of the art summarization systems as well as used for task-based evaluation and comparison of different automatic AZ lebeling systems.

2 Related work

2.1 Summarization in Scientific Literature

Scientific literature continues to be a major domain for summarization research along with news articles. Different types of summaries can be generated for such documents. For example, one could be interested in automatically generating an abstract-like summary for an article or a group of articles, or one may require a customized summary describing specific types of information (e.g. experiments or results) in articles only. Further, sentences in such summaries may be a paraphrased representation of the information present in the original documents (abstractive summarization) or may be a subset of those in the original article (extractive summarization).

An important characteristic of scientific articles is the presence of citations. Citations have been used in different summarization systems. Recent work such as that by (Abu-Jbara and Radev, 2011), (Qazvinian et al., 2010) and (Qazvinian and Radev, 2010) make use of citation sentences in other scientific papers to summarize the contributions of a paper. Although it is the ideas of one paper that are being summarized, this approach involves searching for references to the paper in other papers, and extracting sentences from them to build summaries.

Other recent work such as that of (Qazvinian and Radev, 2010) uses Markov Random Fields to detect patterns that create context data (background information) for a paper, while (Mei and Zhai, 2008) use citations as a measure of "impact" in a field and use it for summarization.

Latent Semantic Analysis based methods have also been used for summarization of documents. (Steinberger et al., 2005) use LSA along with anaphora resolution to improve document summarization while (Ozsoy et al., 2010) propose multiple LSA based summarization algorithms in which the sentence selection criteria is modified using the "concept" matrix derived at the end of singular value decomposition (SVD) step.

In this paper we use argumentative zones (AZ) for extractive summarization of scientific papers. Extractive summarization generates summaries by selecting a subset of the sentences from the original document. We use a classifier trained using the author-created abstracts of articles to identify sentences from the full document for a system-generated summary and use clustering to further select sentences. AZ information is used both as a feature in classification as well as a guiding step during clustering.

2.2 Argumentative Zoning and NLP Tasks

Argumentative Zoning (AZ) classifies sentences from scientific text based on their rhetorical status in terms of problem solving (e.g."What are the contributions of the paper?"), intellectual attribution (sentences that describe prior work etc) and relatedness amongst articles. The original AZ scheme of (Teufel and Moens, 2002), applied to the domain of computational linguistics, included five rhetorical zone categories (Aim, Background, Own, Contrast and Basis)

and a fully supervised classifier was trained to classify each sentence in scientific articles in one of these categories. Subsequent work and applications of this scheme to other domains (e.g. chemistry, biology) have resulted in finer-grained AZ classifications.

Most approaches to automatic AZ detection rely on fully supervised machine learning. A high accuracy above 80% have been reported with the best of these approaches. (Guo et al., 2011a) has developed an approach based on active learning which performs (as its best) as well as fully supervised approaches but requires only a small amount of labeled data.

Most work on information structure has been evaluated directly on manually annotated data sets. Previous task-based evaluations, mostly conducted on AZ, include information retrieval and extraction tasks, along with literature review in biomedicine (Tbahriti et al., 2006) (Ruch et al., 2007), (Guo et al., 2011b).

(Teufel and Moens, 2002) reported experiments which suggest that AZ should also be helpful for automatic summarization. They used zones to identify and "summarize" new contributions in scientific papers. Sentences from the Aim, Contrast and Basis zones were used to highlight new contributions of a paper. When including information about "background work" in a summary, directly using sentences labeled with the Background zone reduced precision. They therefore trained a classifier based on annotated data that identifies sentences from the Background zone for a short "summarized" version of the document. Although this work suggests that AZ could be useful for summarization, it does not develop or employ an actual summarization system.

Related work by (Farzindar and Lapalme, 2004) used "thematic" structures (rather than AZ) (Introduction, Context, Judicial Analysis and Conclusion) in law judgments to generate summaries. They identified "cue" strings for each of these themes and used verb classes to filter out citation sentences. To summarize the text they used a heuristic function based on position of paragraphs in a document, position of paragraph in a thematic segment, tf-idf distribution and cue words specific to each theme. The summary lengths were controlled by using the distribution of themes in the abstract to select a proportionate number of sentences from each theme. However, scientific articles differ from law judgments because the documents are highly structured and contain "sections" which are defined by the authors.

In this paper we investigate whether AZ could be used to support a summarization system in the scientific domain. We focus on biomedicine and experiment with the AZ scheme developed for biology by (Mizuta et al., 2006). We employ manual AZ annotations in the main experiments (in order to investigate the direct impact of AZ on summarization) but also report experiments where automatic annotations from the weakly supervised AZ labeling system of (Guo et al., 2011a) are used. We integrate the AZ labels into a summarization system as features and also use them to aid the final sentence selection process in summarization. We perform both direct and task-based evaluation which shows that both methods can support automatic summarization.

3 Method

Most scientific papers contain an abstract which provides a short description of the work presented in the paper. The abstracts are created by the authors and can be regarded as summaries of papers. Using such abstracts as the gold-standard we describe a method for generating summaries. The summaries can vary in length (i.e. be more elaborate or concise than the original abstracts) which is useful in the scientific domain where users (e.g. scientists) have highly varied summarization needs.

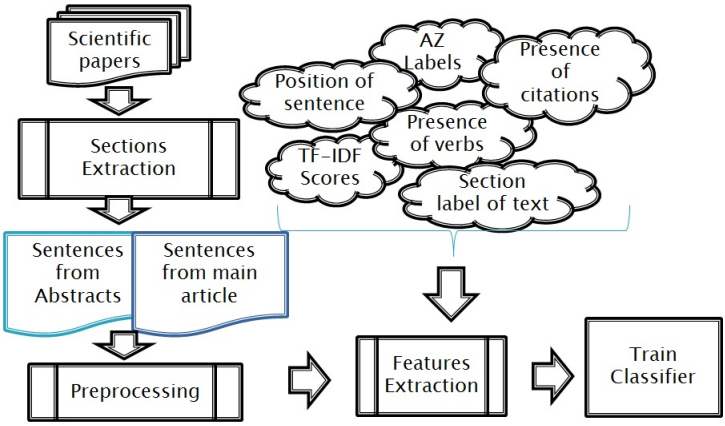

Figure 1: Schematic diagram showing the training phase of the summarization system.

Our method has two main stages: classification and sentence clustering. The classifier creates an initial candidate set of sentences for the summary, and the sentence clusterer identifies groups of similar sentences in this set which are then used to create the final summary. The clustering step, employed by many summarization systems, removes redundancy from the candidate pool and thus improves the quality of the summary.

Figure 1 gives an overview of the training phase of the summarization system. Sentences from the training articles are pre-processed as described in section 4.1. and annotated with the section labels (i.e. the section of the article to which the sentence belongs) and zone labels. They also undergo stop word removal and lemmatization. After pre-processing, the feature vector representations of the sentences are created and used to train a classifier using the Weka tool kit[1].

After training, the system can accept documents for summarization. An article is pre-processed and its feature vector representation is created as during training. A parameter specified by a user controls the compression ratio by adjusting the classifier threshold as well the number of clusters used. After classification, the positively labeled instances are filtered using a sentence clusterer, and a final summary is generated. Figure 2 shows an overview of the execution phase of the summarization system.

The next section describes the actual methods and features used for classification. Section 3.2 gives details about the clustering stage and section 3.3 describes how the parameter specifying the compression ratio is used to adjust the length of the summaries.

3.1 Sub-component for classification

Let A be the set of sentences in the abstracts of papers, and let D be the sentences in the main sections of the papers. Using the set of sentences in A and D, we trained a classifier that learns

[1]http://www.cs.waikato.ac.nz/ml/weka

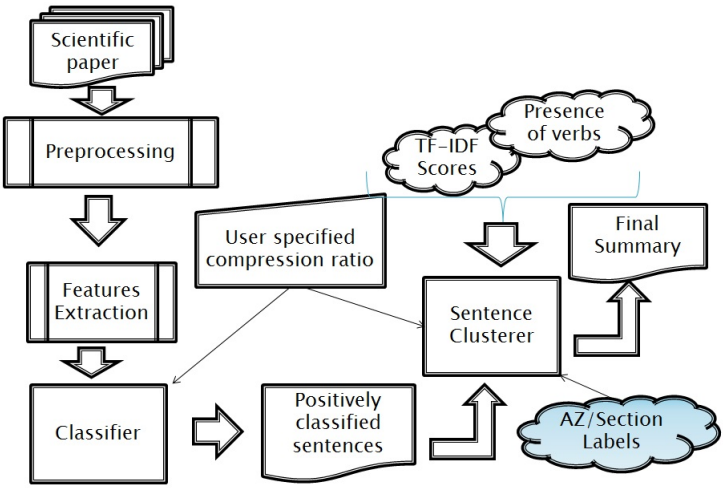

Figure 2: Schematic diagram showing the execution phase of the summarization system.

how to generate a set of sentences $C, C \subseteq D$, which is the candidate set of sentences that are to be made part of a summary.

We require both positive and negative labeled instances for training a classifier. The sentences in the abstract can be considered as positive labeled instances but those in the main text are unlabeled, i.e. they could be positive or negative. The problem of training a classifier using positive and unlabeled data has been studied before. A state-of-the-art method has been described in (Elkan and Noto, 2008), where the classifier is built using positive and unlabeled instances. The model predicts probabilities that differ by a constant factor from the actual conditional probabilities of being positive. Using the constant factor, one can estimate the probabilities of positive and negative instances. We employ this method to train a classifier for selecting the candidate set of sentences (referred to as the "non-traditonal classifier" based method in section 4.3.2).

Instead of using the positive and unlabeled data, one could artificially generate some labeled data and use that for training a classifier. Consider a similarity metric $\omega(S_1, S_2)$ that returns a score indicating the similarity between two sentences S_1 and S_2. Using this similarity metric ω [2] we can identify those sentences in the main text that are most similar to the sentences in the abstract and label them as positive instances, while the others can be labeled as negative instances. A traditional classifier model based on Support Vector Machines was built using these positive and negative instances.

[2]We used two measures – n-gram overlap based similarity between sentences and cosine similarity between sentence feature vectors – and found that the latter gave better results.

3.1.1 Features used for classification

We used various features for representing the training and test samples used by the classifier, including the new AZ feature as well as features that have proved successful in previous related works, e.g. (Abu-Jbara and Radev, 2011).

- Verbs feature: Sentences in the abstract tend to contain many verbs. For example, text fragments like "We showed that", "we found that", "We used", "we proved" are very common in abstracts, often using past tense. Using the StanfordNLP Part-of-speech (POS) tagger (Toutanova et al., 2003), each sentence was tagged and verbs along with their tenses were identified and included in the feature set for that sentence.
- tf-idf values: TF-IDF scores for each sentence were used as features for the sentences. The size of tf-idf features is the size of the vocabulary. Each word in the vocabulary along with its tf-idf value in a sentence were used as features.
- Citation and reference occurrences: Sentences containing citations are frequently found where published related work is discussed. They tend to occur in the background, prior or related work sections. We also keep track of sentences that contain references to figures and tables. These point to a section in the same document, while a citation points to a different document. Each sentence is assigned two boolean features, indicating the presence of a citation and a reference to figures or tables, respectively.
- Argumentative zones: Each sentence is labeled with one of eight AZ categories both manually and automatically using the system of (Guo et al., 2011a).
- Locative features: Sentences tend to have locative characteristics, e.g. most sentences describing prior work occur in the beginning of a paper, while those describing future work tend to occur at the end. Position of sentences has earlier been found to be useful in summarization tasks (Baxendale, 1958) (Conroy and O'leary, 2001).

We experimented with different combinations of these features. Citation and location based features were only used by the traditional classifier, as these features are unavailable when the original abstracts are used directly for training.

3.2 Sub-component for clustering

A well rounded summary should briefly describe the nature of the problem, the work conducted, and the nature of the results obtained, without repeating any information. Once the sentences have been classified, a clustering step is used to remove redundancy from them and to identify similar sentences. Using the section labels to group similar sentences, we applied the k-means clustering (Lloyd, 1982) to detect clusters within each group. By selecting the centroid from each of the k-clusters in each section group, the final set of sentences were identified for a summary.

An alternative to using the section labels for grouping sentences is to make use of AZ. Sentences with the same AZ label can be grouped together, and the clusters can be identified within each group. We experimented with this option as well. The feature vector representation of sentences used for clustering consists of tf-idf weights as well as variables indicating the presence or absence of verbs.

3.3 Controlling the length of summaries

The compression ratio of a summary is defined as the ratio of the number of sentences in the summary generated and the number of sentences in the original article. Using the compression ratio as an input parameter to the system, the length of the summaries can be controlled.

The compression ratio is used to adjust the classification threshold of the classifier. If the number of sentences is too low, the classification threshold is reduced by a fixed step size and sentences are re-classified. This process is repeated until the the compression ratio is a fixed constant t % more than the actual compression ratio required. This relaxed compression ratio is used so that the clustering stage has enough sentences to choose from.

In clustering, the compression ratio is used to determine the number of sub-clusters to be created within each AZ/section label group. Let the compression ratio be denoted by cr, the length of original document be l and the number of distinct AZ labels/section labels in the classified set be m. Then the number of clusters k is given by :

$$k = ceil(\frac{cr * l}{m}) \quad (1)$$

where $ceil(x)$ is a function that returns the smallest integral value that is greater than or equal to the real number x.

4 Experiments and Results

4.1 Data and Pre-processing

We used a corpus of 50 biomedical articles sourced from a number of journals on cancer which are available online at PubMed[3]. The corpus contains 580 sentences in the abstracts and 7,989 sentences in the main body. The sentences were annotated according to the AZ annotation scheme of (Mizuta et al., 2006). Eight AZ categories[4] appeared in the annotated data[5], including Background, Conclusion, Problem, Connection, Method, Difference, Result and Future work. Inter-annotator agreement between the two annotators (one domain expert and one computational linguist) was high $\kappa = 0.83$ according to Cohen's kappa (Cohen, 1960).

	Sentence Type	Training data	Test data	Validation set
Biomedical corpus	Abstract sentences	308	206	66
	Main article sentences	5046	2943	-

Table 1: Details of data set

For the experiments with automatically obtained AZ labels, we used the weakly-supervised method of (Guo et al., 2011a) to identify the AZ category of each sentence. Based on the active learning and self-training, the method was trained using just 10% of labeled data in a corpus of 1000 biomedical articles. With accuracy of 81% it performs similarly with supervised methods that employ all the labels (Guo et al., 2010).

[3]http://www.ncbi.nlm.nih.gov/pubmed/

[4]Please see the paper of (Mizuta et al., 2006) for the full details of the annotation scheme and examples of different zone categories.

[5]The data and the source code of the methods described in this paper are available on request.

We split the articles in our corpus into 3 sets for training, testing and validation. The validation set was created from a small set of sentences from abstracts and was used to learn a classifier from positive and unlabeled training samples (Elkan and Noto, 2008).

All sentences were tagged using the Stanford NLP POS tagger (Toutanova et al., 2003) with the Penn treebank tagset[6]. In addition, the articles were lemmatized using the Stanford NLP lemmatizer[7] and stop words were removed using stop-lists available on the Internet.

4.2 Experiments

We evaluated the method on two tasks: full document and customized summarization. In full document summarization, a user-specified compression ratio is used to automatically summarize the contents of the entire article. In customized summarization, the user specifies the length and the focus of the summary to be generated (e.g. a summary of the "methods" described in the paper only).

4.2.1 Evaluation Measures

The ROUGE-N measure (Lin, 2004) is used frequently for evaluation of summarization systems. ROUGE stands for Recall Oriented Understudy for Gisting Evaluation and the ROUGE-N score is calculated by counting the number of overlapping N-grams between a user generated/reference summary and a system summary. ROUGE does not consider the length of the summaries, and therefore, if an entire article is returned, it could get the best ROUGE score as the number of n-gram matches will be high. Therefore, compression ratios (cr), i.e. ratio of the number of sentences in the summary ($|S_{summary}|$) generated and the number of sentences in the original article ($|S_{article}|$) are also frequently used.

$$cr = \frac{|S_{summary}|}{|S_{article}|} \tag{2}$$

We used as the primary evaluation metric the F_1 [8] measure, calculated using the number of overlapping n-grams between the summary generated at different compression ratios and the abstracts created by the authors.

4.3 Full article summarization

In this task, sentences from the abstracts were used to learn how to generate full length summaries of articles. Different combinations of features were used to train classifiers.

4.3.1 Training

Sentences from the abstracts were used to train a non-traditional classifier of (Elkan and Noto, 2008) and to create an artificial set of positive and negative instances for training the traditional classifier. The artificial data set was created by selecting such sentences from the main text that were similar to sentences from the abstract. The similarity criteria was based on the cosine distance between the feature vectors of the sentences. The following section describes the results for both these methods with different combinations of features.

Figure 3: Full Document summarization results using non-traditional classifier and compression ratio of 10 %

4.3.2 Results

Figure 3 shows the performance of the non-traditional classifier methods for summarization when manual AZ labels are used. We varied the compression ratio between 5% and 25% in steps of 5% and studied the performance. We report here the results using the compression ratio of 10% because it produces summary length that corresponds the closest to the length of the actual abstracts. As can be seen, during clustering, the use of AZ labels considerably improves the F_1 scores and also improves both precision and recall (ROUGE-1). The features used during classification are the verb features, the tf-idf features and the AZ label features. Other features (e.g. locative and citation based) were not used in this method as they are unavailable in the sentences from the abstracts and in the training data.

Figure 4 shows the performance of the traditional classifier based summarization, again using manual AZ labels. Here the results are better when clustering employs the AZ labels instead of section labels for grouping sentences. Features based on location of sentences and citations were used as the training data consists of sentences from the main text. The use of citation features along with locative features improves the performance of the summarizer, though the non-traditional classifier outperforms the traditional classifier.

The use of section labels for clustering is a tough baseline to beat, as these sections contain sentences that the authors themselves deemed fit to belong to those sections. For example, sentences belonging to a section called “Result” could be considered to identify sentences relating to “Results”, but the use of sentences belonging to the argumentative zone called “Result” are not confined just to the “Result” section, and the use of the AZ labels shows a significant improvement in performance. We also experimented using clustering without creating cluster groups based on sections or AZ and found that the use of AZ labels improves performance. The improvement in F_1 scores when using AZ during the clustering stage was found to be statistically significant ($p < 0.03$).

Finally, we performed an experiment using automatically detected AZ labels by the method of (Guo et al., 2011a). Using the best feature configurations for the task, this results in a small (2%) drop in F_1 scores when compared to the use of manual labels, but slight improvement when compared to the use of section labels (See Figure 5).

4.4 Customized summarization

In this task, the system generates summaries for some parts of the paper based on user requirements. We evaluated the system on two customized summary tasks that our experts found useful for biomedical literature review: the summarization of "Results" in a paper and the "Discussion" in a paper. The evaluation was done against gold-standard summaries for 50 articles, generated by a human expert (an expert in biomedical research). The expert was asked to generate the customized summaries by selecting sentences from the main body of the articles and to ensure that the summaries generated do not exceed 40 % of the full article length. The gold-standard summaries were also used for training as described in the next section.

4.4.1 Training

The gold-standard summary set was split for training and testing (60-40 % split). The sentences from the gold-standard were used as positive labels for training the classifier, while the negative instances were labeled in two ways.

In the first method, sentences from the main article, which were not part of the gold-standard summary, were labeled as negative instances. Thus, in this case, the whole set of sentences from the article is available for training. In the second method, the AZ labels of the sentences are used to get a reduced set of negative instances. Sentences from the zone best suited to the customized summary task are selected. For example, in the customized summarization task for "Results"' in a paper, the negative instances will only contain sentences which are not part of the gold-standard and which belong to the "Results" zone. This method is referred to as "Zone pre-selection"' in the results section.

4.4.2 Results

For the customized summarization task, the summary lengths are controlled based on the number of sentences desired instead of the compression ratio. Estimating a compression ratio based on the full length of the article is not suitable because the task focuses on summarizing a "part" of the article (only the "results" for example), and not the entire article. The "part" of the article that is summarized is based on the "type" of information the user is interested in, and is not by itself, explicitly demarcated in the original article.

In this task, therefore, if x is the number of sentences required in the summary, the the number of clusters are given by:

$$n = ceil(\frac{x}{m}) \tag{3}$$

When zone pre-selection is employed, the clustering stage was found to be less useful for the "Results" and "Discussion" summarization tasks, because the classification stage itself was able to identify a good set of sentences to be used for the summary. The problem of redundant information is reduced, because the summaries are generated of some "parts" of the document and not the entire document, reducing chances of redundancy.

It must also be noted that this behaviour may not be universally true for all types of customized summaries. For example, summarization of the "Background" work in a paper, which usually contains more information and tend to be larger sections, may contain redundant information and the classifier may not be as selective due to the increase in length of the text being summarized.

Customized Summary Type	Features	Precision	Recall	F1
Summarize Results	Verbs, tf–idf	0.1649	0.4766	0.2451
	Verbs,tf–idf,AZ	0.1613	0.4906	0.2428
	Verbs,tf–idf, Zone pre–selection	**0.3312**	**0.6253**	**0.4330**
Summarize Discussion	Verbs, tf–idf	0.1178	0.3318	0.1739
	Verbs,tf–idf,AZ	0.1285	0.3354	0.1858
	Verbs,tf–idf, Zone pre–selection	**0.1838**	**0.4959**	**0.2682**

Figure 6: Customized Summarization results for summary length of 15 sentences

Customized Summary Type	Zone Pre–selection	Precision	Recall	F1
Summarize Results	Weakly Supervised AZ	0.3257	0.6145	0.4257
	Manually labeled AZ	0.3312	0.6253	0.4330
Summarize Discussion	Weakly Supervised AZ	0.1867	0.4882	0.2702
	Manually labeled AZ	0.1838	0.4959	0.2682

Figure 7: Comparison of customized summarization results using weakly supervised and manually labeled AZ

Figure 6 presents results for the two customized summarization tasks. The use of zone pre-selection improves the results considerably against the baseline system which does not make use of zone pre-selection. There is a 76 % improvement in F_1 scores in the "Results" task and an improvement of 54 % in the "Discussion" task. It can also be seen that the use of AZ as a feature for classification does not cause significant change in performance. This was also noticed in the full document summarization task, where AZ were found to be most effective during the clustering stage and not during the classification stage.

Figure 7 compares the performance of the best performing customized summarization configuration (Zone pre-selection) using weakly supervised AZ labels. An analysis of the errors made by the weakly supervised automated AZ labeling method showed that the "Results" and "Conclusion" AZ labels account for 9% and 20% of the errors respectively. The "Conclusion" AZ category is one where the annotators to have most disagreement, partly because many sentences include elements of both discussion and some other zone (e.g. methods or results), yet annotators are asked to assign each sentence to one category only. Nevertheless, our experiments shows that the performance of the summarization system when using automatically generated AZ labels is comparable to that of a system using manually labeled AZ labels.

The results presented in this section are promising, showing that AZ can yield improvements in both full document and customized summarization tasks in biomedicine.

Conclusion and Future Work

Most work on the information structure of scientific literature has been evaluated directly against manually labeled data. Task-based evaluation has mainly concentrated on information retrieval and extraction tasks. We have investigated whether AZ could be used to benefit summarization of scientific articles. Although previous work had suggested that AZ can improve summarization, no experiment had been conducted using a full AZ scheme and a real summarization system.

We developed a simple summarization system that uses a classifier to identify a set of candidate sentences, and uses clustering along with AZ labels to reduce redundancy in the summaries generated. The system is capable of creating full document summaries of different length and information density as well as customized summaries based on user requirements. Both types of summaries can be helpful for users in the scientific domain.

We evaluated the summarization performance on both full document and customized summarization and reported statistically significant improvement in performance scores when using AZ labels. The system outperforms a strong baseline method that uses section labels instead of the AZ labels. The improvement of approximately 7 % in F_1 scores in the full document summarization and an improvement of 54-76 % in customized summarization clearly shows that AZ can benefit automatic summarization.

Our main focus was on manual AZ annotations because we wanted to investigate the direct impact and the upper bound of AZ on summarization. However, also our pilot experiments using automatic AZ annotations show improvement in summarization performance. Future work could use our method as a framework for task-based evaluation of AZ labeling systems.

In this initial investigation on the topic, we kept the summarization framework intentionally simple for evaluation purposes. Future work could optimise the use of AZ for state-of-the-art summarization systems and also explore further ways of integrating AZ in the task. For example, our experiments show that zones are useful for building better clusters. Instead of employing clustering to reduce redundancy, one could investigate the use of diversity ranking algorithms. Once the sentences have been grouped based on zone labels, as described in section 3.2, diversity ranking algorithms, e.g. (Radlinski et al., 2008), could be used to obtain a ranked list of topically or information "diverse" sentences, from which the summary could be built.

Alternatively, instead of using a classification and clustering based approach, sentences from the main article could be selected based on a diversity ranking algorithm and then the final summary could be built using the distribution of zones in the abstracts or gold standard summaries as a "summary template".

Although we focused on AZ due to its good applicability to different scientific domains, success in previous task-based evaluations, and the availability of a weakly-supervised AZ detection method which enables easy porting between NLP tasks, it would be interesting to investigate and compare the usefulness of other schemes of information structure for summarization.

Acknowledgement

The first author's studies at the University of Cambridge were partially funded by the Cambridge Overseas Trust. We would also like to thank Dr. Ilona Silins, University of Cambridge for creating the gold-standard summaries for the customized summarization task. The work in this paper was also funded by the Royal Society (UK), EPSRC (UK) grant EP/G051070/1 and EU grant 7FP-ITC-248064.

ABSTRACT
Text-to-scene conversion requires knowledge about how actions and locations are expressed in language and realized in the world. To provide this knowlege, we are creating a lexical resource (*VigNet*) that extends FrameNet by creating a set of intermediate frames (*vignettes*) that bridge between the *high-level* semantics of FrameNet frames and a new set of *low-level* primitive graphical frames. Vignettes can be thought of as a link between *function* and *form* – between what a scene means and what it looks like. In this paper, we describe the set of primitive graphical frames and the functional properties of 3D objects (*affordances*) we use in this decomposition. We examine the methods and tools we have developed to populate VigNet with a large number of action and location vignettes.

KEYWORDS: text-to-scene conversion, world knowledge, frame semantics, visual semantics, linguistic annotation, crowdsourcing.

1 Introduction

3D graphics authoring is a difficult process, requiring users to master a series of complex menus, dialog boxes, and often tedious direct manipulation techniques. Natural language offers an interface that is intuitive and immediately accessible to anyone, without requiring any special skill or training. The WordsEye system (Coyne and Sproat, 2001) lets users create 3D scenes by describing them in language. It has been used by several thousand users to create over 10,000 scenes by merely describing them. We have tested WordsEye as an educational tool with rising 5th grade children in a summer enrichment program where it was found to significantly improve literacy skills over the students who had taken the more traditional version of the course (Coyne et al., 2011b). As one of the students said "When you read a book, you don't get any pictures. WordsEye helps you create your own pictures, so you can picture in your mind what happens in the story." The students were also introduced to WordsEye's face and emotion manipulation capabilities – the children loved including themselves and other people in scenes and modifying the facial expressions. We are currently experimenting with automatically depicting Twitter tweets as a way to bring text-to-scene visualization to a wider audience and to test the limits of the system in an open domain with ill-formed text. In this paper we describe a new set annotation tools and the graphical primitives we have developed in order to build a knowledge base that maps linguistic constructs into semantic frames representing spatial relations and other graphical relations.

WordsEye currently focuses on directly expressed spatial relations and other graphically realizable properties. As a result, users must describe scenes in somewhat stilted language. Our goal is to build a comprehensive text-to-scene system that can handle a wide range of input text. When considering sentences such as *John is washing an apple* and *John is washing the floor*, it becomes apparent that different graphical knowledge is needed to generate scenes representing the meaning of these two sentences (see Figure 1): the human actor is assuming different poses, he is interacting differently with the thing being washed, and the water, present in both scenes, is supplied differently. If we consider the types of knowledge needed for scene generation, we find that we cannot simply associate a single set of knowledge with the English verb *wash*. Instead we need to take into account the arguments of the verb as well.

Knowledge about verbs and their arguments is encoded in FrameNet (Ruppenhofer et al., 2010). FrameNet is a lexical resource focused on representing semantic relations and their possible instantiations in lexical items. In FrameNet, lexical items are grouped into frames that represent their shared semantic structure. A FrameNet frame consists of a set of frame-based roles, called *frame elements* (FEs). For example, the COMMERCE_SELL frame includes frame elements for Seller, Goods, and Buyer. These and other FEs represent the key roles that characterize the

meaning of the lexical units in that frame. Frames can contain any number of individual lexical units. The COMMERCE_SELL frame, for example, has lexical units for words like *retail*, *sell*, and *vend*. The exact expression of FEs for a given sentence constitutes what FrameNet refers to as a *valence pattern*. Valence patterns map grammatical roles to frame element for a given verb. Every verb typically has many valence patterns, representing the various ways that verb can be used in sentences. So, for the verb *give*, the sentence *John gave the book to Mary* has the valence pattern of: ((Donor Subject) (Theme Object) (Recipient Dep/to)). And *John gave Mary the book* has the valence pattern of ((Donor Subject) (Recipient Object) (Theme Dep/NP)). FrameNet also supports *frame-to-frame relations* – these allow frames to be inherited, to perspectivize each other, or to map to a sequence of temporally ordered subframes.

(Coyne et al., 2011a) describes an extension to FrameNet called *vignettes*. Vignettes are frames that represent the graphical realization of actions and compound objects such as locations. Vignettes can be thought of a bridge between the *high-level* semantics encoded by FrameNet and the *low-level* semantics (spatial relations and other graphical properties of objects) required to construct a 3D scene. Vignettes inherit high-level semantics from FrameNet via normal frame-to-frame inheritance and decompose into low-level graphical frames using a new SUBFRAME-PARALLEL frame-to-frame relation. Vignettes can be defined not only for actions but also for locations or any other compound objects. For example, a living room might contain a sofa, coffee table, and fireplace in a particular arrangement

There is a long history in artificial intelligence and cognitive linguistics of decomposing meaning into semantic primitives. These efforts fall into two broad classes – those focusing on primitive features of objects used to distinguish one object from another (for example in prototype theory (Rosch, 1973)) and those focused on state changes, temporal relations, and causality (Miller and Johnson-Laird, 1976). Conceptual Dependency (Schank and Abelson, 1977) is an early representational system that specifies a small number of state-change primitives into which all meaning is reduced. In lexical conceptual structure (Jackendoff, 1985), lexical relations are decomposed into a similar set of primitives. VerbNet (Kipper et al., 2000) grounds verb semantics into a small number of causal primitives representing temporal constraints tied to causality and state changes. In contrast to these causally and temporally oriented approaches, vignettes map semantics into sets of graphical constraints active at a single moment in time. This allows for and emphasizes *contextual entailment* rather than causal and temporal reasoning.

In order to apply graphical primitives to objects, it is necessary to know how objects are used and can be manipulated. The concept of *affordances* (Gibson, 1977; Norman, 1988) was introduced in the study of ergonomics and the psychological interpretation of the environment and has been examined as well from a philosophical perspective (Haugeland, 1995). Affordances are traditionally considered to be the qualities of objects in the environment that allow people or animals to interact with them. For example, the door of a refrigerator provides an affordance that allows access to the interior of the refrigerator, and the handle on a door provides an affordance that allows the door to be grasped in order to open and close it. We take a slightly broader view and include as affordances any functional or physical property of an object that allows it to participate not only in actions with people but also in relations with other objects.

One of our main tasks is to define vignettes to represent a wide variety of actions and locations. Previous work explored different methods for building location vignettes. Sproat (2001) attempted to extract associations between actions and locations from text corpora. While producing interesting associations, the extracted data was fairly noisy and required hand

editing. Furthermore, much of the information that we are looking for is common-sense knowledge that is taken for granted by human beings and is not explicitly stated in corpora. In other work Rouhizadeh et al. (2010) and Rouhizadeh et al. (2011b), Amazon Mechanical Turk (AMT) was used to collect information about locations of different objects, their parts, and surrounding objects. Various corpus association and WordNet similarity measures were applied to filter the undesirable AMT inputs.Reasonably clean data was achieved by this approach. In Rouhizadeh et al. (2011c) AMT was used for building a low-level description corpus for locations by collecting free-form text descriptions of room locations based on their pictures. The WordsEye NLP module was used to extract location elements from processed descriptions. Objects and other elements of locations were extracted in the form of RELATION–GROUND–FIGURE. Directly collecting objects of locations with AMT was investigated in Rouhizadeh et al. (2011a). AMT was then used for annotating the orientation of those objects (for more details see subsection 4.1).

This paper is structured as follows. In Section 2, we describe the graphical primitives used in vignettes as well as the set of affordances on 3D objects that enable vignettes to specify their arguments in a generic way. In Section 3, we describe how we choose and process lexical patterns to serve as input valence patterns to be used in defining action vignettes. In Section 4, we describe the annotation tools and graphical user interfaces we have developed to define location vignettes and action vignettes (with their associated valence patterns). We also describe the user interface we developed for assigning affordances and normalized part names to 3D objects. We conclude and describe future work in Section 5.

2 Vignettes and Affordances

In this section we examine, in more detail, the set of primitive graphical frames used by vignettes and the 3D object affordances used in applying those graphical primitives.

2.1 Primitive Graphical Frames

We observe that visual scenes can be decomposed into a relatively small and recurring set of primitive graphical relations. These relations represent different spatial and graphical properties such as positions, orientations, sizes, surface properties, character poses, and facial expressions. So, for example, *the man washing the floor* can be decomposed into a set of relations consisting of the man in a kneeling pose on the floor, with a bucket to his side, and holding a sponge that he applies to the floor. To capture the different manners of performing actions within the same high-level semantic frame, we define a specialized type of sub-frame called a *vignette* (Coyne et al., 2011a). Vignettes can be thought of as a bridge between *form* (the way scenes look) and *function* (what is happening or conveyed in a scene). They encode and map low-level graphical relations to the high-level semantics encoded by FrameNet. To make this decomposition, the following sets of primitive graphical frames (grouped by type) are used:

Venue and time of day: This specifies the typical time of day and the *venue*. The time of day is graphically realized by controlling the position and brightness of light sources within the scene (such as the sun position). The venue represents the local human-scale area where the action takes place and what can be seen at one time. For example, a living room or a kitchen would be a venue, but a typical house as a whole would contain many venues. The venues, themselves, are arrangements of 3D objects, and hence can be represented by location vignettes.

Holding/Touching target or patient: These specify that an agent is holding or touching an object. They vary in how the target object is situated. Arguments are provided to specify the particular body part and pose involved in holding or touching the object.

GRASP/TOUCH-ON-SELF: *button one's shirt*
GRASP/TOUCH FIXTURE: *hold a doorknob*
GRASP/TOUCH NON-FIXTURE: *hold a coffee mug*
POSITION-THEME-MANUALLY: *put a picture on a wall*

Apply Handheld Instruments: These specify a handheld instrument being applied to an object. Handheld instruments typically have affordances (see section 2.2), such as a HANDLE that allow them to be held and a INSTRUMENT-HOTSPOT, such as the blade of a knife or tip of a pencil, that is applied to a target. Undirected instruments (playing a violin) often involve specialized poses that are associated with the use of those instruments.

APPLY-INSTRUMENT-TO-HELD-PATIENT: *write on a handheld notepad*
APPLY-INSTRUMENT-USING-WORKSURFACE: *cut carrots on a table*
APPLY-INSTRUMENT-TO-TARGET: *paint the wall*
POSITION-THEME-WITH-INSTRUMENT: *roast the marshmallow*
USE-UNDIRECTED-INSTRUMENT: *play the violin. talk on the phone*

Using stationary machines/fixtures: *Fixtures* are large stationary objects. *Machines* are fixtures that can be operated to achieve some effect. Machines, such as ovens, can affect a PATIENT. The patient can rest on the machine's PATIENT-AREA affordance. Other machines, such as vending machines, can have INPUT/OUTPUT-AREA affordances. They differ from instruments in that they are not held or otherwise supported by the user. See Section 2.2 for a listing of affordances.

APPLY-MACHINE-TO-PATIENT: *boil the potatoes on the stove*
USE-FIXTURE/MACHINE: *open the door*

Looking/gesturing at target: In these frames, the agent is looking or gesturing at an object or in some direction. The particular pose or manner of gesturing can be specified.

LOOK-AT-TARGET: *glance across the room*
GESTURE-AT-TARGET: *wave at the stranger*
LOOK-AT-WITH-INSTRUMENT: *take a picture of friends*

Aiming and projectiles: In these frames, the agent is aiming or hurling an object at a remote target. A projectile can be either included or not.

HURL-PROJECTILE-AT-TARGET: *throw the stone, kick the ball*
AIM-INSTRUMENT-AT-TARGET : *shoot the rifle*
AIM-FIXTURE/MACHINE-AT-TARGET : *shoot the cannon*

Agent-in-Motion: In these frames, the agent is moving, possibly in or with a vehicle. This frame includes a source or goal location and an area or path for the motion.

SELF-MOTION: *swim across the lake*
USE-VEHICLE: *ride the horse*
PUSH-OR-PULL-FIXTURE/VEHICLE: *push the wheelbarrow*

Humans and Poses: These include facial expressions, body poses, and other body states. In the two-person interaction case, a set of specialized two-person poses can be specified.

STANCE: *stand. jump, sit, ...*
FACIAL-EXPRESSION: *happy, excited, ...*
THOUGHT-SPEECH-BUBBLE: *think about home*
WEAR: *dressed in old pair of jeans*
TWO-PERSION-INTERACTION: *John hugged Mary*

Low-Level Spatial and Graphical Primitives: This is a grab-bag of lower level primitives such spatial relations and surface properties (colors, textures, reflectivity). These are often used to specify relations and properties on objects in the vignette (often to represent the resulting state of an object from an action) rather than to directly encode the main action of the input text.

PART-OF: one entity is part of another

POSITION: *A flower in a vase.* Note that spatial relations rely on the spatial regions and affordances on the objects. (Coyne et al., 2010) Therefore the exact realization of spatial relations, like other graphical primitives, will depend on the exact set of arguments and the affordances they provide.

POSITION-BETWEEN: a figure is between a ground1 and a ground2

ORIENTATION: an entity is facing a target object or direction

SURFACE-ATTRIBUTE: the shininess, color, texture, or transparency of an entity

LIGHT-PROPERTIES: a light source color or brightness

ENTITY-SIZE-SHAPE: the size or shape of an entity

ENTITY-STATE: an entity is folded, crumpled, shattered, etc.

We note the following: 1) These graphically primitive frames themselves can sometimes be conceptually decomposed into even finer-grained graphical operations. For example, to put a character in a given pose, it is necessary to individually orient the limbs in a certain way. So it could be argued that the set of graphical relations described above are not truly primitive. Our focus, however, is to capture the cognitively salient graphical features of a scene. We therefore handle these very low-level details in our 3D graphics subsystem rather than attempting to represent them directly with vignettes. 2) If needed, a graphical frame can specify not just an entity as an argument, but also what affordance on that entity is used. For example in USE-FIXTURE/MACHINE, the TOUCH-CONTROL affordance (such as a button or switch to turn on a piece of electronics) would typically be used. If a non-default value is needed, or there is no default, it can be specified as an argument to the graphical primitive itself. 3) The graphical primitives can also include arguments for necessary supports or containers. For example, the various GRASP primitives specify not only a GRASPED-THEME argument, but also allow a CONTAINER-FOR-THEME. This allows a single primitive to handle actions like *John held the coffee* which actually involves holding a coffee mug rather than the coffee itself. We do this for convenience. In all cases, the relations between containers and supports could be specified with separate graphical primitives.

2.2 Affordances and Spatial Tags

In order to apply graphical relations to actual 3D objects we need knowledge of the structure of those objects. For example, opening a door involves grasping the doorknob, and putting a flower in a vase involves putting the stem of the flower into the container area of the vase. This knowledge of objects is captured by the notion of *affordances*. These affordances constrain how objects and human characters interact with one another in the world. Note that fairly complex poses like riding a bicycle can be accomplished by using the FOOTHOLD (pedal), GRIP-CONTROL (handlebars), and SEAT-STRADDLING (seat) affordances. We identified the following set of affordances by examining over 2000 3D objects in our library and identifying what parts of those objects would function as affordances. The interface we used for assigning these affordances to the 3D objects is described in Section 4.3.

Human Location: WALKING-AREA, PATH, WALKTHROUGH-OPENING, DOOR-GATE, VIEWING-WINDOW, VIEWING-OPENING-AFFORDANCE

Hotspot: INSTRUMENT-HOTSPOT, MACHINE-PATIENT-AREA, SOUND-SOURCE, LIGHT-SOURCE
Container and Surface: WORK-SURFACE, MACHINE-PATIENT-AREA, STORAGE-AREA, CONTAINER-BASIN, CAP-COVER, RECEPTICLE
Self-Support: SEAT-WITH-BACK, SEAT, SEAT-STRADDLING, HANDHOLD, FOOTHOLD, HANDHOLD-FOOTHOLD, LYING-SUPPORT, ARM-REST, LEG-REST, HEAD-REST
Touch-Grip: INSTRUMENT-GRIP, CARRYING-GRIP, OPEN-CLOSE-GRIP, PUSH-PULL-GRIP, TOUCH-CONTROL, GRIP-CONTROL, PEDAL, EYEPIECE, EARPIECE, NOSEPIECE, MOUTHPIECE, INSERTION-PIECE
Functional area: OUTPUT-AREA, INPUT-AREA, DISPLAY, WRITING-AREA
Spatial regions: BASE, STEM, CANOPY, TOP-SURFACE, BOTTOM-SURFACE, WALL

3 Preparation for Action Vignette Annotation

In this section we discuss how we prepared a set of approximately 1000 core verbs and their arguments to serve as input for the action vignette annotation process. These verbs were manually chosen, using subjective judgements, to include verbs that are commonly used as well as those that are concrete in nature and hence could be readily depicted. We also specified relative priorities to further guide our annotation efforts. Some of these verbs are shown in Figure 6. The list of actual verb phrases to annotate was obtained from the British National Corpus (BNC), which we parsed with the MICA parser (Bangalore et al., 2009). An AWK script was written to extract verbs from the output along with particles, direct and indirect objects, and prepositional phrases which convey salient information about the action. These verb-argument tuples provided the skeletal sentences and valence patterns representing the typical ways these verbs would be used. It is these verb-argument tuples that would then be annotated.

3.1 Parsing

MICA (Bangalore et al., 2009) is a dependency parser that uses tree insertion grammars and supertagging. A supertag is an elementary tree of a tree grammar, associated with a lexical item. The tree insertion grammar MICA is trained on was automatically extracted from a TIG-converted version of the Penn Treebank. The parser first assigns n-best supertags to an input token sequence, and then extracts from the lattice of super-tags the most likely complete tree insertion grammar derivation. Each supertag carries information about the syntactic context the lexical item may occur in and other lexical information. The Mica post-processor can use this information to augmented the resulting dependency parse with deep linguistic features, such as ubcategorization information and voice. Verbal arguments associated with each supertag can be identified as *deep syntactic* roles (subject, object, indirect object in normalized active-voice word order). The referents of empty arguments in control and raising constructions can be identified and re-attached to their verbs. This makes extraction of verb/core-argument seeds much easier and more reliable.

3.2 Extraction and Sorting

The script works in the following way: any verb that is not marked as passive voice is recorded by the script in its lemma form, which then looks for verb particles, objects, and prepositional phrases. Verb particles, irrespective of their position in the original sentence, are placed with the verb, and the verb–particle combination is treated as a distinct lexical item. The script then searches for the direct and indirect objects of the verb. Object pronouns which refer to people are normalized to *someone*, and those referring to objects to *something*; the exception is *them*, which is ambiguous in this respect. Reflexive pronouns are similarly normalized to

oneself. Articles are normalized to *a* or *an*, and possessive adjectives to *one's*. No other noun modifiers are preserved. The script then looks for prepositions which are children of the verb, and finds their objects, making the same modifications to these objects as to direct and indirect objects. The preposition and its objects are returned as a single *prepositional phrase* unit. The direct object, indirect object, and prepositional phrase are returned after the verb in the order in which they appear in the sentence. Finally, if the script detects an infinitive verb which is subject-controlled by the verb being processed, the phrase *to do something* is added to the very end of the phrase.

There were, at times, problems with the parse which impeded the function of the extractor, prompting the addition of code in the extractor work around these errors. For example, the contraction *I'm* was parsed as two lexical items by MICA: *I* and *'m*. However, *'m* was not recognized as a form of the word *am*—itself a form of the verb *to be*—but rather was analyzed as a distinct verb. Thus, the extractor was modified to detect and fix this particular case.

After a list of verb phrases was produced from the BNC, it was pared down to a more manageable size. First, the verb phrases were sorted by frequency, so that the most common phrases appeared at the top of the list. From this, we filtered out verb phrases based on whether they were part of our list of core verbs. Some examples of final extracted verb-argument tuples:
(131 (:VERB "eat") (:DIRECT-OBJECT "something")) – 131 verb phrases with *eat* and a pronoun.
(24 (:VERB "eat") (:DIRECT-OBJECT "a meal")) – 24 verb phrases with *eat* and *meal*.

4 Annotation Methods and Tools

In this section we describe some of the different methodologies and user interfaces we have developed for defining vignettes and assigning affordances and normalized part-names to 3D objects.

4.1 Using AMT to build location vignettes

We have been investigating the use of Amazon Mechanical Turk (AMT) for building locations vignettes. The inputs to our AMT tasks are 'typical' photos of different rooms, that show large objects typical of that particular room. We carefully selected the picture from the results of image searches using Google and Bing. Turkers of each task had to be in the US and had previous approval rating of at least 99%. Restricting the location of the Turkers increases the chance that they are native speakers of English, or at least have good command of the language.

Phase 1: Collecting the functionally and visually important objects of rooms

The functionally important objects for a room are those that are required in order for the room to be recognized or to function properly. The visually important objects are those that help define the basic structural makeup of that particular room instance, such as large objects and those that are fixed in location. Examples of those objects in a kitchen can be "stove", "oven", "sink", "cabinets", and so on. After collecting the objects from several AMT tasks, we post-process them with the following steps (Rouhizadeh et al., 2011a):

1. Manual checking of spelling and converting plural nouns to singular.
2. Removing conjunctions such as "and","or", and "/".
3. Substituting the objects belonging to the same WordNet synset with the most frequent word of the synset. ("tub", "bath", and "bathtub" ⇒ "bathtub")

4. Substituting words with major substrings in common (“night stand", “night-stand" ⇒ “nightstand").
5. Selecting the head nouns of compounds (“computer monitor" ⇒ “monitor").

Phase 2: Collecting the visual properties of the rooms

Turkers should determine the room layout (diagonal or horizontal), room size (small, medium, or large), ceiling height, wall texture (painted color, wallpaper pattern, fabric, wood paneling, tile, concrete, or stone), and floor texture (tile, wood, carpeted, stone, or concrete).

Phase 3: Collecting the spatial relations between the objects

For each object **O** that is collected in phase 1 Turkers should answer the following questions: (see Figure 2)

1. Is **O** located against a wall? If so, determine the wall.
2. Is **O** near another object? If so, determine the object, determine the direction (front, back, or side), and the distance (1 ft, 2 ft, 3 ft, or 4 ft or more).
3. Is **O** supported by (i.e. on, part of, or attached-to) another object? If so, determine the object.
4. Is **O** facing another object? (e.g. chair facing a table) If so, determine the object.

We have completed phases 1 and 2 for 85 rooms and are now performing phase 3 for those rooms. To evaluate the results of phase 1, we compare the objects we collect to a gold-standard set of objects that are found in five rooms compiled by an expert. 91% of our collected objects were correct (precision) and we could gather 88% of the objects that we expected (recall).

4.2 Defining Location Vignettes using a Text-to-Scene System

We are also using WordsEye itself to define location vignettes for rooms (see Figures 3, 4). Annotators use WordsEye to textually describe rooms, and in the process see what those rooms look like. Those textual descriptions correspond to the graphical relations needed to define vignettes. We have currently defined about 50 fairly detailed rooms of different types using this method. The main advantage over the menu driven approach described in 4.1 is that the annotator can much more quickly and easily describe simple spatial relations (e.g. *the bed is against the wall and 3 feet to the right of the dresser*) than finding and filling in parameters for the objects, the relations, and their arguments on a complex set of menus. In addition, this method also has advantages over “working blind” with either menus or the purely textual descriptions described in Rouhizadeh et al. (2011c). The visual feedback of seeing the location of the room as it is described lets the annotator gauge how their specifications will actually be interpreted and depicted. In addition, the annotator can work incrementally and base additional input on an actual rendered scene rather than relying on a fleeting mental image or an interpretation of existing text or menu specifications. Furthermore, this makes it easier for annotators to use already-defined locations as a textual and visual starting point for additional variations.

Using the text-to-scene system to depict locations as they are described also serves to ensure that the inputs are well formed. All inputs are parsed and converted to a semantic representation consisting of objects and graphical primitives. As a result the input text is automatically converted into the graphical relations used by the vignette being defined. No post-processing is required. This applies not only to the relations but also to the specific object types that are used in the location. For example, if the user specifies that a chair is in a kitchen, they can pick the specific type of chair and avoid inappropriate chairs like lounge chairs and electric chairs.

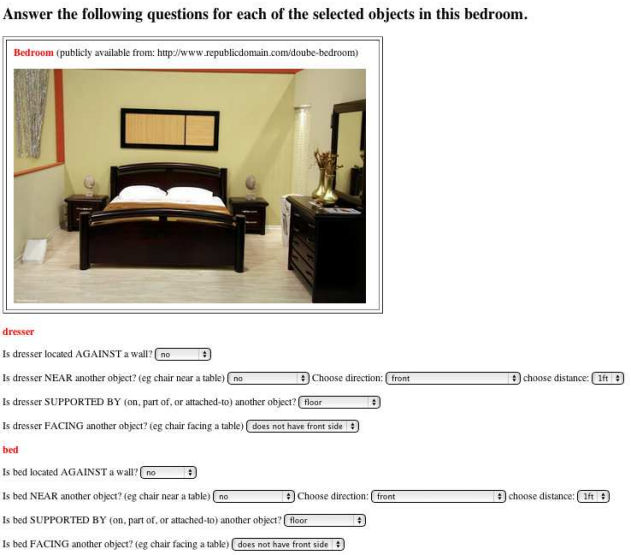

Figure 2: Collecting spatial relations between objects in Phase 3 of the AMT task

Figure 3: Kitchen location vignette defined with WordsEye

Figure 4: Other location vignettes defined with WordsEye

4.3 Assigning Part Names and Affordances

WordsEye utilizes a library of 2200 common 3D objects. The parts of these objects are often named (by the 3D artist who created them) with some abbreviated form of a normal English word. For example, the left and right tusks on one of the 3D models for an elephant are named *ltusk* and *rtusk*. In addition to normalizing part names, we need to specify which parts function as affordances. We developed a web-based user interface to assign both a normalized part name and any corresponding affordances for every part (see Figure 5).

It is important to note that we are defining parts and affordances on actual 3D objects rather than on conceptual types in the ontology. This eliminates a typical problem in ontologies where higher-level concepts define properties that may not apply to all lower level concepts. For example, in WordNet (Fellbaum, 1998), the synset *shoe* has a meronym (part designation) of *shoelace*. Not all types of shoes, however, have shoelaces. In particular, the synset *loafer* is a hyponym of *shoe*, but loafers don't have shoelaces. Since our taxonomy contains actual 3D objects, we can instead assign the exact set of parts, affordances, and other properties that apply to those specific objects. We can then infer by induction that most shoes have laces, but not all.

We have successfully annotated our entire 3D library in this manner, in the process renaming about 18,000 parts and assigning 2,400 affordances. Since our interface lets the annotator assign part names by typing in a word, there were cases of unknown or misspelled words. There were also cases of ambiguity, with multiple word senses for the same input part name. These were fixed in a post-process by automatically finding all problematic cases (those with either no known word sense or more than one) and manually assigning the correct sense.

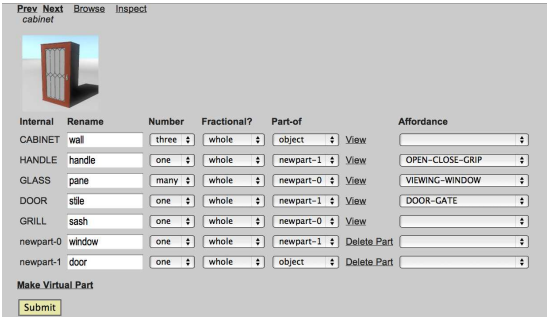

Figure 5: Parts and affordances for a door 3D object

4.4 Defining Action Vignettes

Action vignettes are specialized FrameNet frames that represent different ways of decomposing an action into graphical primitive frames. Like other frames, they can be evoked by a lexical item in its syntactic context. In order to simplify the annotation process, we are currently mapping vignettes directly to valence patterns, bypassing any corresponding FrameNet frames. We are decoupling the vignette definition process from FrameNet for a couple reasons. First, many common verbs (such as *bounce*) have no defined lexical items within FrameNet. About

17% of our core verbs have no FrameNet equivalent. Secondly, the mapping from frames to vignettes would complicate and slow down the annotation process, forcing the annotator to understand much of FrameNet in addition to our graphical primitives. These problems will be addressed in future work (see Section 5).

Annotating action vignettes involves mapping each verb-argument tuple to sets of primitive graphical frames representing how that verb (with arguments) would be depicted. See Figure 7. These decomposed tuples implicitly define new vignettes, where the tuples correspond to valence patterns that specify when that vignette is invoked. Since many tuples can be depicted in the same basic manner (albeit with different input arguments), we allow inheritance between vignettes. Inherited vignettes decompose to the same set of graphical primitives as their parent, but can override the values of the arguments. For example, *wash an apple* and *wash a pear* would invoke the same vignette, which we can think of as WASH-FRUIT-IN-SINK. The user interface supports this functionality by allowing the annotator to select and assign multiple input tuples to the same vignette.

We have so far annotated about 90 core verbs using this interface. In the process, we have specified 450 top-level vignettes and 2500 inherited vignettes (some of which override the inherited values). We have found that the original set of graphical primitives (Section 2.1) has remained fairly stable during this process, with an occasional new parameter or value type being added as new cases were encountered. We have made changes to the user interface (for example, adding different sorting keys and viewing options) based on experience using it. See Figure 8.

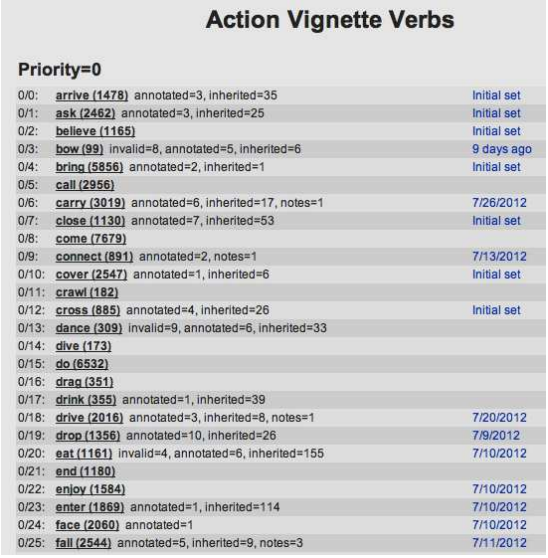

Figure 6: Action Vignette Browser for selecting verbs and showing annotation status

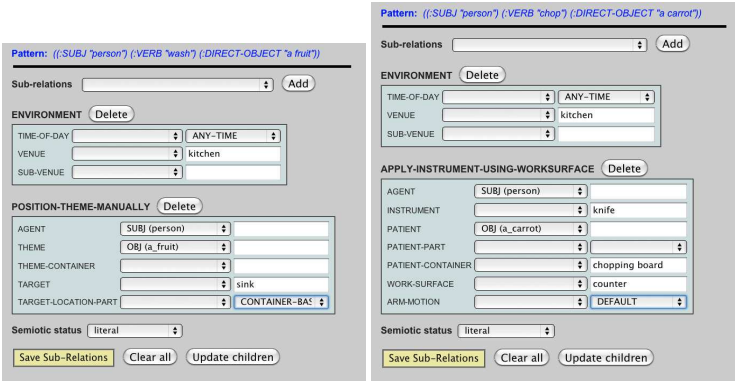

Figure 7: Action Vignette Editor for *wash fruit* and *chop carrot*

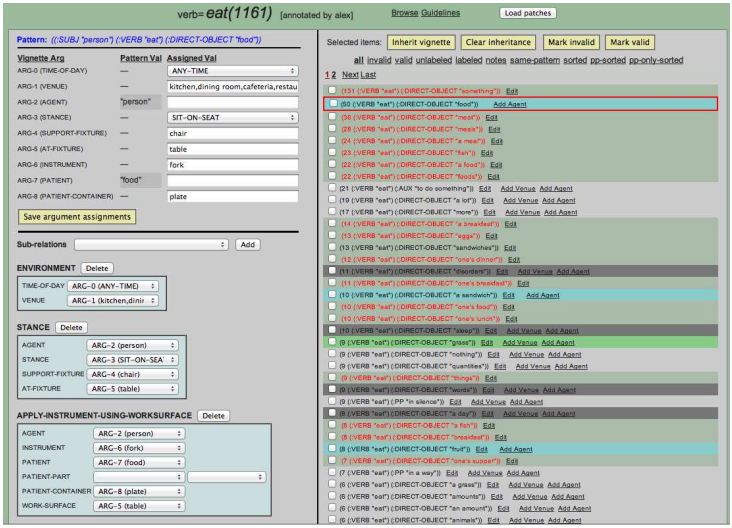

Figure 8: Action Vignette Editor. Left side shows vignette for the current input pattern. Top-left shows vignette arguments and bottom-left shows graphical decomposition applied to those arguments. Right side shows input tuples. Color coding is used on tuples to denote inheritance relations and annotation status. Different filtering and sorting options allow the annotator to focus on particular valence patterns.

5 Conclusion and Future Work

In this paper we have presented approaches to acquiring real-world knowledge to be used in a text-to-scene system. The core of our approach is embodied in the notion of vignettes. Vignettes are frames that are decomposable into grounded graphical relations. To implement vignettes we haved defined a specific set of graphical primitives that allow us to map between high-level to low-level semantics. These graphical primitives enable a wide variety of scenes to specified with a sufficient level of detail. In order to apply these graphical primitives to 3D objects we have defined a set of affordances representing the structure of those objects and how they are used and manipulated. Finally, building on this framework of vignettes, graphical primitives, and affordances, we have developed several methods for populating our resource with both locations and action vignettes. For action vignettes, this involved preparing a corpus of verb-argument tuples to be used as input data and developing tools to annotate that data with vignettes. To define location vignettes we used both AMT crowdsourcing methods and WordsEye, our text-to-scene system, as an annotation tool itself. Our resulting resource (called VigNet) is a lexically-oriented knowledge-base with lexical inputs mapping to vignettes, which in turn map to graphical primitives and actual 3D objects. VigNet will be made publicly available at `http://www.cs.columbia.edu/speech/text2scene`.

Future work includes finishing the vignette annotation process. In addition, action vignettes, as defined in the user interface, will require some amount of post-processing in order to be used. In particular, we need to handle unknown words and word sense ambiguity issues for those words that were typed in by the annotator. Those will be normalized and disambiguated in a separate semi-automatic pass as we did for part names (Section 4.3). We will also perform a separate post-processing task to link vignettes to their corresponding FrameNet frames.

One main challenge in using vignettes is that there won't be a vignette to match every possible input. Instead, it will be necessary to generalize the input arguments to find the closest vignette. For example, a vignette defined for *wash an apple* (using a sink) can be applied to washing any small round fruit. This is partially addressed by annotators listing multiple possible values to fill arguments when defining the vignette. In general, however, finding the closest vignette will involve estimating the semantic distance between the arguments of the candidate vignettes and those of the input sentence. To do this, we will leverage information in our ontology that specifies the sizes, shapes, substances, and other semantic properties of all 3D objects and their parents. We also note that vignettes, themselves, can explicitly specify arbitrarily complex sets of constraints and restrictions on their arguments to help make these matches.

A second major challege in using vignettes is to compose actions vignettes with location vignettes in the course of text-to-scene generation. We intend to accomplish this as follows. If an action is mentioned, then the default venue for that action will evoke a set of possible location vignettes. Any affordances required by the action will be unified with those provided by the location. For example, the vignette for *chop carrots*, might supply a default VENUE of a kitchen and APPLY-INSTRUMENT-USING-WORKSURFACE. The kitchen vignette includes a counter and kitchen table, both of which provide a WORK-SURFACE affordance.

Towards efficient HPSG generation for German, a non-configurational language

ABSTRACT
In this paper, we propose a rule-based method to improve efficiency in bottom-up chart generation with GG, an open-source reversible large-scale HPSG for German. Following an in-depth analysis of efficiency problems in the baseline system, we show that costly combinatorial explosion in brute force bottom-up search can be largely avoided using information already contained implicitly in the input semantics: either (i) information is globally present, but needs to be made locally available to a particular elementary predication, or (ii) semantic configurations in the input have a clear translation to syntactic constraints, provided some knowledge of the grammar. We propose several performance features targeting inflection and extraction, as well as more language-specific features, relating to verb movement and discontinuous complex predicates. In a series of experiments on three different test suites we show that 7 out of 8 features are consistently effective in reducing generation times, both in isolation and in combination. Combining all efficiency measures, we observe a speedup factor of 4.5 for our less complex test suites, increasing to almost 28 for the more complex one: the fact that performance benefits drastically increase with input length suggests that our method scales up well in the sense that it effectively heads off the problem with exponential growth. The present approach of using a generator-internal transfer grammar has the added advantage that it locates performance-related issues close to the grammar, thereby keeping the external semantic interface as general as possible.

TITLE AND ABSTRACT IN GERMAN

Effiziente HPSG-Generierung für das Deutsche

Wir stellen eine regelbasierte Methode vor, zur automatischen Anreicherung der semantischen Eingabe einer reversiblen HPSG des Deutschen, die es erlaubt, teure uninformierte Suche bei der Bottom-Up-Chart-Generierung weitgehend zu vermeiden, indem (i) globale Information, die implizit in der Eingabe vorhanden ist, explizit und lokal verfügbar gemacht wird, und (ii) syntaktische Constraints aus semantischen Konfigurationen abgeleitet werden. Wir schlagen Performanzfeatures für verschiedene Phänomene vor, wie Flexion, Extraktion, Verbbewegung und diskontuierliche komplexe Prädikate. Unsere Experimente zeigen erhebliche Effizienzsteigerungen (Faktor 4.5–Faktor 27.8), deren Zunahme mit steigender Eingabekomplexität korreliert, was die gute Skalierbarkeit unserer Methode belegt. Der generator-interne Transferansatz zeichnet sich weiterhin dadurch aus, daß Performanzaspekte grammatik-nah behandelt werden, wodurch die externe Semantikschnittstelle so allgemein wie möglich bleibt.

1 Introduction

1.1 HPSG bottom-up generation and non-configurationality

Recent advances in the efficiency of bottom-up chart generation with reversible HPSG grammars (Carroll and Oepen, 2005), namely local ambiguity factoring under subsumption and index accessibility filtering, appear to have solved the most pressing efficiency problems associated with HPSG generation for English, turning reversible linguistically motivated grammars like the ERG (Copestake and Flickinger, 2000) into interesting resources for offline and online surface generation. While the efficiency measures implemented in the LKB and ACE generators (see section 1.2) are also effective for German, these measures appear to be insufficient to resolve generation performance issues for GG, a large-scale HPSG for German originally developed at DFKI (Müller and Kasper, 2000; Crysmann, 2003, 2005, 2007). In fact, even on moderately complex inputs, the generator quickly runs into a combinatorial explosion, having so far prevented the grammar from being usable for any serious real-time NLG tasks.

Upon closer inspection of the source of the inefficiency, it became quickly apparent that the observed performance problems are the result of a conspiracy of several factors, most of which can be subsumed under the notion of non-configurationality:

- Relatively free constituent order

  In contrast to English, constituent order in German clauses is relatively free, permitting permutation of complements, including the subject, as well as interspersal of modifiers in pretty much any position. As a result, chart size grows rather quickly, with ambiguity packing being ineffective until rather large, i.e. mostly clausal, structures are built.

- Verb placement

  German finite verbs display a placement alternation between clause-initial (V1/V2) and clause-final realisation, determined by clausal construction type. Under a bottom-up regime, both left-branching and right-branching structures must be explored. Furthermore, PPs and sentential complements easily extrapose across final verbs, thereby increasing the search space even more. In the case of particle verbs, initial placement of the verb leaves the particle in final position, giving rise to discontinuous lexical items, related by (simulated) head movement (Kiss and Wesche, 1991; Müller and Kasper, 2000; Crysmann, 2003, among others).

- Argument composition

  Auxiliaries, modals, raising verbs, and, optionally, control verbs form a verb cluster with their non-finite complements. Arguments of upstairs (=governing) and downstairs (=governed) verbs can be interleaved (e.g. *... weil ein Buch*$_2$ *er*$_1$ *ihm*$_2$ *zu kaufen*$_2$ *versprach*$_1$ 'because he$_1$ promised$_1$ to buy him$_2$ a book$_2$.'), making it necessary to compose arguments of the downstairs verb (*kaufen* 'buy') onto the valence lists of the upstairs verb (*versprechen* 'promise'), resulting in the creation of complex predicates.

  Argument composition interacts with both free constituent order and verb placement. In particular the latter means that some members of the composed valence list must be hypothesised before the initial verb has been encountered, leading to partially underspecified valence lists (e.g. *Letzte Woche versprach*$_1$ *ein Buch*$_2$ *er*$_1$ *ihm*$_2$ *zu kaufen*$_2$ 'Last week, he$_1$ promised$_1$ to buy him$_2$ a book$_2$.'). Since the underspecified valencies are not constrained as to the identity of the argument (no semantic Skolem constants), any chart

item (e.g., *letzte Woche* 'last week') that matches the underspecified syntactic description can sneak in (i.e., locally satisfy the hypothesised valency), thereby creating massive local ambiguity.

- Partial VP fronting

  Verb fronting in German may leave some (or all) arguments behind for realisation in the *Mittelfeld* (e.g. *Kaufen*$_2$ *[soll*$_1$ *er*$_{1,2}$ *ihm*$_2$ *das Buch*$_2$ *morgen]. / Das Buch*$_2$ *kaufen*$_2$ *[soll*$_1$ *er*$_{1,2}$ *ihm*$_2$ *morgen]. / Ihm*$_2$ *das Buch*$_2$ *kaufen*$_2$ *[soll*$_1$ *er*$_{1,2}$ *morgen].* 'He$_{1,2}$ should$_1$ buy$_2$ him$_2$ the book$_2$ tomorrow.'). Since the core sentence has to be generated before it combines with the fronted element, construction of the core sentence needs to proceed without any access to valence information. As a result we experience a massive combinatorial explosion that can only be controlled very late, i.e. once the entire sentential structure has been built.

- Rich inflection

  While not a problem in itself, the fact that German NPs are inflected for case multiplies the existing performance issues, most specifically in the case of underspecified valence information, since irrelevant case inflection can only be detected quite late.

In the present paper we suggest a method that automatically enriches the input semantics in such a way, as to derive local syntacto-semantic constraints from the global semantic configuration: as a consequence we shall be able to eliminate globally unsuccessful generator hypotheses early on in bottom-up chart generation.

Figure 1: Enriched input MRS for *Du sollst schnarchen* 'You should snore'

1.2 The ACE generator

The open source ACE platform (http://sweaglesw.org/linguistics/ace/) implements a natural language generator based primarily on chart generation (Kay, 1996). The input to the generation system is a grammar and the semantics of the utterance to be generated (expressed in Minimal Recursion Semantics, or MRS (Copestake et al., 2005)). The grammar is primarily a declarative formalism, in that it defines a bidirectional relationship between MRSes and strings. The generator's output is the list of all strings which are related to the input MRS by the grammar. To combat the exponential worst-case complexity of the chart generation algorithm,

ACE deploys two key efficiency measures described by (Carroll and Oepen, 2005), namely ambiguity packing under subsumption and index accessibility filtering. In these respects it is quite similar to the LKB parser-generator system (Copestake, 2002). While ACE, just like the LKB, supports not only parsing and generation modes, but also MRS-based transfer, its main advantage resides in its processing efficiency: compared to the LKB, generation speed on the LOGON Rondane treebank (1169 items, avg. sentence length: 14.13) is 14.7 times better than that of the LKB, bringing average generation times down from 6.34s (LKB) to 0.43 (ACE).

2 MRS term rewriting for generation efficiency

The central mechanism by which we intend to address the generation efficiency problem is to automatically enrich the input semantics to the generator in such a way that global information implicitly present in the MRS representation will be made explicit and locally available on relevant elementary predications. By doing so, we will make them ultimately accessible to the grammar during generation. By means of an automated and quasi-deterministic rewrite step on the input MRS, we hope to strike a good balance between a maximally grammar-independent external semantic interface, suitable for application developers, and an enriched input to the generator that will hopefully reduce brute-force search by means of automatically derived syntacto-semantic constraints.

2.1 The LOGON MRS term rewrite system

Within the context of the LOGON MT project (Oepen et al., 2004, 2007), the LKB processing and development platform was extended with a term rewrite system for semantic representation using Minimal Recursion Semantics (Copestake et al., 2005).

In the LOGON system, a *transfer grammar* is a sequential, resource-sensitive set of rewrite rules which, when applied one after another in order, transform an MRS produced by a source-language grammar into an MRS suitable for NLG with the target-language grammar. We adopt the same formalism for a different purpose. A rewrite rule is a tuple of patterns for matching pieces of MRSes, consisting of an *input* pattern, a *context* pattern, a *filter* pattern and an *output* pattern. A rule $< I, C, O, F >$ causes a part of the current MRS matching the input pattern I to be replaced with the output O, provided that the context C also matches the input MRS and the filter F does *not* match. The patterns can be interdependent, so that e.g. the output can copy information matched by the input and the context. Each of the four patterns I, C, O, F contains any number of descriptions of elementary predications[1].

In an MRS (cf. figure 1), an elementary predication consists of a predicate name and any number of named roles, whose values are logical variables. A description of an elementary predication can use a regular expression to constrain which predications can match it. Several sorts of type constraints can be imposed on the values of individual roles, including unifiability with, subsumption by, or equality to a particular type (*x,e,u,i,h*). As for *properties*, i.e. features, of such variables, matching is restricted to mere unifiability. Finally, it is possible to specify that two or more variables matched in different elementary predication descriptions within the same rule have the same identity, by assigning a coreference tag. Similarly, for variable properties.

Formally, the rewrite system has the computational power of a Turing machine. As such, it is not possible to give bounds on the time complexity of applying an arbitrary rule set. However, in practice the operation is tractable for the types of rule sets considered here.

[1] Descriptions involving handle constraints are also possible, though less common.

2.2 Implementation of term rewrite system in ACE

The ACE platform, similarly to the LKB, allows grammarians to interpose a step of term rewriting between the declarative portion of the grammar and the publicly displayed MRS. The purpose of this is to allow grammarians additional freedom in designing the MRS schema described by the grammar proper, while maintaining a semantic interface that is more stable between grammar revisions and also affording an opportunity to remove remnants of non-semantic information. Since the term rewrite system is not bidirectional, separate rule sets are used after parsing and before generation.

The external MRS input to the generator is passed through the *pre-generation* rewrite system, resulting in a so-called internal MRS input (cf. figure 1). It is this MRS that is used to identify the initial set of grammar entities that need to be added to the chart. The immediate result of chart generation is a set of strings together with the sequence of grammar rules and lexemes that licensed them, and the MRS corresponding to that analysis. The result MRSes are passed through the *post parsing* rewrite rules, resulting in external MRSes. Only those strings whose corresponding external MRSes are subsumed[2] by the external MRS input are output.

A single rule can match an MRS multiple ways. Due to resource sensitivity, the order in which the matches have the rule applied can in principal affect the outcome. When a rule matches the input in K different places, there are $K!$ possible match orderings to try, which could each yield a different result, making the complexity of the operation worse than exponential. In practice, this issue can be so severe that the time spent in the rewriting process dominates the overall generation time. However, through careful rule-writing it is possible to ensure commutativity. ACE features a mode in which only one (arbitrary) match ordering is performed, rather than executing all $K!$ orderings (only to determine that they all have identical results). We exploit this feature to reduce the time spent in rewriting to a fraction of the overall generation time.[3]

2.3 Rule-based enrichment of input semantics

In this subsection, we shall present in some detail the individual efficiency measures our transfer grammar automatically derives from the generic external semantic representation. The efficiency measures we implemented can be largely classified into three groups: inflection-related measures, which mainly reduce the number of inflectional variants in the chart, German-specific measures related to verb placement and argument composition, and finally, extraction-related measures.

Most of the enrichment was done by means of having the transfer grammar augment semantic variables with additional performance features. Values of these features are typically atomic types (cf. figure 1 for a sample MRS: performance features are prefixed with two dashes and rendered in blue). In one case, i.e. *oind*, the transfer grammar adds an additional role argument (individual variable) to relevant elementary predications. On the grammar side, rules were additionally constrained according to these efficiency features. Unless specialised to some value by the MRS rewrite grammar, the enriched grammar rules will apply just as before, enabling us to measure performance gains by simply activating or deactivating blocks of transfer rules.

[2] By subsumption of MRSes, it is meant that every predicate in the input MRS must be realised in the output MRS, and the identity of the logical variables is the same (modulo renaming). It is considered permissible for the output MRS to be more specific than the input MRS, permitting, inter alia paraphrase generation by input underspecification.

[3] Average transfer processing times on the three test suites discussed in this paper are as follows: MRS: 13.2ms, TSNLP: 12.1ms, Babel: 29.4ms. Transfer times are already included in the overall processing time reported in table 1 below.

In this subsection, we shall discuss each measure in turn, together with brief remarks on the implementation and an estimate of the expected benefits.

2.3.1 Inflection

Case (*cas*) One of the most straightforward efficiency measures to come up with when confronted with a highly inflectional language such as German is to eliminate inflected forms from the chart that cannot possibly be part of a globally well-formed realisation. While some inflectional forms are readily filtered by the semantic input or the lexicon, namely predicate-inherent information such as TAM (tense/aspect/mood) and number/gender for nominal expressions, this is not the case for morphosyntactic case, which is determined by properties of the governing predicate.

In a configurational language, the expected inefficiency of inflecting every NP for all possible cases, even irrelevant cases may be suboptimal, but not really a matter for concern, since the NP will locally combine with its governing predicate, rendering NPs in irrelevant cases inert during further search. In a non-configurational language such as German, which features argument composition, heads combine with complements that are not their own arguments but rather those of a predicate they compose with, i.e., they need to cater for unknown raised arguments by means of underspecified valence lists. As a result, the identity of the inherited arguments is not known, so any XP present in the chart, however inflected, can sneak into these underspecified lists, to be ruled out, in the majority of cases, only when a significantly larger structure has been built. Unfortunately, languages with an articulate case system tend to be of the non-configurational, rather than the configurational type.

In order to predict the case for NPs, we developed a set of 35 rules that derive case requirements from lexical and structural properties of the input semantics (cf. the `--CAS` feature in figure 1). While some cases are indeed trivial, e.g., predicting the case of obliques, or arguments of prepositions, others are not: first, since individuals can be arguments to more than one predicate, as witnessed in relative clause constructions, such individual variables must be exempted from case prediction. Second, raising and, in particular, voice alternation can change case assignment properties. Thus, the transfer grammar must carefully anticipate these properties in a case by case fashion.

Apart from an overall slight reduction in chart size, we expect this feature to be particularly useful in all constructions involving locally underspecified valence lists, including the quite common case of separable particle verbs and raising and control constructions, as well as more specific, yet quite expensive ones like partial VP fronting.

Punctuation (*punct*) The implementation of punctuation in GG (Kilian, 2007) follows that of the English ERG in using inflectional rules. Even when limiting ourselves to basic sentence punctuation (commas, period, question mark, exclamation mark), almost every chart item can be inflected in 5 different ways, given that it cannot be known a priori which chart item will end up, e.g., at the right periphery of the entire sentence, where sentence mode (declarative/interrogative/imperative) is expressed. What is globally known, however, is sentence mode: all it takes is to distribute exactly this information onto every elementary predication (cf. `--PUNCT` in figure 1). Abstracting away from quotations, every sentence will be in only one of the three modes, so the number of punctuation variants for each chart item can be brought down to 3 (instead of 5).

This measure, while simple-minded and straightforwardly implemented (5 rules), is nevertheless

expected to be highly efficient, given that it indiscriminately targets almost every lexical edge (heads and dependents alike) and therefore has a significant impact on the overall size of the search space, given the bottom-up regime of the generator. The only edges that do not benefit from this (or any other measure discussed in this paper) are those corresponding to semantically empty lexical items, like, e.g., auxiliaries, relative pronouns etc.

2.3.2 Verb movement and direction of branching (sub)

A peculiarity of German syntax that has quite strong repercussions on processing efficiency is verb placement: while non-finite verbs are placed in phrase-final position, finite verbs display an alternation between final and initial position: in relative clause, embedded interrogatives, as well as subordinate clauses introduced by a complementiser or subordinating conjunction, the finite verb is realised in final position, otherwise initially, including matrix clauses.

The global construction type ("matrix order" vs. "subordinate order") can be calculated from properties of the input semantics, in particular, by taking into consideration sentence mode (declarative vs. interrogative), the kind of embedding (relativisation, complementation, type of conjunction), as well as the presence and nature of the topicalised element (embedded V2 vs. embedded wh vs. that-clause). The pre-generation transfer grammar uses this information to determine for each verb whether it is in a "subordinate" or "non-subordinate" context (cf. `--SUB` in figure 1). In addition to predicting direction of branching for simple verbs, the main benefit of this feature is that we can decide when to hypothesise head movement of the verb.

2.3.3 Discontinuous complex predicates

Coherent vs. non-coherent constructions (*coh*) Probably one of the strongest factors responsible for generation inefficiency is due to discontinuous complex predicates leading to local underspecification of valence lists that permit sneaking in from any XP edge in the chart, triggering massive combinatorial explosion. Fortunately, whether some predicate permits argument composition or not is a lexical matter, with composition being restricted to auxiliaries, modals, raising and control verbs. Thus, the transfer grammar marks the arguments of non-finite complements of modals etc., as to their potential of undergoing argument composition (*coh +*). Likewise, arguments of finite verbs that are expressed periphrastically (perfective, future, passives) are marked for composition. With arguments of all other predicates being marked with a negative value, underspecified valence lists can be protected to some degree against illicit intrusion of arguments (cf. `--COH` in figure 1). This feature is expected to be particularly helpful in those cases where we are confronted with entirely underspecified valence lists, as with separable particle verbs and partial VP fronting.

Predicting upstairs objects (raising/control) As discussed in the introduction, discontinuous verb clusters may necessitate hypothesising valencies of the initial verbs to be realised in the *Mittelfeld*, in particular objects of initial raising and control verbs that intersperse with the arguments of the final verb or verb cluster. Since the subcategorisation requirement of the upstairs verb are not known during bottom-up construction of the *Mittelfeld*, additional arguments are hypothesised even in cases where the initial verb takes no complement at all. Furthermore, such hypothesised argument slots provide potential for illicit intrusion.

On the basis of the predicate argument structure, however, it is quite straightforward to decide not only whether an argument should be hypothesised or not, but also to determine its identity. To this end, the transfer grammar redundantly encodes the upstairs verb's object as an additional

argument role (*oind*) which is used by the grammar to restrict any additional argument slot.

Predicting properties of raised subjects (*sind*) The last feature relating to complex predicates targets modals and subject raising verbs, which agree with a subject that is not their own argument. In order to limit the number of inflected variants of potentially expensive items in the chart (they all trigger argument composition), the transfer derives the person-number information of the syntactic subject from the argument structure of their non-finite argument (cf. `--SIND` in figure 1). Since the scope of this feature is limited, we did not have any a priori expectation as to whether the potential gains in certain construction will be sufficient to offset the overhead incurred by the extended rule set.

2.3.4 Non-local dependencies

Long distance dependencies, like topicalisation, wh-fronting and relativisation are a notorious source of inefficiency in syntactic processing. In German, extraction is very common: even in ordinary declaratives, some constituent is extracted from the matrix or an embedded clause and placed into the sentence-initial *Vorfeld*, a kind of topic position. In the external MRS, the distinguished individual variable of the topicalised element is represented as an information-structural property of the proposition or question relation (TPC feature). Topicalised elements can be arguments, modifiers (scopal or intersective), as well as heads, in the case of (partial) VP fronting. Moreover, as a side-effect of wide-spread scrambling, there is no canonical position even for arguments, let alone adjuncts, so gap prediction is vital.

Local vs. non-local realisation (*top*) Predicting local vs. non-local realisation of arguments is expected to be both straightforward and effective: given that the individual variable of the topicalised element is already registered in the external MRS, it is almost sufficient to redundantly encode this fact as a property of the variable, thereby making it visible on the governing predicate as well, i.e., the context from which extraction proceeds, and mark all remaining arguments as local (cf. `--TOP` in figure 1). This basic scenario gets, of course, slightly more complicated given the fact that individual variables can be arguments of more than one predicate, which may or may not be a reason for concern: in the case of across-the-board extraction from coordinate structures, it can be harmless, whereas in the case of relativisation, we are confronted with the possibility of an individual which is realised locally with respect to the upstairs predicate, yet non-locally within the relative clause. In the transfer grammar, this is resolved by means of a three-valued system of types (+,−,*na*), where Boolean values correspond to topicalised (+) and non-topicalised (−) realisation, whereas *na* represents the neutral case (relativisation). Both local head-complement rules (*na_or_−*) and complement extraction rules (*na_or_+*) are made sensitive to this distinction.

As a consequence of this feature, we expect some considerable reduction in chart size: with the exception of relativised arguments, all arguments will be marked as either local or non-local, thereby eliminating a great deal of non-determinism.

Predict extraction type and gap site (*tpc*) While prediction of argument extraction as sketched above can reduce some of the complexity incurred by long-distance dependencies, it is rather moot when it comes to items that are not represented on the argument structure of the local head at all, e.g. modifiers.

Taking into consideration the semantic relation that the topicalised elementary predication enters in with some other elementary predication, it is possible to detect, from the external

MRS, both modifier status (scopal vs. intersective) and location of the gap site, i.e. the modified item. In a similar way, it is possible to identify cases of (partial) VP fronting.

Complementing the *top* feature, which marks extraction as a property of arguments, the transfer grammar introduces a feature *tpc* to identify the locus of the gap as a property of the head. Values of this feature serve to distinguish further between different types of extraction, e.g. intersective vs. scopal modification, verb fronting and plain argument extraction (cf. `--TPC` in figure 1). Extraction rules are made to be sensitive to properties of the head, accordingly. The ordered transfer rules first try to detect instances of modifier fronting and partial VP fronting and mark the event variable of the elementary predication corresponding to the head for the appropriate extraction type. All remaining verbal and predicative elementary predications are marked as a potential site for argument extraction, thereby ruling out modifier or verb fronting from these sites.

A priori, it is difficult to assess the efficiency of this feature. However, given the rather unconstrained nature of modification, and therefore modifier extraction, it is safe to expect some decent benefit.

3 Evaluation

In order to assess the impact of the proposed measures on generation efficiency, we carried out several experiments on three different regression test suites for German: the Babel test suite (Müller, 2004), the TSNLP test suite (Lehmann et al., 1996), and the German version of the CSLI MRS test suite. The test suites were parsed, and successfully analysed test items were subsequently disambiguated using the Redwoods treebank annotation tool (Oepen et al., 2002). This left us with a total of 2,259 semantic input representations for the generator (Babel: 609, TSNLP: 1547, MRS: 103).

None of the test suites used in the experiments here was specifically designed for the purposes of NLG. Rather, all three are general purpose, phenomenon-oriented regression test suites. However, there are some differences in the design of the individual test suites that we expect to affect the impact of our performance improvements: while the MRS and TSNLP test suites consist of rather short utterances (MRS: 4.44 words/item, TSNLP: 4.76 words/item), Babel is slightly more complex (6.76 words/item). Another important difference relates to the kind of phenomena included in the test suite: to give an example, TSNLP includes a fair amount of non-sentential items for testing NP-internal agreement, a phenomenon which should be entirely unaffected by most of the efficiency measures suggested here, which are all targeted at clausal syntax.

All test runs were performed on a Linux (kernel 2.6.32) compute server with 12 Intel Xeon X5650 2.67GHz CPUs and 16GB RAM, running 4 processes in parallel (on an otherwise idle machine). The ACE generator was run in standard configuration, i.e. with a memory limit of 1.2 GB for forest creation plus another 300 MB for unpacking. The number of realisations per item was limited to 1000. Tests have been profiled using [incr tsdb] (Oepen, 2002).

In addition to comparing the performance of the full pre-generation transfer grammar to that of the baseline, we conducted a number of additional test runs to evaluate the effectiveness of each performance feature on its own (*+feature*), as well as each feature's contribution to the combined performance (*−feature*).

3.1 Results

The main results are summarised in tables 1 and 2, giving crucial performance indicators (overall processing time and passive edges) for all three test suites. Comparing baseline performance (*Base*) to the combined effect of all features (*All*), we observe a speedup of around a factor of 4.5 for MRS and TSNLP test suites. On the more complex Babel test suite efficiency gains even go up to a factor of almost 28.[4] As indicated in table 1, average speedup on all three test suites is at 18.5.

Table 1: Processing time and speedup factor

Similarly positive efficiency factors can be observed regarding space consumption (edges), although space savings typically fall short of time savings, given the fact that we are using a generator with ambiguity packing.[5]

Table 2 also details generation coverage achieved by each test run: on MRS and TSNLP test suites, coverage is 100% throughout. On Babel, we achieve full coverage, once a sufficient number of efficiency measures is enabled (second half of table 2). Test runs for baseline performance, as well as those with only a single performance feature activated at a time (top half of table 2), occasionally run into memory exhaustion, accounting for reduced coverage. However, since coverage on all test runs is either greater or equal to that of the baseline, a potential floor effect benefits the baseline more than any other runs, thus leaving the significance of our results unaffected.

[4] Apparently, combination of features pays off much better in terms of time savings than mere multiplication of individual factors would suggest, an effect that has been previously noted in the context of chart generation (Carroll and Oepen, 2005).

[5] Passive edges reported in table 2 are packed edges: thus, any edge filtered by our performance features can lead to time savings at several points during generation, namely edge creation, packing, and unpacking.

Table 2: Generation coverage and space consumption (passive edges)

Investigating the impact of the individual features in more detail, we find that almost all of them are effective on at least two of the three test suites. The only exception is *+sind*, the feature which calculates subject agreement information for raising and modal verbs: not only do we not find any clear benefits in isolation; its inclusion also proves detrimental in combination with other features. Given that this measure is highly specific, its failure to give rise to positive effects is hardly surprising. All other features are effective not only in isolation (top half of the table), but we can observe from the runs in the lower half of each table (leave-one-out) that each feature still has an impact when used in combination.

Starting with the inflection-oriented features, i.e., *cas* and *punct*, we find that both have consistent impact on all test suites. However, the effect of controlling punctuation is clearly stronger than that of predicting case: in fact, punctuation is the second to third most effective feature of all features tested. We believe that this is due to the following factors: first, predicting morphosyntactic case can only ever have an effect on nominal expressions (nouns, determiners, attributive adjectives), whereas punctuation will affect every lexical item in the chart that corresponds to some elementary predication in the input, targeting nominal and non-nominal expressions alike. Furthermore, while case prediction only reduces the number of potential complements, predicting punctuation also has an effect on heads and modifiers. Second, sentential punctuation is a global feature, i.e., all elementary predicates will be specialised in the same way. Case assignment, however, is a local property, and must therefore cater for the situation where an individual variable is shared by two or more governing predicates, as, e.g., in the case of relativisation. As a net effect, individual variables must be exempt from case prediction in these cases. This explanation is further supported by the fact that the reduction factor on passive edges is very close to the theoretically maximal value for punctuation of 1.67 (5/3).

The features related to verb placement and argument composition (*sub,oind,coh*) all lead to performance improvements, albeit to differing degrees, depending on the feature and the test suites: while prediction of verb placement, i.e., direction of branching and presence/absence of verb movement (*sub*), leads to consistently good effects on all three test suites, as does the prediction of the absence/identity of the initial verb's object (*oind*), the *coh* feature, which exclusively caters for argument composition, shows more variable behaviour: though beneficial otherwise, space savings on TSNLP are negligible, with processing times even going up slightly. This may not be too surprising: while prediction of verb placement and direction of branching affect every clause, the *coh* feature will only show an effect in constructions involving particular predicates or tenses, which is a situation that can vary depending on the concrete input.

Finally, the two extraction features *top* and *tpc* show again consistent and highly effective performance improvements across all test suites, both in isolation and in combination. This confirms quite neatly our initial expectation that these two efficiency measures are largely independent, the former (*top*) targeting complement extraction, by virtue of their being represented on the head's argument structure, the latter (*tpc*) targeting the remaining cases, most notably gap prediction for adjunct extraction. Finally, the fact that long distance dependencies are not only costly, but also frequent and not specific to any particular construction, explains why good gap prediction gives rise to consistently high performance benefits across all test suites.

Before we close the presentation of the main results, we would like to briefly compare the efficiency of the measures proposed here to those suggested by Carroll and Oepen (2005), namely index accessibility filtering and ambiguity packing. Disabling each of these previously established performance features in turn (cf. the last two rows in tables 1 and 2), we can show that the detrimental effect shown on our test data is comparable to that incurred by disabling one of the features investigated here.

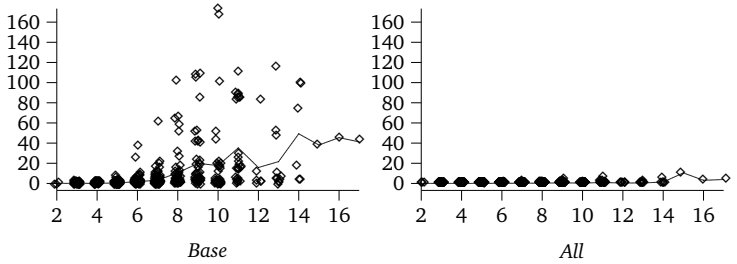

Figure 2: Processing time (in s) per string length (babel)

3.2 Discussion

We have observed during the presentation of the main results that the majority of MRS-derived efficiency features show comparable speedup effects across the three different test suites, when used in isolation. Notable exceptions were the somewhat more construction and, therefore, input-specific features *coh* and *oind* which are highly dependent on the presence of complex predicates. However, we observed quite strong differences (a factor around 5.5) as to the cumulative effects between babel on the one hand and the less complex TSNLP and MRS test suites on the other. In order to better understand the significance of the experiments reported on here we shall investigate the differences and discuss what practical implications will ensue.

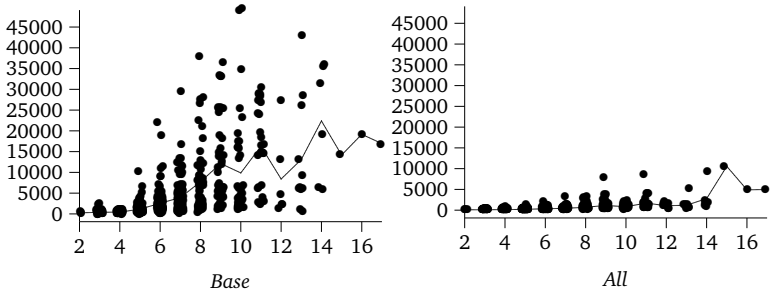

Figure 3: Passive edges per string length (babel)

The most obvious difference between Babel and the other two test suites is of course input length: by artificially reducing average input length on Babel to slightly above (4.85) that of TSNLP (by filtering out longer inputs), the cumulative speedup factor reduces to a factor around 9.5, compared to 27.5, which is still not fully comparable, yet much closer to the factor of 4.5 observed for MRS and TSNLP suites.[6] The impact of input length on relative generation speedup is also corroborated by the scatter plots of time and space (passive edge) consumption shown in figures 2 and 3: without any of the efficiency measures proposed in this paper, processing time begins to explode already at an average sentence length of 8 (see figure 2), averaging at around 8.4s. With the efficiency measures, processing time never even comes close to that level, leading to massive performance gains on longer inputs. The comparison of passive edges in figure 3 confirms even more clearly how the current efficiency measures particularly counter the combinatorial explosion observable with the baseline. To summarise, while all test suites witness good reduction of average processing times, it is clear that the real benefit of the generation efficiency measures suggested here becomes apparent with longer (and therefore more complex) inputs. For practical purposes, in particular for online processing, taming of the worst case complexity for longer inputs is more important than speedup factors on the relatively short utterances characteristic of MRS and TSNLP test suites.

Before we close, we should like to address the issue of how our method could be ported to grammars for languages other than German: while some of the concrete features we used are somewhat specific to German (or Dutch), others should be easily portable. The punctuation feature, as well as the the two extraction-related features *top* and *tpc* should be useful to improve generation efficiency in a wide range of languages: in a small experiment carried out with the ERG (Copestake and Flickinger, 2000) on the Rondane treebank (see section 1.2), we observed a 10.5% reduction in generation time for punctuation alone. We expect that other features, such as the *cas* feature will be useful for other less configurational languages, such as Slavic languages, given the fact that elaborate case systems and relatively free word order often go hand in hand.

3.3 Related work

An alternative strand of approaches towards efficient processing of unification grammars builds on the idea of compiling these grammars into formalisms with better worst-case complexity

[6] Reducing average string length to slightly below that of the MRS test suite (4.37), results in a cumulative speedup factor of only 5.4.

than native unification-based processing, such as CFG or TAG: e.g., Kiefer and Krieger (2000) proposed a CFG superset approximation of HPSG for parsing English and Japanese. However, this method has so far never been successfully applied to German, let alone for generation. Furthermore, despite potentially better raw performance, CFGs are plagued by at least as severe locality issues as bottom-up HPSG generation. TAGs, by contrast, with their extended domain of locality, constitute a much more interesting target formalism for compiling an HPSG generation grammar. In the literature, two such approaches have been reported: Kasper et al. (1995) describe a method of compiling Klaus Netter's HPSG of German to TAG, but the compilation did not cover the full grammar but only a fragment, and, unfortunately, no performance measures are reported for either parsing or generation. Becker and Lopez (2000) specifically capitalise on the fact that TAG's extended domain of locality gives rise to an a priori expectation towards greater generation efficiency, and, building on Kasper et al. (1995), they describe a compilation of the Verbmobil English and Japanese HPSG grammars into LTAG. Again, however, no performance tests are reported that could substantiate the claim of increased generation performance with the compiled grammar. Furthermore, to the best of our knowledge, no such compilation has ever been carried out for German.

In the context of native unification-based processing, Gardent and Kow (2007) suggest a method to enrich the semantic input to an FTAG of French with tree features that permit almost deterministic selection of generation paraphrases. Moreover, Gardent and Kow (2005) argue that such selection also leads to performance improvements, as they show on the basis of sample sentences. With respect to the German LFG (Rohrer and Forst, 2006; Cahill et al., 2007), Zarrieß and Kuhn (2010) propose a transfer approach to provide f-structure input for the XLE surface realiser from shallow semantic representations. The main motivation for this was that f-structures contain a high level of syntactic and even morphosyntactic detail that make them less suitable for paraphrasing and, more generally, for deployment in natural language generation systems. Zarrieß and Kuhn (2010) also discuss the impact of grammatical function prediction from semantic roles for generator efficiency: depending on the complexity of the transfer rules, they observe considerable differences in average generation time, ranging from 246.14s for the "naive rules" to 36.2s for their "informed rules", which operate on configurations rather than individual roles. Nakanishi et al. (2005) propose a beam search approach to tackle generation efficiency for an English HPSG. We believe their approach to be complementary to ours, since MRS enrichment can prune the search space with certainty and without locality restrictions, such that a future system using both methods will be able to provide good results at smaller beam sizes, taking advantage of a division of labour between transfer-based treatment of non-local and probabilistic pruning of local dependencies.

Conclusion

We have proposed a method to improve generation efficiency with GG, a reversible HPSG of German. Using a term rewrite system integrated into the generator, we automatically enrich the purely semantic input representation with additional syntacto-semantic constraints, derived from the semantic configuration. Evaluating our method on three different regression test suites for German, we have shown that this approach is highly successful in taming combinatorial explosion in bottom-up chart generation, leading to significant speedup factors: while on less complex inputs, we achieved a speedup by a factor of around 4.5, performance gains increase considerably on more complex inputs, yielding a speedup factor of almost 28, which shows that our method scales up well to increasing input lengths.

ABSTRACT

In this paper, we present a study of the collaborative writing process in Wikipedia. Our work is based on a corpus of 1,995 edits obtained from 891 article revisions in the English Wikipedia. We propose a 21-category classification scheme for edits based on Faigley and Witte's (1981) model. Example edit categories include spelling error corrections and vandalism. In a manual multi-label annotation study with 3 annotators, we obtain an inter-annotator agreement of $\alpha = 0.67$. We further analyze the distribution of edit categories for distinct stages in the revision history of 10 featured and 10 non-featured articles. Our results show that the information content in featured articles tends to become more stable after their promotion. On the opposite, this is not true for non-featured articles. We make the resulting corpus and the annotation guidelines freely available.[1]

TITLE AND ABSTRACT IN GERMAN

Eine Korpusbasierte Studie von Änderungstypen in Exzellenten und Nicht-Exzellenten Wikipedia-Artikeln

In dieser Arbeit stellen wir eine Studie über den kollaborativen Schreibprozess in Wikipedia vor. Unsere Studie basiert auf einem Korpus aus 1.995 Änderungen in 891 Artikelrevisionen der englischen Wikipedia. Wir schlagen ein Klassifikationsschema mit 21 Änderungenstypen vor, basierend auf dem Modell von Faigley and Witte (1981). Unter den Änderungenstypen befinden sich beispielsweise Rechtschreibkorrekturen und Vandalismus. In einer manuellen multi-label Annotationsstudie mit 3 Annotatoren erzielen wir eine Interrater-Reliabilität von $\alpha = 0.67$. Wir analysieren außerdem die Verteilung von Änderungstypen zu unterschiedlichen Stadien in der Revisionsgeschichte von 10 exzellenten und 10 nicht-exzellenten Artikeln. Unsere Ergebnisse zeigen, dass der Informationsgehalt in exzellenten Artikeln nach ihrer Auszeichnung tendenziell stabiler wird. Im Gegensatz dazu ist das bei nicht-exzellenten Artikeln nicht der Fall. Das dabei entstandene Korpus und die Annotationsrichtlinien stellen wir zur freien Verfügung.

1 Introduction

Team work on a single product is a common process in daily life. Online collaboration software supports project management, version control systems enable the collaborative development of source code, and recent developments in cloud computing have generated new ways of collaborating on single files. A lot of research has been devoted to the development of user-friendly tools and editors for collaborative writing (Noel and Robert, 2004). Free tools include web-based software such as Zoho Writer, Google Drive or Etherpad, as well as Wikis such as Twiki, Foswiki and MediaWiki. Corpora for analyzing the writing process mostly come from the educational domain (Lee and Webster, 2012). An exception is the Digital Variants Archive[2], which contains contemporary texts by Spanish and Italian authors including various revisions of those texts. However, these corpora only consist of textual revisions by one author. Although there are many tools enabling users to collaboratively write texts, little work has been done to analyze the underlying collaboration process of the data that is created with these tools. One possible reason is that few corpora for analyzing collaborative writing are available.

Since their invention in the mid 90s, Wikis have become one of the most important tools for creating and sharing contents. They enable a detailed tracking of changes, as they usually implement a revision control system which saves every change to a page. At the time of writing, the number of revisions in the English online encyclopedia Wikipedia kept growing by 3.2 million revisions each month.[3] Various studies have processed parts of that data for different tasks such as extracting sentence simplification (Woodsend and Lapata, 2011) or spelling error correction (Zesch, 2012).

Whenever an editor of a page in Wikipedia saves changes, a new revision is created. As one revision may contain a set of distinct local changes, we distinguish between revisions and edits. We define an *edit* as a coherent local change, usually perceived by a human reader as one single editing action. For a pair of adjacent revisions, we denote the previous revision with r_{v-1} and the newer revision with r_v. For each (r_{v-1}, r_v)-pair, we calculate a set of n edits $e^k_{v-1,v}$ (where $k = \{0, 1, ...n-1\}$) that have been made to transform r_{v-1} into r_v (see Section 3.2). We label edits with *edit categories*.

Our contribution in this study is three-fold. First, we develop a classification system for edit categories based on established models from research on the writing process (Faigley and Witte, 1981). This addresses the proposal of Ferschke et al. (2012a) to investigate on the classification of textual revisions. The goal is to facilitate data extraction for NLP applications building upon revision history data. Second, we compile and annotate a corpus tailored towards a qualitative analysis of Wikipedia revisions and based on a set of edits and release it for free access to the research community. To the best of our knowledge, such a corpus is not available yet. Third, based on the annotations in our corpus, we analyze differences in the collaborative writing process of featured and non-featured articles. Featured articles are promoted as such after an internal reviewing process which confirms the required quality standards in Wikipedia (cf. Section 3.2). Although it was not possible to identify a relationship between a certain type of collaboration and article quality in terms of featured and non-featured articles, we show that the collaborative behavior among authors significantly changes once an article is awarded featured status.

The rest of this paper is structured as follows: Section 2 presents the related work. In Section

[2] `http://www.digitalvariants.org/` (accessed 2012-10-29)
[3] Source: `http://stats.wikimedia.org/EN/TablesDatabaseEdits.htm` (accessed 2012-10-29)

3, we describe our edit classification scheme and the corpus. Furthermore, we explain and evaluate the manual annotation of our corpus. Section 4 discusses the findings of our study with respect to related approaches. Finally, we summarize the main conclusions.

2 Related Work

2.1 Collaborative Writing

Sommers (1980) investigated the connections between writing and quality, particularly with respect to differences in the types of edits performed by experienced and unexperienced writers. Her analysis shows that unexperienced writers tend to revise at the sentence or word level, i.e. to make changes on the surface of the text. On the contrary, experienced writers are rather concerned with the meaning and structure of the entire text, that is, they make changes to the text base. In the later research, there has been a shift from revising one's own work (single-author writing) to collaboratively working on a single document (collaborative writing), cf. Ede and Lunsford (1990). Generally, the importance of collaborative writing has grown over the last decades and receives increased interest due to recent developments in the Web 2.0. Collaboration in Wikipedia has been subject to a series of studies (Liu and Ram, 2011). Wikipedia's revision history reflects a type of distributed collaboration, as the interaction between authors is strictly indirect. The communication between authors takes place via the metadata related to each revision in Wikipedia such as the author comment, the revision timestamp and the author name or IP address.

2.2 Edit Classification Schemes

Faigley and Witte (1981) present the first taxonomy capturing the intentions behind a textual change. Their scheme is designed to analyze the effects of edits on meaning. They define meaning as either inserting new information to the text or deleting old information. Edits which affect meaning are called *Text-Base Changes*; edits which do not affect meaning are called *Surface Changes*. They further divide Surface Changes into *Formal Changes* (mostly copy-edits like spelling corrections etc.) and *Meaning-Preserving Changes* (paraphrases). Text-Base Changes are split into *Microstructure* and *Macrostructure Changes*, where the former describe minor changes and the latter refer to changes that affect the summary or gist of the entire text. Meaning-Preserving Changes, Microstructure Changes and Macrostructure Changes are further divided into Additions, Deletions, Substitutions, Permutations, Distributions and Consolidations. Various studies have classified edits in Wikipedia; we compare them in Table 1.

Pfeil et al. (2006) propose a taxonomy of 13 categories, aiming to compare cultural differences in the writing process of one article in four language versions of Wikipedia (German, Dutch, French and Japanese). Their taxonomy is based on an analysis of the data, not on existing revision theories. Two annotators manually examined and labeled the 500 revision pairs in their corpus. They allowed for multi-labeling and resolved disagreement by discussion. No inter-annotator agreement is reported.

Jones (2008) analyzes differences in the collaborative writing process of featured and non-featured articles in Wikipedia. His taxonomy is based on Faigley and Witte's (1981) distinction between Macrostructure and Microstructure changes. His corpus consists of 10 Wikipedia articles which were nominated to be featured in January 2007, from which 5 were actually promoted and the other 5 were denied the featured article status. For the annotation process, he relies on revision comments that have been generated either by the authors or automatically,

[a] As Liu and Ram (2011) state, this category includes grammar and spelling changes. Hence, it is not entirely a Text-Base category.

Table 1: Three studies classifying revisions in Wikipedia and the categories they use.

not on the actual revision texts. As only one person annotated the corpus, no inter-annotator agreement is reported.

Liu and Ram (2011) study the relationship between collaboration and article quality in Wikipedia, aiming to identify types of authors (e.g. Starter, Copy Editors, All-round contributors). Their taxonomy builds on Pfeil et al. (2006). However, they transformed the taxonomy into higher-level categories, merging clarification and grammar-spelling into sentence modification. By doing this, they are able to automatically identify edit categories; however, because the annotation of edits is not done manually, no inter-annotator agreement can be reported. While the automatic identification of edit categories allows for analyzing a larger corpus, it blurs Faigley and Witte's (1981) distinction between Surface and Text-Base changes. The authors do not report on the quality of the automatic edit category identification. Their corpus consists of 1,600 English Wikipedia articles from March 2010, divided into each 400 articles which have been nominated as either featured, good, B- or C-class according the WikiProject article quality grading scheme[4]. Using these four kinds of Wikipedia-internal evaluated quality grades, Liu and Ram (2011) study the relationship between collaboration and article quality. For their analysis, the authors used only the revisions before the respective nomination of the articles. The novel contribution of their work is that they calculate edits with a higher granularity (sentence level). Each (r_{v-1}, r_v)-pair may be multi-labeled with a list of edit categories to reflect the number of edits.

Other approaches propose special purpose classification systems for Wikipedia edits. Among the latter, Chin et al. (2010) focus on vandalism classification. Their top-level categories are Revert, Delete, Insert and Change; their system cannot easily be compared to the aforementioned systems, which distinguish between Text-Base and Surface changes. They introduce a basic

[4] `http://en.wikipedia.org/wiki/Wikipedia:Version_1.0_Editorial_Team/Assessment` (accessed 2012-10-29)

distinction between content and format changes. Content includes text, links and images, format refers to HTML/CSS and templates. Fong and Biuk-Aghai (2010) present a system to automatically calculate and categorize edits. Similar to our system, their system computes a list of basic edit actions on the unparsed source text (i.e. including markup). Edits are calculated with granularity at the sentence and token level. The authors suggest a set of rules and categories to label the basic edit actions calculated before. Examples of their categories are (De)Wikify, Content Modification or Spelling Correction. The implementation and evaluation of their system is rather preliminary. Bronner and Monz (2012) distinguish between Factual and Fluency edits. They segment adjacent revisions into edits and classify them in a supervised machine learning system. Their system successfully classifies edits into Factual and Fluency edits with a maximum accuracy of 0.88.

Except for Bronner and Monz (2012), all of the above presented annotation studies label pairs of adjacent revisions, not edits. Hence, even if multi-labeling is applied, it is not possible to reassign each local edit $e^k_{v-1,v}$ with a category from the set or list of categories assigned to the (r_{v-1}, r_v)-pair. No manual annotation study which explicitly analyzes the agreement between raters has been carried out so far. Hence, the reliability of previous annotations is unclear. We address these issues as we annotate a set of edits rather than revisions. Furthermore, we evaluated our annotation study with a detailed inter-annotator agreement and error analysis.

3 Proposed Edit Classification

3.1 Classification Scheme

Our approach of classifying edits in Wikipedia builds upon previous work on document revision classification (Faigley and Witte, 1981) and studies about edits in Wikipedia (Pfeil et al., 2006; Jones, 2008; Liu and Ram, 2011). We follow Faigley and Witte (1981) and define the top level layers *Surface* and *Text-Base*, which differentiate between meaning-preserving and meaning-changing edits. However, contrary to Faigley and Witte (1981), we do consider all deletions and insertions of text as Text-Base changes. The only categories for textual edits in the Surface layer are PARAPHRASE and RELOCATION, cf. Table 2. To keep the taxonomy manageable, we do not follow Faigley and Witte (1981) in their fine-grained distinction of textual edits in Additions, Deletions, Substitutions, Permutations, Distributions and Consolidations. Our taxonomy is hierarchical with the three top layers *Wikipedia Policy*, *Surface* and *Text-Base*. Table 2 presents a short explanation and example for each category.

VANDALISM and REVERT are edit categories related to **Wikipedia Policies**. We define VANDALISM as an edit deliberately compromising Wikipedia's integrity (Adler et al., 2011). A REVERT undoes past edits by restoring previous revisions or parts of them (Flöck et al., 2012). As for the **Surface** layer, we include changes to the markup, as well as relocations, spelling and grammar corrections and paraphrases. We define all elements related to the Wiki markup language (see the examples in Table 2) as MARKUP. This includes HTML code, which can also be used in Wikipedia to render the layout of a page. The RELOCATION category is assigned to edits which move entire lines (copy-paste). We use the SPELLING/GRAMMAR category to label corrections of spelling or grammatical errors. Edits which rephrase or paraphrase words or sentences without altering their meaning, are labeled with the PARAPHRASE category. In the **Text-Base** layer, we define the INFORMATION category which labels meaning-changing edits to the text itself. We use the FILE category to label edits related to media types like images, videos or audio files. The REFERENCES category is assigned to edits affecting internal and external links as well as

Category	Description	r_{v-1}	r_v
Wikipedia Policy *Invalid edits as defined by internal Wikipedia Policies and respective defense mechanisms*			
Vandalism	Edits deliberately compromising Wikipedia's integrity	Einstein's **key** insight was	Einstein's **cheese master** insight was
Revert	Edits restoring a previous state of a page	**Hahahahhahahahahahahaha:)**	
Surface *Edits not affecting the meaning of the text*			
Paraphrase	Textual edits paraphrasing words or sentences	denominations **like** the	denominations **such as** the
Spelling/Grammar	Edits correcting spelling or grammatical errors	in **the** Ireland	in Ireland
Relocation	Edits moving entire lines[a]	**... -->** {{ChineseText}} **[[Category ...**	**...Dynasty}}** {{ChineseText}} ***[[Chinese...**

Template-Modify		{{**Unit** m|2|1}}	{{**Convert**|2|m|**ft**|1}}
Other	*Segmentation Errors*	[[pirate**s]]**	[[pirate**]]s**

[a] To increase readability, line breaks are omitted in the examples.

Table 2: Classification of Wikipedia edits with truncated examples from our corpus. Where necessary, we added the context, while the actual edit is bold-faced in r_{v-1} and/or r_v.

bibliographical citations. Different from Liu and Ram (2011), we do not distinguish between links and citations, as these edits refer to the same action in the sense of referencing something. Finally, the TEMPLATE category labels all edits related to templates. In Wikipedia, templates are indicated by double curly brackets and are used for including text from other pages, creating standardized messages or other automated text generation tasks.

All Text-Base edits and those in the MARKUP category are further divided into Insertions (I), Deletions (D) and Modifications (M). Insertions apply when new content or markup is added to the article, i.e. if the content or markup of $e^k_{v-1,v}$ has not been present in r_{v-1} but is present in r_v. Correspondingly, deletions remove the content or markup of $e^k_{v-1,v}$, so that the text that has been present in r_{v-1} is not present in r_v. Modifications apply to content and markup belonging to the same segment which has been changed from r_{v-1} to r_v. Here, we define a *segment* as the source element which is affected by the category of the respective edit, e.g. for modifications of the MARKUP, a markup element must be changed, for FILE edits, the embedded file must be changed etc. Correspondingly, a TEMPLATE-M edit must change the type of the template (i.e. its name) and not just a parameter of the template, as indicated in the respective example in Table 2.

We classify changes to the source text of a Wiki page, as opposed to the visual changes on the pages surface, i.e. the translated HTML which is displayed in the browser. We believe this yields a more accurate analysis of the writing process itself. Our taxonomy is geared toward edits in Wikis; however, it is fully language independent.

3.2 Corpus Construction

To draw conclusions about the relationship between the writing process and article quality, we determine distinguished articles based on the *featured* label[5] as defined by the Wikipedia community (Stvilia et al., 2008). Wikipedia has an internal review system to label articles that meet certain predefined quality criteria, e.g. they should be comprehensive, contain images where appropriate etc. The highest status an article can achieve is the featured status. Kittur and Kraut (2008) validated a set of articles with ratings from external users and found that the agreement between the external ratings and the internal ratings according to the WikiProject article quality grading scheme is substantial. For each featured articles (FA) in the English Wikipedia, we selected a non-featured article (NFA) with equal character length. From these article pairs, we randomly selected 10 pairs with equal or almost equal edit frequency (i.e. number of revisions per day) from different size ranges (see Table 3). Although we can assume that the FAs in our corpus have high quality, the NFAs show a broad quality spectrum according to the ratings by the WikiProjects' quality assessment teams, ranging from Start- to Good-class articles. However, none of the NFAs have been rated with the highest quality scores, namely featured or A-class. The selected articles cover a range of topics on historical, scientific and political issues. The youngest article is almost 6 years, the oldest is more than 9. We call the result *Wikipedia Quality Assessment Corpus* (WPQAC).

***Pre* and *Post* Revision Groups** From these article pairs, we selected 891 revisions containing 1,995 edits for the annotation study. From the FAs, we took the revision at the time of promotion to featured status (referred to as r_{prom}) specified on the respective Talk page as the reference and divided the article history into a *pre* and a *post* stage. *Pre* denotes all revisions made

[5] `http://en.wikipedia.org/wiki/Wikipedia:Featured_articles` (accessed 2012-10-29)

FA	NFA	Size	Freq.
1941 Atlantic hurricane season	Dactylic hexameter	18	0.1
William de Corbeil	European Liberal Democrat and Reform Party	26	0.1
Victoria Cross (Canada)	Erlang (programming language)	27	0.2
Deinosuchus	Intel 8086	32	0.2
Winfield Scott Hancock	Dhole	44	0.2
Laplace-Runge-Lenz vector	United Nations Relief and Works Agency	63	0.2
Introduction to general relativity	Subwoofer	70	0.4
United States Academic Decathlon	John Cage	78	0.5
Song Dynasty	Haile Selassie I	106	1.1
Euclidean algorithm	United Methodist Church	109	0.5

Table 3: The size of the latest revision (in 1,000 characters including Wiki markup) and edit frequency (average number of revisions per day) in WPQAC are equal for each FA-NFA pair.

Group	N_e	N_r	N_e/N_r
pre-FA	515	234	2.2
post-FA	485	144	3.4
pre-NFA	496	256	1.9
post-NFA	499	257	1.9
all	1995	891	2.2

Table 4: Revision groups in the annotated part of WPQAC with absolute numbers of edits and revisions.

previously to r_{prom} and *post* all revisions made after r_{prom}. Then, for each of the ten article pairs, we selected approximately 200 edits, namely each 50 edits from (r_{v-1}, r_v)-pairs

- in the second quarter of the pre stage of the FA article history (**pre-FA**),
- in the second half of the post stage of the FA article history (**post-FA**),
- in a pre-FA parallel stage in the NFA article history (**pre-NFA**),
- in a post-FA parallel stage in the NFA article history (**post-NFA**).

This way, we ensure that pre and post stage are comparable for all article pairs in our corpus with respect to the date of promotion of the FA. The annotated corpus is therefore split into four groups, with about 500 edits each, see Table 4. Slight differences in the sizes of the groups result from the fact that we had to choose adjacent revisions for each article and stage. These revisions contain diverging numbers of edits which did not always sum up to precisely 50.

The corpus has been selected to reflect the entire range of possible edits in Wikipedia, including bot edits, vandalism and reverts. Hence, no further filtering is done.

Edit segmentation The raw data for our corpus is extracted from the English Wikipedia Revision History, from the dump as of April 2011. We process the revision content (text with markup) using the Wikipedia Revision Toolkit (Ferschke et al., 2011). We do not parse the revision text, as we want to include both edits affecting the content and edits affecting the layout into one taxonomy. For each (r_{v-1}, r_v)-pair, we calculate all of the n changes $e^k_{v-1,v}$ that have been made to the current revision via an adapted version of the diff comparison algorithm by Heckel (1978). The algorithm splits each revision into its lines and numbers them. Then, it compares each line in r_{v-1} with each line in r_v to find differences in terms of inserted, deleted, modified and relocated lines. Although we only work with data from the English Wikipedia in this study, the segmentation process is fully language independent.

Inside modified lines, we additionally detect and mark changes (i.e. deletions, insertions and modifications) in situ using Neil Fraser's google-diff-match-patch library[6]. The last step is only done where the ratio of the number of overall changes in that line to the number of tokens in that line does not exceed a certain threshold. The latter serves to avoid splitting heavily edited lines into a very high number of counterintuitive edits. If, for example, stopwords like "the" or "a" are the only unchanged segments inside a modified line, we want the entire line to be marked as modified. We do further post-processing to recognize and merge associated edits, e.g. when adding a link (to merge `[[` and `]]`). This may yield errors as Wiki markup is a context-sensitive language and hence difficult to parse. In the manual annotation study, we annotate segmentation errors due to associated edits which have not been detected and merged by our algorithm with the OTHER category (cf. Table 2).

Our annotation study is carried out on edits as calculated by the segmentation algorithm explained above. The basic types of edits which the algorithm detects are insertions, deletions, modifications and relocations. Correspondingly, each (r_{v-1}, r_v)-pair can create more than one object to classify, depending on the number of edits it contains. Our annotated corpus consists of $N_r = 891$ revisions containing $N_e = 1,995$ edits. The median of edits per revision is 1, the standard deviation is 14.5 with a minimum of 1 and a maximum of 55 edits per revision. That is, most of the changes in our corpus modify articles in only one particular place.

3.3 Annotation Study

We employed three non-native speakers with working knowledge of the Wikipedia policies and markup to label the corpus based on written annotation guidelines. We define the annotation task as a multi-label classification, i.e. each $e^k_{v-1,v}$ calculated from a (r_{v-1}, r_v)-pair is assigned a set of categories $Y \subset L$, where L is the set of categories as defined in Table 2 (hence $|L| = 21$ and $|Y| \geq 1$). If, for example, an entire sentence is rewritten, this might not only affect the words but also the markup (e.g. when a bold-faced word is deleted) or references (e.g. when a link is added). Such an edit would be multi-labeled with INFORMATION-M and MARKUP-D or REFERENCE-I respectively. Further guidelines include the following:

- Edits labeled as VANDALISM, REVERT, RELOCATION or OTHER cannot be multi-labeled.
- If $e^k_{v-1,v}$ is labeled as VANDALISM, all $e^0_{v-1,v}, e^1_{v-1,v}, ...e^n_{v-1,v}$ must be labeled as VANDALISM, since all of those edits have the same author (with bad intentions).
- Edits removing or inserting white spaces or line breaks are labeled as MARKUP.

For the annotation of edits, we used the Apache UIMA[7] Cas Editor. That way, we were able to directly annotate on the source files which are produced by the UIMA pipeline we use to extract the raw text for each revision and to segment each (r_{v-1}, r_v)-pair into a list of edits. The annotators had access to all metadata information (author name, comment etc.) and the entire text of r_{v-1} and r_v.

We derive the gold standard annotations by means of a majority vote for each category. That means, for each $e^k_{v-1,v}$ which has been labeled with $l \in L$ by at least 2 annotators, we assign the category l in the gold standard. If all 3 annotators disagreed, i.e. if an edit was labeled with none of the categories at least 2 times, it is assigned the OTHER category in the gold standard. For example, one edit changed "...algorithm *will* not terminate..." to "...algorithm *does* not

[6] `http://code.google.com/p/google-diff-match-patch/` (accessed 2012-10-29)
[7] Unstructured Information Management System, `http://uima.apache.org/` (accessed 2012-10-29)

terminate...". One annotator labeled this edit as PARAPHRASE, the other one as INFORMATION-M and the third one as SPELLING/GRAMMAR. We observed this kind of total disagreement in 5.7% of all edits. The gold standard annotations have not been manually corrected subsequently.

Inter-annotator Agreement To estimate the reliability of the annotations, we compute the inter-annotator agreement per category using the multi-rater Kappa κ measure (Fleiss, 1971), see Table 5. For each edit, the proportion of agreeing votes (i.e. judgment pairs) out of the total number of pairs is calculated. With regard to the overall agreement, we need an appropriate agreement measure for multiple raters and multi-labeled edits. We employ Krippendorff's Alpha (Krippendorff, 1980) with a set-valued distance function, MASI (Passonneau, 2006). For each edit, we have a set of categories and consider the possibly partial agreement in the assigned category sets. The overall agreement in terms of Krippendorff's Alpha is $\alpha = 0.67$. This is at the lower boundary of what is usually considered to allow for drawing tentative conclusions (Krippendorff, 1980). To the best of our knowledge, no annotation study based on edit categories in Wikipedia has been carried out, hence, this value is hard to judge as we cannot compare it to other studies. We discuss the κ values across categories below (cf. Error Analysis).

Edit- vs. Revision-based Category Distribution To measure the absolute number of revisions labeled with a certain category C_r, we built the set of edit categories over all $e^k_{v-1,v}$ in each (r_{v-1}, r_v)-pair. When comparing the absolute number of edits labeled with a certain category C_e to C_r in Table 5, we observe that the MARKUP-D, SPELLING/GRAMMAR and PARAPHRASE categories have on average the highest number of edits per revision (more than two). All of them belong to the Surface layer, whereas many of the Text-Base edits (e.g. FILE, REFERENCE) show a lower ratio of edits per revision. This might be due to the fact that authors carrying out copy-edit changes have a focus on the entire article and change the text in various places which results in a higher number of edits. To the contrary, Text-Base edits may have a focus on a limited part of the article and hence edit in only one place. Furthermore, we could conclude that authors changing the article's text base save their edits more often, as this creates a higher number of revisions.

Single- vs. Multi-label Annotation Almost 15% of the edits are multi-labeled, and more than 30% of all revisions are multi-labeled. This shows that a lot of information would be lost if we opted against a multi-label annotation. The label cardinality, i.e. the average number of assigned categories per edit, cf. Tsoumakas et al. (2010), is $LC = \frac{1}{|D|}\sum_{i=1}^{|D|}|Y_i| = 1.2$ and the label density, i.e. the average fraction of assigned categories per edit, is $LD = \frac{1}{|D|}\sum_{i=1}^{|D|}\frac{|Y_i|}{|L|} = 0.06$, where D denotes our data set.

Error Analysis We turned the multi-labeled data into single-labeled data by transforming each unique category set which has been assigned to one of the edits into a new category $t \in T$. In our corpus, $|T| = 90$. Tsoumakas et al. (2010) refer to this transformation method as *Label Powerset*, as $T \subseteq P(L)$. We created and analyzed confusion matrices over the unique category sets for each annotator with respect to the gold standard. About 25% of all disagreement in terms of confused categories is due to edits which are labeled with the OTHER category in the gold standard. This is partly related to the fact that we labeled edits where all 3 annotators disagreed with the OTHER category in the gold standard. Furthermore, this category is not

Label	κ	P_O	Edits		Revisions		C_e

[a]Excluded from top level categories. For that reason, percentages in the bottom rows do not sum up to 100%.

Table 5: Inter-annotator agreement, where κ is Fleiss' Kappa per category/layer and P_O the observed agreement per category/layer. C_e resp. C_r and % are the absolute numbers and percentages of edits resp. revisions labeled with a certain category in the gold standard.

well-defined. Further categories with low agreement are PARAPHRASE, FILE-M and MARKUP-M (cf. Table 5). FILE-M occurred only once in the gold standard. More than 40% of cases of disagreement involving MARKUP-M are labeled as OTHER in the gold standard, either due to segmentation errors (cf. Section 3.2), or because of general disagreement between all annotators. The PARAPHRASE category was not used consistently among the annotators and frequently confused with INFORMATION-M and SPELLING/GRAMMAR. Hence, the distinction between PARAPHRASE (non-meaning change) and INFORMATION-M (meaning change) has not been clear in many cases. For example, one edit replaced "several" with "many". Two annotators annotated this edit as PARAPHRASE, one as INFORMATION-M. A common problem in each of the categories was the distinction between insertions, modifications and deletions, particularly in the INFORMATION category. The annotators did not consequently adhere to the annotation guidelines (cf. Section 3.1) in some cases. If, for example, an edit *deletes* the word "not" in a phrase like "it is not a sacrament" (cf. Table 5), this edit also *changes* the meaning, which complicates the annotation of such edits.

One annotator labeled many instances of MARKUP-D as INFORMATION-D (9% of all cases of

disagreement with respect to the gold standard annotations). Furthermore, one annotator frequently (8%) forgot to multi-label MARKUP-I when larger portions of text were inserted (e.g. INFORMATION-I, REFERENCE-I instead of INFORMATION-I, REFERENCE-I, MARKUP-I).

For future work, we recommend to ignore edits labeled with the OTHER category. Categories with low agreement such as PARAPHRASE and MARKUP-M should be used with a grain of salt.

4 Discussion

4.1 Edit Category Distribution

The category distribution in our corpus partly corresponds with that in Pfeil et al. (2006) for the French, German, Japanese and Dutch Wikipedia, cf. Table 1. Additions of INFORMATION and REFERENCES are the most frequent categories.[8] VANDALISM in our corpus accounts for about 7% of all edits, which confirms the findings of Potthast (2010). Insertions clearly outnumber modifications and deletions, consistent with the studies of Jones (2008) and Pfeil et al. (2006). These findings confirm that our annotated corpus is a representative sample with regard to the collaborative writing process in Wikipedia.

Jones (2008) quotes only around 3% of edits in his *Add link* category, as compared to 28% in Pfeil et al. (2006) and 11% in the REFERENCE-I category in our corpus. Despite the fact that the categories might not fully overlap in their definitions, the low number in Jones's (2008) study could be an indicator that his approach to label edit categories based on the authors' comments does not fully capture the extent of certain edits.

The high deviation of absolute numbers of VANDALISM edits and REVERTS in our corpus is surprising. Manual inspection of the data shows that there are some Reverts of REVERTS (so called edit wars). Also, when comparing C_r to C_e for REVERT and VANDALISM in Table 5, apparently the number of edits per revision is much higher for REVERTS than for VANDALISM. This might be a particularity in our corpus, but we could also assume that vandals usually change a small portion of text, e.g. by inserting a swear word. On the other hand, authors applying a REVERT might not only revert vandalism but also undo legitimate edits which do not conform with their point of view.

4.2 Collaborative Writing and Quality

We designed WPQAC as a corpus to study differences in the quality of FAs and NFAs. To gain insights into the writing process, we analyzed the category distributions for different revision groups (cf. Table 4). Table 6 shows the Pearson correlations over category distributions between relevant groups. These calculations are based on the category frequencies of multi-labeled edits (Table 5, column C_e) for the revision groups.

Over all categories, we can see significant ($p < 0.01$, using Student's t-test) correlations between all of the groups, i.e. the frequencies of types of edits do not show significant differences among the revision groups. Generally, FAs and NFAs show a relatively high correlation. However, the correlation for pre-FA and post-FA revisions is clearly lower, as compared to pre-NFA and post-NFA. To reduce possible noise, we excluded the smaller categories from the groups and calculated the same correlations only for categories used to label at least 20 edits, i.e. with $C_e \geq 20$. As indicated in Table 6, the correlations between the pre-FA and post-FA as well as

[8] Ignoring Pfeil's (2006) *Format* category, which has partial overlap with our MARKUP category.

Group	r (all)	r (Top-16)	r (Jones, 2008)	Correlation criteria
All	0.87*	0.80*	0.91*	FA/NFA
All	0.90*	0.84*	—	pre/post
FA	0.72*	0.57	0.68	pre/post
NFA	0.87*	0.81*	—	pre/post
pre	0.86*	0.80*	—	FA/NFA
post	0.68*	0.52	—	FA/NFA

Table 6: Pearson correlation r between frequency distributions of edit categories by revision group for all and for the 16 largest categories. For comparison, we added the corresponding numbers for Jones's (2008) study. Values marked with * are statistically significant for $p < 0.01$.

post-FA and post-NFA are not statistically significant when calculated for the top 16 categories, i.e. we can assume that the two distributions come from different samples.

For the SPELLING/GRAMMAR and REFERENCE categories, deviances between the absolute number of edits in FAs and NFAs are particularly high (see Table 5). This is mainly because post-FA revisions show a higher number of SPELLING/GRAMMAR corrections and a lower number of REFERENCE edits as compared to pre-FA and NFAs. Improvements of style and grammar or spelling corrections are essential edits to produce thorough and high-quality content, hence, the higher number of this type of edits in post-FA revisions might be the result of the increased attention by experienced Wikipedia authors (Liu and Ram, 2011). The lower number of REFERENCE edits in post-FA revisions is not very surprising, as FAs need to be "well-researched", i.e. "verifiable against [...] reliable sources" according to Wikipedia's FA criteria[9] and we assume that this is the case for post-FA revisions. The high number of MARKUP-D edits in the post-FA revision group is due to one particular (r_{v-1}, r_v)-pair which deleted 42 markup tags in various places across the entire revision text.

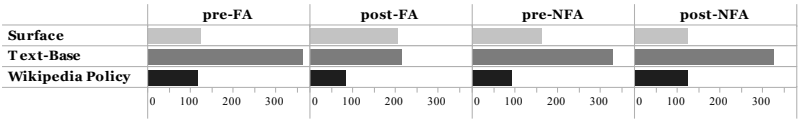

Figure 1: Absolute number of edits C_e for layers in revision groups.

It is not possible to verify the distinction between experienced and unexperienced authors as explained by Sommers (1980) for the collaborative writing process in Wikipedia. As can be seen in Table 5, the number of Surface respective Text-Base edits is higher respective lower for FAs compared to NFAs. This might be due to the fact that not only experienced authors work on FAs and vice versa.

The relationship between the distribution of edit types and quality has earlier been addressed by Jones (2008), who included in his corpus all FA revisions before and after their promotion. Like ours, his analysis shows a high correlation between FAs and NFAs, while pre-FA and post-FA differ significantly, cf. Table 6. Although it is hard to explain the reasons for this difference with his data, our corpus shows a clear difference in the ratio of Surface to Text-Base edits when

[9] http://en.wikipedia.org/w/index.php?title=Wikipedia:Featured_article_criteria&oldid=506642325

comparing post-FA revisions to pre-FA, pre-NFA and post-NFA revisions, cf. Table 5. Hence, even if we cannot find significant differences in the editing history of FAs and NFAs, there is a deviation in the collaborative writing process (in terms of editing behavior) before and after the promotion of FAs. The distinctive behavior of the post-FA revision group as compared to pre-FA and NFA revisions suggests that the nomination and promotion as FA triggers a distinguished type of collaboration. The collaborative writing process in post-FA revisions can be characterized through a relatively high number of surface edits (in particular, Spelling/Grammar corrections) and a low number of changes to the Text-Base. Figure 1 highlights the distinction between different revision groups. The lower number of Text-Base edits and the higher number of copy-edits in post-FA revisions can be interpreted as a sign of stability which FAs show after their promotion.

Conclusion

As explained in the above, there is a need for corpora to analyze the collaborative writing process. To address this problem, we introduced a classification scheme of edits established on previous work of the writing research. We applied this scheme to annotate a sample from the revision history of the English Wikipedia. To verify the reliability of our annotations, we measured and analyzed the inter-annotator agreement across categories. We published our corpus, providing free access to the research community. Furthermore, we compared the edit category distribution in featured and non-featured article revisions. Our findings show that featured articles differ from non-featured articles mainly because of a distinguished process of collaboration after an article achieved featured status. This collaboration process includes a higher number of surface changes and on the opposite a lower number of edits changing the meaning.

Further work should incorporate a deeper analysis of article quality and quality flaws in Wikipedia (Ferschke et al., 2012b). Since revisions in Wikipedia are accompanied by metadata and in particular, user comments, an analysis of the metadata based on edit categories might yield interesting results. Although we analyzed edit categories in the English Wikipedia, our approach (i.e. the classification scheme and the edit segmentation) can be applied to any language version of Wikipedia. Given that other language versions might use existing information in the English Wikipedia and translate it rather than creating completely new content (e.g. to keep the language versions with a smaller set of authors up-to-date), our taxonomy can also be used to distinguish between surface edits and edits which add new information, similar to the approach of Bronner and Monz (2012).

Finally, there remains a need for more data. Our assumptions have to be confirmed on a larger corpus. We will address this issue by augmenting the labeled corpus with an automated approach using Machine Learning on the annotated data.

Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg-Professorship Program under grant No. I/82806, and by the Hessian research excellence program “Landes-Offensive zur Entwicklung Wissenschaftlich-ökonomischer Exzellenz” (LOEWE) as part of the research center “Digital Humanities”. We thank the anonymous reviewers for their helpful remarks.

A Computational Cognitive Model for Semantic Sub-network Extraction from Natural Language Queries

Suman DEB ROY Wenjun ZENG

Department of Computer Science
University of Missouri – Columbia, USA.

ABSTRACT

Semantic query sub-network is the representation of a natural language query as a graph of semantically connected words. Such sub-networks can be identified as sub-graphs in larger ontologies like DBpedia or Google knowledge graph, which allows for domain and concepts identification, especially in noisy queries. In this paper, we present a novel standalone NLP technique that leverages the cognitive psychology notion of semantic *forms* for semantic sub-network extraction from natural language queries. Semantic *forms*, borrowed from cognitive psychology models, are one of the fundamental structures employed by human cognition to construct semantic information in the brain. We propose a computational cognitive model by means of conditional random fields and explore the interaction patterns among such *forms*. Our results suggest that the cognitive abstraction provided by semantic *forms* during labelling can significantly improve parsing and sub-network extraction compared to pure lexical approaches like parts of speech tagging. We conduct experiments on approximately 5000 queries from three diverse datasets to demonstrate the robustness and efficiency of the proposed approach.

KEYWORDS: Cognitive Linguistics, Forms, Query, Search, Subnets, Semantic

Proceedings of COLING 2012: Technical Papers, pages 727–744,
COLING 2012, Mumbai, December 2012.

1 Introduction

The efficiency of natural language (NL) search often depends on detection of keywords in a query, followed by construction of some meaningful connected network comprising of such keywords (Herdagdelen, 2010). This connected network of keywords is called a semantic subnet (Booth, 2009). These keywords together comprise what is called a semantic field (Croft, 2003). The goal of our research is to efficiently recover the semantic sub-network from NL queries.

Prior research suggests three main motivations for extracting semantic subnets from NL queries. Firstly, extracted query subnets can be used to generate a candidate set of concepts within a larger ontology (like of DBpedia RDF network/ Google knowledge graph), which may align to the words in the query subnet and assist domain identification and query expansion (Booth, 2009). Secondly, a query subnet can act as a NL interface to concept graph databases (Popescu, 2003), facilitating semantic information retrieval (Kauffman, 2007) and improved query understanding and semantic search (Hu, 2009). Finally, semantic subnets enable identification of event structures within sentences (McClosky, 2011) and assist higher-level NLP tasks, like Question Answering (QA) (Huang, 2009).

It is possible to detect semantic keywords in NL queries using methods like Named Entity Recognition (NER) or Semantic Role Labelling (SRL) (Collobert, 2011). Both techniques provide a higher level of abstraction than the basic syntax tree. However, our task goes a step further: we aim to find out *how these keywords are semantically connected* in terms of a network. This is very difficult to achieve using NER alone, since detecting the named entities provides limited information about their relations. SRL does a better job at concept level parsing using predicate logic, but is bound by the strict predicate grammar. Therefore, although techniques such as NER and SRL is core to NLP, there is an inherent gap between requirements of intelligent tasks (like QA) and several state-of-the-art NLP techniques (Finkel, 2009).

As search is becoming more collaborative and social, queries turn noisier (Hu, 2009). Often, the conceptual structure of the NL query is difficult to extract using simple (Parts-Of-Speech) POS-based dependency parsing. Imprecision of NL usage is a major obstacle to computation with NL. Therefore, it is necessary to develop a technique that partially relaxes the rigid grammar of the language. While imprecise or varied grammatical constructions are difficult to capture using POS or predicate logic, note that the human cognition can often eliminate such noise to interpret meaning. If we assume that 'meaning' of a NL sentence is captured in its semantic subnet, then it would be logical to conclude that human cognition possesses a more noise-resistant process of extracting semantic subnets. A rational explanation for this is the presence of an improved model for detecting semantics in NL and subsequently constructing semantic information in the brain.

Cognitive psychology has a number of interesting theories on how the human mind deals with imprecision, uncertainty and complexity of language (Chater, 2006). One such theory, called the structure-of-intellect model, proposes that humans perceive concepts contained within the words of a sentence as a semantic *form* (Guilford, 1977). His model has been widely used to study the cognitive intellect and the kinds of information that humans can extract from any observed

argues that human cognition is robust to noise because it dynamically changes the resolution at which data is to be semantically interpreted (Croft, 2004).

Recognizing the potential of cognitive approaches in semantic information modelling, we propose to leverage semantic *forms* in the extraction of semantic sub-networks from NL queries. These semantic *forms*, when connected in some networked pattern, becomes responsible for understanding the scope and context of a concept, and assists functional retrieval of related concepts and question answering/response (Carroll, 1993). Thus, our main insight in modelling semantic *forms* and their interaction patterns in NL is grounded on the idea: *the subsurface form space demonstrates the query intent (expresses semantics) better than superficial (lower) query syntactical features, which might vary depending on diverse query construction.* In other words, the higher is the level of abstraction for labelling, the more robust the extraction should become. This idea of cognitive abstraction provided by semantic *forms* is shown in Fig. 1.

The main contributions of this paper are:

- We propose the use of semantic *forms*, borrowed from cognitive science, as label category for NL sequence labelling tasks.
- We propose a conditional random field based method of implementing the structure of intellect model, by labelling query words with semantic *forms* and analyzing the interconnected patterns in which such *forms* exist within a semantic field.
- We perform experiments on three diverse query datasets consisting of TREC, QA-type and Web queries to justify the robustness of our approach to varying noise levels. Our approach comprehensively outperforms existing works on query subnet detection (Booth, 2009).

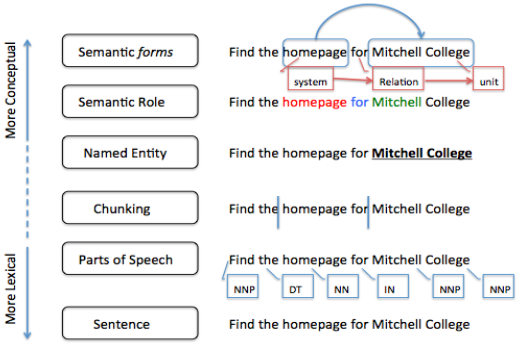

FIGURE 1 – Level of abstraction in different NLP techniques: from lexical to conceptual.

The rest of this paper is organized as follows: in Section 2 we discuss related work and the scope of the paper. Section 3 introduces the notion of semantic *forms* and their interactions. In Section 4, we describe the proposed model for labelling query words with linked semantic *forms*. Section

aids better NL interfaces that precisely map a NL query into a suitable graph database. In the next two sub-sections, we describe the related work and scope of this paper.

2.1 Related Work

Semantic subnet extraction from NL queries is essentially a method of query reformulation, wherein a query is represented in an alternative form that eases its interface with different types of databases for concept detection. A detailed analysis of query reformulation techniques is available in (Clifford, 1990) and (Herdagdelen, 2010). Substantial efforts have been exhausted in trying to enhance the role of NL interfaces in converting a natural language query into a graph database query (Booth, 2009) (Popescu, 2003). A semantic network of Resource Description Format (RDF) concepts (DBpedia) can be considered one such graph database (Auer, 2007). Several problems like word-sense disambiguation (Bruce, 1994), specificity of grammar (Manning, 1999) and keyword (not semantic) based approaches inhibit portability of several existing NLP techniques across systems and domains (Kaufmann, 2007). The closest work to our research is (Booth, 2009), which uses a POS-based approach in extracting subnets from queries. The accuracy of query subnet extraction compared to a human standard can be evaluated using metrics such as Consistency Index (Cardona, 2009). The results stated in (Booth, 2009) are tested on a very limited number of queries (approx. 12), which does not come close to capturing the diversity in human query constructions or web scale. In contrast, we provide empirical results on 5000 queries from three query datasets with different noise levels.

Substantial efforts have also been spent in detecting named entities in sentences. This task, called Named Entity Recognition (NER) seeks to locate and classify words such as names, organizations, places etc. in a NL sentence (Guo, 2009). A similar NLP task is SRL, which involves finding target verbs (predicate) in a sentence that resemble some 'action' (Collobert, 2011). Models have also strived to combine these two techniques (Finkel, 2009). In this paper, we will use Conditional Random Fields (CRF) (Lafferty, 2001) to capture the cognitive model in terms of finite state automata, with each *form* state dependent on the previous *form* state and on the current symbol word being processed. The resulting Markov chain of possible states can be solved using the Viterbi Algorithm, implemented using dynamic programming (Manning, 1999).

J. P. Guilford introduced the structure-of-intellect model in (Guilford, 1977), which covers the notion of semantic *forms* as 'products'. 'Products' are the result of applying some cognitive operation (cognition, retention etc.) on specific content (semantic, symbolic etc.). The model has since been used, studied and analysed substantially in the cognitive science community. A detailed view of human cognitive semantics in linguistics is provided in (Croft, 2004). Probabilistic models of cognitive linguistics are described in (Chater, 2006). An insightful introduction to human cognitive abilities is available in (Carroll, 1993).

2.2 Motivation

We strive to better model the conceptual linkage among words in a query sentence, such that the linked semantic field (query subnet) can be searched for in a larger network of RDF based

We abstract the problem to the level of cognitive semantics, by making use of the concept of semantic *forms*. According to existing cognitive psychology, *forms* are used by the human psyche to process and store semantic information structures in the brain (Carroll, 1993). *To the best of our knowledge, computationally modelling semantic forms borrowed from the domain of cognitive psychology has not been previously used in semantic query understanding in the domain of natural language processing*.

3 The Cognitive Structure-of-Intellect Model

The main hypothesis proposed by the Structure-of-Intellect model is that *human cognition is robust to noisy sentence constructions because it strives to detect semantic information at different levels of granularity*. The noisier the sentence, the coarser is the granularity of semantic information detection employed by the human cognition. In this section, we qualitatively introduce the different semantic *forms* from Guildford's structure-of-intellect cognitive model and describe how *form* interaction patterns play a key role in semantic subnet extraction.

3.1 Granular Hierarchies in Semantic Information

Semantic *forms* consist of five entities that capture the structure of information contained within a natural language sentence as perceived by the human cognition. A remarkable thing about semantic *forms* is that they are structured as granular hierarchies (i.e. one *form* is composed of other *forms*). Following is a description of the semantic *forms* starting with finer granularity:

Unit: Every item of a query sentence can be regarded as part of some chunk, of which *units* are the most basic entities. *Units* will cover most words of a sentence, from intangible ideas like 'love' to tangible objects like 'cars'. For example, the name 'Anna Chakvetadze' is a *unit*. The cognition of semantic *units* has to do with one's vocabulary (Guilford, 1977).

Class: When *units* have one or more attributes in common, they can be grouped in *classes*. *Units* belonging to a *class* will share connectivity to at least one common attribute node. *Classes* can be narrow or broad. For example, the *unit* 'Anna Chakvetadze' can belong to the very broad *class* 'female', a moderately broad *class* 'Russia' or a narrow *class* 'Tennis'. The size of the *class* (narrow/ broad) qualitatively determines the size of the search space for related concept retrieval.

Relation: *Relations* are *kinds* of connections between *units*. When any two entities are connected in the semantic network, there are three items of information involved – two *units* and the *relation* between them. *Relations* between search keywords play an integral role in realizing *class* or *unit* interconnections in the query. For example, 'Steffi Graf' and 'Andre Agassi' could be connected by the *relation*: *married*, while both belonging to the *class: tennis players*.

System: A *system* is the most complex item in semantic information. *Systems* are composed of more than two interconnected *units*. *Systems* may also comprise of overlapping *classes*, multiple interconnecting *units* and diverse *relations*. They often occur as an order or sequence of *units*. Add 'Maria Sharapova' and 'Sasha Vujacic' to the previous example of 'Steffi Graf' and 'Andre Agassi', and we get a *system*: *married sportspersons*.

Word	Thursday	witches	market	driving	mansion	school
Form	*unit*	*class*	*system*	*relation*	*Unit*	*system*

TABLE 1 – Examples of *forms* attached to query words.

4 The Proposed Computational Cognitive model

In our proposed approach, consider each observed symbol as the tuple: {word, POS tag, NP chunk number}. We can employ basic sequence labeling idea here, by considering the chain of *forms* that link the tuples as hidden states. Using the training data, a CRF model (McCallum, 2000) can then assign optimal state chains to samples of observed symbols, from which we learn the kinds of *form* chains (interactions) that exist. Steps for computationally modeling the cognitive notion of semantic *forms* are described in this section.

We begin with formal definitions, followed by describing some pre-processing techniques and finally, the detailed description of model features.

4.1 Formal Definitions

Consider an NL sentence *Q*. Our assumption is that *Q* is a carrier of information. Every word is a linguistic variable in *Q*. It is well known that information is expressible as a restriction (i.e. a constraint) on the values that a variable can take (Zadeh, 1998). By this flow of thought, consider *W* as a constrained variable in *Q*, let *R* be the constraining relation in *Q* and ζ (zeta) represent how *R* constrains W. Then, every NL sentence *Q* can be represented as: $Q \rightarrow W\ \zeta\ R$

It is possible for *W* to be a vector-valued random variable. The primary constraint *R* is a restriction on the *form* values that can be probabilistically assigned to *W*. Hence, *W* can take up values of different *forms* from the set (*unit, class, … , transform*) with probabilities (p_{unit}, p_{class}, …, $p_{transform}$) respectively. Thus, *W* is constrained using the probability distribution *R* as:

$$W\ \zeta\ (p_{unit} \backslash unit + \ p_{class} \backslash class + \cdots + p_{transform} \backslash transform)$$

The singular variable *W* takes values from the universe of discourse *U*, such that values of *W* are singletons in *U*. On the other hand, the semantic *form* of *W* is a variable whose values depend on the granular collections in *U*. Said alternately; *the granular precision of a word in U is expressed through its semantic form*. The type of *form* assigned to a word depends on the cluster size of elements in *U* that have common attributes or behaviour related with the concepts of that word.

The overall process is described at an abstract level in Fig. 2, where ellipses represent the *form* of a word. Consider four key words W1, W2, W3, and W4 in the query (*Q*) that need to be connected as some semantic subnet. Let $Form(W1)$ denote the *form* associated with the word *W1*. In step (i): we are uncertain of the semantic subnet connection among the words. In (ii), our goal is to label the words with semantic *forms* to help extract the query subnet. In (iii), we use the *form* interconnection patterns (described in Section 4.3.3.2) to retrieve the connection among the *forms* for the four words when they exist together in some *Q*. Finally, in (iv), we can connect the words as a query subnet by shadowing the connected *form* pattern that exists among the *forms*.

known Python NL toolkit stop word list. We used the Stanford POS tagger for POS tagging. For long queries, chunking is necessary. The chunking process is inspired by (Huang, 2009).

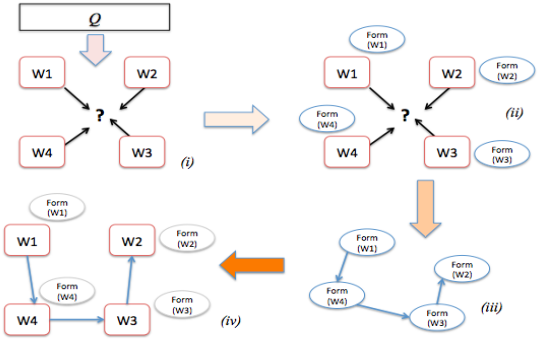

FIGURE 2 – Overview of process flow from receiving input query *Q* to subnet extraction.

Chunking: Consider *Q* to be a query sentence in natural language *L* containing words belonging to the vocabulary set *V*. Let S_Q be the sequence of POS-tagged symbols associated with *Q*, i.e.

$S_Q = \{s_1, s_2, \dots, s_N\}$, where $s_n = \langle w_n, t_n \rangle$, $w_n \in V$, $t_n \in T'$ for *N* words in Q.

Given S_Q we can define the k^{th} chunk ($\mathcal{C}_k$) as: $\mathcal{C}_k = (\langle w_i, t_i \rangle, \langle w_{i+1}, t_{i+1} \rangle, \dots, \langle w_j, t_j \rangle)$ for some $i < j \leq N$ and $1 \leq k \leq M$ for a total of *M* chunks in the query. We assume that no two chunks have any common words, i.e. chunks are non-overlapping. Then, the task involves determining all the *M* chunks based on S_Q, s.t. $\mathcal{C} = \{\mathcal{C}_1, \mathcal{C}_2, \dots \mathcal{C}_k, \dots, \mathcal{C}_M\}$.

This generates the chunked query set: $S_{QC} = \{\langle s_1, \mathcal{C}_1 \rangle, \dots, \langle s_l, \mathcal{C}_1 \rangle, \langle s_{l+1}, \mathcal{C}_2 \rangle, \dots, \langle s_N, \mathcal{C}_M \rangle\}$, where $\mathcal{C}_1 = (s_1, \dots, s_l)$, $s_l \in S_Q$, for some l, $1 \leq l \leq N$. Following similar methods as used in (Huang, 2009) and given $\{s_{i-1}, s_i, s_{i+1}\}$, we can find $p(c_1, c_2, \dots, c_N \mid S_Q)$ as:

$$p(c_1, c_2, \dots, c_N \mid S_Q) = \Psi \prod_{i=1}^{N} p(s_{i-1} | s_i, c_i)\, p(s_{i+1} | s_i, c_i)\, p(s_i | c_i)\, p(c_i) \qquad (1)$$

$$\Psi = 1 / p(s_1, s_2)\, p(s_2, s_3) \dots, p(s_{N-1}, s_N)$$

and c_i represents if s_i is inside, outside or start of some NP chunk. The individual probabilities of Eq. (1) can be estimated from the training set.

4.3 *Form* Tagging Using CRFs

The task of tagging words of a sentence with semantic *forms* from the set of *forms* (*F*) leverages a CRF model. The result is the set S_{QF} of *form* labelled words. First, we briefly describe CRF in the light of our problem, followed by feature functions and learning weights.

A *state feature* is an element of $\boldsymbol{l_f}$ of the structure $state(y, \boldsymbol{x}, i)$ where *i* is the input position, *y* is a label and $\boldsymbol{x}$ is the input sequence. A *transition feature* is an element of l_f of the structure $tran(y, y', \boldsymbol{x}, i)$ where *y*, y' are labels.

The global feature vector for an input sequence $\boldsymbol{x}$ and a label sequence $\boldsymbol{y}$ is:

$$\boldsymbol{F}(\boldsymbol{y}, \boldsymbol{x}) = \sum_i \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{x}, i) \quad (2)$$

Individual feature functions are described in Section 4.3.2. A conditional distribution that obeys the Markov property, which is: $p\left(Y_i \middle| \{Y_j\}_{j \neq i}, \boldsymbol{X}\right) = p(Y_i | Y_{i-1}, Y_{i+1}, \boldsymbol{X})$ can be written as:

$$p_{\boldsymbol{\lambda}}(\boldsymbol{Y}|\boldsymbol{X}) = \frac{\exp\{\boldsymbol{\lambda}.\boldsymbol{F}(\boldsymbol{Y}, \boldsymbol{X})\}}{Z_{\boldsymbol{\lambda}}(\boldsymbol{X})} \quad (3)$$

where $Z_{\boldsymbol{\lambda}}(\boldsymbol{x}) = \sum_{\boldsymbol{y}} \exp\{\boldsymbol{\lambda} . \boldsymbol{F}(\boldsymbol{y}, \boldsymbol{x})\}$.

Note the denominator of Eq. (3) is independent of $\boldsymbol{y}$. Then the most probable sequence of *form* labels ***(y*)*** for the input sequence $\boldsymbol{x}$ is:

$$\boldsymbol{y}^* = \arg max_{\boldsymbol{y}}\, p_{\boldsymbol{\lambda}}(\boldsymbol{y}|\boldsymbol{x}) = \arg max_{\boldsymbol{y}}\, \boldsymbol{\lambda}.\boldsymbol{F}(\boldsymbol{y}, \boldsymbol{x}) \quad (4)$$

Eq. (4) can be solved using the Viterbi Algorithm (McCallum, 2000).

4.3.2 Feature Functions

Feature functions are key components of CRF (see Fig. 3). The general structure of a feature function is $z(f_{i-1}, f_i, \boldsymbol{x}, i)$ which looks at two adjacent states f_{i-1}, f_i, the whole input sequence $\boldsymbol{x}$ where *i* is the current location in this sequence, and assigns some weight. They can be defined in different ways, e.g., we have a feature like: if the current word is 'Nile' and the current state is '*unit*' then we give the feature a positive weight, otherwise not. Each feature function has a binary output and can take as inputs the value of a feature and particular values of the current *form* f_i and the previous *form* f_{i-1}. We use the training corpus queries to build the atomic feature set for the CRF. Let F_u, F_r, F_c, F_s represent *unit, relation, class* and *system respectively*.

In the examples below, a binary value of 1 indicates the presence of the feature, and 0 the lack of the feature. 'λ' denotes logical AND. We implement four types of binary atomic features:

(1) *Simple Feature Function*: A simple feature function depends only on a word and its connected *form*. For example,

$$z(f_{i-1}, f_i, \boldsymbol{x}, i) = \begin{cases} 1, & if\ x_i = ´\ music´ \wedge f_i = F_s \\ 0, & otherwise \end{cases}$$

(2) *Overlapping Feature Function*: An overlapping feature function depends on *form* of a word and on its successor word. Under normal conditions, Hidden Markov Models (HMMs) are unable to realize overlapping features (unlike CRFs). A suitable example would be:

$$z(f_{i-1}, f_i, \boldsymbol{x}, i) = \begin{cases} 1, & if\ x_i = ´\ and´ \wedge f_{i-1} \neq F_r \\ 0, & otherwise \end{cases}$$

734

(3) *Form Transition Feature Function*: A *form* transition feature function depends on successive *forms* such as:

$$z(f_{i-1}, f_i, \boldsymbol{x}, i) = \begin{cases} 1, & if\ f_{i-1} = F_r \wedge f_i = \{F_u, F_c\} \end{cases}$$

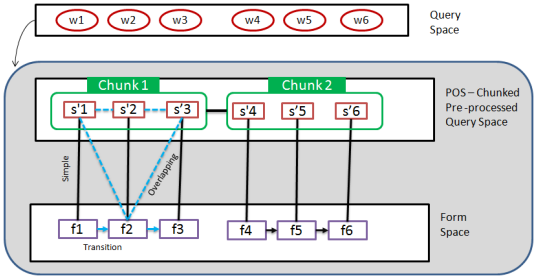

FIGURE 3 – Different features functions in the CRF model: from query words to *form* labeling.

In Fig. 3, each '*s*' element in the POS-chunked pre-processed query space represents a tuple <word, POS, NP Chunk number>. There are 828 atomic features in our system, obtained from words in the vocabulary and shifted-conjugation patterns.

This initial feature set is then grown using feature induction (McCallum, 2003), resulting in a total of 23,713 features. A quasi-Newton method is used to adjust all parameters of the CRF model to increase the conditional likelihood. When training the CRF, we use pre-conditioning to ensure fast convergence of the conjugate gradient method (Sha, 2003). On average, our technique requires 12-13 forward-backward iterations to reach an objective function value, which is in close proximity (~96%) to the maximum.

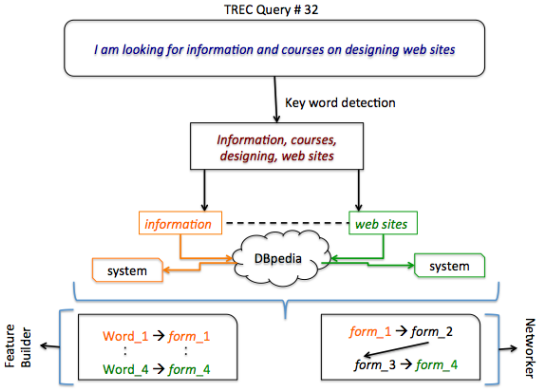

FIGURE 4 – Feature Builder and Networker learning from training queries.

4.3.3 Feature Generation

4.3.3.1 State features

The CRF labeller's state feature set is assorted using a feature builder. The feature builder is trained using a seed set of words and their related *forms* obtained using DBpedia RDF resource (Fig. 4). DBpedia contains structured information collected from Wikipedia and has been extensively used for semantic analysis of content (Auer, 2007). The RDF semantic network of DBpedia is arranged in granular categories. Thus, for every node (which represents a concept word), we can calculate the normalized degree centrality, which gives us an estimate of the generality of the node. The more general concept nodes have higher centralities (Coursey, 2009).

Fig. 4 illustrates how words and their tagged *forms* are collected from a training query. Keywords are identified from a query by stemming and eliminating stop words. Using DBpedia to classify the word into a semantic *form* follows this. The vocabulary containing words → *forms* is updated as more training examples are seen and used by the feature builder.

4.3.3.2 Transition features

Given enough training samples of the sentence Q, the variable W and constraint R, we can deduce the pattern ζ, which identifies how R constrains W. This pattern ζ contains information about the ordering in Q with respect to W (recall W could be vector-valued) such that they are mapped to R. That is to say, every *form* has some specific interaction pattern with other *forms* when they exist together/adjacent in Q. This interaction pattern among *forms* in U is signified by ζ. Interaction patterns provide insight into the question: how are three or more *forms* connected when appearing in Q? For example, if we see words $\{A, B, C\}$ having *forms* {*relation, class, unit}* respectively, then would the query subnet be of the ordering A-B-C, B-A-C or C-A-B?

The networker learns interaction patterns at the chunk level, modelling each chunk as a potential branch for a rooted semantic query subnet. This viewpoint is derived from the observation that branches of most annotated query subnets are composed of individual or contiguous chunks of the original query. The *form* interaction set $\tilde{F}$ is a simple ordered set: $\{(f_i, f_j)\}$, where $f_i, f_j \in F$ representing a complete or part of a directed chain $f_i \rightarrow f_j$. We only use *forms* connected within a chunk to populate the set $\tilde{F}$. Fig. 5 shows results collected using a Trellis diagram.

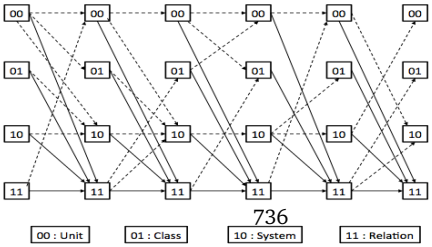

FIGURE 5 – Trellis diagram of possible Viterbi paths representing sequence of labeled *forms*.

measure: $z(f_{i-1}, f_i, \boldsymbol{x}, i) = 1\ if\ f_i = b\ and\ f_{i-1} = a$ and assign weights to this feature based on *K* training subnet samples as:

$$w_{a,b} = 1 + \log[\ \sum_{1 \le k \le K} n(a,b) * |k|/K\ ] \quad (5)$$

where *k* is the *kth* sample in the training set of subnets, *n(a,b)* = 1 if the *form* transition $a \rightarrow b$ appears as some edge of the *kth* sample subnet and $|k|$ is the length of the subnet branch containing $a \rightarrow b$. If the *form* transition $a \rightarrow b$ is not present, then *n(a,b)* = 0.

Eq. (5) achieves a simple goal: it takes the human labelled subnets into consideration while allocating weights for transition feature functions. The more we notice a particular *form* transition repeated, the higher the weight it is given as a potential transition feature.

From the *form* interaction patterns $\tilde{F}$ and the chunk set $\mathcal{C}$, the networker builds a set $S_{QF} = \{\langle s_1, f_1, \rangle, \dots, \langle s_3, f_3, \rangle, \dots, \langle s_6, f_6, \rangle\}$ structured as a tree $G = (S_{QF}, E)$ where $E \in \tilde{F}$. If $|\mathcal{C}_i|$ represents the number of POS-tagged symbols in some chunk $\mathcal{C}_i \in \mathcal{C}$, then the height of subnet is $\le \max(|\mathcal{C}_i|)$, taking into account that consecutive *units* within a chunk may be collapsed into a single node. G is the semantic subnet.

5 Experiments

5.1 Data Description, Evaluation Metrics and Benchmarks

Data: We test our model on each of these three datasets: (a) The TREC 2011 (TREC) web topic dataset has 50 topics (Clarke, 2011). Each topic has 1-7 queries associated with it. All queries within a topic resemble similar search intent. There are a total of 243 queries in the TREC topic dataset. 77% of the queries in the TREC dataset have 11-14 words. (b) The Microsoft Question Answering Corpus (MSQA), which is aimed at querying documents belonging to the Encarta-98 encyclopedia (MSQA, 2008). There are 1365 usable queries in this dataset and 85% of the queries have 5-10 words. (c) The last dataset consists of ~ 3400 raw search query feeds collected from a commercial web search engine (denoted as 'WSE'). Queries containing 4-20 words are chosen for evaluation. The distribution of average number of words per query is shown in Fig. 6.

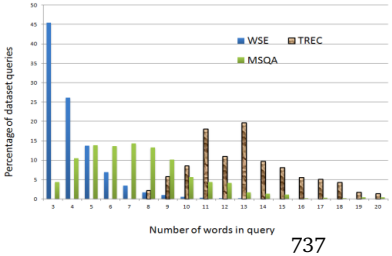

FIGURE 6 – Distribution of avg. number of words per query in the three datasets.

The three datasets represents gradually rising levels of challenge in terms of query construction

Query ID	Query Sentence	Query Subnet
TREC 43	*Find reviews of the various TV and movie adaptations of The Secret Garden*	
TABLE 2 – Example of query subnet generated from query.

Several other small optimizations are implemented: (a) we collapse consecutive *units* into a single *unit* when creating the subnet. (b) We use a simple root selection algorithm: when only *relation* words are found connecting two chunks $\mathcal{C}_i, \mathcal{C}_j \in \mathcal{C}$, we search $\mathcal{C}_{j+1}$ for *units* or *classes*. If $\mathcal{C}_{j+1}$ lacks a *unit* or *class*, we search $\mathcal{C}_{i-1}$instead. For example, in the query #TREC43 (Table 2), '*various TV'* and '*movie adaptations'* are connected by the conjunction '*and'*. Therefore, we search in $\mathcal{C}_{j+1} = '\ of\ The\ Secret\ Garden'$ and since we find a sequence of two *units* ('Secret', 'Garden'), we collapse it to a single *unit* and represent it as root.

We used annotators to hand label the queries in the datasets to build query subnet trees. The inter-annotator agreement on subnet structure was 72.3%. Disagreements were limited to just 1 node position in 82% disagreed cases. Thus, we consider this hand labelled set as the gold standard for comparing the machine generated subnet.

Metrics: Since our output (query subnet) is a tree where each node belongs to the set of query words, a 'tree-likeness' metric is essential to judge quality of results produced in terms of *structure*. We use *Consistency Index* (*CI*) as a metric to judge the quality of the subnet generated (Cardona, 2009). Mathematically, *CI* can be defined as:

$$CI = node\ position\ matches\ between\ T1\ \ and\ T2/\#\ nodes\ in\ T2$$

where, *T1* represents the query subnet tree generated by a machine algorithm, *T2* is the query subnet tree of the gold standard and # represents the number of nodes. In (Booth, 2009), the authors evaluate their subnets using simple measures like 'nodes correctly resolved' or 'semi-correctly resolved'. However, we believe that *CI* captures the effect of *structural relatedness* more intuitively. Table 3 lists the average *CI* values obtained for various datasets for the proposed approach and the comparison benchmarks.

Benchmarks: We compare the proposed model (*formNet*) against 3 benchmarks. We test our model against (a) the POS based approach introduced in (Booth, 2009) for generating subnets from query sentences (called *posNet*), (b) a non-*form* CRF (denoted as *nfCRF*) used in (Sha, 2003), whose features are based on POS only, and (c) a non-chunked version of our model (denoted as *noChnk*), to compare the gain due to semantic *forms* vs. chunking.

5.2 Test Results

We measure the average CI for queries in each dataset with our technique against the above benchmark techniques. Results are reported in Table 3. For each dataset, we provide a detailed bar graph describing percentage of queries that produced outputs in some particular CI range.

TREC: Fig. 7(A) shows that *formNet* achieves *CI*=1 for 63.1% queries. In fact, only 9.2% of the

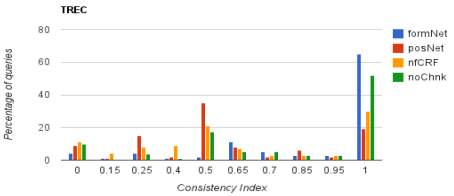

FIGURE 7. (A) – Percentage of queries that yielded some CI for TREC

	posNet	*formNet*	nfCRF	noChnk
TREC	54.8	***83.6***	58.6	74.0
MSQA	53.6	***79.5***	43.3	77.3
WSE	48.2	***73.2***	36.1	68.4

TABLE 3 – Evaluation results for various datasets in terms of average CI (%)

MSQA: Table 3 shows that *formNet* provides average *CI*=0.795 for MSQA queries whereas the benchmark *posNet* produces an average *CI*=0.536. This signifies ~ 49% improvement in performance. Fig. 7(B) shows that *formNet* can retrieve 55% queries with perfect match and produces a *CI*>0.5 for 85% queries in the dataset. In contrast, the benchmark *posNet* could only produce *CI*>0.5 for 38% queries. TREC queries are grammatically richer than MSQA; therefore a drop in overall performance is expected when evaluating MSQA. Interestingly, *forms* seem to be playing a stronger role in MSQA, since a traditional CRF performs poorly in this case.

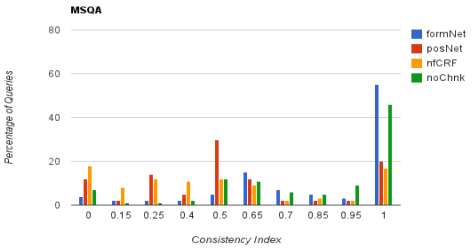

FIGURE 7. (B) – Percentage of queries that yielded some CI for MSQA

WSE: WSE queries are most diverse in construction and number of words. In Fig. 7(C), we see that performance is reduced for all techniques, but *formNet* still performs better than *posNet* by 51.86%. Observe that *noChnk* performs worst for TREC when compared to *formNet* than for any other dataset as indicated in Table 3 (difference between average CI for *formNet* and *noChnk*). This reaffirms our previous observation from the query data: TREC queries consist of longer

substantially better than *noChnk* for MSQA and WSE datasets, whereas no chunking for TREC significantly deteriorates performance. This indicates that chunking has a stronger impact in TREC, a dataset where 77% queries have more than 11 words (Fig. 6). In comparison, only ~10.8 % queries in MSQA and 7.6% queries in WSE have more than 9 words.

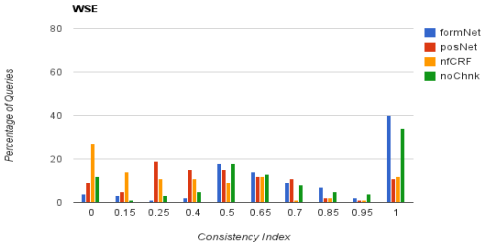

FIGURE 7. (C) – Percentage of queries that yielded some CI for WSE.

Cross Dataset Testing: Different datasets differ in query structure, context and length of query. To ensure robustness to different training environments, we perform cross dataset testing, i.e., train on one dataset and test on another (read TRAIN_TEST). Here, we report *formNet* performance. The average *CI* achieved by *formNet* is as follows: TREC_MSQA: 0.53, TREC_WSE: 0.44, MSQA_TREC: 0.68, MSQA_WSE: 0.58. We can observe that cross dataset testing provides best results when we train on MSQA and test on TREC. This is potentially due to the fact that the TREC dataset query structures are quite limited in construction, which are contained within queries of MSQA. Performance is worst when we train on TREC and test on WSE. This is potentially due to the diverse and noisy queries in WSE not captured during limited training over TREC. Nevertheless, for MSQA_WSE, *formNet* retrieves query subnets with *CI* > 0.5 in 73.1% cases and *CI* > 0.75 in 33% cases, suggesting robustness of *formNet* to web scale.

6 Conclusion

Several papers on computational cognitive psychology dwell on the fact that cognitive psychology models cannot be purely verified on the basis of behavioural experiments (Chater, 2006). For researchers in the domain of NLP, a fascinating possibility is to model cognitive techniques computationally and test their robustness to noise in NL. Natural languages are undeniably imprecise, especially in the realm of semantics. The primary reason of this imprecision is the fuzziness of class boundaries (Zadeh, 1998). Surprisingly, robustness to imprecision is often achieved by slightly relaxing the rigidity imposed by lexical grammar, by means of parsing at a higher abstraction than POS.

In this paper, we reproduce the structure-of-intellect model of cognitive psychology computationally. Exploring the various interactions among the semantic *forms* provides insights

ABSTRACT

This paper proposes a method for extracting translations of morphologically constructed terms from comparable corpora. The method is based on compositional translation and exploits translation equivalences at the morpheme-level, which allows for the generation of "fertile" translations (translation pairs in which the target term has more words than the source term). Ranking methods relying on corpus-based and translation-based features are used to select the best candidate translation. We obtain an average precision of 91% on the Top1 candidate translation. The method was tested on two language pairs (English-French and English-German) and with a small specialized comparable corpora (400k words per language).

TITLE AND ABSTRACT IN ANOTHER LANGUAGE, FRENCH

Extraction de lexiques bilingues spécialisés à partir de corpus comparales : traduction compositionnelle et ordonnancement

Cet article propose une méthode permettant d'extraire des traductions de termes morphologiquement construits à partir de corpus comparables. La méthode se base sur la traduction compositionnelle et exploite des équivalences traductionnelles au niveau morphologique, ce qui nous permet de générer des traductions "fertiles" (des paires de traductions dans lesquelles le terme cible a plus de mots que le terme source). Des méthodes d'ordonnancement s'appuyant sur des traits extraits du corpus et des paires de traduction sont utilisées pour sélectionnner la meilleure traduction candidate. Nous obtenons une précision de 91% sur le Top1 en moyenne. La méthode a été testée sur deux paires de langues (anglais-français et anglais-allemand) et sur un corpus comparable spécialisé de petite taille (400k mots par langue).

Introduction

Comparable corpora are composed of texts in different languages which are not translations but deal with the same subject matter and were produced in similar situations of communication. They are used in Computer-Aided Translation to provide technical translators with domain-specific bilingual lexicons when there is no parallel data available (e.g. translation memories, multilingual terminologies). This situation happens when translators have to translate texts which deal with emerging technical domains or when the translation is done from/to an under-resourced language. Comparable corpora also have the advantage of containing more idiomatic expressions than parallel corpora do because the target texts do not bear the influence of the source language. Indeed, Baker (1996) observed that translated texts tend to bear features like explicitation, simplification, normalization and levelling out. As a consequence, one of the difficulties with comparable corpora is that the translation of a source term may not be present in its "normalized" or "canonical" form but rather in the form of a morphological or paraphrastic variant (e.g. *post-menopausal* translates to *après la ménopause 'after the menopause'* instead of *post-ménopausique*). Another limitation is that algorithms output, for each source term, a set of candidate translations instead of just one target term. This state of affairs makes it very challenging for translators to use lexicons extracted from comparable corpora in real-life situations (Delpech, 2011).

The solution that consists in increasing the size of the corpus in order to find more translation pairs or to extract parallel segments of text (Fung & Cheung, 2004; Rauf & Schwenk, 2009) is only possible when large amounts of texts are available. In the case of the extraction of *domain-specific* lexicons, we quickly face the problem of data scarcity: in order to extract high-quality lexicons, the corpus must contain text dealing with very specific subject domains and the target and source texts must be highly comparable. If one tries to increase the size of the corpus, one takes the risk of decreasing its quality by adding out-of-domain texts. Studies support the idea that the quality of the corpora is more important than its size. Morin *et al.* (2007) show that the discourse categorization of the documents increases the precision of the lexicon despite the data sparsity. Bo & Gaussier (2010) show that they improve the quality of the extracted lexicon if they improve the comparability of the corpus by selecting a smaller – but more comparable – corpus from an initial set of documents.

This paper proposes methods for ranking and extracting canonical translations as well as translation variants, with a special focus on the extraction of *fertile* translations. In parallel texts processing, the notion of fertility has been defined by Brown *et al.* (1993). They defined the fertility of a source word *e* as the number of target words to which *e* is connected in a randomly selected alignment. Similarly, we call a fertile translation a translation pair in which the target term has more words than the source term. The identification of fertile translations is useful because (i) they frequentlty correspond to non-canonical translations, e.g. paraphrastic variants and (ii) they tend to correspond to vulgarized forms of technical terms (e.g. « cytotoxic » vs. « toxic to the cells ») which are useful when the translator translates lay science texts. Up to now, fertility has received little attention in the field of comparable corpora processing. To our knowledge, only Daille & Morin (2005) and Weller *et al.* (2011) tried to extract translation pairs of different lengths from comparable corpora. Daille & Morin (2005) focus on the specific case of multi-word terms whose meaning is not compositional and tried to align these multi-word terms with either single-word terms or multi-word terms using a context-based approach. Weller

et al. (2011) concentrate on translating noun compounds as noun phrases. Similar to the approach presented here, Claveau & Kijak (2011) use translation equivalences between morphemes to generate translations and can handle fertility. However it is not suited for comparable corpora since it requires domain-specific parallel data (in their case, a multilingual terminology) to learn alignment probabilities.

Our method is based on compositional translation. We chose this approach because: (i) according to Namer & Baud (2007), compositional terms form a major part of the new terms found in technical and scientific domains, this is not restricted to the field of biomedicine as it is generally believed ; (ii) compositionality-based methods have been shown to clearly outperform context-based ones for the translation of terms with compositional meaning, both in terms of translation accuracy and rank of the correct candidate translation (Morin & Daille, 2010) ; (iii) we believe that compositionality-based methods offer the opportunity to generate fertile translations if combined with a morphology-based approach. This method, which we call morpho-compositional translation, consists in: **(i) decomposing** the source term into morphemes: *post-menopause* is split into *post-* + *menopause*[1] ; **(ii) translating** the morphemes to bound morphemes or fully autonomous words: *post-* becomes *post-* or *après, menopause* becomes *ménopause* ; **(iii) recomposing** the translated elements into a target term: *post-ménopause 'post-menopause'*, *après la ménopause 'after the menopause'*. Fertile translations can be generated because we allow bound morphemes to be translated to autonomous lexical items (e.g. prefix *post-* → preposition *après*). The proposed ranking methods exploit various corpus-based and translation-based features.

This paper falls into 4 sections. Section 1 outlines recent research in compositional approaches to bilingual lexicon extraction. Section 2 explains the methods we designed for translation generation and ranking. Section 3 describes our experimental data. Section 4 presents and discusses the results of our experimentations.

1 Compositional approaches to bilingual lexicon extraction

The core of compositional translation consists in generating candidate translations following the principle of compositionality: "*the meaning of the whole is a function of the meaning of the parts*" (Keenan & Faltz, 1985, pp. 24-25). Once the candidate translations have been generated, one generally ranks them and selects the TopN candidate translations. Generation methods are described in section 1.1. Ranking methods are described in section 2.3.

1.1 Generation methods

Compositional translation consists in decomposing the source term into atomic components, translating these components into the target language and recomposing the translated components into target terms. Existing implementations differ on the kind of atomic components they use for translation.

Lexical compositional translation (Baldwin & Tanaka, 2004; Grefenstette, 1999; Morin & Daille, 2009; Robitaille *et al.*, 2006) deals with multi-word term to multi-word term alignment and uses lexical words as atomic components: *rate of evaporation* is translated into French as

[1]We use the following notations: trailing hyphen for prefixes (*a-*), leading hyphen for suffixes (*-a*), both for confixes (*-a-*), no hyphen for autonomous morphemes (*a*) and a plus sign (+) for intra-word morpheme boundaries. The term *confix* is borrowed from Martinet (1979) and refers to neoclassical (Latin or Ancient Greek) roots.

taux d'évaporation by translating *rate* to *taux* and *evaporation* to *évaporation* using dictionary lookup. Recomposition may be done by permuting the translated components (Morin & Daille, 2010) or with translation patterns (Baldwin & Tanaka, 2004).

Sublexical compositional translation deals with single-word term translation. The atomic components are subparts of the source single-word term. Cartoni (2009) translates neologisms created by prefixation with a formalism called Bilingual Lexeme Formation Rules. Atomic components are the prefix and the lexical base: Italian neologism *ricostruire 'rebuild'* is translated into French *reconstruire* by translating the prefix *ri-* to *re-* and the lexical base *costruire* as *construire*. Weller *et al.* (2011) translate two types of single-word term. German single-word terms formed by the concatenation of two neoclassical roots are decomposed into these two roots, then the roots are translated into target language roots and recomposed into an English or French single-word term, e.g. *Kalori*$_1$*metrie*$_2$ is translated as *calori*$_1$*metry*$_2$. German NOUN$_1$+NOUN$_2$ compounds are translated into French and English NOUN$_1$ NOUN$_2$ or NOUN$_1$ PREP NOUN$_2$ multi-word terms, e.g. Elektronen$_{N1}$-mikroskop$_{N2}$ is translated to *electron*$_{N1}$ *microscope*$_{N2}$. Garera & Yarowsky (2008) translate various compound sequences (NOUN$_1$+NOUN$_2$, ADJ$_1$+NOUN$_2$ ...). They generate an English literal gloss of the compounds with the compositional method (for instance, the English gloss for the Albanian word *hekurudhë 'railway'* is *iron path*). Then, they search for entries in *Lx*-to-English dictionaries where the entry in language *Lx* is a word-to-word translation of the English gloss (e.g. *iron path* matches the German entry *Eisenbahn* and the Italian entry *ferrovia*). The final candidate translations are the fluent English translations proposed by the bilingual dictionaries (e.g. *Eisenbahn* and *ferrovia* both translate to *railway* ; *railway* is considered as a potential translation for *hekurudhë*).

1.2 Ranking and selection methods

Generally, compositional translation generates several possible translations for one source term. One has to find a way to rank the translations from the most to the least reliable. Garera & Yarowsky (2008) tried two ranking methods: (i) a probability score $\mathcal{P}$ based on the number of different languages exhibiting the association between the literal gloss and the fluent translation ; (ii) the probability score $\mathcal{P}$ combined with the similarity of the source and target words' contexts using context-based methods like in the work of Rapp (1995) and Fung (1997). Robitaille *et al.* (2006) extract translation pairs from a corpus built by querying a search engine with a set of seed translation pairs. They select the candidate translations which are semantically related to the target seed terms. The semantic similarity measure is based on the number of hits containing the seed term and/or the candidate translation (Jaccard coefficient). Other works simply select the candidate translations which occur in the target corpus (Weller *et al.*, 2001 ; Morin and Daille, 2010) or which are significantly attested on the Web (Cartoni, 2009).

Only Baldwin and Takana (2004) use machine learning. They train a SVM classifier with corpus-based, dictionary-based and translation pattern-based features and use the value returned by the classifier (a continuous value between -1 and +1) to rank the candidate translations. Their approach is tantamount to point-wise approaches in learning-to-rank. To our knowledge, no research work has investigated the possible contribution of advanced learning-to-rank algorithms to candidate translations ranking. Learning-to-rank algorithms are widely used in Information Retrieval for ranking documents from the most to the least relevant to a given query (Li, 2011). They can be easily ported to the problem of ranking the candidate translations of a source term. There exists three families of learning-to-rank algorithms: **point-wise** (for a given a query-

document pair, predict its relevance score or label: ranking is treated as a regression or classification problem), **pair-wise** (for a given query and two documents, indicate which of the two documents is the most relevant) and **list-wise** (given a query and a list of documents, indicate how to order the documents: this last family straightforwardly represents learning-to-rank problem). According to the tests of Liu (2009), list-wise algorithms generally outperform the two other approaches.

1.3 Challenges of compositional translation

Compositional translation faces four main challenges which are: **morphosyntactic variation:** source and target terms' morphosyntactic structures are different: *anti-cancer*$_{NOUN}$ → *anti-cancéreux*$_{ADJ}$ *'anti-cancerous'* ; **lexical variation:** source and target terms contain semantically related - but not equivalent - words: *machine translation → traduction automatique 'automatic translation'* ; **terminological variation:** a source term can be translated to different target terms: *oophorectomy → ovariectomie 'oophorectomy', ablation des ovaires 'removal of the ovaries'* ; **fertility:** the target term has more content words than the source term. Note that fertility can have two origins. In the case of ***surface*** **fertility**, the target term has more words than the source term but source and target terms have the same number of morphemes. Source and target languages differ in the way they concatenate morphemes to form words: *bi-dimensional → deux dimensions 'two dimensions'*. In the case of ***semantic*** **fertility,** the target term has more morphemes than the source term. Source and target languages differ in the way they combine elements of meaning to create new words: *voie de glace 'route of ice' → ice climbing route, aquarelle* (not decomposable) → *water color*.

Solutions to morphosyntactic, lexical and to some extent terminological variation have been proposed in the form of thesaurus lookup (Robitaille *et al.*, 2006), morphological derivation rules (Morin & Daille, 2010), morphological variant dictionaries (Cartoni, 2009) or morphosyntactic translation patterns (Baldwin & Tanaka, 2004; Weller *et al.*, 2011). Although it is not specifically outlined in their paper, the work of Garera & Yarowsky (2008) can theoretically handle semantic fertility and lexical divergence. However, their method depends on a large number of dictionaries with a substantial coverage of compounds. Surface fertility has been addressed by Weller *et al.* (2011) for the specific case of German NOUN+NOUN compounds. The method presented here is able to deal with surface fertility and to generate and rank translations for a large variety of morphologically constructed words.

2 Translation method

2.1 Principle of morpho-compositional translation

The idea of morpho-compositional translation is to apply the principle of compositional translation at the morpheme-level rather than at the lexical level and to allow translation equivalences between bound and autonomous morphemes in order to generate fertile translations. It relies on the assumptions that: **(i) a lexical item can be decomposed into smaller components**. These components may be **free**, i.e. they can occur in texts as autonomous lexical items like *toxicity* in *cardiotoxicity* or **bound**, i.e. they cannot occur as autonomous lexical items, in that case they correspond to bound morphemes like *-cardio-* in *cardiotoxicity* ; **(ii) a bound component can be translated to an autonomous or a bound component:** *-cardio-* can be translated to *-cardio-* or *cœur 'heart'* or *cardiaque 'cardiac'*. Thus, *cardiotoxicity* can be

translated to *toxicité cardiaque 'cardiac toxicity'* or *toxicité pour le cœur 'toxicity to the heart'* or *cardiotoxicité 'cardiotoxicity'*.

Like other sublexical approaches, the main idea behind morpho-compositional translation is to go beyond the word level and work with subword components. In our case, these components are morpheme-like items which either (i) bear referential lexical meaning like confixes (*-cyto-, -bio-*) and autonomous lexical items (*cancer, toxicity*) or (ii) can substantially change the meaning of a word, especially prefixes (*anti-, post-*) and some suffixes (*-less, -like*). Unlike other approaches, morpho-compositional translation is not limited to small set of source-to-target structure equivalences. It takes as input a morphologically constructed single-word term which can be the result of prefixation '*pretreatment*', confixation '*densitometry*', suffixation '*childless*', compounding '*anastrozole-associated*' or any combinations of the four. Its output is a set of single or multi-word candidate translations. For instance, *postoophorectomy* may be translated to *postovariectomie 'postoophorectomy'* or *après l'ovariectomie 'after the oophorectomy'* or *après l'ablation des ovaires 'after the removal of the ovaries'*.

Section 3.2 explains the algorithm for generating candidate translations. Section 3.3 describes different methods for ranking the candidate translations.

2.2 Generation algorithm

The generation method is described in the algorithm 1. A detailed version of the algorithm can be found in the feasibility study of Delpech *et al.* (2012).

Algorithm 1 Generate translations

Require: *source_term, target_corpus*
translations ← *Ø*
for all *{c1, ... ci}* in DECOMPOSE *(source_term)* ***do***
  for all *{e1, ... ej}* in CONCATENATE (*{c1, ... ci}*) **do**
    for all *{t1, ... tk}* in {TRANSLATE (*e1*) × … TRANSLATE (*ej*)} **do**
      if $k \neq j$ **then**
        continue
      for all*{t1, ... tk}* in PERMUTATE (*{t1, ... tk}*) **do**
        for all *{w1, ... wl}* in CONCATENATE (*{t1, ... tk}*) **do**
          for all *match* in MATCH (*{w1, ... wl}, target_corpus*) **do**
            add *match* to *translations*
return *translations*

The DECOMPOSE function splits the source term into minimal components *{c1, ... ci}* by matching substrings of the term with lists of prefixes, confixes, suffixes and lexical items and respecting some length constraints on the substrings. When several splittings are possible, only the ones with the highest number of components are retained.

The CONCATENATE function generates all possible concatenations of a list of components. For example, if the term "*abc*" has been split into 3 components *{a, b, c}*, then there are 4 different concatenations : *{a,bc}, {ab,c}, {a,b,c}, {abc}* (for *n* components, we have 2^{n-1} possible concatenations). When called used after the decomposition, the concatenation of the components increases the chances of matching the entries of the linguistic resources used by the TRANSLATE function. When called after the permutation, the concatenation is used to recreate a set of target words *{w1, ...wl}* from the set of translated components.

The TRANSLATE function uses two kinds of linguistic resources to generate translations. Bilingual resources map elements across languages. Variation resources are used to handle variation at the lexical and morphological level. Hence, the output of TRANSLATE(*e*) correspond to *Trans(e) U Trans(Var^{src}(e)) U Var^{tgt}(Trans(e))* where *Trans* is a bilingual resource, *Var* a variation resource, *src* is the source language and *tgt* is the target language. For example, *toxic* can be translated to *toxique 'toxic', toxicité 'toxicity'* or *vénéneux 'poisonous'*. If one element can not be translated then the translation of the whole fails.

The PERMUTATE function serves to capture the fact that components' order may be different in the source and target language (distortion). As a general rule, *O(n!)* procedures should be avoided but we are permuting small sets (up to 4 items).

The MATCH function returns a series of tokens which occur in the target corpus and whose lemmas match the generated target words *{w_1, ... w_l}*. We allow for 3 stop words between each lemma. For example, if the system generates the target words *{toxique, cellule} 'toxic, cell'* from *cytotoxic,* it will match *"toxique pour les cellules" 'toxic to the cells'*. We consider that two matches are one and the same translation if they correspond to the same series of *(lemma, part-of-speech)* pairs. For example, *toxique pour les cellules* and *toxique pour la cellule 'toxic to the cell'* correspond to the same translation.

2.3 Ranking methods

We have considered four parameters for ranking the translations: frequency of the translation, part-of-speech translation probability, context similarity and the reliability of the resources used for translating the components of the source term. These parameters can be used separately or in a combined manner.

The frequency (FREQ) corresponds to the number of occurrences of the translation in the target corpus divided by the total number of words in the target corpus.

The part-of-speech translation probability (POS) corresponds to *P(y|x)*, the probability that a source term with part-of-speech *x* will be translated to a target term with part(s)-of-speech *y*, e.g. it is more probable that a NOUN is translated by another NOUN or by a NOUN PREP NOUN sequence rather than an ADVERB. The part-of-speech translation probabilities were acquired by running the software ANYMALIGN (Lardilleux, 2008) on the EMEA corpus (Tiedemann, 2009) which had been previously pos-tagged with the linguistic analyzer XELDA[2]. ANYMALIGN outputs a phrase translation table. Each line of the translation table corresponds to an alignment *a = {lem$_s$, pos$_s$, lem$_t$, pos$_t$, p(s|t), p(t|s)}* where *pos$_s$* is the parts-of-speech of the source phrase, *pos$_t$* is the parts-of-speech of the target phrase and *pos(t|s)* is the probability of translating the source phrase to the target phrase. From these alignments, we obtain *P(y|x)* with the following formula:

$$P(y|x) = \frac{\sum_{\{a \in A | pos_s = x,\ pos_t = y\}} p(t|s)}{\sum_{\{a \in A | pos_s = x\}} p(t|s)}$$

The context similarity (CONT) corresponds to the method used for ranking translations in context-based approaches. For each source term and target term we build a *context vector*. This vector indicates the number of times the term co-occurs with each word of the corpus within a

[2] http://www.temis.com

contextual window of 5 words around the term. The number of co-occurrences is normalized with the log-likelihood ratio (Dunning, 1993). Then, the vector of the source term is translated into the target language. Finally, the source vector and the target vector are compared: the most similar the vectors, the most likely the target and source terms are translations of each other. The similarity between source vector *s* and target vector *t* is computed with the weighted jaccard:

$$WeightedJaccard(s,t) = \frac{\sum_{w \in s \cap t} min(c(s,w), c(t,w))}{\sum_{w \in s \cap t} max(c(s,w), c(t,w)) + \sum_{w \in s \setminus t} c(s,w) + \sum_{w \in t \setminus s} c(t,w)}$$

where *c(s, w)*, respectively *c(t, w),* is the normalized number of co-occurrences between the source, respectively target, term and word *w*. Note that for multi-word terms, the context vector corresponds to the union of the context vectors of the lexical words that compose the multi-word term.

The resources score (RESO) corresponds to:

$$RESO(t) = \frac{1}{|T|} \sum_{i=1}^{|T|} rel(T_i)$$

where *T* is the total number of components in the target term *t* and $rel(T_i)$ is the reliability of the target component T_i. The reliability of a component is a float value between 0 and 1 inclusive. It depends on the nature of the component and on the resources which were used to generate it. We defined 8 types of target components: 1) the target component is a lexical item found in a general-language dictionary ; 2) target component is a lexical item which was found by cognate matching ; 3) target component is a lexical item which is a lexical variant of the translation (found in general language dictionary or by cognate matching) ; 4) target component is a lexical item which is a morphological variant of the translation ; 5) target component is a lexical item which is the translation of a bound morpheme ; 6) target component is a prefix ; 7) target component is a confix ; 8) target component is a suffix. We tuned the reliability values associated to these 8 types of target components empirically: we tested several arrangements[3] of reliability values on a training dataset (described in section 3.3) and retained the arrangement that gave the best rankings.

Scores combination (COMBI) is the linear combination of the FREQ, POS, CONT and RESO scores.

Learning-to-rank algorithms (LTR) were also tested. We tried three list-wise algorithms: AdaRank (Li & Xu, 2007), Coordinate Ascend (Metzler & Croft, 2000) and LambdaMart (Wu *et al.*, 2010). We used the implementations available in the RankLib software[4]. The predictive variables are the FREQ, POS, CONT and RESO scores. We trained the models on the training dataset described in section 3.3.

3 Data

We worked with 3 languages: English as source language and French and German as target languages.

[3] all 8-arrangement with repetition of {0, 0.2, 0.4, 0.6, 0.8, 1}

[4] http://people.cs.umass.edu/~vdang/ranklib.html. We set the metric to optimize on the training data to MAP (Manning *et al.*, 2008) ; all other parameters were left to default.

3.1 Comparable corpora

Our corpus is composed of specialized texts from the medical domain dealing with breast cancer. We define specialized texts as texts being produced by domain experts and directed towards either an expert or a non-expert readership (Bowker & Pearson, 2002). The texts were collected from scientific papers portals and from information websites targeted to breast cancer patients and their relatives. Each corpus has approximately 400k words (cf. table 1). All texts were pos-tagged and lemmatized with XELDA. We also computed the comparability of the corpora[5]. The English-French corpus' comparability is 0.71 and the English-German corpus' comparability is 0.45. The difference in comparability can be explained by the fact that German texts on breast cancer were hard to find (especially scientific papers): we had to collect texts in which breast cancer was not the main topic. This may have added out-of-domain words.

	EN	**FR**	**DE**
Expert readership	218.3k	267.2k	197.2k
Non-expert readership	198.2k	184.5k	201.7k
TOTAL	416.5k	451.75k	398.9k

TABLE 1: Composition and size of corpora (nb. of words)

3.2 Resources for generation

Tables 2 and 3 show the size of the resources we used for generation.

General language dictionary: We used the dictionary which is part of the XELDA software. This dictionary was used for generating translations but also for computing the corpus comparability and for translating the context vectors for the context similarity measure (CONT score).

Cognate dictionary: We built this resource automatically by extracting pairs of cognates from the comparable corpora. We used the same technique as Hauer & Kondrak (2011): a SVM classifier trained on examples taken from online dictionaries[6].

Morpheme translation table: this resource was created manually by translators since there exists no publicly available morphology-based bilingual dictionary. This translation table links the English bound morphemes contained in the source terms to their French or German equivalents (which can be bound morphemes or lexical items).

In order to handle the variation phenomena described in section 1.3, we used a **dictionary of synonyms** and lists of **morphologically related words**. The dictionary of synonyms is part of the XELDA software. Morphologically related words were collected by stemming the words of the comparable corpora and the entries of the bilingual dictionary with the algorithm of Porter (1980).

The DECOMPOSE function uses the entries of the morpheme translation table (242 entries) and a list of 85k lexical items composed of the entries of the general language dictionary and English words extracted from the Leipzig Corpus (Quasthoff *et al.*, 2006).

[5]We used the measure defined by Bo & Gaussier (2010) which indicates, given a bilingual dictionary, the expectation of finding, for each word of the source corpus, its translation in the target corpus and *vice-versa.*

TABLE 3: Nb. of entries in the monolingual resources

3.3 Datasets for evaluation and training

We extracted morphologically constructed source terms from the English texts in a semi-supervised manner: **(i)** we wrote a short seed list of English bound morphemes. We automatically extracted from the English texts all the words that contained these morphemes. For example, we extracted the words *postchemotherapy* and *poster* because they contained the string *post-* which corresponds to a bound morpheme of English ; **(ii)** The extracted words were sorted: those which were not morphologically constructed were eliminated (like *poster*), and those which were morphologically constructed were kept (like *postchemotherapy*). The morphologically constructed words were manually split into morphemes. For example, *postchemotherapy* was split into *post-*, *-chemo-* and *therapy* ; **(iii)** if some bound morphemes which were not in the initial seed list were found when we split the words during step (ii), we started the whole process again, using the new bound morphemes to extract new morphologically constructed words.

We also added hyphenated terms like *ER-positive* to our list of source terms. With this method, we collected 2025 source terms. Then, we excluded all the source terms which could be translated with the general language dictionary and whose translation was present in the target corpus. Finally for each language pair, we divided the source terms into two groups:

The evaluation dataset contains source terms which could be translated with the UMLS meta-thesaurus (Bodenreider, 2004) and whose translation was in the target corpus – these terms, along with their UMLS translations, constitute the reference lexicon for the evaluation.

	EN → FR	EN → DE
EVALUATION dataset	126 → 163	90 → 104
TRAINING dataset	642 → 1953	584 → 1826

TABLE 4: Size of datasets

The training dataset contains source terms which could not be translated with the general-language dictionary or the UMLS but for which we could generate translations with our method. This generated translations were manually annotated by translators. These terms, along with their annotated translations, were used as training data for learning the ranking models and to tune the reliability values used in the RESO score. We used four classes for the annotation: *exact, acceptable, related* and *wrong*. An exact translation is a canonical translation like *cytoprotection → Zellschutz* (DE), *protection des cellules 'protection of the cells'* (FR). An acceptable translation is a variant of the canonical translation: *cytoprotection → protéger les cellules 'protect the cells', cytoprotecteur 'cytoprotective'.* A related translation is a translation which is only semantically related to the source term: *insecure → ohne Sicherheit 'without safety'.* All other translations are wrong translations. We computed inter-annotator agreement on a set of 100 randomly selected translations. We used the Kappa statistics (Carletta, 1996) and obtained a high agreement (0.77 for English to German translations and 0.71 for English to French).

4 Results

4.1 Related work

Generally, systems are compared using the *TopN* precision: the percentage of source terms with at least one exact translation among the *TopN* candidate translations. Compositional-translation methods tend to give better results when they are applied to general language texts rather than domain-specific texts. Indeed, it is easier to find translations of the components since they belong to the general language and large corpora are also easier to collect. **Working with general language texts,** Baldwin & Tanaka (2004) were able to generate candidate translations for 92% of their source terms and they report 43% (gold-standard) to 84% (silver standard) of correct translations on Top1. Corpus' size exceeds 80M words for each language. Cartoni (2009) works on the translation of prefixed Italian neologisms into French. He finds that between 42% and 94% of the generated neologisms occur more than five times on the Internet. Garera & Yarowski (2008) obtain translations for 13% of the source words and the best precision is 39% for the Top10 candidate translations (for German and Swedish). **Regarding domain-specific translation,** Robitaille *et al.* (2006) collect translation pairs in an incremental manner. They start with a list of 9.6 pairs (on average) with a precision of 92% and end up with a final output of 19.6 pairs on average with a precision of 81%. Morin & Daille (2010) could generate candidate translations for 15% of their source terms and they report 88% of correct translations on Top1. The size of their corpus is 700k words per language. Weller *et al.* (2011) obtained correct English translations for 18% of their German compounds. Their corpus contains approximately 1.5M words per language.

4.2 Generation

We tested several combinations of linguistic resources. Table 5 only shows the results for the best combination. For English to French translation, the best results where obtained with all the combined resources, closely followed by the combination of the general language and the cognate dictionary. For English to German translation, the best results were obtained with the combination of the general language and the cognate dictionary. Morphologically related words and synonyms tend to increase the number of generated translations to the cost of translation accuracy.

	EN → FR	**EN → DE**
# source terms	126	90
# source terms with no translation	40 (32%)	34 (38%)
# source terms with at least one translation	86	56
# nb of translations / source term	2.05	2.6
# at least one reference translation (UMLS)	68 (79%)	40 (71%)
# at least one exact translation (translators or UMLS)	81 (94%)	51 (91%)

TABLE 5: Results of generation

Regarding English to French translations, we were able to generate translations for 86 of the 126 English source terms (68%). Among these 86 source terms, 79% had the UMLS reference translation among their candidate translations. Regarding English to German translations, we were able to generate translations for 56 of the 90 English source terms (62%). Among these 56 source terms, 71% had a reference translation among their candidate translations. We noticed that the algorithm generated translations which were not in the UMLS lexicon but which were exact translations according to the translators. For example, the German reference translation for *mastectomy* is *mastektomie*. The system generated the reference translation *mastektomie* but also translations like *ablation der brust, abschnitt der brust, brustentfernun, entfernung der brust* which are all exact translations. Thus, if we take into account these translations, we find that 94% and 91% of the source terms had at least one exact translation for English to French and English to German respectively. Among all these correct translations 21% and 10% were fertile translations for English to French and English to German respectively.

There are several reasons for untranslated source terms. In 30% of the cases, silence is due to the coverage of the linguistic resources: some of the components could not be translated and the translation of the whole source term failed. Another 30% of target terms do not have a compositional meaning: *breastfeeding* → *allaitement* (FR), *stillen* (DE). The third reason is due to lexical variation (~ 20%), e.g. *radio+sensitivity* translates to *strahlen+toleranz* but *toleranz 'tolerance'* has a different meaning than *sensitivity*. There was also cases of semantic fertility (~ 13%).

Errors were mainly due to problems in word reordering when generating fertile translations, especially with German. Other errors were due to wrong translations in the cognate dictionary and translations which were inappropriate in the context, e.g. the translation of *gynae* to *frau*

'woman' in *gynaecomastia → Frau gegen Brust 'women against breast'*. If we look at the part of fertile translations in the incorrect translations, we find that they constitute half of the English to French incorrect translations and 80% of the English to German incorrect translations. We think it is due to the morphological type of the languages involved in the translation. As a matter of fact, fertile variants are more natural and more frequent in French than in German. English and German are Germanic languages with a tendency to build new words by agglutinating words or morphemes into one single word. Noun compounds such as *anthracycline-containing* or *Anthracyclin-enthaltende* are common in these two languages. Conversely, French is a Romance language which prefers to use phrases composed of two nouns and a preposition rather than a single-noun compound. For example, *anthracycline-containing* would be translated as *comprenant une anthracycline 'containing an anthracycline'*. There is no non-fertile equivalent in French (**anthracycline-contenant* would be ungrammatical). It is the same with the bound/free morpheme alternation. The term *cytotoxic* will be translated into German as *zytotoxisch* whereas in French it can be translated as *cytotoxique* or *toxique pour les cellules 'toxic to the cells'*.

4.3 Ranking

Table 6 indicates the precision on Top1, 2 and 3, i.e. the percentage of source terms which have at least one exact translation (found in the UMLS or according to the translators) on the TopN candidate translations.

	EN → FR			**EN → DE**			**Average**
	Top1	**Top2**	**Top3**	**Top1**	**Top2**	**Top3**	**Top1**

LTR LAMBDAMART	.86	.91	.93	.88	.91	.91	.87

TABLE 6: Results of ranking

We tested the ranking methods described in section 2.3: the scores FREQ, POS, CONT and RESO separately, a linear combination of these scores (COMBI) and three learning-to-rank algorithms (LTR). We also randomly ranked the translations to serve as a baseline. On average, the best precision on Top1 (91%) is obtained with the linear combination and Coordinate Ascend. All ranking methods perform better than the baseline. For English to French, the best rankings were obtained with the linear combination and Coordinate Ascend. For English to German, the best

rankings were obtained with the POS parameter alone, closely followed by the linear combination and Coordinate Ascend.

We expected learning-to-rank algorithms to perform much better than simple methods like part-of-speech probabilities or the linear combination of several scores. This might be due to the small size of our training dataset (approx. 600 ranked lists per language). We note that the context similarity score (CONT) is the least performing ranking method. Similarly, Garera and Yarowsky (2008) note only a small performance gain when they use context similarity. This might be due to the fact that context-based methods need the source and target words to be very frequent in the corpora to work properly. The lower quality of the German translations can be explained by the fact that the English-German corpus is much less comparable than the English-French corpus (0.45 vs. 0.71).

Conclusion and perspectives

We have proposed a new compositional translation method for domain-specific bilingual lexicon extraction from comparable corpora. We obtain an average precision of 91% on the Top1 candidate translation. English-to-French translation performs slightly better than English-to-German translation, probably due to the morphological type of the languages and to the lower quality of the German data.

Future work includes the improvement of the identification of morphological variants. The morphological families extracted by the stemming algorithm are too broad for the purpose of translation. For example, the words *desirability* and *desiring* have the same stem but they are too distant semantically to be used to generate translation variants. We need to restrict the morphological families to a smaller set of morphological relations (e.g. noun → relational adjective). Furthermore, some work needs to be done on lexical variation: we used a dictionary of synonyms, but a thesaurus, which contains a large variety of semantic relations, may help us better in tackling lexical variation. Another improvement will be to use translation patterns to recompose the components into a target language term structure instead of using the PERMUTATE and CONCATENATE functions.

Our investigation of the contribution of learning-to-rank algorithms to the problem of candidate translations ranking shows encouraging results and we should further pursue this line of research. Future experiments include: testing other learning-to-rank approaches (pair-wise, point-wise), increasing the number of predictive variables (e.g. source/target term frequency ratio, number of components...) and finding ways to increase the size of the training dataset at a lesser cost.

Acknowledgment

The research leading to these results has received funding from the French National Research Agency under grant ANR-08-CORD-013 and from the European Community's Seventh Framework Programme (FP7/2007-2013) under Grant Agreement no 248005. We would like to thank the company LINGUA ET MACHINA (www.lingua-et-machina.com) for supporting this research as well as Clémence de Baudus and Kiril Isakov for their participation in the annotation task and Van Dang for his help with the RankLib software.

ABSTRACT
In this paper, we propose a time-line based framework for topic summarization in Twitter. We summarize topics by sub-topics along time line to fully capture rapid topic evolution in Twitter. Specifically, we rank and select salient and diversified tweets as a summary of each sub-topic. We have observed that ranking tweets is significantly different from ranking sentences in traditional extractive document summarization. We model and formulate the tweet ranking in a unified mutual reinforcement graph, where the social influence of users and the content quality of tweets are taken into consideration simultaneously in a mutually reinforcing manner. Extensive experiments are conducted on 3.9 million tweets. The results show that the proposed approach outperforms previous approaches by 14% improvement on average ROUGE-1. Moreover, we show how the content quality of tweets and the social influence of users effectively improve the performance of measuring the salience of tweets.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (CHINESE)

基于用户社会影响力和文本质量的推特话题摘要

本文提出了一个基于时间轴的推特话题自动摘要框架。话题按照时间顺序分成子话题，各子话题中根据文本的重要度和多样性对推特文本进行排序和抽取以生成摘要。我们使用相互增强式图模型同时考虑文本内容、作者社会影响力和文本质量进行排序。实验结果表明：1）本文提出的模型在基准模型上ROUGE-1平均提高了14%；2）作者社会影响力和文本质量有效地改进了文本重要度的度量。

KEYWORDS: Topic summarization, Twitter, Timeline summarization, Content quality, Social influence.

KEYWORDS IN CHINESE: 话题摘要，推特，时间轴上的摘要，文本质量，用户社会影响力 .

1 Introduction

Recently, Twitter [1] has become one of the most popular social networking sites. It enables people to freely post short messages (called tweets) up to 140 characters. Twitter has rapidly gained worldwide popularity, with over 140 million active users generating over 340 million tweets daily in March 2012 [2]. The rapid proliferation of Twitter posts presents a big obstacle for efficient information acquisition. It is impossible for a user to get an overview of important topics on Twitter by reading all tweets everyday. In addition, because of information redundancy and the informal writing style, it is time consuming to find useful information about a topic from a huge number of tweets. The tremendous volume of tweets suggests summarization as the key to facilitating the requirements of topic exploration, navigation, and search from hundreds of thousands of tweets. Specifically, a summary that provides representative information of topics with no redundancy and well-written sentences would be preferred.

In this paper, we focus on the problem of topic summarization in Twitter, which aims to provide a short and compact summary for a collection of tweets on the same or similar topics. We take individual tweets as the basic constituents to compose the summary. Here, tweets are to a certain extent analogous to sentences in traditional extractive document summarization, which has been extensively studied in past decades (Ani Nenkova, 2011). However, we argue that summarizing tweets is substantially different from summarizing news documents owing to the following reasons. First, tweets are streamed with detailed time-stamps delivering real-time information of users' continuous updates and comments that, provide temporal information for tracing topic evolution over time. This timeliness feature motivates us to summarize tweets along time line. Second, tweets are commonly expressed in an informal way. Only some of them obey standard grammar requirements, while others are written in arbitrary styles. For instance, tweets may contain many abbreviations, spelling errors, or information fragments. This requires the summarization algorithm to be aware of the content quality of the tweets when ranking and selecting salient tweets as summaries.

Furthermore, tweets are created on and spread through social networks. The authority of the author of the tweets, as well as the social networks (e.g. follower-followee relationship) of the author, usually plays an important role in demonstrating the salience of the tweets. People may be particularly interested in tweets from celebrities or opinion leaders. To be specific, if there are two tweets stating the same information, and one is published by an influential user and the other is not, we assume the former is more important than the latter on account of two interesting observations about Twitter users. First, users with a high influence have a larger audience. Their tweets are apt to be read by more users than those of non-influential users. Second, encouraged by the interactions with their followers, influential users are more likely to publish informative tweets of better readability, less error, and preferable completeness than common users. This guides us to develop a unified framework to simultaneously model the information from the content and the authors of tweets.

We therefore propose modeling and formulating tweet ranking in a unified mutual reinforcement graph, where the social influence (i.e. authority) of users and content quality of tweets are taken into consideration simultaneously in a mutually reinforcing manner. Particularly, we leverage the follower-followee relationship connecting different authors, upon which the social influence of users can be inferred. We define the content quality of tweets, including readability and

[1] http://twitter.com
[2] http://blog.twitter.com/2012/03/twitter-turns-six.html

content richness, as a measure of the regularity of written language and the pointless degree of the content. The above information is jointly employed in a graph-based ranking algorithm. In order to avoid redundancy in the result, the final summary is generated by selecting tweets from the previous ranking results with the traditional Maximal Marginal Relevance(MMR) algorithm (Carbonell and Goldstein, 1998). We conduct experiments on a real data set containing 3.9 million tweets. Compared with two popular graph-based summarization approaches, namely Lexrank (Erkan and Radev, 2004) and phrase graph (Sharifi et al., 2010a), the experimental results show that:

- The reinforcement summarization model integrating social influence and content quality achieves a considerable performance and outperforms the standard LexRank and the phrase graph summarization approaches.
- The social influence of users and the content quality of tweets help to more effectively measure the salience of tweets.

The rest of this paper is organized as follows. Related work is introduced in Section 2. Next, we present a detailed introduction of our approach in Section 3. Section 4 shows the experiments and results, and we conclude this work with directions for future study in section 5.

2 Related work

2.1 Extractive document summarization

A substantial amount of work has been done on extractive text summarization (Lloret and Palomar, 2012). Many text features, such as term frequency, sentence position, query relevance and sentence dependency structure, have been investigated for sentence salience estimation. They are usually weighted automatically by applying certain learning-based mechanisms or tuned experimentally to build a feature-based summarization system (Fuentes et al., 2007) (Wong et al., 2008). Previous research shows that a combination of sentence position, fixed-phrase and sentence length give the best results in learning-based sentence selection (Ani Nenkova, 2011). Meanwhile, feature-based approaches have been widely used in the top five participating systems in DUC[3] 2005-2007.

In addition, different types of links among sentences and documents are employed by graph-based approaches to measure sentence salience, such as LexRank (Erkan and Radev, 2004), TextRank (Mihalcea, 2004), and Mutual Reinforcement Chain(MRC) (Wei et al., 2008). LexRank and TextRank make use of pairwise similarity between sentences, hypothesizing that the sentences similar to most of the other sentences in a cluster are more salient. In contrast to the single level PageRank in LexRank and TextRank, MRC considers both internal and external constraints on three different levels, document, sentence, and term and achieves promising improvement.

2.2 Micro-blog summarization

Recently, researchers have conducted a number of investigations on micro-blog(e.g. Twitter) summarization. Instead of ranking sentences in traditional document summarization, micro-blog posts are ranked to select salient ones for the generation of topic-sensitive and query-sensitive summary. Both feature-based and graph-based approaches are exploited to measure the salience of posts under an extractive summarization framework. Taking into consideration

[3] http://www-nlpir.nist.gov/projects/duc/data.html

the evolutionary characteristic of topics along time line, researchers have also started to explore the evolutionary summarization of events in micro-blog.

In feature-based approaches, a variety of statistical and linguistic features have been extensively investigated, such as, language model (O'Connor et al., 2010), tweet frequency (Shiells et al., 2010), term frequency (Liu et al., 2011) (Takamura et al., 2011) (Parthasarathy, 2012), TF-IDF (Frederking, 2011) (Chakrabarti and Punera, 2011), hybrid TF-IDF (Sharifi et al., 2010b), KL-divergence (Zubiaga et al., 2012), time delay (Takamura et al., 2011), and topic relevance (Long et al., 2011). Among them, simple term frequency has proven to be extremely extraordinary for topic-sensitive micro-blog summarization because of the unstructured and short characteristics of micro-blog posts according to Inouye and Kalita (2011). As for micro-blog summarization, some micro-blog specific features such as text normalization, the content of shared web pages (Liu et al., 2011), and user behavior in conveying relevant content (Harabagiu and Hickl, 2011), have proven useful for result improvement.

The phrase graph algorithm is the most frequently studied graph-based approach in micro-blog summarization. Sharifi et al. (2010a), Beaux Sharifi and Kalita (2010), and Sharifi (2010) propose a phrase reinforcement summarization algorithm on leverage of trending phrase or phrases specified by a user in micro-blog posts. It achieves substantial improvements on ROUGE results by taking advantage of the link structure among words. Nichols et al. (2012) generate journalistic summary for events in world cup games by employing phrase graph algorithm only on the longest sentence in each tweet. Additionally, PageRank-like algorithms such as LexRank and TextRank have also been investigated by Inouye and Kalita (2011).

Evolutionary summarization approach segments post stream into event chains(usually along time line) and produces the final summary by incorporating the summary extracted for each event. A simple and effective method for detecting events from a post stream is to separate the stream according to the bursty period of post volume (Nichols et al., 2012) (Zubiaga et al., 2012). Long et al. (2011) provide an even particular separation according to the topical words that are recognized by their frequency in #hashtags and the entropy in the corpus. Chakrabarti and Punera (2011) argue that different types of events should be detected even when they are temporally close. They utilize a modified Hidden Markov Model to detect the event chain by learning the underlying hidden state representation of repeated events.

3 Topic summarization by time line with mutual reinforcement model

We begin this section with a formal definition of the work presented in this paper. We formulate the problem of topic summarization in Twitter as follows: given a topic τ depicted by a #hashtag [4], we can obtain a tweet collection $T = \{t_1, t_2, \cdots, t_N\}$ containing the #hashtag, where N is the number of tweets in a time span. Each tweet is attached with a time mark. We take a time-line approach to summarize T to fully capture the rapid topic evolution over time. Specifically, the summary for the topic consists of:

- a set of sub-topics $\omega = \{\omega_1, \omega_2, \cdots, \omega_K\}$ based on the distribution of tweets over time, where K is the number of sub-topics;
- at most M salient tweets as the summary for each sub-topic $\omega_i, 1 \leq i \leq K$.

[4] #hashtags are user-annotated topics in tweets.

There are three major steps generating a time-line summary for a topic. First, we conduct a topic segmentation that segments the tweet stream of the topic into sub-topic clusters in terms of the posting time, in which each cluster describes a sub-topic. Second, tweets in each sub-topic cluster are ranked according to tweet salience by a reinforcement ranking model taking advantage of the content quality of tweets and social influence of the authors. Third, we generate the summary for each sub-topic upon the tweet ranking results by removing the redundant tweets at the whole topic level. In the following sub-sections, we will present the three steps respectively.

3.1 Sub-topic segmentation

The key issue of sub-topic segmentation is to detect the breaking point of sub-topics in the tweet stream. We observe that in comparison to the internal portion of a sub-topic, some statistics of the stream make dramatic changes, called bursty, at breaking points, for example, tweet volumes, term frequency, participating users, and variety of #hashtags. Among them, term frequency bursty is most correlated to topic evolution according to our analysis. Therefore, we segment the sub-topics by detecting term frequency bursty. Typically, a sub-topic occurs associated with several words and covers their bursty period. We break sub-topic segmentation down to the bursty period identification of associated words and the lifetime detection for sub-topics.

First, we track every word in the stream to identify their bursty period. Terms without a bursty period will be discarded. We assume that the term frequency satisfies a binomial distribution in the bursty period (Fung et al., 2005).

$$tf(w) = \binom{I}{i} p(w)^i (1-p(w))^{I-i} \tag{1}$$

$$p(w) = \sum_{i=1}^{I} \frac{tf_i(w)}{Count_i(tweet)} \cdot \frac{1}{I}$$

Where I is the total length of time in days in the stream, $p(w)$ represents the bursty probability of word w, and $tf_i(w)$ is the term frequency of w at i^{th} time. $Count_i(tweet)$ denotes the number of tweets at i^{th} time. We compute the mean value of $tf(w)$. The period in which the term frequency is larger than $2 * mean$ is a bursty period of the corresponding word.

The lifetime of sub-topics is detected depending on the bursty period of associated words. Terms whose half bursty period overlap with each other are recognized as a set of sub-topic-associated words, denoted by w_a. The lifetime of the sub-topic covers a continuous period where

$$tf_i(w_a) > \alpha \cdot mean_a + \beta \cdot var_a \tag{2}$$

$$tf_i(w_a) = \sum\nolimits_{w \in w_a} tf_i(w)$$

where $tf_i(w_a)$ is the term frequency of associated words at i^{th} time. $mean_a$ and var_a denote the expectation and variance of term frequency respectively by blending words in associated words set during the overlapped time period. α and β adjust the length of the sub-topic lifetime, which are selected empirically. In the experiment, we set α as 1.4 and β as 0.4. The sub-topic consists of tweets published in the corresponding lifetime. Time periods contain no bursty words and those with an associated term frequency below the threshold are regarded as noisy periods and kept out from the later summary generation.

3.2 Mutual reinforcement model based sub-topic summarization

We define salient tweets as those similar to most of the tweets in the sub-topic, published by influential users, and presented in a good writing style. The first is consistent with the salience in document summarization. We emphasize the second because Twitter is a social network, in which influential users have a wider audience and more affirmative interaction with others. Tweets published by influential users are more likely to dominate the topic. The last is set against the informal writing style of Twitter.

Inspired by Wei et al. (2008), we propose a unified mutual reinforcement summarization model taking advantage of relations among tweets, words, and users for tweet salience measurement. Figure 1 shows the overview of the proposed model. The similarity of tweets to the sub-topic benefits from both the content similarity among tweets and the word coverage in the sub-topic cluster. In document summarization, the contribution of relationships among sentences to the performance improvements has been recognized (Wan et al., 2007). Sharifi et al. (2010a) found that sequences of words that encompassed the topic phrase highly overlapped when considering a large number of tweets for a single topic. The social influence of users contributes to salience measurement via author relation. And the content quality of tweets is incorporated at the tweet level.

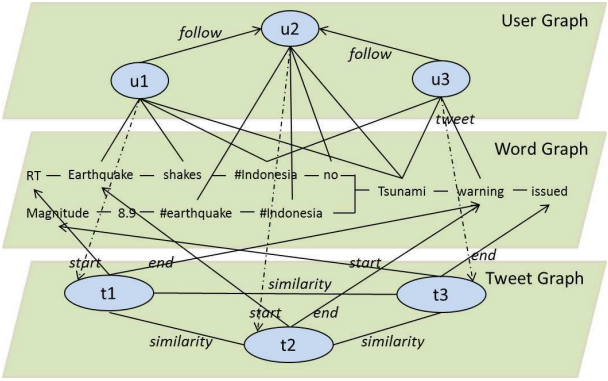

Figure 1: The Unified Mutual Reinforcement Graph Model

The mutual reinforcement model is formed with three PageRank-like models for word, tweet, and user respectively, but in a unified and interrelated way. The ranking of one of them is derived not only from the relationships with instances of itself, but is also affected by the other two. In the model, tweets connect to each other through syntactic similarities. If two tweets have a non-zero cosine similarity, there is a link between them. Words are linked through their co-occurrence in the same tweet. And users are naturally associated by following-followee relationship. If user u_i follows user u_j, a direct edge from u_i to u_j is created. Furthermore, we create edges among users, words, and tweets through authorship and consisting relationship. If user u_i published tweet t_j, we connect u_i with t_j and all words in t_j according to authorship. And t_j is linked to every word it consists of. In Figure 1, we illustrate the connection between

tweet and words through *start* and *end* links to avoid too many lines. *Start* specifies the first word of a tweet and *end* denotes the last word.

3.2.1 Mutual reinforcement based tweet ranking

We can then formulate the ranking algorithm for the mutual reinforcement model.

A tweet is salient if it is published by an influential user, written in regular language style, contains important terms and connects to other salient tweets. The ranking score of a tweet in sub-topic collection ω_k is defined as,

$$\begin{aligned} Score^{(r+1)}(t_i) = \alpha_1 \cdot [(1-d) \cdot \frac{quality(t_i)}{\sum_{t_j \in \omega_k} quality(t_j)} + d \cdot \sum_{t_j \in adj[t_i]} \frac{Sim(t_i, t_j)}{\sum_{t \in adj[t_j]} Sim(t_j, t)} \cdot Score^{(r)}(t_j)] \\ + \beta_1 \cdot \sum_{w \in t_i} Score^{(r)}(w) + \gamma_1 \cdot Score^{(r)}(u_i) \end{aligned} \tag{3}$$

where $Score^{(r)}(t)$, $Score^{(r)}(w)$, and $Score^{(r)}(u)$ denote the ranking score of tweet t, word w and user u in r^{th} iteration respectively. $adj[t_i]$ represents tweets connecting to t_i directly, $Sim(t_i, t_j)$ denotes the cosine similarity between t_i and t_j, u_i is the author of t_i, and $quality(t_i)$ refers to the content quality of t_i which will be detailed in Section 3.2.2. In order to assign high scores for tweets of good quality, we diversify the random walk probabilities (Brin and Page, 1998) of tweets using content quality. High quality tweets will be selected at high probabilities, while low quality ones are selected at low probabilities. Here, d is the damping factor, set to 0.85 as described in Brin and Page (1998).

A user is influential if he publishes salient tweets, uses important terms, and connects to other influential users. The ranking score of a user is defined as,

$$\begin{aligned} Score^{(r+1)}(u_i) = \alpha_2 \cdot \sum_{t \in \omega_k \cap T_{u_i}} Score^{(r)}(t) + \beta_2 \cdot \sum_{w \in t, t \in \omega_k \cap T_{u_i}} Score^{(r)}(w) \\ + \gamma_2 \cdot [(1-d) \cdot \frac{F_{static}(u_i)}{\sum_{u \in U_{\omega_k}} F_{static}(u)} + d \cdot \sum_{u_j \in flw[u_i]} \frac{1}{|frd[u_j]|} \cdot Score^{(r)}(u_j)] \end{aligned} \tag{4}$$

where T_{u_i} denotes the tweets published by u_i, and U_{ω_k} refers to all users who published tweets in ω_k. $flw[u_i]$ represents followers of u_i, and $frd[u_j]$ refers to the users u_j follows. $F_{static}(u_i)$ is regarded as a topic-irrelevant static influence of user u_i. It is predicted by a linear SVM model using features derived from several statistics, including the number of followers, the number of messages, the number of lists, the follower/following ratio, the zombie followers in proportion to all followers, and the number of mentions and retweets the user received. Similar to content quality, we use the static influence of users to differentiate the random walk probabilities of users with the purpose of assigning high scores for users with high static influence.

A phrase term is important if it is contained in salient tweets, used by an influential user, and connects to other important terms.

$$\begin{aligned} Score^{(r+1)}(w_i) = \alpha_3 \cdot \sum_{t \in \omega_k \cap T_{w_i}} Score^{(r)}(t) + \gamma_3 \cdot \sum_{u \in U_{\omega_k} \cap U_{w_i}} Score^{(r)}(u) \\ + \beta_3 \cdot [(1-d) \cdot \frac{df(w_i)}{\sum_{w_j \in t, t \in \omega_k} df(w_j)} + d \cdot \sum_{w_j \in adj[w_i]} \frac{1}{|adj[w_j]|} \cdot Score^{(r)}(w_j)] \end{aligned} \tag{5}$$

where T_{w_i} denotes tweets containing word w_i and U_{w_i} refers to users who used w_i. $df(w_i)$ is the document frequency of term w_i. And $adj[w_i]$ represents the words connnecting to w_i. The random walk probability of terms is initialized by their normalized document frequency with the purpose of assigning high scores for words with high document frequency. α_i, β_i, and γ_i are used to balance the relative weight of tweets, words, and users. They are selected in accordance with Wei et al. (2008)'s work. Wei et al. (2008) proved that the three level unified mutual reinforcement model will converge on unique $Score(t_i)$, $Score(u_i)$, and $Score(w_i)$. We will not repeat the demonstration here. Finally, a ranked tweet list $\omega_k^{'}$ is formed by ranking tweets in ω_k according to the score assigned by the model.

3.2.2 Content quality estimation

We employ a logistic regression model to estimate the content quality used in Section 3.2.1. The content quality of tweets is estimated according to two aspects: readability and content richness. The former measures how easy a tweet is to read. In particular, tweets have high readability if they are written in regular language style using ordinary vocabulary, and have low readability if not. The latter quantifies how much useful information a tweet contains. Instead of calculating the absolute readability and the content richness, we learn models to compare the values of two tweets. Given tweets t_i and t_j, we set their relative quality as

$$quality(t_i, t_j) = \begin{cases} 1, quality(t_i) > quality(t_j) \\ 0, quality(t_i) = quality(t_j) \\ -1, quality(t_i) < quality(t_j) \end{cases} \quad (6)$$

Naturally, for a given group of tweets, if the relative quality of any two tweets has been identified, a ranking list of those tweets with respect to the quality can be generated, and vice visa. Consequently, the relative quality estimation problem is converted into quality ranking. We learn a unified logistic regression model to rank the quality of tweets according to their regression score. The model considers readability and content richness simultaneously. Table 1 and Table 2 present the feature set we used.

Feature	Description
OOV words	The proportion of OOV words in tweet
#hashtags	The proportion of #hashtags in tweet
Mentions	The number of user names appearing in the tweet
Capital letter	Normalized length of capital letters fraction
Punctuation	Normalized length of punctuation character
Emoticon	The number of emoticons
Ellipsis	The number of ellipsis
Stop word	Normalized length of stop word fraction
Character per word	Average character per word
Length	Number of characters in tweet

Table 1: Features for readability estimation

Feature	Description
Celebrity	Normalized word length of celebrities
URL	Share URL or not
URL rank	Alexa rank of shared URL
InfoToNoise	Normalized word length after removing stop word
Word length	The number of words
NE length	Normalized word length of named entities

Table 2: Features for content richness estimation

3.3 Summary generation by removing redundancy

Finally, we will generate a summary for each sub-topic from its corresponding ranked tweets. A straightforward method would be to select the top-ranked tweets of the sub-topics. However, this method would generate a redundant summary both at the tweet and sub-topic levels. At the tweet level, using a similarity link between tweets when measuring the salience of a tweet leads to close ranking scores being assigned to similar tweets. Tweets with high similarity may be chosen simultaneously. At the sub-topic level, the tweet stream is segmented into sub-topics and noisy tweet collections along time line. Two sub-topics describing the same content may be separated by several noisy collections. To avoid redundancy, we employ the MMR algorithm to generate the final summary.

$$S_k = \underset{t_i \in \omega_k' \setminus S_k}{argmax} [\lambda \cdot Sim_1(t_i, w_{a,k}) - (1-\lambda) \cdot \underset{t_j \in S_k \cap S_{k-1}}{max} Sim_2(t_i, t_j)] \quad (7)$$

Where S_k is the summary generated for sub-topic ω_k. Sim_1 represents the cosine similarity between current tweets and the associated terms $w_{a,k}$ of ω_k. And Sim_2 is the cosine similarity between current tweet and tweets selected in S_k and S_{k-1}, based on the observation that a topic changes continuously. λ is the weight emphasizing the importance of the two types of similarities, which is set as 0.5 in the experiment.

4 Experiment

4.1 Data set

We take earthquake event as an example in our experiment. Note that our approach does not leverage topic (e.g. earthquake) specific features. It can generate summary for topics beyond earthquake as well. We obtain 12.7 million English tweets containing the keyword *earthquake* published between September 2010 and April 2012 using the public Twitter API [5]. As #hashtags are regarded as user annotated topics in Twitter, we select the 30 most popular #hashtags related to earthquake as the topics from the collected tweet corpus. Then, we pick out tweets relevant to each topic using two methods of keyword matching. First, tweets containing the corresponding #hashtag are chosen. Second, if the #hashtag is a compound word concatenated of several words, it split into a phrase. Tweets containing the phrase are also selected. In total, we obtain 3.9 million tweets for the 30 topics, which are segmented into 84 sub-topics. Each sub-topic contains 66,416 tweets on average because of the co-occurrence of the #hashtags.

We ask two Ph.D. students(who have not participated in this work) to label 10 salient tweets as

[5] http://windowsphone.uservoice.com

reference for each sub-topic. Given that it is fairly difficult to select 10 tweets from thousands, we filter some tweets beforehand if they satisfy one of the following conditions:

- The length of the word is less than 3.
- It contains no words other than topic words, keyword *earthquake* and stop words.
- It contains no words other than URLs

After filtering, we are left with 26,874 tweets on average for each sub-topic. To make it easy for labeling, the remaining tweets are ranked according to syntactic similarity with the sub-topic. We further remove repetition in the ranking list in case different users post identical tweets. Finally, there are 10,616 tweets for each sub-topic in the ranking list. Annotators select the top tweet in the ranking list, and decide if it should be added to the summary, until 10 tweets have been chosen. We merge their annotation by maintaining the same tweets as the final reference summary. The inter-annotator agreement of annotation is 73%.

In the experiment, we remove spam tweets and extremely short tweets to clear the data. Some users post very similar tweets for certain kinds of promotion. For example, identical content was posted with different URLs attached for a backpack promotion. If a user continuously posts tweets with a content similarity of more than 0.9, all those tweets published by him or her are regarded as spam tweets and removed. We also ignore extremely short tweets less than 3 words in length because they are too short to deliver complete information. In addition, to get a better estimation of similarity between tweets, we conduct some preprocessing before the similarity computation: 1) all words in tweets are stemmed; 2) the topic terms and keyword *earthquake* are neglected due to their occurrence in nearly every tweet; 3) some functional #hashtags and news agencies such as #fb and #BBC are excluded because they are usually irrelevant to the topics and only provide an information source; 4) the stop words are removed, including standard stop words and stop word abbreviations commonly used in Twitter, for instance, *you are* shortens to *ur*.

In the following sections, we present the experimental results on a real-life data set to verify the effectiveness of our summarization approach. We conduct four experiments to evaluate the performance of the reinforcement summarization model, the contribution of social influence and content quality to the model, the correctness of sub-topic segmentation, and the accuracy of the content quality estimation model. The performance of the social influence of users has not been evaluated due to the difficulty of data acquisition. It is hard to label the influence of users, or to collect such information automatically. Therefore, in this paper, we evaluate the end-to-end contribution of social influence under the whole summarization framework.

4.2 Evaluation metric

We evaluate the performance of our summarization system using ROUGE (Lin and Hovy, 2003), which is widely-used in summarization evaluation. It measures the overlap of N-grams between the predicted summary and the reference, which is defined as,

$$ROUGE = \frac{\Sigma_{t \in S_{ref}} \Sigma_{gram_n \in t} Count_{match}(gram_n)}{\Sigma_{t \in S_{ref}} \Sigma_{gram_n \in t} Count(gram_n)}$$

where n is the word length of n-gram, S_{ref} denotes the reference summary, $Count(gram_n)$ is the number of n-grams comprising sentences in the reference summary and $Count_{match}(gram_n)$ computes the maximum number of n-grams appearing both in the summary generated by our system and the reference summary.

4.3 Evaluation of the reinforcement model

In order to evaluate the effectiveness of the reinforcement model, we construct two baselines, namely the phrase graph model (Sharifi et al., 2010a) and the LexRank algorithm (Erkan and Radev, 2004). Both of them are graph-based algorithms, homologous with the reinforcement model. And they are currently the most popular two graph-based algorithms for summarization. Phrase graph measures sentence similarity depending on word frequency as well as the word distance from the topical word in a sentence. LexRank is a PageRank-like summarization algorithm, which calculates sentence salience using the random walk model. Table 3 shows the comparison results of our approach and the baseline methods in terms of ROUGE-1 values. In

Algorithm	ROUGE-1
Phrase graph	0.4286
LexRank	0.3865
Our approach	**0.4617**

Table 3: A comparison of three summarization algorithms[6]

the experiment, α_i, β_i, and γ_i are set as $[\alpha_1, \alpha_2, \alpha_3] = [1, 0.5, 0.25]$, $[\beta_1, \beta_2, \beta_3] = [0.5, 1, 0.5]$, and $[\gamma_1, \gamma_2, \gamma_3] = [0.25, 0.5, 1]$, the same as that in Wei et al. (2008). As seen from Table 3, the proposed approach outperforms both the LexRank and phrase graph methods. It obtains a relative improvement of 20% and 8% compared with the two baselines respectively. We also find that LexRank and phrase graph tend to assign high salience scores to long sentences containing several #hashtags. Some of them are pointless tweets and irrelevant to the topic. For example: *@lightskintess77 =o you could check to see if you had an earthquake by looking it up here: 4 minutes ago #TAB##TAB#5.8 #TAB##TAB#Virginia*. It contains #hashtag *#Virginia*, but the content is not very relevant to the main topic *Virginia earthquake*. It is more like a personal message.

Because LexRank accumulates the information from neighboring sentences (or tweets), its similarity estimation mainly depends on commonly used words, not words with very high IDF scores, especially in short sentences, which increase the chances of selecting pointless information such as personal messages. In comparison to LexRank, phrase graph performs better because it computes the salience of tweets relying on the topical words in the cluster and takes word order into consideration.

Pointless and low quality tweets hurt the performance of both of the baseline models. In comparison to them, our proposed reinforcement model incorporating content quality and social influence emphasizes tweet salience by not only considering the similarity, but also the influence of its author, its readability, and its content richness. These factors penalize the pointless tweets and tweets of low quality when measuring their salience and achieve substantial results.

4.4 Evaluation of social influence and content quality for summarization

We further investigate the effectiveness of the social influence of authors and the content quality of tweets for tweet summarization in detail. To verify the usefulness of content quality, we test

[6]Our approach outperforms LexRank with a significance level of p=0.07. The improvement on Phrase graph is not significant

its contributions in the reinforcement model, LexRank, and phrase graph separately. We remove content quality from the reinforcement model by replacing the random walk probabilities of tweets with a unified weight. The more the performance decreases, the more useful the content quality is. Meanwhile, the content quality is integrated into LexRank and phrase graph. In LexRank, we initialize the random walk probability with the quality score of tweets. And in phrase graph, we change the weight of each word into the weighted summation of its term frequency in every tweet it appears, with the content quality of the tweet as the weight. Table 4 shows the results.

Similar to content quality, we evaluate the contribution of social influence by removing it from the reinforcement model. The salience of tweets is then inferred in the two-level PageRank-like iteration derived from related tweets and words. γ_1, γ_2, γ_3, α_2, and β_2 in section 3.2.1 are set as zero. We set $[\alpha_1,\alpha_3] = [1,0.5]$, and $[\beta_1,\beta_3] = [0.5,1]$ according to Wei et al. (2009). We have not integrated social influence into the LexRank and phrase graph as verification due to the high complexity. Table 5 shows the results.

Model	ROUGE-1
Reinforcement model	0.4617
w/o content quality	**0.4503(-2.5%)**
LexRank	0.3865
LexRank + content quality	**0.3956(+2.4%)**
Phrase graph	**0.4286**
Phrase graph + content quality	0.3959(-7.7%)

Table 4: Effectiveness of content quality

Model	ROUGE-1
Reinforcement model	0.4617
w/o social influence	**0.4310(-6.6%)**

Table 5: Effectiveness of social influence

We can see from Table 4 that the content quality of tweets proves useful in both the reinforcement model and LexRank. The ROUGE-1 is improved by about 2.4% by integrating content quality. We observe in the result that tweets selected by every model pair overlap except for individual pointless tweets. For example, *OMG! This footage on TV now of the earthquake and ensuing tsunami in #Japan is so crazy. My thoughts are with everyone there! Stay strong!*. Content quality excludes such pointless tweets from the final summary by reducing the transition probability. However, the ROUGE-1 in the phrase graph model decreases after it is combined with content quality. It is probably because of the rough assignment of the quality score to words. The content quality of tweet is a measurement based on all words contained in the tweet. It is not so fair to distribute this quality to every word equally.

Table 5 indicates that social influence is an important part of the reinforcement model. The performance decreases rapidly in ROUGE-1 after removing it. The comparison between the results(before and after removing social influence) suggests that more tweets posted by influential users are selected by the former.

4.5 Evaluation of sub-topic segmentation

It is difficult for editors to segment a tweet stream containing hundreds of thousands of tweets into several sub-topics. We have noticed that each sub-topic is a cluster of tweets. Adjacent sub-topics are required to focus on different subjects, which make it a special text clustering task. Thus, we treat each sub-topic as a cluster and automatically compute the average cosine similarity between adjacent ones as an indicator of segmentation performance. The lower the average cosine similarity is, the better performance the segmentation achieves. Table 6 shows the results.

Approach	Cosine similarity
Uniform segmentation	0.835
Nichols et al. (2012)	0.674
Ours	**0.670**

Table 6: Evaluation of sub-topic segmentation

We compare our method with uniform segmentation and the method in Nichols et al. (2012). Uniform segmentation separates the tweet stream into identical length time slots. Tweets in each time slot form a sub-topic. The number of sub-topics equals the number generated by our method. Nichols et al. segment the tweet stream by detecting the extreme changes in update volume per minute. The moment in which the update volume per minute exceeds 3*median(update volume) is a segment. In the experiment, 2.8 sub-topics are produced on average for each topic by our method, and 3 by Nichols et al. (2012). From Table 6 we can see that our method achieves comparable result to Nichols et al. (2012). Both of them lead to lower average cosine similarities between adjacent sub-topics in comparison to uniform segmentation.

4.6 Evaluation of content quality

In this sub-section, we evaluate the performance of the content quality classifiers. We randomly select 3,000 tweets from an additional tweet corpus for content quality training and evaluation. One of two labels, H(high quality) and L(low quality), are assigned to every tweet. Tweets that have good readability and cover rich content are labeled H, otherwise L. A tweet is regarded as having good readability if it does not include too many abbreviations, ellipses, spelling errors, #hashtags, or mentions. In addition, a tweet is viewed as containing rich content if it 1) describes an event or an interesting topic, 2) contains crisp, clear, and effective text that is easy to understand, 3) provides some insight about the event or topic beyond simply stating that it occurred, or 4) reflects a useful opinion on some topics. We learn two logistic regression models using features described in section 3.2.2 and unigrams respectively, denoted as LRO and LRU. Five-fold cross-validation is conducted to evaluate the performance. Table 7 shows the results as well as the result of the Random classification model.

The LRO model obtains promising results for both high and low quality tweets. It achieves substantial improvements in comparison to the LRU model and random classification model. The result of random classification reflects the imbalanced distribution of data. Tweets of high quality in a tweet stream are rare, leading to a proportion of 13% in the annotated data. Low quality tweets account for 87%, which makes it difficult to achieve a very good prediction. However, our concern is the performance on tweets of high quality because we want to select good tweets for summary generation. The precision of high quality tweets increases by 0.429

Method	Data	Precision	Recall	F-score	Accuracy
Random	H	0.130	0.500	0.206	0.500
	L	0.870	0.500	0.635	
LRU	H	0.321	0.636	0.427	0.765
	L	0.931	0.786	0.852	
LRO	H	**0.559**	**0.714**	**0.627**	**0.883**
	L	**0.952**	**0.910**	**0.931**	

Table 7: Evaluation of Content Quality

and 0.238 separately, which dramatically increases the probability of high quality tweets being selected.

A deep analysis of the features reveals several interesting facts. Whether a tweet includes a URL is highly valued by the model. This is mainly because tweets with URLs are usually news titles or shared information, such as videos and games from corresponding websites. They are written in formal language and deliver rich information. Another highly useful feature is the number of ellipsis. Ellipsis is used frequently in Twitter. They are usually used to leave out a part of sentences, or as a break between two irrelevant sentences. Tweets involving more than one ellipsis become difficult to read. In addition, the word length of tweets, the number of emoticons, and the stop word ratio are useful for measuring content quality.

4.7 Discussion

To make it easier for annotators to label the reference, we rank all the tweets before annotation. The ranking procedure used in selecting the reference tweets makes tweets most similar to the corpus have a higher priority for selection. However, rank is not the only aspect the annotators considered (e.g. tweets with low readability or content richness will not be selected). It is just used to reduce the annotation workload. Annotators go through the top N tweets in the ranked list until 10 reference tweets are selected (N may be 100, 1000, or more). A summarization algorithm considering similarity will benefit from this corpus. But both the mutual reinforcement model and the two baselines have not integrated the heuristics to rank tweets to create the corpus. They are compared in fair head start.

5 Conclusion

In this paper, we propose summarizing tweet streams with regard to topics along time line to produce an overview of topic evolution, which is expressed by sub-topics in chronological order. For each sub-topic, a set of salient tweets is selected to produce the summary by ranking them according to salience. Different from traditional documents, tweets suffer a great deal from pointless information and irregular writing style. We thus model the salience of a tweet by using a unified mutual reinforcement graph to incorporate the social influence of users and the content quality of tweets. The experimental results show that the proposed approach achieves substantial improvements in comparison to LexRank and phrase graph. Furthermore, the content quality and the social influence show great effectiveness in measuring the salience of tweets. In the future, we plan to exploit more specific relationships among tweets, such as retweeting in the reinforcement model to rank tweets for summary generation.

S-restricted monotone alignments: Algorithm, search space, and applications

Steffen Eger
Goethe University Frankfurt, Grueneburg-Platz 1, 60323 Frankfurt am Main, Germany
steffen.eger@yahoo.com

Abstract
We present a simple and straightforward alignment algorithm for monotone many-to-many alignments in grapheme-to-phoneme conversion and related fields such as morphology, and discuss a few noteworthy extensions. Moreover, we specify combinatorial formulas for monotone many-to-many alignments and decoding in G2P which indicate that exhaustive enumeration is generally possible, so that some limitations of our approach can easily be overcome. Finally, we present a decoding scheme, within the monotone many-to-many alignment paradigm, that relates the decoding problem to restricted integer compositions and that is, putatively, superior to alternatives suggested in the literature.

Title and Abstract in German

S-beschränkte monotone Alignierungen: Algorithmus, Suchraum und Anwendungen

Wir präsentieren einen einfachen Alignment-Algorithmus für monotone 'many-to-many' Alignierungen im Bereich Graphem-zu-Phonem-Konversion und verwandten Gebieten wie z.B. Morphologie, und besprechen sinnvolle Erweiterungen. Darüber hinaus geben wir kombinatorische Formeln im Bereich der monotonen 'many-to-many' Alignierungen und im Bereich des Decoding in G2P an, die suggerieren, dass vollständige Enumeration hier im Allgemeinen möglich ist, sodass ein paar Einschränkungen unseres Ansatzes leicht behoben werden können. Schließlich präsentieren wir ein Decoding-Schema, innerhalb des Paradigmas von 'many-to-many' Alignierungen, dass das Decoding-Problem mit beschränkten Zahlenkompositionen in Beziehung setzt und das in der Literatur vorgeschlagenen Alternativen vermeintlich überlegen ist.

Keywords: many-to-many alignments, monotone alignments, string transduction, restricted integer compositions, grapheme-to-phoneme conversion.

Keywords in German: many-to-many Alignierungen, monotone Alignierungen, String-Überführungen, beschränkte Zahlenkompositionen, Graphem-zu-Phonem-Konversion.

Proceedings of COLING 2012: Technical Papers, pages 781–798,
COLING 2012, Mumbai, December 2012.

1 Introduction

Grapheme-to-phoneme conversion (G2P) is the problem of transducing, or converting, a grapheme, or letter, string $\mathbf{x}$ over an alphabet Σ_x into a phoneme string $\mathbf{y}$ over an alphabet Σ_y. A crucial first step thereby is finding *alignments* between grapheme and phoneme strings in training data. The classic alignment paradigm has assumed alignments that were

(i) *one-to-one* or *one-to-zero*; i.e. one grapheme character is mapped to at most one phoneme character; this assumption has probably been a relic of both the traditional assumptions in machine translation (cf. (Brown et al., 1990)) and in biological sequence alignment (cf. (Needleman and Wunsch, 1970)). In the field of G2P such alignment models are also called ϵ-scattering models (cf. (Black et al., 1998)).

(ii) *monotone*, i.e., the order between characters in grapheme and phoneme strings is preserved.

It is clear that, despite its benefits, the classical alignment paradigm has a couple of limitations; in particular, it may be unable to explain certain grapheme-phoneme sequence pairs, a.o. those where the length of the phoneme string is greater than the length of the grapheme string such as in

exact igzækt

where $\mathbf{x}$ has length 5 and $\mathbf{y}$ has length 6. In the same context, even if an input pair can be explained, the one-to-one or one-to-zero assumption may lead to alignments that, linguistically, seem nonsensical, such as

p	h	o	e	n	i	x
f	–	iː	n	i	k	s

where the reader may verify that, no matter where the ϵ is inserted, some associations will always appear unmotivated. Moreover, monotonicity appears in some cases violated as well, such as in the following,

centre sentər

where it seems, linguistically, that the letter character *r* corresponds to phonemic r and graphemic word final *e* corresponds to ə.

Fortunately, better alignment models have been suggested to overcome these problems. For example, (Jiampojamarn et al., 2007) and (Jiampojamarn and Kondrak, 2010) suggest 'many-to-many' alignment models that address issue (i) above. Similar ideas were already present in (Baldwin and Tanaka, 1999), (Galescu and Allen, 2001) and (Taylor, 2005). (Bisani and Ney, 2008) likewise propose many-to-many alignment models; more precisely, their idea is to *segment* grapheme-phoneme pairs into non-overlapping parts ('co-segmentation'), calling each segment a *graphone*, as in

ph	oe	n	i	x
f	iː	n	i	ks

which consists of five graphones.

The purpose of the present paper is to introduce a simple, flexible and general monotone many-to-many alignment algorithm (in Section 3) that competes with the approach suggested in (Jiampojamarn et al., 2007).[1] Thereby, our algorithm is an intuitive and straightforward generalization of the classical Needleman-Wunsch algorithm for (biological or linguistic) sequence alignment. Moreover, we explore valuable extensions of the presented framework, likewise in Section 3, which may be useful e.g. to detect latent classes in alignments, similar to what has been done in e.g. (Dreyer et al., 2008). We also mention limitations of our procedure, in Section 4, and discuss the naive brute-force approach, exhaustive enumeration, as an alternative; furthermore, by specifying the search space for monotone many-to-many alignments, we indicate that exhaustive enumeration appears generally a feasible option in G2P and related fields. Next, in Section 6.1 we briefly mention how we perform training for string transductions in the monotone many-to-many alignment case. Then, a second contribution of this work is to suggest an alternative decoding procedure when transducing strings $\mathbf{x}$ into strings $\mathbf{y}$, within the monotone many-to-many alignment paradigm (in Section 6.2). We thereby relate the decoding problem to restricted integer compositions, a field in mathematical combinatorics that has received increased attention in the last few years (cf. (Heubach and Mansour, 2004), (Malandro, 2012), (Eger, 2012a)). Finally, we demonstrate the superiority of our approach by applying it to several data sets in Section 7.

It must be mentioned, generally, that we take G2P only as an (important) sample application of monotone many-to-many alignments, but that they clearly apply to other fields of natural language processing as well, such as transliteration, morphology/lemmatization, etc. and we thus also incorporate experiments on morphology data. Moreover, as indicated, we do not question the premise of monotonicity in the current work, but take it as a crucial assumption of our approach, leading to efficient algorithms. Still, 'local non-monotonicities' as exemplified above can certainly be adequately addressed within our framework, as should become clear from our illustrations below (e.g. with higher-order 'steps').

2 S-restricted monotone paths and alignments

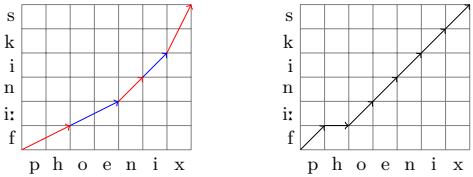

Figure 1: Monotone paths in two-dimensional lattices corresponding to the monotone alignments between $\mathbf{x}$ = phoenix and $\mathbf{y}$ = fi:niks given in Section 1. In the left lattice, we have arbitrarily (but suggestively) colored each step in either red or blue.

Denote by $\mathbb{Z}$ the set of integers, by $\mathbb{N}$ the set of non-negative integers, and by $\mathbb{R}$ the set of real numbers. Consider the two-dimensional lattice $\mathbb{Z}^2$. In $\mathbb{Z}^2$, we call an ordered list of pairs $(\alpha_0, \beta_0) = (0,0), \ldots, (\alpha_k, \beta_k) = (m,n)$ a *path* from $(0,0)$ to (m,n), and we call

[1]The many-to-many alignment algorithm designed in (Jiampojamarn et al., 2007) is an extension of a one-to-one stochastic transducer devised in (Ristad and Yianilos, 1998). Moreover, (Brill and Moore, 2000) learn the weighted edit distance between string pairs where edit operations may encompass arbitrary subsequences of strings, a setting also closely related to our problem of monotone many-to-many alignments.

$(a_i, b_i) := (\alpha_i, \beta_i) - (\alpha_{i-1}, \beta_{i-1})$, $i = 1, \ldots, k$, *steps*. Moreover, we call a path λ in the lattice $\mathbb{Z}^2$ from $(0,0)$ to (m,n) *monotone* if all steps (a,b) are non-negative, i.e. $a \geq 0$, $b \geq 0$, and we call the monotone path λ *S-restricted* for a subset S of $\mathbb{N}^2$ if all steps lie within S, i.e. $(a,b) \in S$.

Note that S-restricted monotone paths define *S-restricted monotone alignments*, between strings $\mathbf{x}$ and $\mathbf{y}$. For example, the two paths in Figure 1 correspond to the two monotone alignments between $\mathbf{x}$ = phoenix and $\mathbf{y}$ = fi:niks illustrated above. Thus, we identify S-restricted monotone paths with S-restricted monotone alignments in the sequel.

Moreover, note that the set and number of S-restricted monotone paths allow simple recursions. To illustrate, the number $T_S(m,n)$ of S-restricted monotone paths from $(0,0)$ to (m,n) satisifies

$$T_S(m,n) = \sum_{(a,b) \in S} T_S(m-a, n-b), \tag{1}$$

with initial condition $T_S(0,0) = 1$ and $T_S(m,n) = 0$ if $m < 0$ or $n < 0$. As will be seen in the next section, under certain assumptions, *optimal* monotone alignments (or, equivalently, paths) can be found via a very similar recursion.

3 An algorithm for S-restricted monotone alignments

Let two strings $\mathbf{x} \in \Sigma_x^*$ and $\mathbf{y} \in \Sigma_y^*$ be given. Moreover, assume that a set S of allowable steps is specified together with a real-valued similarity function $\mathsf{sim} : \Sigma_x^* \times \Sigma_y^* \to \mathbb{R}$ between characters of Σ_x and Σ_y. Finally, assume that the *score* or value of an S-restricted monotone path $\lambda = (\alpha_0, \beta_0), \ldots, (\alpha_k, \beta_k)$ is defined additively linear in the similarity of the substrings of $\mathbf{x}$ and $\mathbf{y}$ corresponding to the steps (a,b) taken, i.e.

$$\text{score}(\lambda) = \sum_{i=1}^{k} \mathsf{sim}(x_{\alpha_{i-1}+1}^{\alpha_i}, y_{\beta_{i-1}+1}^{\beta_i}), \tag{2}$$

where by $x_{\alpha_{i-1}+1}^{\alpha_i}$ we denote the subsequence $x_{\alpha_{i-1}+1} \ldots x_{\alpha_i}$ of $\mathbf{x}$ and analogously for $\mathbf{y}$. Then it is not difficult to see that the problem of finding the path (alignment) with maximal score can be solved efficiently using a very similar (dynamic programming) recursion as in Equation (1), which we outline in Algorithm 1. Moreover, this algorithm is obviously a straightforward generalization of the classical Needleman-Wunsch algorithm, which specifies S as $\{(0,1),(1,0),(1,1)\}$.

Note, too, that in Algorithm 1 we include two additional quantities, not present in the original sequence alignment approach, namely, firstly, the 'quality' q of a step (a,b), weighted by a factor $\gamma \in \mathbb{R}$. This quantity may be of practical importance in many situations. For example, if we specify sim as log-probability (see below), then Algorithm 1 has a 'built-in' tendency to substitute 'smaller', individually more likely steps (a,b) by larger, less likely steps because in the latter case fewer negative numbers are added; if sim assigns strictly positive values, this relationship is reversed. We can counteract these biases by factoring in the *per se* quality of a given step. Also note that if q is added linearly, as we have specified, then the dynamic programming recursion is not violated.

Secondly, we specify a function $\mathsf{L} : \left(\Sigma_x^* \times \Sigma_y^*\right) \times \mathsf{colors} \to \mathbb{R}$, where colors is a finite set of 'colors', that encodes the following idea. Assume that each step $(a,b) \in S$ appears in

C, $C \in \mathbb{N}$, different 'colors', or states. Then, when taking step (a, b) with color $c \in \mathsf{colors}$ (which we denote by the symbol $(a, b)^c$ in Algorithm 1), we assess the 'goodness' of this decision by the 'likelihood' L that the current subsequences of $\mathbf{x}$ and $\mathbf{y}$ selected by the step (a, b) 'belong to'/'are of' color (or state) c. As will be seen below, this allows to very conveniently identify (or postulate) 'latent classes' for character subsequences, while increasing the algorithm's running time only by a constant factor.

To summarize our generalizations over the traditional sequence alignment approach, (i) we allow arbitrary non-negative steps S corresponding to S-restricted monotone alignments, (ii) we include a goodness measure q that evaluates the 'quality' of a given step $(a, b) \in S$ taken, and (iii) we color each step in C different colors and assess the goodness of color c for the subsequences of $\mathbf{x}$ and $\mathbf{y}$ selected by the current step (a, b) as the 'likelihood' L that these subsequences are of color c. Finally, we define the score of a monotone path as an additive linear combination of all three components discussed so that an efficient dynamic programming recursion applies. Note that the algorithm's running time is $O(C|S|mn)$ and is thus linear in the number of colors, the size of S, and the string lengths m and n.[2]

Algorithm 1 Generalized Needleman-Wunsch (GNW)

procedure GNW($x_1 \dots x_m, y_1 \dots y_n$; S, $\mathsf{sim}, \mathsf{q}, \mathsf{L}$)
  $M_{ij} \leftarrow -\infty$ for all $(i, j) \in \mathbb{Z}^2$ such that $i < 0$ or $j < 0$
  $M_{00} \leftarrow 0$
  for $i = 0 \dots m$ **do**
    for $j = 0 \dots n$ **do**
      if $(i, j) \neq (0, 0)$ **then**
        $M_{ij} \leftarrow \max_{(a,b)^c \in S} \{M_{i-a,j-b} + \mathsf{sim}(x^i_{i-a+1}, y^j_{j-b+1}) + \gamma \mathsf{q}(a, b) + \chi \mathsf{L}\big((x^i_{i-a+1}, y^j_{j-b+1}), c\big)\}$
      end if
    end for
  end for
  return M_{mn} ▷ M_{mn} holds value of path with maximal score
end procedure

Algorithm 2 (Hard) EM Training

procedure EM($\{(\mathbf{x}_i, \mathbf{y}_i) \mid i = 1, \dots, N\}$; S, T, $\hat{\mathsf{sim}}_0, \hat{\mathsf{q}}_0, \hat{\mathsf{L}}_0$)
  $t \leftarrow 0$
  while $t < T$ **do**
    for $i = 1 \dots N$ **do**
      $(\mathbf{x}^a_i, \mathbf{y}^a_i) \leftarrow$ GNW($\mathbf{x}_i, \mathbf{y}_i; S, \hat{\mathsf{sim}}_t, \hat{\mathsf{q}}_t, \hat{\mathsf{L}}_t$)
        ▷ $(\mathbf{x}^a_i, \mathbf{y}^a_i)$ denotes the alignment between $\mathbf{x}_i$ and $\mathbf{y}_i$
    end for
    $\hat{\mathsf{sim}}_{t+1}, \hat{\mathsf{q}}_{t+1}, \hat{\mathsf{L}}_{t+1} \leftarrow f(\{\mathbf{x}^a_i, \mathbf{y}^a_i \mid i = 1, \dots, N\})$
      ▷ The function f extracts (count) updates from the aligned data
    $t \leftarrow t + 1$
  end while
end procedure

[2] But also note the dependence of the running time on the definition of sim, q and L.

As to the similarity measure sim employed in Algorithm 1, a popular choice is to specify it as the (logarithm of the) joint probability of the pair $(\mathbf{u}, \mathbf{v}) \in \Sigma_x^* \times \Sigma_y^*$, but a multitude of alternatives is conceivable here such as the χ^2 similarity, pointwise mutual information, etc. (see for instance the overview in (Hoang et al., 2009)). Also note that $\mathsf{sim}(\mathbf{u}, \mathbf{v})$ is usually initially unknown but can be iteratively estimated via application of Algorithm 1 and count estimates in an EM-like fashion (cf. (Dempster et al., 1977)), see Algorithm 2.[3] As concerns q and L, we can likewise estimate them iteratively from data, specifying their abstract forms via any well-defined (goodness) measures. The associated coefficients γ and χ can be optimized on a development set or set exogenously.

4 Exhaustive enumeration and alignments

In the last section, we have specified a polynomial time algorithm for solving the monotonic S-restricted string alignment problem, under the following restriction; namely, we defined the score of an alignment additively linear in the similarities of the involved subsequences. This, however, entails an independence assumption between successive aligned substrings that oftentimes does not seem justified in linguistic applications. If, on the contrary, we specified the score, $\mathrm{score}(\lambda)$, of an alignment λ between strings $\mathbf{x}$ and $\mathbf{y}$ as e.g.

$$\mathrm{score}(\lambda) = \sum_{i=1}^{k} \log \Pr\big((x_{\alpha_{i-1}+1}^{\alpha_i}, y_{\beta_{i-1}+1}^{\beta_i}) \,|\, (x_{\alpha_{i-2}+1}^{\alpha_{i-1}}, y_{\beta_{i-2}+1}^{\beta_{i-1}})\big)$$

(using joint probability as similarity measure) — this would correspond to a 'bigram scoring model' — then Algorithm 1 would not apply.

To address this issue, we suggest *exhaustive enumeration* as a possibly noteworthy alternative — enumerate *all* S-restricted monotone alignments between strings $\mathbf{x}$ and $\mathbf{y}$, score each of them individually, taking the one with maximal score. This brute-force approach is, despite its simplicity, the most general approach conceivable and works under all specifications of scoring functions. Its practical applicability relies on the sizes of the search spaces for S-restricted monotone alignments and on the lengths of the strings $\mathbf{x}$ and $\mathbf{y}$ involved.

We note the following here. By Equation (1), for the choice $S = \{(1,1),(1,2),(1,3),(1,4),(2,1)\}$, a seemingly reasonable specification in the context of G2P (see next section), the number $T_S(n,n)$ of S-restricted monotone alignments is given as (for explicit formulae for specific S, cf. (Eger, 2012b))

$$1, 1, 3, 7, 16, 39, 95, 233, 572, 1406, 3479, 8647$$

for $n = 1, 2, \ldots, 12$ and e.g. $T_S(15,15) = 134,913$. Moreover, for the distribution of letter string and phoneme string lengths we estimate Poisson distributions (cf. (Wimmer et al., 1994)) with parameters $\mu \in \mathbb{R}$ as listed in Table 4 for the German Celex (Baayen et al., 1996), French Brulex (Content et al., 1990) and English Celex datasets, as used in Section 7. As the table and the above numbers show, there are on average only a few hundred or few thousand possible monotone many-to-many alignments between grapheme and phoneme string pairs, for which exhaustive enumeration appears, thus, quite feasible; moreover, given enough data, it usually does not harm much to exclude a few string pairs, for which alignment numbers are too large.

[3] The variant of EM that we describe is sometimes called *hard* EM while e.g. (Jiampojamarn et al., 2007) present a soft EM version; but see the discussion in (Samdani et al., 2012).

Dataset	μ_G	μ_P	$P_{[G>15]}$	$P_{[P>15]}$
German-Celex	9.98	8.67	4.80%	1.62%
French-Brulex	8.49	6.71	1.36%	0.15%
English-Celex	8.21	7.39	1.03%	0.40%

Table 1: Avg. grapheme and phoneme string lengths in resp. data set, and probabilities that lengths exceed 15.

5 Choice of S

Choice of the set of steps S is a question of *model selection*, cf. (Zucchini, 2000). Several approaches are conceivable here. First, for a given domain of application one might specify a possibly 'large' set of steps Ω capturing a preferably comprehensive class of alignment phenomena in the domain. This may not be the best option because it may provide Algorithm 1 with too many 'degrees of freedom', allowing it to settle in unfavorable local optima, and thus may lead to suboptimal alignments (we find appropriate step restriction to have dramatic effects on alignment quality, which we investigate more thoroughly in subsequent research). A better, but potentially very costly, alternative is to exhaustively enumerate all possible subsets S of Ω, apply Algorithm 1 and/or Algorithm 2, and evaluate the quality of the resulting alignments with any choice of suitable measures such as alignment entropy (cf. (Pervouchine et al., 2009)), average log-likelihood, Akaike's information criterion (Akaike, 1974) or the like. Another possibility would be to use a comprehensive Ω, but to penalize unlikely steps, which could be achieved by setting γ in Algorithm 1 to a 'large' real number and then, in subsequent runs, employ the remaining steps $S \subseteq \Omega$; we outline this approach in Section 7.

Sometimes, specific knowledge about a particular domain of application may be helpful, too. For example, in the field of G2P, we would expect most associations in alignments to be of the type M-to-1, i.e. one or several graphemes encode a single phoneme. This is because it seems reasonable to assume that the number of phonetic units used in language communities typically exceeds the number of units in alphabetic writing systems — 26 in the case of the Latin alphabet — so that one or several letters must be employed to represent a single phoneme. There may be 1-to-N or even M-to-N relationships but we would consider these exceptions. In the current work, we choose $S = \{(1,1),(2,1),(3,1),(4,1),(1,2)\}$ for G2P data sets, and for the morphology data sets we either adopt from (Eger, 2012b) or use a comprehensive Ω with 'largest' step $(2,2)$.

6 Decoding

Decoding is the process of generating $\hat{\mathbf{y}} \in \Sigma_y^*$ given $\mathbf{x} \in \Sigma_x^*$. Below, we explain how we perform this process, within the S-restricted monotone many-to-many alignment framework.

6.1 Training a string transduction model

We first generate monotone many-to-many alignments between string pairs with one of the procedures outlined in Sections 3 and 4. Then, we train a linear chain conditional random field (CRF; see (Lafferty et al., 2001)) as a graphical model for string transduction on the aligned data. The choice of CRFs is arbitrary; any transduction procedure tr would do, but we decide for CRFs because they generally have good generalization properties. In all cases, we use window sizes of three or four to predict $\mathbf{y}$ string elements from $\mathbf{x}$ string elements.

6.2 Segmentation

Our overall decoding procedure is as follows. Given an input string $\mathbf{x}$, we exhaustively generate all possible segmentations of $\mathbf{x}$, feed the segmented strings to the CRF for transduction and evaluate each individual resulting sequence of 'graphones' with an n-gram model learned on the aligned data, taking the $\mathbf{y}$ string corresponding to the graphone sequence with maximal probability as the most likely transduced string for $\mathbf{x}$. We illustrate in Algorithm 3. As to the size of the search space that this procedure entails, any segmentation

Algorithm 3 Decoding

procedure decode($\mathbf{x} = x_1 \dots x_m$; $\hat{k}$, α, β, tr)
  $Z \leftarrow \emptyset$
  for $s \in \mathscr{C}(m, \hat{k}, \alpha, \beta)$ **do** ▷ $\mathscr{C}(m, \hat{k}, \alpha, \beta)$: the set of all integer compositions of m with $\hat{k}$ parts, each between α and β
    $\hat{\mathbf{y}} \leftarrow \mathsf{tr}(s)$
    $z_{\hat{\mathbf{y}}} \leftarrow \text{ngramScore}(\mathbf{x}, \hat{\mathbf{y}})$
    $Z \leftarrow Z \cup \{z_{\hat{\mathbf{y}}}\}$
  end for
  $z_{\hat{\mathbf{y}}^*} \leftarrow \max_{z_{\hat{\mathbf{y}}}} Z$
  return $\hat{\mathbf{y}}^*$
end procedure

of a string $\mathbf{x}$ of length m with k parts uniquely corresponds to an *integer composition* (a way of writing m as a sum of non-negative integers) of the integer m with k parts, as in,

		ph		oe		n		i		x
7	=	2	+	2	+	1	+	1	+	1

It is a simple exercise to show that there are $\binom{m-1}{k-1}$ integer compositions of m with k parts, where by $\binom{m}{k}$ we denote the respective binomial coefficient. Furthermore, if we put restrictions on the maximal size of parts — e.g. in G2P a reasonable upper bound l on the size of parts would probably be 4 — we have that there are $\binom{k}{m-k}_l$ integer compositions of m with k parts, each between $\alpha = 1$ and $\beta = l$, where by $\binom{k}{m}_{l+1}$ we denote the respective *polynomial coefficient* (Comtet, 1974). To avoid having to enumerate segmentations for all possible numbers k of segment parts of a given input string $\mathbf{x}$ of length m — these would range between 1 and m, entailing $\sum_{k=1}^{m} \binom{m-1}{k-1} = 2^{m-1}$ possible segmentations in total in the case without upper bound[4] — we additionally train a 'number of parts' prediction model with which to estimate k as $\hat{k}$; we call this in short *predictor model*.

To illustrate the number of possible segmentations with a concrete example, if $\mathbf{x}$ has length $m = 15$, a rather large string size given the values in Table 4, there are

$$2472, 2598, 1902, 990, 364, 91, 14, 1$$

possible segmentations of $\mathbf{x}$ with $k = 8, 9, 10, 11, 12, 13, 14, 15$ parts, each between 1 and 4.

For the sake of completeness, we note that our above discussion presumed that there are no 'empty' parts in integer compositions, that is, that all parts in the integer composition

[4] In the case of upper bounds, (Malandro, 2012) provides asymptotics for the number of restricted integer compositions, which are beyond the scope of the present work, however.

2PKE. abbreche**t**, entgegentrete**t**, zuzieh**t**
z. ab**zu**brechen, entgegen**zu**treten, zu**zu**ziehen
rP. redet, **reibt**, tr**eibt**, verbind**et**
pA. **ge**redet, **ge**r**ieben**, **ge**tr**ieben**, verb**u**nd**en**

Table 2: String pairs in morphology data sets 2PKE and rP (omitting 2PIE and 13SIA for space reasons) discussed by (Dreyer et al., 2008). Changes from one form to the other are in bold (information not given in training). Adapted from (Dreyer et al., 2008).

are integers between 1 and the upper bound l. When converting graphemes to phonemes, we find it unlikely that a sound would be uttered without there being a corresponding letter that gives rise to this sound,[5] i.e. our assumption seems justified. In the general monotone alignment case, however, the zero case would have to be included, e.g. when converting phonemes to graphemes, or in the morphology data sets discussed below, where e.g. segmentations as in

$$\begin{array}{ccccccccccccc} & & \emptyset & & \mathrm{m} & & \mathrm{a} & & \mathrm{c} & & \mathrm{h} & & \mathrm{t} \\ 5 & = & 0 & + & 1 & + & 1 & + & 1 & + & 1 & + & 1 \end{array}$$

seem justified to convert German third person verb form *macht* into participle form *gemacht*. Analogously as above, we find that there are $\binom{k}{m}_{l+1}$ integer compositions of m with k parts, each between 0 and l. To illustrate again, when $m = 15$, there are $37080, 142749, 831204, 2268332, \ldots$ possible segmentations of $\mathbf{x}$ with $k = 8, 9, 10, 11, \ldots$ parts, each between 0 and 4. Obviously, these numbers are much larger than those where all parts are ≥ 1, which is problematic not only from the point of view of computing resources but may also affect accuracy results because more alternatives are provided from which to select. Luckily, as illustrated below, it should usually be possible to specify modeling choices where zero parts do not occur.

7 Experiments

We conduct our experiments on three G2P data sets, the German Celex (G-Celex) and French Brulex data set (F-Brulex) taken from the Pascal challenge (van den Bosch et al., 2006), and the English Celex dataset (E-Celex); and on the four German morphology data sets discussed in (Dreyer et al., 2008), which we refer to, in accordance with the named authors, as rP, 2PKE, 13SIA and 2PIE, respectively. Both for the G2P and the morphology data, we hold monotonicity, by and large, a legitimate assumption so that our approach would appear justified. As to the morphology data sets, we illustrate in Table 7 a few string pair relationships that they contain, as indicated by (Dreyer et al., 2008).

7.1 Alignments

We generate alignments for our data sets using Algorithms 1 and 2 and, as a comparison, we implement an exhaustive search bigram scoring model as indicated in Section 4 in an EM-like fashion similar as in Algorithm 2, employing the CMU SLM toolkit (Clarkson and Rosenfeld, 1997) with Witten-Bell smoothing as n-gram model. For Algorithm 1, which we also refer to as unigram model in the following, we choose steps S as shown in Table

[5] As an exception might be considered e.g. extra terminal vowel sounds like in Italian *sport*, pronounced as s p o r t ə. As pointed out by a reviewer, other such exceptions might include short vowels in Arabic or Hebrew script that are generally not graphemically represented.

E-Celex	$\{(1,1),(2,1),(3,1),(4,1),(1,2)\}$
rP	$\{(0,2),(1,1),(1,2),(2,1),(2,2)\}$
2PKE	$\{(0,2),(1,1),(2,1),(2,2)\}$
13SIA	$\{(1,1),(1,2),(2,1),(2,2)\}$
2PIE	$\{(1,1),(1,2)\}$

Table 3: Data set and choice of S. For all three G2P data sets, we select the same S, exemplarily shown for E-Celex. The choice of S for rP and 2PKE is taken from (Eger, 2012b). For 13SIA and 2PIE we use comprehensive Ω's with largest step $(2,2)$ but the algorithm ends up using just the outlined set of steps.

	Perplexity	$H(L\,\vert\,P)$
2PKE-Uni	7.002 ± 0.04	$\mathbf{0.094 \pm 0.001}$
2PKE-Bi	$\mathbf{6.865 \pm 0.02}$	0.141 ± 0.003
rP-Uni	9.848 ± 0.09	$\mathbf{0.092 \pm 0.003}$
rP-Bi	$\mathbf{9.796 \pm 0.05}$	0.107 ± 0.006
Brulex-Uni	22.488 ± 0.35	$\mathbf{0.706 \pm 0.002}$
Brulex-Bi	$\mathbf{22.215 \pm 0.21}$	0.725 ± 0.003

Table 4: Conditional entropy vs. n-gram perplexity ($n = 2$) of alignments for different data sets. In bold: Statistically best results. $K = 300$ throughout.

3. As similarity measure sim, we use log prob with Good-Turing smoothing and for q we likewise use log prob; we outline the choice of L below. Initially, we set γ and χ to zero. As an alignment quality measure we consider conditional entropy $H(L\,|\,P)$ (or $H(P\,|\,L)$) as suggested by (Pervouchine et al., 2009). Conditional entropy measures the average uncertainty of a (grapheme) substring L given a (phoneme) substring P; apparently, the smaller $H(L\,|\,P)$ the better the alignment because it produces more consistent associations.

In the following, all results are averages over several runs, 5 in the case of the unigram model and 2 in the case of the bigram model. Both for the bigram model and the unigram model, we select K, where $K \in \{50, 100, 300, 500\}$, training samples randomly in each EM iteration for alignment and from which to update probability estimates.

In Figure 2, we show learning curves over EM iterations in the case of the unigram and bigram models, and over training set sizes. We see that performance, as measured by conditional entropy, increases over iterations both for the bigram model and the unigram model (in Figure 2), but apparently alignment quality decreases again when too large training set sizes K are considered in the case of the bigram model (omitted for space reasons); similar outcomes have been observed when similarity measures other than log prob are employed in Algorithm 1 for the unigram model, e.g. the χ^2 similarity measure (cf. (Eger, 2012b)). To explain this, we hypothesize that the bigram model (and likewise for specific similarity measures) is more susceptible to overfitting when it is trained on too large training sets so that it is more reluctant to escape 'non-optimal' local minima. We also see that, apparently, the unigram model performs frequently better than the bigram model.

The latter results may be partly misleading, however. Conditional entropy, the way (Pervouchine et al., 2009) have specified it, is a 'unigram' assessment model itself and may therefore be incapable of accounting for certain contextual phenomena. For example, in the 2PKE and rP data, we find alignment possibilities of the following types,

–	g	e	b	t		g	e	–	b	t
ge	g	e	b	en		g	e	ge	b	en

where we list the linguistically 'correct', due to the prefixal character of *ge* in German, alignment on the left and the 'incorrect' alignment on the right. By its specification, Algorithm 1 *must* assign both these alignments the same score and can hence not distinguish between them; *the same holds true for the conditional entropy measure*. To address this issue, we evaluate alignments by a second method as follows. From the aligned data, we extract a random sample of size 1000 and train an n-gram graphone model (that can account for 'positional associations') on the residual, assessing its perplexity on the held-out set of size 1000. Results are shown in Table 4. We see that, in agreement with our visual impression at least for the morphology data, the alignments produced by the bigram model seem to be slightly more consistent in that they reduce perplexity of the n-gram graphone model, whereas conditional entropy proclaims the opposite ranking.

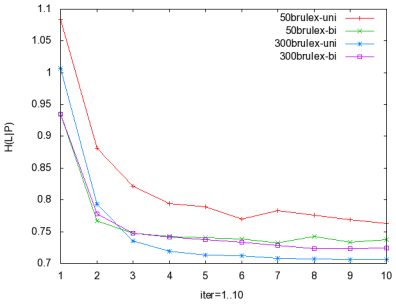

Figure 2: Learning curves over iterations for F-Brulex data, $K = 50$ and $K = 300$, for unigram and bigram models.

7.1.1 Quality q of steps

In Table 5 we report results when experimenting with the coefficient γ of the quality of steps measure q. Overall, we do not find that increasing γ would generally lead to a performance increase, as measured by e.g. $H(L\,|\,P)$. On the contrary, when choosing as set of steps a comprehensive Ω as in Table 5, where we choose $\Omega = \{(a,b)\,|\,a \leq 4, b \leq 4\}\backslash\{(0,0)\}$, for $\gamma = 0$, we find values of 0.278, 0.546, 0.662 for $H(L\,|\,P)$ for G-Celex, F-Brulex and E-Celex, respectively, while corresponding values for $\gamma = 10$ are 0.351, 0.833, 1.401. Contrarily, $H(P\,|\,L)$, the putatively more indicative measure for transduction from $\mathbf{x}$ to $\mathbf{y}$, has 0.499, 0.417, 0.598 for $\gamma = 0$ and 0.378, 0.401, 1.113 for $\gamma = 10$, so that, except for the E-Celex data, $\gamma = 10$ apparently leads to improved $H(P\,|\,L)$ values in this situation, while $\gamma = 0$ seems to lead to better $H(L\,|\,P)$ values.

In any case, from a model complexity perspective,[6] increasing γ may certainly be beneficial. For example, Table 5 shows that with $\gamma = 0$, Algorithm 1 will select up to 15 different steps for the given choice Ω, most of which seem linguistically questionable. On the contrary, with a large γ, Algorithm 1 employs only four resp. five different steps for the G2P data; most

[6]Taking into model complexity is e.g. in accordance with Occam's razor or Akaike's information criterion.

importantly, among these are $(1,1)$, $(2,1)$ and $(3,1)$, all of which are in accordance with linguistic reasoning as e.g. outlined in Section 5. Thus, we can think of q as a 'regularization term' that prevents the algorithm from 'overfitting' the data.

7.1.2 Colors

We briefly discuss here a possibility to detect latent classes via the concept of colored paths. Assume that a corpus of colored alignments is available and let each color be represented by the contexts (graphones to the left and right) of its members; moreover, define the 'likelihood' L that the pair $p_{x,y} := (x_{\alpha_{i-1}+1}^{\alpha_i}, y_{\beta_{i-1}+1}^{\beta_i})$ is of color c as the (document) similarity (in an information retrieval sense) of $p_{x,y}$'s contexts with color c, which we can e.g. implement via the cosine similarity of the context vectors associated with $p_{x,y}$ and c. For number of colors $C = 2$, we then find, under this specification, the following kinds of alignments when running Algorithms 1 and 2 with $\gamma = 0$ and $\chi = 1$,

a	nn	**u**	al		ph	**o**	n	**e**	me
&	n	**jU**	l		f	**@U**	n	**i**	m

where we use bold font to distinguish the two color classes, and use original E-Celex notation for phonemic characters. It is clear that the algorithm has detected some kind of consonant/vowel distinction on a phonemic level here. We find similar kinds of latent classes for the other G2P data sets, and for the morphology data, the algorithm learns (less interestingly) to detect word endings and starts, under this specification.

7.2 Transductions

We report results of experiments on transducing $\mathbf{x}$ strings to $\mathbf{y}$ strings for the G2P data and the morphology data sets. We exclude E-Celex because training the CRF with our parametrizations (e.g. all features in window size of four) did regularly not terminate, due to the large size of the data set ($> 60{,}000$ string pairs). Likewise for computing resources reasons,[7] we do not use ten-fold cross-validation but, as in (Jiampojamarn et al., 2008), train on the first 9 folds given by the Pascal challenge, testing on the last. Moreover, for the G2P data, we use an ϵ-scattering model with steps $S = \{(1,0),(1,1)\}$ as a predictor model from which to infer the number of parts $\hat{k}$ for decoding and then apply Algorithm 3.[8] For alignments, we use in all cases Algorithms 1 and 2 with $\gamma = 0$ and $\chi = 0$. As reference for the G2P data, we give word accuracy rates as announced by (Bisani and Ney,

[7] E.g. a single run of the CRF on the G-Celex data takes longer than 24 hours on a standard PC.

[8] We train the ϵ-scattering model on data where all multi-character phonemes such as *ks* are merged to a single character, as obtained from the alignments as given by Algorithms 1 and 2.

	CRF-3	CRF-4	CRF-4*	DSE-F	DSE-FL	Mos3	Mos15	M-M+HMM	BN	MeR+A*
F-Brulex		93.7	**94.6**					90.9	93.7	86.7

Table 6: Data sets and word accuracy rates in percent. **DSE-F**: (Dreyer et al., 2008) using 'pure' alignments and features. **DSE-FL**: (Dreyer et al., 2008) using alignments, features and latent classes. **Mos3, Mos15**: Moses system with window sizes of 3 and 15, resp., as reported by (Dreyer et al., 2008). **M-M+HMM**: Many-to-many aligner with HMM and instance-based segmenter for decoding as reported by (Jiampojamarn et al., 2007). **BN**: (Bisani and Ney, 2008) using a machine translation motivated approach to many-to-many alignments. **MeR+A***: Results of Moses system on G2P data as reported by (Rama et al., 2009). **CRF-3** Our approach with window size of 3 and 3-gram scoring model (see Algorithm 3). **CRF-4**: Our approach with window size of 4 and 3-gram scoring model. **CRF-4***: Our approach with window size of 4 and 4-gram scoring model and 2-best lists (i.e. in Algorithm 3, obtain $\hat{\mathbf{y}}_1$ and $\hat{\mathbf{y}}_2$ as the two most probable transductions of s). In bold: Best results (no statistical tests). Underlined: best results using 'pure' alignments.

2008), (Jiampojamarn et al., 2007), and (Rama et al., 2009), who gives the Moses 'baseline' (Koehn et al., 2007).

For the morphology data we use exactly the same training/test data splits as in (Dreyer et al., 2008). Moreover, because (Dreyer et al., 2008) report all results in terms of window sizes of 3, we do likewise for this data. For decoding we do not use a (complex) predictor model here but rely on simple statistics; e.g. we find that for the class 13SIA, k is always in $\{m-2, m-1, m\}$, where m is the length of $\mathbf{x}$, so we apply Algorithm 3 three times and select the best scoring $\hat{\mathbf{y}}$ string. To avoid zeros in the decoding process (see discussion in Section 6.2), we replace the $(0, 2)$ steps used in the rP and 2PKE data sets by a step $(1, 3)$.

Results are shown in Table 6. For the G2P data, our approach always outperforms the best reported results for pipeline approaches (see below), while we are significantly below the results reported by (Dreyer et al., 2008) for the morphology data in two out of four cases. Contrarily, when 'pure' alignments are taken into consideration — (Dreyer et al., 2008) learn very complex latent classes with which to enrich alignments — our results are clearly better throughout. In almost all cases, we significantly beat the Moses 'baseline'.

8 Discussion

We believe our alignment procedure to be superior to the one presented in (Jiampojamarn et al., 2007) (and likewise for the 'machine translation motivated' approach outlined by (Bisani and Ney, 2008)) from a number of perspectives. First, it is more flexible and general in that it allows the specification of arbitrary non-negative steps S and arbitrary similarity measures sim. Moreover, as we have shown, our approach can very easily and conveniently be adapted to incorporate step quality measures, which may turn out to be very useful in detecting the 'right' choice of S (i.e. as a 'regularization term'); and our approach can also easily be generalized to incorporate the modeling of latent classes as e.g. done in (Dreyer et al., 2008), within a polynomial running time framework; further generalizations such as semi-ring specifications (Mohri, 2002) are obvious but not discussed in the current

work (cf. (Eger, 2012b)). Secondly, our algorithm appears very simple and intuitive, while being computationally equivalently tractable and making the same sorts of independence assumptions as in (Jiampojamarn et al., 2007).

As regards decoding, (Jiampojamarn et al., 2007) use a grapheme segmentation module where each grapheme letter can form a chunk with its neighbor or stand alone, a decision that is based on local context and instance-based learning. We hold this approach to be insufficient because (besides the obvious drawback that, as we have shown, larger chunks than two seem appropriate for G2P) it unecessarily restricts the search space for grapheme segmentation; once a decision is made to join two letters, it cannot be reversed and alternative segmentations are not considered. The same holds true for the phrasal decoder approach outlined in (Jiampojamarn et al., 2008), the critique of which is already uttered in (Dreyer et al., 2008), namely, that the input string is segmented into substrings which are transduced *independently* of each other, ignoring context. Contrarily, for decoding $\mathbf{x}$, we compute *all* possible segmentations of $\mathbf{x}$ and score them (in conjunction with the transduced $\hat{\mathbf{y}}$ strings) with higher order n-gram models, which is clearly superior to the named approaches because it takes both context into account and does not restrict search space. Moreover, *given an adequate predictor model*, we found that enumerating all possible restricted integer compositions is so fast that no further investigation of restricting search space is necessary.[9]

While we thus believe our individual components for alignment and decoding to be superior to the mentioned approaches, our modeling of string transductions adheres to a pipeline approach — in (Jiampojamarn et al., 2008)'s words — that, as they suggest, is inferior to a unified framework, as they present it. All our components can be integrated within such a framework, which is scope for future research. In contrast with (Dreyer et al., 2008), we believe our alignments (*per se*) to be more adequate (they use one-to-one and one-to-zero alignments), which the performance measures corroborate, while their idea to enrich alignments with a multitude of latent classes (more complex than representable in our framework) obviously outperforms our method on certain data sets such as those encountered in morphology, where e.g. latent *word* classes may be of great importance.

Conclusion

We have presented a simple and general framework for generating monotone many-to-many alignments that competes with (Jiampojamarn et al., 2007)'s alignment procedure. Moreover, we have discussed crucial independence assumptions and, thus, limitations of this algorithm and shown that exhaustive enumeration (among other methods) can overcome these problems — in particular, due to the relatively small search space — in the field of monotone alignments. Additionally, we have discussed problems of standard alignment quality measures such as conditional entropy and have suggested an alternative decoding procedure for string transduction within the monotone many-to-many alignment framework that addresses the limitations of the procedures suggested by (Jiampojamarn et al., 2007) and (Jiampojamarn et al., 2008). In future work, we intend to explore more extensively, in particular, the effects of appropriate step restriction and regularization upon alignment quality.

[9] We used the algorithm presented in (Updyke, 2010).

ABSTRACT
While there have been many studies on measuring the size of learners' vocabulary or the vocabulary they should learn, there have been few studies on what kind of words learners actually know. Therefore, we investigated theoretically and practically important models for predicting second language learners' vocabulary and propose another model for this vocabulary prediction task. With the current models, the same word difficulty measure is shared by all learners. This is unrealistic because some learners have special interests. A learner interested in music may know special music-related terms regardless of their difficulty. To solve this problem, our model can define a learner-specific word difficulty measure. Our model is also an extension of these current models in the sense that these models are special cases of our model. In a qualitative evaluation, we defined a measure for how learner-specific a word is. Interestingly, the word with the highest learner-specificity was "twitter". Although "twitter" is a difficult English word, some low-ability learners presumably knew this word through the famous micro-blogging service. Our qualitative evaluation successfully extracted such interesting and suggestive examples. Our model achieved an accuracy competitive with the current models.

KEYWORDS: Learner-specificity, vocabulary prediction, Rasch model.

Proceedings of COLING 2012: Technical Papers, pages 799–814,
COLING 2012, Mumbai, December 2012.

1 Introduction

When learning second languages, vocabulary knowledge is as important as, or sometimes more important, than grammar. The importance of vocabulary knowledge has been a main focus in the last decade in the field of second language acquisition (SLA).

Studies regarding vocabulary knowledge of second language learners have been mainly focusing on two major tasks: devising methods for measuring the size of the second language vocabulary of learners for testing purposes (Schmitt et al., 2001; Laufer and Nation, 1999; Nation, 1990) and determining the words that the learners *should* learn (Nation, 2006). However, there have been few studies on what kind of words learners *actually* know. This is the basic research question for our research.

To study what words second language learners actually know, we focused on the *vocabulary prediction* task. In this task, we aim to build a model that predicts, given a word and a learner, whether or not the learner knows the word. As far as we know, Ehara et al. (2010) is the only study that dealt directly with the vocabulary prediction task. They applied this task to a reading support user interface for second language learners that automatically identifies the words unfamiliar to the learner on a Web page.

The vocabulary prediction task is important for both theory and application. From the theoretical point of view, this task is interesting in that it mines the words second language learners know and creates a model on what kinds of words learners actually know. From the model, we can interpret the patterns or tendency of the learners' process of memorizing second language words. Studying the vocabulary prediction task may also lead to determining if learners actually learn words that SLA experts recommend.

From the application point of view, this task can be used in user-adaptation for reading and writing applications to support second language learners. Ehara et al. (2010)'s model is of this type. They successfully showed the effectiveness of their system. With the increase in Web-based language learning environments, possible data sources for learners' vocabulary knowledge are also increasing. Studying the vocabulary prediction task can shed light on these data sources, and they can be used to further understand the vocabulary knowledge of second language learners.

By using machine learning terminology, the vocabulary prediction task can be categorized as a binary classification task: given a word and a learner, it predicts whether or not the learner knows the word. Therefore, a number of machine learning methods, such as a support vector machine (SVM) for the binary classification task, can be used as predictors. However, to answer our research question, what kind of words learners *actually* know, we want predictors to be able to do more than just predict. Rather, we want predictors that are practical and useful for analysis. Specifically, we list the following properties we want predictors to have.

interpretable weight vector Most predictors use weight vectors trained with data. Weight vectors of some models can be interpreted as quantitative measures of word difficulty and learner ability. Interpretable weight vectors are essential for analysis to find the patterns or tendency of learners' process of memorization, and to further understand the basic research question: what kind of words do second language learners actually know?

out-of-sample Settings in the vocabulary prediction task can be divided into two for handling new words: *in-matrix* and *out-of-sample*. The in-matrix setting does NOT support new

words, i.e., there is at least one training dataset for all the words appearing in the test data. This can be seen as filling in the blanks of a learner-word matrix. In contrast, the *out-of-sample* setting support new words, i.e., some or all words in the test data are missing in the training data. To create the training data, we need to ask learners whether or not they know the words. Thus, creation of the training data is very financially costly and burdensome for learners. In a realistic setting, we can ask learners about only a small subset of words, and the predictors usually have to predict all the rest. The out-of-sample setting is more difficult but more realistic than the in-matrix setting.

learner-specific word difficulty This is the core beneficial property of the proposed model. Some interpretable weight vectors can determine word difficulty. However, the perceived difficulty of a word differs from learner to learner. For example, a learner interested in music may know music-related words that even high-level learners may not be familiar with. For another example, suppose that normally difficult words are used in the names of well known commercial products and services. In this case, again, low-ability learners may know these words through the product names. Thus, it is preferable for a model to be able to detect this kind of learner specialty.

	weight vector is interpretable	out-of-sample	learner-specific word difficulty
Rasch	✓	-	-
Ehara et al. (2010)	✓	✓	-
Proposed	✓	✓	✓

Table 1: Properties of models. The proposed model supports all preferred properties. Ordinary binary classifiers only can classify: their weight vectors are not interpretable as *word difficulty* and *learner ability* as those of the other models listed here.

Table 1 summarizes the models explained in this paper. We can see that only the proposed model supports all the properties. Although ordinary binary classifiers, such as SVMs, can be used for the vocabulary prediction task, their weight vectors cannot be used to determine word difficulty and learner ability that we want for analysis. Thus, we ruled out typical binary classifiers.

The structure of this paper is as follows. We first focus on extending the basic interpretable model: the Rasch model (Rasch, 1960; Baker and Kim, 2004). Although the Rasch model lacks many of the preferred properties, it provides a rough idea for the vocabulary prediction task. To explain why the Rasch model lacks many of these properties, we then introduce *the general form* of the likelihood of the Rasch model. This generalization provides a way of supporting the preferred properties. Through this generalization, we can derive the Rasch model, the model proposed by Ehara et al. (2010), and the proposed model.

The contributions of this paper are as follows:

- We introduce the general form of likelihood of the Rasch model that can explain the reason this model lacks the desired properties.
- We propose a model that supports all desired properties using this general form.
- In an evaluation, our model successfully detected the specialties of second language learners, which the current models cannot detect.

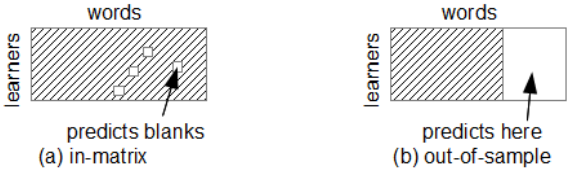

Figure 1: Two problem settings; (a) in-matrix, (b) out-of-sample.

2 Problem setting

Let U be a set of learners, and V be a set of vocabulary. We denote the number of learners as $|U|$ and the number of words as $|V|$. A datum can be expressed using the triplet (y, u, v). Here, $y \in \{0, 1\}$ is the label denoting whether or not learner u knows word v, $(1, u, v)$ means that learner u knows word v, and $(0, u, v)$ means he/she does not know word v. Using these notations, the vocabulary prediction task is defined to predict the label y given (u, v). We denote a dataset of N data as $\mathcal{D} = \{(y_1, u_1, v_1), \ldots, (y_N, u_N, v_N)\}$.

For simplicity, we assume that for one learner $u \in U$ and word $v \in V$ pair, there exists only one label y. This restriction enables us to depict the data set in a matrix form, as shown in Figure 1. The rows of the matrix correspond to learners and the columns of the matrix correspond to words. Under this assumption, for one row (learner) and one column (word), there is only one cell; thus, only one label y. With this restriction, N is the number of cells in the matrix.

The dataset we used in the evaluation agrees with this restriction; however, we cannot always assume this restriction in a realistic setting. This is the reason we did not directly jump to matrix-based prediction methods such as low-rank approximation using singular value decomposition. For example, in a realistic dataset, such as word-click logs in a reading support system, contradiction and repetition are common. For contradiction, if both $(1, u, v)$ and $(0, u, v)$ appear in the dataset, it may mean these two datasets are unreliable. Repetition of multiple $(1, u, v)$ may mean that learner u is more familiar with word v than just one $(1, u, v)$. All the models that we explain in the later sections of this paper can handle these cases.

Figure 1 explains the *in-matrix* and *out-of-sample* settings. The hashed areas denote the training data, and the blank areas denote the test data. In the *in-matrix* setting, the test data are randomly placed in the matrix.

3 Rasch model

Although the vocabulary prediction task is quite novel, there have been a substantial amount of work in SLA about which words a learner *should* learn first. Many studies recommend learners to learn words according to word frequency in general corpora because word frequency can be used as a rough measure of word difficulty. Of course, the learner does not necessarily learn the words in this recommended order. As stated in the introduction, it is one of our research questions to check if learners *actually* learn in this order.

Still, we can come up with the idea that the difficulty of words determines the learners' knowledge of second language words. This idea leads to a very simple model of vocabulary prediction shown in Figure 2. With this model, we predict a learner's vocabulary with the following steps:

1. We rank words according to a measure of word difficulty.
2. We decide the threshold for a learner.
3. Words with greater difficulty than the threshold are predicted to be unfamiliar to the learner, and vice versa.

Although this model seems too simple, it is the core idea of the Rasch model, which has been widely used in language testing.

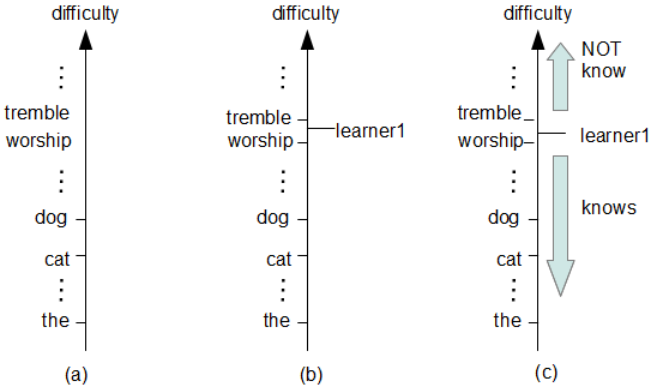

Figure 2: Simple vocabulary prediction model. (a) First, assume there is a difficulty measure that maps each word to a point on the axis of the measure. (b) Second, each learner's ability is also mapped to a point on the same axis. (c) Third, the words with the greatest difficulty to the point designating the learner's ability is predicted to be unfamiliar to the learner, and vice versa.

Given learner u and word v, the Rasch model models the probability of learner u knowing word v as follows:

$$P\left(y=1|u,v\right)=\sigma\left(a_u-d_v\right), \tag{1}$$

where $\sigma\left(t\right)=\left(1+\exp(-t)\right)^{-1}$ denotes the logistic sigmoid function. There are two kinds of parameters to be trained:

d_v the difficulty of word v,
a_u the ability of learner u.

In the Rasch model, the subtraction of two parameters $a_u - d_v$ in Eq. (1) denotes exactly the same mechanism as the simple vocabulary prediction in Figure 2. Here, d_v maps each word v into a point on the axis, and a_u works as a threshold. When $P(y=1|u,v)\geq 0.5$, we can assume learner u knows word v. Due to the logistic sigmoid function, $P(y=1|u,v)\geq 0.5$ holds true if and only if $a_u - d_v \geq 0$, that is, $a_u \geq d_v$. Therefore, the Rasch model determines that learner u knows all words whose word difficulty d_v is lower than the learners' ability a_u. Note that not only the ability of learner a_u but also the difficulty of word d_v is estimated from the data in the Rasch model.

The priors for the parameters are usually set as follows:

$$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0,\eta_a^{-1}\right) \quad (\forall u\in U), \tag{2}$$
$$P\left(d_v|\eta_d\right) = \mathcal{N}\left(0,\eta_d^{-1}\right) \quad (\forall v\in V), \tag{3}$$

where $\mathcal{N}$ denotes the probability distribution function of the normal distribution. Frequently, the hyper parameters η_a and η_d are set as $\eta_a = \eta_d$. If $\eta_a = \eta_d$, the parameters, d_v and a_u of the Rasch model can be obtained using a standard log-linear model solver.

One of the notable problems with the Rasch model is that it does not take into account the *out-of-sample* setting. That is, it cannot predict words that do not appear in the training set. For example, if there is a new word in a document in a reading support system, we need to re-create the training set with the new word for the system to be able to predict that word as well. This restriction makes the application systems using the vocabulary prediction task impractical.

4 General form of likelihood

In the previous section, we stated that the Rasch model does work under the out-of-sample setting, which frequently occurs in a realistic setting. This section attempts to locate the fundamental reason the out-of-sample problem arises by generalizing the likelihood of the Rasch model.

Let us discuss the difficulty parameter d_v of the Rasch model from another perspective. If we define a function as $f(v) = d_v$, we can understand that d_v is a function that takes word v as its argument and returns the difficulty of word v. This means that we do not need to allocate the number of variables $|V|$ to determine the difficulty of a word as the Rasch model does. Instead, all that we need is a function that returns word difficulty for given word v.

We can further extend f to be the form $f(u, v)$: a function that takes learner u and word v as its argument and returns the difficulty of word v for learner u. By using $f(u, v)$, we can generalize the likelihood function of the Rasch model as follows:

$$P\left(y = 1|u, v\right) = \sigma\left(a_u - f\left(u, v\right)\right). \tag{4}$$

The Rasch model is a special version of Eq. (4) where we set $f(u, v) = d_v$. We can see that the fundamental cause of the out-of-sample problem in the Rasch model comes from this poorly designed f. There is a 1-to-1 mapping between parameters and words in this design of f. Therefore, if some words are missing in the training set, parameters arise that are not trained.

Note that Eq. (4) generalizes only the likelihood of the Rasch model. Of course, to fully define a model, we must define priors as well. Moreover, the priors must be designed carefully; otherwise, a model can produce poor results regardless of the design of f.

One may think of extending the learner ability parameter a_u to be a function as well. Of course, we can do this extension in theory. However, unlike word difficulty parameters, little information is practically available for learners. Therefore, it is preferable for a model to require as little information from learners as possible. Since the complex design of f may require much information, we kept the learner ability parameter a_u simple.

4.1 Shared difficulty model

By redesigning f in the general form of likelihood, we can cope with the out-of-sample setting. One way to design f to be able to do this is to set it as $f(u, v) = \mathbf{w}^\top \boldsymbol{\phi}(v)$. Here, $\boldsymbol{\phi} : V \to \mathcal{R}^K$ is a feature function. Given word v, it returns a feature vector for it. Let K be the dimension of the feature space. Typically, frequencies from large corpora can be used as features.

Even if there is a new word in the test data and there are words in the training data that share the same features with the new word, the word difficulty of the new word can be obtained by calculating $\mathbf{w}^\top \phi(v)$. The full form of the likelihood becomes the following.

$$P\left(y=1|u,v;\mathbf{w}\right)=\sigma\left(a_u-\mathbf{w}^\top\phi\left(v\right)\right). \tag{5}$$

Priors for the likelihood Eq. (5) are set as follows. We call this model the shared difficulty model.

$$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0,\eta_a^{-1}\right) \quad (\forall u\in U), \tag{6}$$

$$P\left(\mathbf{w}|\eta_w\right) = \mathcal{N}\left(\mathbf{0},\eta_w^{-1}I\right), \tag{7}$$

where I denotes the $K\times K$-sized identity matrix. If we set $\eta_w=\eta_a$, this model reduces to a simple l2-norm-regularized logistic regression as Ehara et al. (2010) used. However, they did not mention the out-of-sample setting or the general likelihood.

5 Proposed model

One problem in both the Rasch and shared difficulty models is that all learners share a single word difficulty measure. This means that the same ranking of a word is shared by all the learners, e.g., the word "tremble" is more difficult than *worship* according to all the learners. Thus, the Rasch and shared difficulty models cannot take into account a leaner's specialty.

In reality, it is common that even low-ability learners know difficult words with the help of their interests in a specific topic. For example, learners who are interested in music are likely to have a large vocabulary of music-related words in second languages regardless of the difficulty of the words. Modeling this kind of learner specialty is essential in designing user-adaptive supports for second language learners.

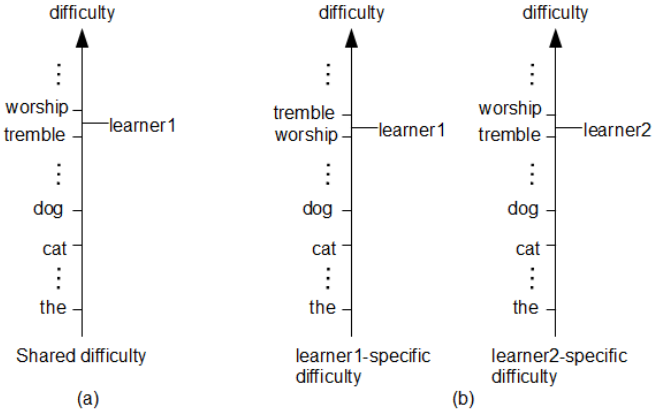

Figure 3: Learner-specific word difficulty.

Figure 3 illustrates the difference between the shared word difficulty and learner-specific word difficulty. On the left side of the difficulty axis, words are plotted according to difficulty. On the

Name	Design of f	Priors	Notes
Rasch	$f(u,v) = d_v$	$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0, \eta_a^{-1}\right)$ $P\left(d_v|\eta_d\right) = \mathcal{N}\left(0, \eta_d^{-1}\right)$	-
Shared difficulty model (Ehara et al., 2010)	$f(u,v) = \mathbf{w}^\top \phi(v)$	$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0, \eta_a^{-1}\right)$ $P\left(\mathbf{w}|\eta_w\right) = \mathcal{N}\left(\mathbf{0}, \eta_w^{-1} I\right)$	Reduced to Rasch model if $\phi(v)$ is 1-dimensional and $\phi(v) = 1$.
Proposed	$f(u,v) = \mathbf{w}_u^\top \phi(v)$	$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0, \eta_a^{-1}\right)$ $P\left(\mathbf{w}_0\right) = \mathcal{N}\left(\mathbf{0}, \eta_w^{-1} I\right)$ $P\left(\mathbf{w}_u|\mathbf{w}_0\right) = \mathcal{N}\left(\mathbf{w}_0, \lambda^{-1} I\right)$	Reduced to the shared difficulty model if we set $\mathbf{w}_u = \mathbf{w_0}$ $(\forall u \in U)$.

Table 2: Summary of models explained so far. The Rasch model is a special case of the shared difficulty model, and the shared difficulty model is a special case of the proposed model.

right side of the axis, learner thresholds are plotted according to the learners' ability parameters a_u. The predictor determines that a learner does not know all the words above his/her threshold. In Figure 3 (a), all three learners share the same word difficulty. Therefore, the model cannot represent a learner who knows the word "worship" but does not know the word "tremble". This problem can be solved by introducing a difficulty axis for every learner as Figure 3 (b) does. In (b), "learner 1" is modeled as knowing the word "worship" but not the word "tremble", while "learner 2" is modeled as knowing the word "tremble" but not the word "worship". This kind of flexible modeling is impossible in the Rasch and shared difficulty models.

With the general model explained above, we can easily explain the fundamental cause of this problem: in the current models, $f(u,v)$ depends only on v, and does not depend on u. Therefore, tackling this problem is simple: let $f(u,v)$ depend on u as well. In the proposed model, we define $f(u,v) = \mathbf{w}_u^\top \phi(v)$. The full form of the likelihood is shown as follows.

$$P\left(y = 1|u, v; \mathbf{w}_u\right) = \sigma\left(a_u - \mathbf{w}_u^\top \phi(v)\right). \tag{8}$$

This likelihood has far more parameters to be trained than the current models. Since the dimension size of the feature space is K, $\mathbf{w}_u$ is a K-dimension vector. Since we have $|U|$ learners, we have $K|U|$ parameters to tune in total. Priors must be carefully designed to tune this large number of parameters. We designed the priors as follows:

$$P\left(a_u|\eta_a\right) = \mathcal{N}\left(0, \eta_a^{-1}\right) \quad (\forall u \in U), \tag{9}$$

$$P\left(\mathbf{w}_0\right) = \mathcal{N}\left(\mathbf{0}, \eta_w^{-1} I\right), \tag{10}$$

$$P\left(\mathbf{w}_u|\mathbf{w}_0\right) = \mathcal{N}\left(\mathbf{w}_0, \lambda^{-1} I\right). \tag{11}$$

Eq. (11) is an important prior that does not appear in the current models. This prior makes $\mathbf{w}_u$ close to $\mathbf{w}_0$ and makes $\mathbf{w}_u$ dependent on each other. The larger the λ, the stronger this effect.

Note that both the shared difficulty model discussed by Ehara et al. (2010) and the Rasch model are actually special cases of the proposed model; we *extended* the Rasch and shared difficulty models into the proposed model. The constraints to reduce the proposed model into these models are summarized in Table 2.

6 Estimation of model parameters

This section describes methods for estimating the model parameters. We use maximum-a-posteriori (MAP) estimation for all three models: Rasch, shared difficulty, and proposed. As we explained, the shared difficulty and Rasch models are special cases of the proposed model. Therefore, we first explain the optimization of the proposed model.

The negative log of the negative log posterior of the proposed model takes the following form:

$$l\left(\mathbf{W},\mathbf{a},\mathbf{w_0}\right) = \sum_{i=1}^{N} nll\left(y_i,u_i,v_i\right) + \frac{\lambda}{2}\sum_{u\in U}\left\|\mathbf{w}_u-\mathbf{w_0}\right\|^2 \quad (12)$$

$$+ \frac{\eta_w}{2}\left\|\mathbf{w}_0\right\|^2 + \frac{\eta_a}{2}\sum_{u\in U} a_u^2 \ . \quad (13)$$

We define the negative log likelihood function of the proposed model as $nll\left(y,u,v\right) \stackrel{\text{def}}{=} \log\left(1+\exp\left(-y\left(a_u-\mathbf{w}_u^\top\phi\left(v\right)\right)\right)\right)$. We define $\mathbf{W}$ and $\mathbf{a}$ as follows for concise notation: $\mathbf{W}=\{\mathbf{w}_u|\forall u\in U\}$, $\mathbf{a}=\{a_u|\forall u\in U\}$. This function $l\left(\mathbf{W},\mathbf{a},\mathbf{w_0}\right)$ is convex (Kajino et al., 2012) over all the variables $\mathbf{W},\mathbf{a},\mathbf{w_0}$. Thus, the MAP model parameters $\hat{\mathbf{W}},\hat{\mathbf{a}}$, and $\hat{\mathbf{w}_0}$ can be estimated by minimizing $l\left(\mathbf{W},\mathbf{a},\mathbf{w_0}\right)$ w.r.t. $\mathbf{W}$, $\mathbf{a}$, and $\mathbf{w}_0$.

Based on Kajino et al. (2012), we minimize $l\left(\mathbf{W},\mathbf{a},\mathbf{w}_0\right)$ iteratively as follows:

minimizing w.r.t. W, a We fix $\mathbf{w}_0$ and minimize $l\left(\mathbf{W},\mathbf{a},\mathbf{w}_0\right)$ w.r.t. $\mathbf{W}$ and $\mathbf{a}$. Kajino et al. (2012) used the Newton method for this optimization. Using the Newton method requires $O(K^2)$ memory, where K is the dimension of $\mathbf{w}_u$ and $\mathbf{w}_0$. This is problematic when K increases. To tackle this problem, we used L-BFGS (Liu and Nocedal, 1989), which requires only $O(K)$ memory, for this optimization instead. Specifically, we used the library liblbfgs (Okazaki, 2007).

minimizing w.r.t. $\mathbf{w}_0$ We fix $\mathbf{W}$ and $\mathbf{a}$ to minimize l w.r.t. $\mathbf{w}_0$. This minimization can be achieved analytically as follows:

$$\mathbf{w}_0 = \frac{\lambda}{\eta_w+|U|\lambda}\sum_{u\in U}\mathbf{w}_u \ . \quad (14)$$

We repeated these two minimizations iteratively until convergence.

Both the Rasch and shared difficulty models are special cases of the proposed model when $\mathbf{w}_u=\mathbf{w_0}$ $(\forall u\in U)$. This means that the second minimization is unnecessary for the Rasch and shared difficulty models. Thus, the parameters, i.e., the weight vector, of the Rasch and shared difficulty models can be obtained by simply performing the first minimization.

7 Evaluation

7.1 Dataset

We used the same dataset as Ehara et al. (2010) used. The dataset was created in Japan in January 2009. Sixteen English as a second language learners participated in the creation of this dataset. Most were graduate students of the University of Tokyo, and Japanese was the native language of most of them.

Corpus name	Type of English	Size (in token)	Description
British National Corpus (BNC) (The BNC Consortium, 2007)	British	100 mil.	General corpus
The Corpus of Contemporary American English (COCA) (Davies, 2011)	American	450 mil.	General corpus
Open American National Corpus (OANC) (Ide and Suderman, 2007)	American	14 mil.	General corpus
Brown corpus (Francis and Kucera, 1979)	American	1 mil.	General corpus
Google 1-gram (Brants and Franz, 2006)	Mixed	1,024,948 mil.	Huge, but not general

Table 3: Feature sources.

This dataset was designed to be quite exhaustive. Every learner was handed a randomly sorted questionnaire comprising 12,000 words and asked to answer how well he/she knew the words in the questionnaire based on a five-point scale. We regarded level 5 as only $y = 1$; the learner knows the word. Otherwise we regarded $y = 0$; the learner does not know the word. Out of the 12,000 words, 1 word was a pseudo-word, i.e., it looks like an English word but actually is not.

Fifteen learners were paid, and 1 learner was not. Since we found that the unpaid learner's data were too noisy, we used only the data of the 15 paid learners. We had $|V| = 11,999$ words $\times$ $|U| = 15$ learners; 179,985 data points in total.

The negative log of the 1-gram probabilities of each word in each corpus is used as features for training. The collected corpora for feature sources are compiled in Table 3. Ehara et al. (2010) used one large corpus, Google-1gram. However, from the perspective of SLA, it is typically not justified because it is not a general corpus; thus, its frequencies could be biased. To avoid being biased, we collected many general corpora and used them as features.

When training, hyper parameters were chosen by grid search and 5-fold cross validation within the training set. The set of hyper parameters that performed best in this cross validation was selected. Then, we trained the model with all the training sets using the selected hyper parameters. We then applied the model to the test set to obtain the results. For the Rasch and shared difficulty models, each hyper parameter, η_d, η_a, and η_w, was chosen by grid search from $\{0.01, 2^{-3}, 2^{-2}, 2^{-1}, 1.0, 2^1, 2^2, 2^4\}$. For the proposed model, each hyper parameter, η_a, η_w, and λ, was chosen by grid search from $\{2^{-2}, 2^{-1}, 1.0, 2^1, 2^2\}$.

7.2 Evaluation of learner-specificity

Unlike the current models, the proposed model was designed to support learner-specific word difficulty. It is interesting to see which words are the most learner-specific.

For a measure of learner-specificity, we introduce the *variance* of learner-specific word difficulty. In the proposed model, the learner-specific difficulty $f(u,v)$ of word v for learner u is defined as $f(u,v) = \mathbf{w}_u^\top \phi(v)$. Unlike the current models that assign single word difficulty for all learners, we can naturally define the variance of word difficulty over learners. Given the set of estimated weight vectors for all $|U|$ learners, $\{\hat{\mathbf{w}}_u \mid u \in U\}$, for word $v \in V$, we define $Mean(v)$ and $Var(v)$ as follows:

$$Mean(v) \stackrel{\text{def}}{=} \frac{1}{|U|}\sum_{u\in U} f(u,v) = \frac{1}{|U|}\sum_{u\in U} \hat{\mathbf{w}}_u^\top \phi(v), \tag{15}$$

$$Var(v) \stackrel{\text{def}}{=} \frac{1}{|U|}\sum_{u\in U} \Big(f(u,v) - Mean(v)\Big)^2 = \frac{1}{|U|}\sum_{u\in U} \Big(\hat{\mathbf{w}}_u^\top \phi(v) - Mean(v)\Big)^2. \tag{16}$$

Table 4 lists the words with largest variances $Var(v)$ in descending order. $Var(v)$ increases when some low-ability learners know the words and some high-ability learners do not. In other words, it increases when low-ability learners know the word for some reason other than the easiness of the word, and vice versa. Table 4 is constructed from the weight vectors of the proposed model. The weight vectors are trained in the in-matrix setting. Out of 179,985 data points, 177,985 were used for training. Features and hyper parameter tuning are explained in §7.1. 2,000 data points were used to check the accuracy, which was 83.40%.

For example, it is very interesting and noteworthy that the word "twitter" comes at the top of the list of Table 4. This is presumably due to the famous micro-blogging service, Twitter. The word "twitter" itself is a rare word. For example, in the British National Corpus, the frequency of the word "twitter" is merely 17 while the word "the" is 6,043,900. The words whose frequency is the same with the word "twitter" are: "abet", "beguile", and "coddle". Since these three words are in the dataset as well, the rareness of words only cannot explain the large variance of the word "twitter". This dataset was created in Japan in January 2009 when Twitter was not as predominant as it is today. Therefore, some low-level learners knew the word "twitter" through the name of the service while some high-level learners did not. Additionally, Table 4 ranks another similar example at the third: "kindle". The first Amazon Kindle was released in the United States in 2007.

Likewise, we annotated presumable reasons $Var(v)$ increased in the rightmost column of Table 4. Although these reasons are speculation, it is difficult to find the correct reason learners know a word, even for learners themselves, because we usually do not remember how we learned foreign words. Our speculations are intuitive and understandable for Japanese-native English as a Second Language (ESL) learners.

Product name The words "twitter" and "kindle" correspond to this case. When a difficult word is used as the name of a famous product, it is possible that even low-ability learners would know the word through the name of the product, which makes the variance larger.

Loanwords in L1 Some words in the second language are borrowed by the learners' native language, or L1, i.e., *loanwords*. However, the spelling of loanwords in L1 can differ from its original. For example, in the case of the word "mantle", the corresponding loanword in Japanese, the native language for most of learners of the dataset used, is spelled as "mantoru". Therefore, the difficulty has little influence on whether or not learners know the word in this case. Rather, whether or not the learner can perceive the loanword in spite of spelling difference has more influence. Thus, even low-ability learners can

$Var(v)$	word	presumed cause of learner-specificity
0.993	twitter	product name
0.886	waltz	topic specific: music, loanword in L1
0.849	kindle	product name
0.833	rink	homophone in L1 with “link”
0.827	launder	loanword in L1
0.825	bass	topic specific: music
0.823	ultraviolet	topic specific: cosmetics
0.818	chime	topic specific: music
0.804	asphalt	loanword in L1
0.802	harry	homophone in L1 with “hurry”
0.793	wooded	-
0.776	mantle	loanword in L1
0.767	trombone	loanword in L1
0.766	modulate	topic specific: computer programming
0.763	homeroom	loanword in L1
0.760	harness	-
0.760	bog	-
0.755	hearth	confused with “health”
0.750	convent	-
0.748	hurdle	loanword in L1
0.733	parson	homophone in L1 with “person”
0.732	vector	loanword in L1
0.731	haven	homophone in L1 with “heaven”
0.719	gadget	loanword in L1
0.714	lizard	-
0.713	smelt	homonym in English: past particle of “smell”
0.709	shin	homophone in L1 with “sin”
0.708	placebo	loanword in L1
0.707	lagoon	-
0.702	aha	-

Table 4: Top 30 words with largest variances $Var(v)$ in descending order. Large $Var(v)$ suggests large learner-specificity. Japanese is the native language (L1) of this dataset.

perceive the meaning of the word through its corresponding loanword in L1, which makes the variance larger.

Homophones in L1 If there are two words that are homophones in the learners' native language, and one of the two words is easier than the other, a low-ability learner may mistake the difficult one for the easy one. For example, a large variance of the word “rink” is caused by low-ability learners' mistake for the word “link” because the Japanese language does not distinguish “l” and “r”. For example, Japanese has no distinction between “par” and “per”, the large variance of the word “parson” is presumably due to some learners mistaking this word for the word “person”.

Topic specific Low-ability learners interested in a topic are likely to know the words of that topic regardless of the words' difficulty.

Homonyms in English "smelt" is a verb that means extracting metals by heat. Yet, it is also the past participle of the word "smell". Although the conjugated forms were removed from this dataset, some low-ability learners presumably did not notice it and thought that they were asked if they knew the word "smelt" as the past participle of the word "smell". Some high-ability learners presumably knew that the word "smelt" has a meaning other than the past participle of "smell" and not asked about "smelt" as the past participle. If they did not know what was the meaning other than the past participle of "smell", they answered no in the dataset.

Note that the variance of the learners' response y for a word in the raw data *cannot* produce an interesting listing as in Table 4 because y is binary, 0 or 1. It trivially lists words of which half the learners in the dataset know. For example, if there are 15 learners in a data set, it is trivial to determine the words with the highest variance of y as those that 8 learners knew and 7 learners did not, or 7 learners knew and 8 learners did not. This means that many words have the highest y variance. In this dataset, $1,408$ of $11,999$ words had the highest y variance. Therefore, y variance does not produce any interesting results.

In contrast to Table 4, the words with smallest $Var(v)$ are trivial. They are words all the learners knew or all the learners did not know. The 30 words with the smallest variances were: am, beach, doll, during, eastern, equal, excellent, green, handwriting, hungry, important, logic, love, luck, marine, paradise, shop, technical, writing, pet, unknown, loose, maker, acquittal, arduous, cot, exchequer, hindsight, innuendo, and purr.

Finally, we investigated the accuracy in the out-of-sample setting. We split the $11,999$ words into $2,000$ words for the test set and the rest for the training set. The size of training data was $149,985$ and the size of test data was $30,000$. Hyper parameter tuning and feature set were the same as we stated in §7.1. The Rasch model achieved 66.32%, the shared difficulty model (Ehara et al., 2010) achieved 77.67%, and the proposed model achieved 77.81%.

8 Related Work

The proposed model is mathematically very similar to those proposed by Evgeniou and Pontil (2004) and Kajino et al. (2012). However, these models are for totally different purposes than ours: Evgeniou and Pontil (2004) aimed at multi-task learning and Kajino et al. (2012) aimed at crowd-sourcing. As the Rasch model is rarely used for these purposes, they did not mention the relationship between the Rasch and proposed models, let alone the generalization of the likelihood of the Rasch model. Strictly speaking, these two models differ from our model in that they do not include the Rasch and shared difficulty models (Ehara et al., 2010) as special cases while our proposed model does.

We extended word difficulty to learner-specific word difficulty by focusing on the analysis of the vocabulary knowledge of adult second language learners. Aside from second languages, study of vocabulary knowledge is also important for the analysis of child development in terms of native language. In computational linguistics, Kireyev and Landauer (2011) proposed an extension of word difficulty called "word maturity" by focusing on the analysis of child development in terms of native language. Their extension was aimed at "track the degree of knowledge of each word at different stages of language learning" using latent semantic analysis. Thus, both their purpose and method of extending word difficulty differ from ours.

While few have studied the vocabulary prediction task, prediction of text readability has been of great focus (François and Fairon, 2012; Feng et al., 2010; Kate et al., 2010) in computational

linguistics. The relationship between vocabulary knowledge and text readability has been thoroughly studied by educational experts (Nation, 2006).

A substantial amount of work has been done by mainly SLA experts in estimating vocabulary *size*. Two major testing approaches have been proposed: *multiple-choice*, (Nation, 1990), and *Yes/No* (Meara and Buxton, 1987). For *Yes/No* tests, Eyckmans (2004) studied the validity and relation to readability prediction.

In the field of psychology, the shared difficulty model (Ehara et al., 2010) is almost mathematically identical to the linear logistic test model (LLTM) (Fischer, 1983). Also, the vocabulary that humans memorize is studied as "mental lexicon" (Amano and Kondo, 1998), although most of the mental-lexicon work is not aimed at predicting vocabulary.

Conclusion

We proposed a model for the vocabulary prediction task. Although there have been few studies on it, it is interesting from both theoretical and practical points of views.

We introduced three preferred properties for predictors for this task: *interpretable weight vector*, *out-of-sample setting*, and *learner-specific word difficulty*. Typical machine-learning classifiers, such as SVMs, lack the first property, interpretable weight vector. Although the Rasch model has this property, it lacks the latter two properties.

To understand why the Rasch model lacks the latter two properties, we introduced the general form of the Rasch model. From this general form, we derived our proposed model, which supports the latter two properties.

In the qualitative evaluation, we wanted to see which words are the most learner-specific. Therefore, we introduced the variance of learner-specific word difficulty and listed the top 30 words with largest variances. The results exhibited social aspects of the learners. For example, "twitter" and "kindle" came first and third, which suggests that some low-ability learners know these words through service and product names, although they are usually difficult English words. Note that this analysis is possible because the proposed model supports the third property, learner-specific difficulty. Since the current models do not support this property, this analysis is impossible with these models. Moreover, the proposed model achieved accuracy competitive with the current models under the out-of-sample setting, which is more realistic than the in-matrix setting.

Future work includes using topic models to determine learners' specialties. We also plan to introduce a sparse prior, such as Laplace prior, instead of Gaussian prior on the user-specific weight vector in Eq. (11) to obtain a more concise model in which the weights specific to each user only deviate from the overall weights.

ABSTRACT
We present a novel approach for jointly disambiguating and clustering known and unknown concepts and entities with Markov Logic. Concept and entity disambiguation is the task of identifying the correct concept or entity in a knowledge base for a single- or multi-word noun (mention) given its context. Concept and entity clustering is the task of clustering mentions so that all mentions in one cluster refer to the same concept or entity. The proposed model (1) is *global*, i.e. a group of mentions in a text is disambiguated in one single step combining various global and local features, and (2) performs disambiguation, unknown concept and entity detection and clustering *jointly*. The disambiguation is performed with respect to Wikipedia. The model is trained once on Wikipedia articles and then applied to and evaluated on different data sets originating from news papers, audio transcripts and internet sources.

KEYWORDS: Word Sense Disambiguation.

Proceedings of COLING 2012: Technical Papers, pages 815–832,
COLING 2012, Mumbai, December 2012.

1 Introduction

Recent advances in knowledge extraction from resources such as Wikipedia have allowed to create various large-scale knowledge bases and concept networks such as Yago (Suchanek et al., 2008), DBpedia (Bizer et al., 2009) or WikiNet (Nastase and Strube, 2012). To exploit the wealth of world knowledge in these resources for natural language processing tasks such as information extraction, text segmentation or summarization, words and phrases in a document first need to be linked to the relevant entries in the respective knowledge base, i.e. to be disambiguated. This problem has been tackled quite successfully by systems such as *WikipediaMiner* (Milne and Witten, 2008), which are mainly based on word sense disambiguation techniques (Agirre and Edmonds, 2006; Navigli, 2009) thus giving research on word sense disambiguation a new spin.

Concept and entity disambiguation is the task of identifying the correct concept or entity in a knowledge base for a single- or multi-word noun (*mention*) given its context.[1] In this paper we disambiguate with respect to the English Wikipedia and consider each article as a concept. One advantage of linking to Wikipedia is that the internal hyperlinks can be used as training data.

Concept disambiguation models the relation between mentions and concepts (Figure 1a). For instance, the system needs to identify if the mention *crocodile* in the first text points to AMERICAN CROCODILES (ANIMAL), to CROCODILE (LOCOMOTIVE) or to the person RENÉ LACOSTE (TENNIS PLAYER) whose nick name is *Crocodile*. We define concept disambiguation as the task of disambiguating both common nouns such as *crocodile* or *biologist* and proper nouns such as FLORIDA or STATES. While the disambiguation of common nouns is usually called *word sense disambiguation* (WSD), the disambiguation of proper nouns is also known as *entity linking*.

Although most of the work in concept disambiguation and WSD assumes that the knowledge base is complete, several studies show that many mentions have no corresponding entry in the English Wikipedia: While Zhou et al. (2010) report that between 10% and 23.5% of the mentions can not be linked to Wikipedia, Lin and Etzioni (2012) report that one third of their mentions have no corresponding entry in Wikipedia. The task of identifying mentions with no corresponding concept in the respective knowledge base is also known as recognition of NILs. In the example in Figure 1 *Aldecoa* does not refer to any entity listed in the knowledge base.

Concept clustering solves the problem of missing concepts in knowledge bases by clustering mentions within and across documents so that mentions in one cluster refer to the same concept. These clustering approaches, also known as *cross-document coreference resolution*, *sense induction* or *unsupervised word sense disambiguation* (Pedersen, 2006), do not link mentions to entries in an existing knowledge base, but cluster mentions as illustrated in Figure 1b.

We integrate the two research lines of disambiguating and clustering concepts and present a novel approach for joint disambiguation and clustering using Markov Logic (ML). Given an already existing knowledge base, mentions are linked to their corresponding entry in this knowledge base, if one exists (Figure 1a). At the same time, mentions are clustered together with other mentions that refer to the same concept, regardless of whether the referred concept exists in the knowledge base or not (Figure 1b). Figure 1c shows the joint view. In contrast most previous approaches (including systems participating at TAC (Ji et al., 2011)) use three cascaded steps: (1) Disambiguation, (2) identification of NILs, (3) clustering of NILs.

The concept selections for the different mentions (e.g. *American crocodile* and *crocodile*) are interrelated. Joint disambiguation and clustering enables us to exploit such connections:

[1] Although we use in the following the term *concepts* instead of *concepts* and *entities*, we always mean both.

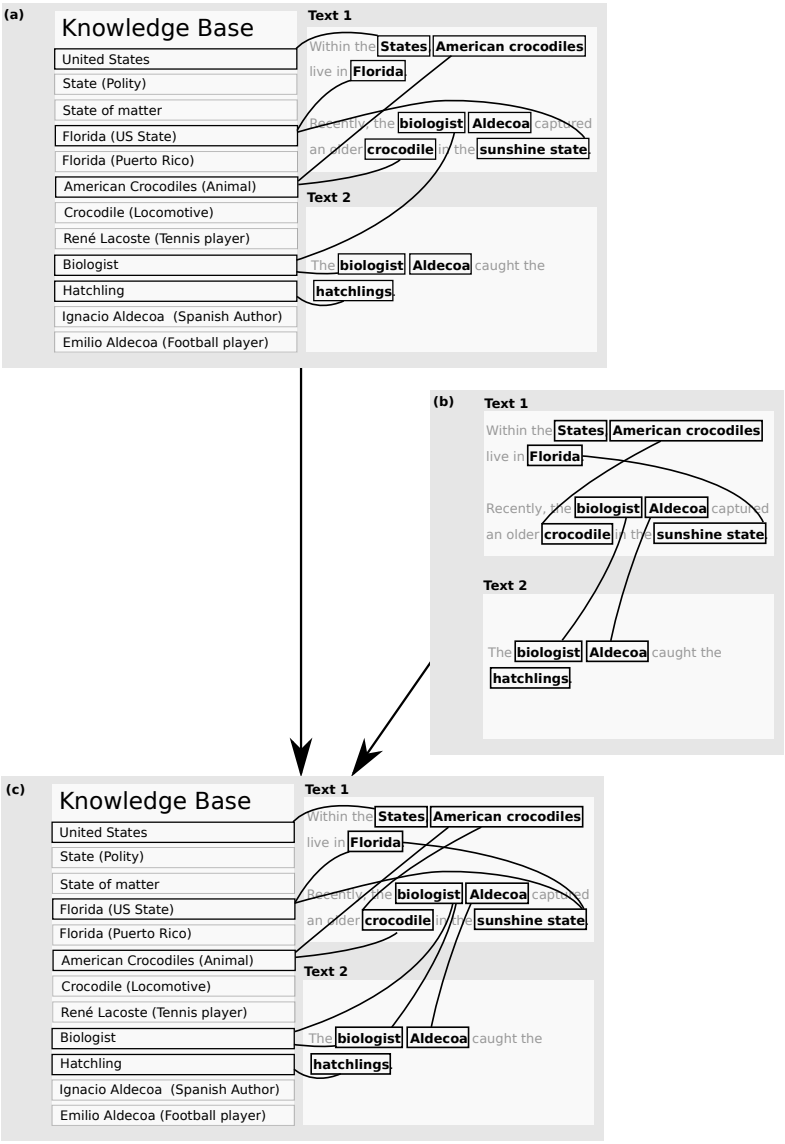

Figure 1: Joint concept disambiguation and clustering

knowledge about which mentions refer to the same concept can support disambiguation decisions. On the other hand, disambiguation influences clustering decisions. In contrast, local approaches which disambiguate mentions independently of each other (Milne and Witten, 2008; Csomai and Mihalcea, 2008) can not take advantage of such relations. Our joint approach disambiguates and clusters groups of mentions at the same time. By using Markov Logic we combine local and global features. Compared to other global models for WSD, e.g. Kulkarni et al. (2009), we do not just consider one single global feature, but combine different global features with local features and learn the weights for their combination.

Our model is trained on Wikipedia only and evaluated on ACE 2005 (annotated by Bentivogli et al. (2010)). Though we are mainly interested in the ACE data, because they provide us with annotations for proper and common nouns, we also evaluate on the TAC 2011 data which are only annotated for named entities. Nevertheless our system performs well compared to the systems participating at the TAC 2011 competition with a much smaller feature set – e.g. McNamee (2010) use 200 features – and without being trained on TAC data specifically.

The paper is organized as follows. Section 2 discusses related work, Section 3 presents our novel approach for joint disambiguation and clustering, and Section 4 presents and analyzes experiments based on ACE 2005 (Bentivogli et al., 2010) and the TAC 2011 data sets.

2 Related Work

In recent years research in monolingual and cross-lingual concept and entity disambiguation has been boosted by shared tasks such as the *Link the Wiki Track* at INEX[2], the *Cross-lingual Link Discovery Task* at NTCIR-9 (Tang et al., 2011) and the *Entity Linking Task* at TAC (McNamee and Dang, 2009; Ji et al., 2010; Ji and Grishman, 2011; Ji et al., 2011).

Dai et al. (2011) is the work that is closest to ours. In order to link gene mentions they perform entity disambiguation and recognition of the NILs at the same time using Markov Logic. In contrast to us they do not cluster mentions, but focus only on one specific type of mentions in a particular domain, namely mentions that refer to genes in a biomedical corpus.

The task of entity disambiguation, recognition of NILs and clustering has been approached in a cascaded way (Ji et al., 2011). Bunescu and Paşca (2006) first decide, if a mention refers to an entity in a knowledge base. Dredze et al. (2010) first disambiguate and then recognize the NILs. NIL recognition is often done by setting a threshold (Han and Sun, 2012). Monahan et al. (2011) interleave entity linking and clustering, but they do not approach the two tasks jointly. After disambiguation they cluster mentions. Then each cluster is assigned an entity in the knowledge base if there exists a corresponding one. Sil et al. (2012) circumvent the NIL problem by an open-database approach instead of disambiguating with respect to only one knowledge base.

Another strand of work that is similar to ours are global disambiguation approaches. While early work often uses local classifiers or rankers that select a concept for each mention independently (Csomai and Mihalcea, 2008; Milne and Witten, 2008; Dredze et al., 2010), recently, various global approaches have been proposed. Kulkarni et al. (2009) propose a method that maximizes local context-concept compatibility and global concept coherence. Fahrni et al. (2011) use a graph-based approach and select the best combination of concepts given the graph structure. Han and Sun (2012) use a generative model integrating topic coherence (one topic per document) and local context compatiblity. Ratinov et al. (2011) describe a two pass method and use

[2]http://www.inex.otago.ac.nz

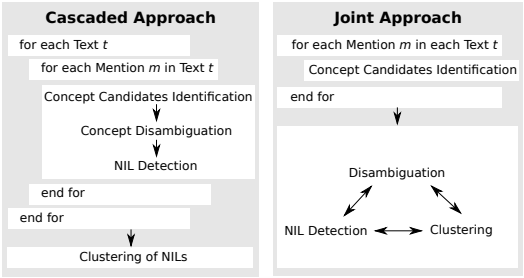

Figure 2: Cascaded approach vs. joint global approach.

the input of the first pass as input for the second one. While all these approaches use a limited number of global features, we integrate and learn the weights for various global features.

While we aim for a general domain disambiguation and clustering system that disambiguates and clusters common and proper nouns, the *Wikify!* (Csomai and Mihalcea, 2008) and *WikipediaMiner* (Milne and Witten, 2008) systems focus on the disambiguation of a few relevant keywords. Chen et al. (2012) only disambiguate person names, while Nothman et al. (2012) perform event linking.

The most prominent research line for sense induction are distributional approaches (Schütze, 1998). Pedersen (2006) gives an overview over state-of-the-art techniques. Recently, the efficency problem caused by the number of necessary comparisons has been addressed (Singh et al., 2011). While Rao et al. (2010) apply streaming clustering, Wick et al. (2012) propose a discriminative hierarchical model and partition entities into trees of latent sub-entities. None of these approaches for clustering also does concept disambiguation at the same time.

3 Approach

Markov Logic enables us to approach the task of disambiguation, recognition of unknown concepts and clustering jointly and to make use of global features. Instead of selecting for each mention – independently from earlier and later decisions – a concept, the concepts for a group of mentions are chosen at the same time.

Figure 2 contrasts the cascaded approach of disambiguation, recognition of unknown concepts and clustering with our joint global approach. As Figure 2 illustrates, first all candidate concepts for all mentions in a document are identified. Then disambiguation, recognition of NILs and clustering is performed using Markov Logic.

3.1 Markov Logic Networks

Markov Logic (ML) combines first-order logic with probabilities (Domingos and Lowd, 2009). A Markov Logic Network (MLN) consists of a set of pairs (F_i, w_i), where F_i is a first-order formula and $w_i \in \mathbb{R}$ is a weight associated with the formula F_i. It builds a template for constructing a Markov Network given a set of constants C. This Markov Network contains a binary node for each possible grounding for each predicate of the Markov Logic Network. If a ground predicate

is true the value of this binary node is 1, otherwise 0. In addition it contains one feature[3] for each ground formula. If a ground formula is true, the feature for this ground formula has the value 1, otherwise 0. The weight of the feature is given by w_i.

The probability distribution in the ground Markov Network is represented by

$$P(X = x) = \frac{1}{Z} \exp\left(\sum_i w_i n_i(x)\right)$$

where $n_i(x)$ is the number of true groundings of F_i in x. The normalization factor Z is the partition function.

To learn the weights for the formulas and to perform MAP inference we use *thebeast*.[4] *thebeast* employs cutting plane inference (Riedel, 2008) and enables us to perform discriminative training using a perceptron.

3.2 Disambiguation and Clustering with Markov Logic

The backbone of our model is the definition of how disambiguation, recognition of NILs and clustering interact. To model these relations we use hard constraints. In the following we will first describe these constraints, before we explain the features in the next section.

Table 1 shows all predicates and formulas used. Each formula is associated with a positive or negative weight. While the weight – except for hard constraints – is learned from training data, the polarity of the weights is set manually. In the following we indicate the direction by the + or − in front of each formula. Formulas with negative weights provide evidence for recognizing NILs. For some formulas the final weight consists of a learned weight w multiplied by a score s (e.g. prior probability). In these cases the final weight for a formula does not just depend on the respective formula, but also on the instantiation, e.g. a specific mention and candidate concept. We indicate such combined weights by the term $w \cdot s$, while w refers to cases where the formula is exclusively weighed by the learned weight. M denotes all mentions and C_m refers to all candidate concepts of a mention m.

Disambiguation and clustering are two different perspectives on the problem of lexical ambiguities. While in concept disambiguation the focus lies on the relation between mentions and concepts, clustering deals with relations between mentions. The tasks of disambiguation and recognition of unknown concepts are interrelated, as both tasks look at mention–concept relations. However, while in concept disambiguation the question is to which concept a mention refers to given its context, the task of recognizing unknown concepts is to determine, if such a concept relation exists for a given mention at all.

To approach disambiguation, recognition and clustering of NILs with ML we define a hidden predicate for each relation we are interested in. The predicate *hasConcept(Mention, Concept)* models the relation between mentions and concepts in the knowledge base (Table 1, p1). To ensure that each mention refers to at most one concept a hard cardinality constraint is defined: for each mention the predicate *hasConcept* is true at most once. This constraint allows us to jointly disambiguate and recognize NILs (Table 1, f1).

[3] Note that *feature* is used differently in this section than in the rest of the paper.
[4] `http://code.google.com/p/thebeast`.

To model if two mentions refer to the same concept, the predicate *hasSameConcept(Mention, Mention)* is used (Table 1, p2). It is true for all mention pairs that refer to the same concept, regardless whether the referred concept exists in the knowledge base or not. This clustering relation is *transitive* and *symmetric* (Table 1, f2, f3).

In order to perform joint disambiguation and clustering it needs to be defined how the mention-concept relation (disambiguation, recognition of NILs) and the clustering relation are interrelated (Table 1, f4, f5). Given that two mentions refer to the same concept in the knowledge base they belong to the same cluster (f5). On the other hand, if two mentions are part of the same cluster and one of them refers to a concept in the knowledge base, the other mention in the cluster has to refer to the same concept (f4). Note, two mentions can also be in the same cluster without referring to a concept in the knowledge base.

3.3 Features

All features have a corresponding predicate which is part of at least one formula. In the following we focus on the features.

3.3.1 Local Features

Local features involve one single mention and its candidate concepts.

Prior probability (p3, f7) The prior probability is defined as the probability that a mention m refers to a concept c. To estimate this probability all internal hyperlinks are extracted from the English Wikipedia dump. For each linked mention (m) it is counted, how many times it links to a particular Wikipedia page ($count_{m,c}$), i.e. concept. This count is normalized by the number of times mention m is linked to Wikipedia pages ($count_m$):

$$p(c|m) = \frac{count_{m,c}}{count_m}$$

Relatedness (p4, f8, f11) This feature reflects the average pairwise relatedness of a candidate concept for a mention to the context and is calculated in the same way as proposed by Milne and Witten (2008). The pairwise relatedness is calculated via

$$rel(c_1, c_2) = \frac{log(max(|C_1|, |C_2|)) - log(|C_1 \cap C_2|)}{log(|W|) - log(min(|C_1|, |C_2|)}$$

where c_1 and c_2 are two concepts, C_1 and C_2 denotes the articles in Wikipedia that link to the articles c_1 and c_2 respectively, and W is the total number of articles in Wikipedia. The more a candidate is related to the context, the more likely it is that a mention refers to it (f8). If a candidate concept for a mention is not at all related to the context, i.e. the average relatedness is zero, this is a negative indicator for a candidate (f11).

Local context similarity (p5, f9) The local context similarity measures how similar the current local context (K_m) – consisting of seven words before and after the mention – is to the local contexts for that concept in Wikipedia. For each mention in the English Wikipedia that is linked to a certain Wikipedia page c we extract the surrounding words (T_c) using the same context definition as above. We then calculate the local context similarity ($sim(c, m)$) for a candidate concept c of a mention m via

$$sim(c,m) = \frac{1}{|K_m|} \sum_{k \in K_m} s(k, T_c)$$

where the first term is used for normalization and $s(k, T_c)$ denotes the frequency of k in T_c divided by the number of times k appears in the context of all concepts in Wikipedia.[5]

String edit distance (p6, f10) This feature accounts for the difference between the mention string used in the text (m) and the preferred name (p) for a candidate concept of m. We assume that the Wikipedia article title and the titles of its redirects are preferred names for a concept (P). To measure the distance between preferred names and the mention in the text we calculate the edit distance[6] ($dist_{m,p}$) and normalize it by the length of the longer string:

$$sim_{m,p} = \frac{dist_{m,p}}{max(|m|, |p|)}$$

If there exists more than one preferred term for a concept, we take the maximum. This feature indicates a negative relation between a candidate concept and a mention. The more distant a preferred name is from a mention, the less likely it is that the mention refers to this concept.

3.3.2 Global Features

In contrast to local features, global features involve more than one mention. From a disambiguation perspective these features define, which mentions are disambiguated jointly.

Shared lemma (p7, f12) The one sense per discourse assumption states that one mention string is used to refer to one sense, i.e. in our case to one concept, in one discourse (Gale et al., 1992). For each document we extract all mentions with the same lemma and the inverse distance in sentences between the two. The bigger the inverse distance is, the closer the two mentions are to each other and the more likely it is that they refer to the same concept.

Head match (p8,f6) The one concept per discourse assumption often applies to mentions that are in a substring relation and share the same syntactic head lemma. We extract all these pairs including the inverse distance between the respective mentions.

Acronyms (p8,f6) In texts, especially in news paper texts, acronyms are often introduced by the following pattern: full name (acronym). We extract all these mention pairs, whereas one mention is the full name and the other one the acronym.[7]

Cross-document n-gram feature (p9,f13) In contrast to the previous features this one is a cross-document feature. The assumption is that we work with a document collection. We extract all mention pairs with the same lemma but coming from two different documents. For each of these mentions we extract all n-grams that include the respective mention and that consist of nouns and adjectives. If the two mentions share at least one of these n-grams, we consider them as referring to the same concept and add as score the number of shared n-grams.

[5] We take its logarithm.

[6] We use the Lingpipe implementation (`http://alias-i.com/lingpipe/`).

[7] In our Wikipedia training data, acronyms are relatively rare. Hence it is difficult to learn a weight for the acronym feature. As it is similar to the head match feature, we use the same predicate and weight for the two features.

Predicates

Hidden predicates	
p1	$hasConcept(m, c)$
p2	$hasSameConcept(m, n)$
Predicates realizing Wikipedia Miner features	
p3	$hasPriorProbability(m, c, s)$
p4	$hasRelatedness(m, c, s)$
Additional predicates involving one mention and one entity	
p5	$hasContextSimilarity(m, c, s)$
p6	$hasStringDistance(m, c, s)$
Predicates involving two mentions (intradocument)	
p7	$isSubStringHeadMatch(m, n, s)$
p8	$haveSameLemma(m, n, s)$
Predicates involving two mentions (cross-document)	
p9	$shareNgram(m, n, s)$

Formulas

Hard constraints			
f1			$\forall m \in M : \lvert\{c \in C : hasConcept(m, c)\}\rvert \leq 1$
f2			$\forall m, n \in M : m \neq n \wedge hasSameConcept(m, n) \rightarrow hasSameConcept(n, m)$
f3			$\forall m, n, l \in M : m \neq n \wedge m \neq l \wedge n \neq l$ $\wedge hasSameConcept(m, n) \wedge hasSameConcept(n, l) \rightarrow hasSameConcept(m, l)$
f4			$\forall m, n \in M : m \neq n \wedge hasSameConcept(m, n) \wedge hasConcept(m, c)$ $\rightarrow hasConcept(n, c)$
f5			$\forall m, n \in M : m \neq n \wedge m \neq n \wedge hasConcept(m, c) \wedge hasConcept(n, c)$ $\rightarrow hasSameConcept(m, n)$
Formulas with learned weights			
f6	$+$	$(w \cdot s)$	$\forall m, n \in M\ \forall c \in C_m : m \neq n \wedge isSubStringHeadMatch(m, n, s)$ $\rightarrow hasConcept(m, c) \wedge hasConcept(n, c)$
f7	$+$	$(w \cdot s)$	$\forall m \in M\ \forall c \in C_m : hasPriorProbability(m, c, s) \rightarrow hasConcept(m, c)$
f8	$+$	$(w \cdot s)$	$\forall m \in M\ \forall c \in C_m : hasRelatedness(m, c, s) \rightarrow hasConcept(m, c)$
f9	$+$	$(w \cdot s)$	$\forall m \in M\ \forall c \in C_m : hasContextSimilarity(m, c, s) \rightarrow hasConcept(m, c)$
f10	$-$	$(w \cdot s)$	$\forall m \in M\ \forall c \in C_m : hasStringDistance(m, c, s) \rightarrow hasConcept(m, c)$
f11	$-$	(w)	$\forall m \in M\ \forall c \in C_m : hasRelatedness(m, c, s) \wedge s = 0 \rightarrow hasConcept(m, c)$
f12	$+$	$(w \cdot s)$	$\forall m, n \in M : m \neq n \wedge hasSameString(m, n, s) \rightarrow hasSameConcept(m, n)$
f13	$+$	$(w \cdot s)$	$\forall m, n \in M : m \neq n \wedge shareNgram(m, n, s) \rightarrow hasSameConcept(m, n)$

Table 1: Predicates and formulas used for disambiguation and clustering (m, n, l represent mentions, M sets of mentions, c concepts and entities, C sets of concepts and entities, and s scores)

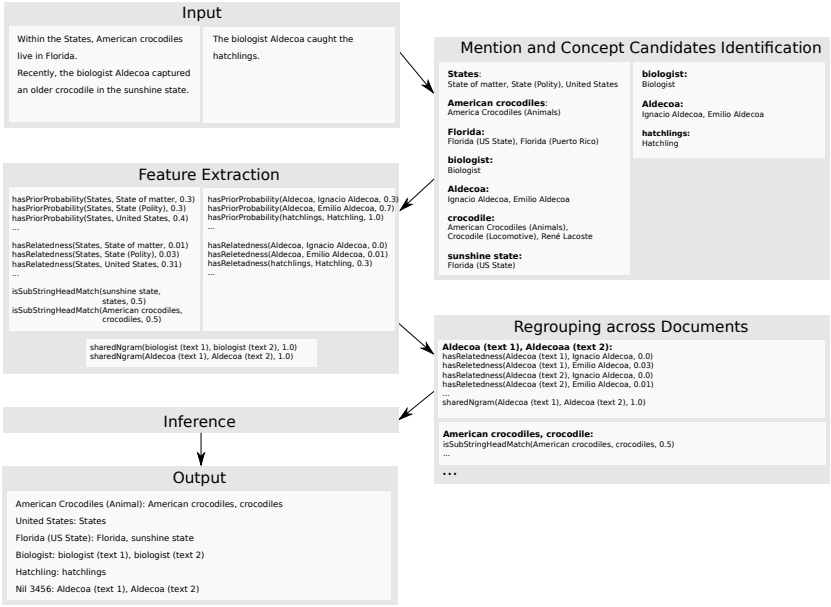

Figure 3: Example for the whole process.

3.4 Illustration of Our Approach

Given several documents – in Figure 3 just two – we first detect mentions in these documents by identifying noun phrases. If a mention is in our lexicon (see Section 4), we obtain all candidate concepts from there. Otherwise we just keep the mention, if it is at most of a length of four tokens and starts and ends with a noun. We keep mentions with no candidate concepts for two reasons: (1) It can happen that during disambiguation and clustering a mention is linked to a concept even if it does not have a candidate concept. (2) As we also want to cluster mentions with no candidate concept, they need to be kept in the network. In the next step we extract all features, we use for disambiguation and clustering (see Section 3.2). As features can cross document boundaries, we then regroup the mentions into pseudo documents, which are given to the inference module. One pseudo document contains all mentions that are linked by global features. The output is shown at the bottom of Figure 3.

4 Experiments

This section describes experiments on two different data sets. All experiments, including the ones for the baseline systems such as *WikipediaMiner*, are based on the same English Wikipedia dump[8], the same lexicon, which includes all anchor texts that occur more than two times with a certain concept (Milne and Witten, 2008),[9] and the same preprocessing. This way we ensure

[8]We use the dump from January 4th, 2012.

[9]We use a query expansion technique and also consider redirects and article titles and retrieve the candidate for the closest anchor.

Dataset	No. of Documents	No. of Mentions	in KB	NILs	Ave. Amb.
WP Training	500	46,810	43,547	3,263	2.18
WP Dev	100	7,197	6,610	587	2.11
ACE 2005	597	29,300	27,184	2,116	5.72
TAC 2011	2162	2250	1124	1126	4.51

Table 2: Datasets: Statistics

that differences in the results are caused exclusively by algorithm and features.

4.1 Data Sets

Disambiguating with respect to Wikipedia has the advantage that training data can be derived from the internal hyperlinks in Wikipedia automatically without manual annotation.

While training and development is done exclusively on Wikipedia (WP Training, WP Dev), we evaluate our approach and compare it to previous work using two data sets containing texts from different sources such as news papers, audio transcription records and the internet (ACE 2005, TAC 2011). Table 2 summarizes some statistics for each data set, namely the number of documents and mentions to disambiguate, the number of mentions with a corresponding concept in the knowledge base (in KB), the number of NILs and the average ambiguity.

4.1.1 Training and Development Data

For training and development we use featured articles from the English Wikipedia data (featured articles are supposed to be of high quality). We randomly select articles among those articles and consider all internal hyperlinks that point to an existing article as an concept-annotated mention. In Wikipedia only the first occurrence of a concept in an article is linked to the respective page. Since our aim is to disambiguate all occurrences we re-wikify the articles: all mentions, that – according to our lexicon – can refer to a linked article, are linked automatically to the respective concept. For training we collect for each annotated mention all candidate concepts from our lexicon. For obtaining NILs we randomly remove some of the concepts from the annotations and the lexicon. The development data set is processed in the same way.

4.1.2 Testing Data

The English part of the *ACE 2005* data set has been manually annotated with links to Wikipedia by Bentivogli et al. (2010). ACE 2005 consists of 597 texts from newswire reports, broadcast news, internet sources and transcribed audio data. Both common and proper nouns that are part of a coreference chain are annotated with one or more links to the English Wikipedia or as NILs. Some of the mentions are annotated with more than one link. We consider a mention as correctly disambiguated, if one of the annotated links is identified.

The English TAC dataset from 2011 consists of 2,250 queries and focuses on named entities such as persons, organizations and locations. A query consists of a query term, i.e. a name for a named entity, and a document, in which the query term appears. The documents are newspaper and web texts. Given our approach we disambiguate the whole document and not just the query terms. In contrast to ACE 2005 the NILs are not just annotated as NILs but also clustered, which allows us to evaluate the entity clustering performance in a direct way and not just its influence on the disambiguation performance as on the ACE data.

4.2 Experiments

4.2.1 Baselines, Other Systems, Upper Bounds

To evaluate our approach we compare it to different baseline systems. For all systems and baselines we cluster the remaining unclustered NILs in a postprocessing step using a string match heuristic, which is a hard-to-beat baseline for this task (Ji et al., 2011). For the upper bound we assume that the clustering is perfect given the disambiguation results.

Upper bound I (UB): The first upper bound shows the performance which can maximally be reached using our lexicon. Each mention is considered as correctly disambiguated, if the correct concept is among the candidates for that mention given our lexicon. If a mention is a NIL according to our gold standard, we also consider it as correct.

Upper bound II (UBD): The second upper bound considers all candidate concepts for all mentions in a document as candidate concepts for a mention. If the correct concept is among these candidates, it is considered as correct. This is the upper bound for our final ML system.

First concept baseline (First concept): In WSD the first sense baseline is known as hard to beat as the distribution of the concepts given a mention obeys Zipf's law. The first concept baseline only makes use of the prior probability of a concept given a mention and always selects the one with the highest prior probability.

WikipediaMiner: WikipediaMiner (Milne and Witten, 2008) is a state-of-the-art system which is freely available. We use version 1.1, extract all the necessary information from the 2012 Wikipedia dump and train it on the same training data that we use to learn the weights for our ML systems.

SVM Rank I (SR I): A common approach for named entity disambiguation is to use a ranker to rank the candidate concepts for each mention and then select the highest ranked concept for each mention. We use SVM^{Rank} (Joachims, 2002) trained on our Wikipedia training data using the same features as for *MLN Dis.* (see below).

SVM Rank II (SR II): This system also uses SVM^{Rank} (Joachims, 2002) and the same features as for *ML Dis.+NILs* (see below).

SVM Rank NIL Classifier II (SRC II): This system uses the *SVM Rank II* system to obtain for each mention the highest ranked concept. Then we apply a classifier to decide for each mention-concept pair, if it is a valid mapping or if the mention is a NIL. We use decision trees as a classifier (Witten and Frank, 2005) and the same features as for *ML Dis.+NILs*.

Other systems: For the TAC 2011 data we also add the best (**Best system**) (Monahan et al., 2011) and median (**Median system**) performance of all participating systems in the English entity linking task at TAC 2011.

4.2.2 Our Systems

ML Dis.: ML system using predicates p1, p3, p4, the local formulas f7, f8 and the global constraint f1. This system uses only information that is also used by WikipediaMiner and do not recognize NILs as no negative information is integrated.

MLN Dis.+NILs: ML system using predicates p1, p3-p6, the local formulas f7-f11 and the global constraint f1. While *ML Dis.* assigns each mention a concept, this system performs concept disambiguation and recognition of NILs jointly.

Table 3: Evaluation on ACE 2005 data

ML Dis.+NILs+Clust.: Joint ML system that performs disambiguation, recognition of NILs and clustering jointly. While we use all predicates and formulas for the TAC data, we do not consider predicate p9, formula f13 on the ACE data.

4.2.3 Results

Table 3 and Table 4 show the results on the *ACE 2005* and *English TAC 2011* data set respectively. We report precision (P), recall (R) and F-measure (F) for the non NILs and the NILs as well as the overall accuracy (Acc), also known as micro-average. In addition we also present the B^3 precision, recall and F-measure for the *TAC data sets* in order to evaluate the entity clustering performance.[10] Significance is calculated for the overall accuracy using a paired t-test.

4.2.4 Discussion of the Results

The full system, which does joint disambiguation, recognition of NILs and clustering (*ML Dis.+NILs+Clust.*), significantly outperforms the other systems in the two tables – except the best performing system at TAC 2011 (*Best system*) – with $p < 0.01$. Bryl et al. (2010) report on the ACE data an F-Measure of 71.5 for non-NILs, but these results are not comparable as they use gold mentions instead of system mentions and consider a mention as correctly disambiguated only if it links to the first mentioned Wikipedia article in the gold standard. Ratinov et al. (2011) – another state-of-the-art system – report an accuracy of 78.8 and a B^3 F-Measure of 76.2 on the TAC 2011 data set (Ratinov and Roth, 2011).

The system *ML Dis.* is close to *WikipediaMiner*. It uses only positive evidence, i.e. the two described *WikipediaMiner* features, and links each mention to a concept in Wikipedia. No NILs are identified. Hence the results for the NILs on the ACE data set are the same as for the first concept baseline (*First Concept*), the ranking systems (*SR I* and *SR II*), which also assign each mention a concept, and *ML Dis.*. On the TAC 2011 data set the results for the NILs differ between the *First Concept* baseline, the ranking systems (*SR I, SR II*) and *ML Dis.*. The difference comes from the fact that the TAC knowledge base is not identifical with the knowledge base we use for disambiguation. If the system links a mention to an entry in our knowledge base, which is not part of the TAC knowledge base, it is considered as NIL. The system *ML Dis.+NILs* performs disambiguation and recognition of NILs jointly. Compared to

[10] We use the offical TAC scoring scripts.

Table 4: Evaluation on TAC 2011

the two step process (*SRC II*), which uses the same features, but performs ranking and the classification of NILs in a cascaded way, the performance of the joint approach (*ML Dis.+NILs*) is higher. As the differences between the systems *ML Dis.+NILs* and *ML Dis.+NILs+Clust.* show, addressing clustering and disambiguation jointly improves the results even further. The improvement mainly comes from two different cases: (1) Mentions with no candidate concepts, which are recognized as NILs in *ML Dis.+NILs* are correctly disambiguated and clustered by *ML Dis.+NILs+Clust*. While for example *ML Dis.+NILs* recognized *Marinello* in "We pretty much know that Marinello, while on the board, has arranged to get future money" as a NIL, *ML Dis.+NILs+Clust.* links it to the correct entry in the knowledge base by also taking into account other occurrences of *Marinello* such as "because the fact that Randy Bauer is already talking about *Beatriz Marinello*". (2) Wrongly disambiguated mentions are – thanks to discourse knowledge – correctly disambiguated. This especially applies to occurrences of common nouns such as *region* or *friends*. Whereas the system *ML Dis.+NILs* wrongly disambiguated *friends* as the TV series, *ML Dis.+NILs+Clust.* correctly links it to the entry on friendship by taking into account other occurrences of *friends* in the text.

5 Conclusions

This paper presents a new approach for joint disambiguation, NIL recognition and clustering using Markov Logic. Our approach significantly outperforms all baseline systems and shows state-of-the-art performance. To our knowledge this is the first approach for joint disambiguation and clustering of concepts and entities. At the moment, we tested on a relatively small data set. For future work, we will work on scalability and on more linguistically informed features.

Acknowledgments. We would like to thank Mathias Niepert for his advice on Markov Logic and *thebeast*. This work has been partially funded by the European Commission through the CoSyne project FP7-ICT-4-248531 and the Klaus Tschira Foundation.

Flexible Structural Analysis of Near-Meet-Semilattices for Typed Unification-based Grammar Design

Rouzbeh FARAHMAND *Gerald PENN*
University of Toronto
{rouzbeh,gpenn}@cs.toronto.edu

Abstract

We present a new method for directly working with typed unification grammars in which type unification is not well-defined. This is often the case, as large-scale HPSG grammars now usually have type systems for which many pairs do not have least upper bounds. Our method yields a unification algorithm that compiles quickly and yet is nearly as fast during parsing as one that requires least upper bounds. The method also provides a natural naming convention for unification results in cases where no user-defined type exists.

Keywords: HPSG, typed feature structures, unification-based grammar.

Proceedings of COLING 2012: Technical Papers, pages 833–848,
COLING 2012, Mumbai, December 2012.

1 Introduction

In Head-driven Phrase Structure Grammars (HPSG, Pollard and Sag, 1994), most of the on-line computation time is spent performing unifications. HPSG type systems are typically large and involve subtyping, so computing a unification involves computing a *join*, the least informative type that is subsumed by both of the argument feature structures' types.[1] Early TFS-based parsing systems like ALE (Carpenter and Penn, 1996) required that every pair of unifiable types have a least common supertype, i.e., joins are uniquely defined wherever they need to be defined. Type hierarchies that have this requirement are called *meet semi-lattices* (MSLs) (Davey and Priestley, 2002), because the existence of a meet for every pair of types is sufficient to guarantee the existence of a join for every unifiable pair of types when the type hierarchy is finite. Later HPSG parsing systems such as the LKB (Copestake and Flickinger, 2000) and PET (Callmeier, 2000) eliminated this restriction, and it is now extremely rare to find a decent-sized HPSG with an MSL type hierarchy. The LKB, at least in some early versions, used an on-line caching algorithm to add joins to the user-defined type system when necessary. PET adds all of the necessary joins in advance, during a grammar compilation stage. In either case, the time it costs to perform these repairs is proportional to the number of new joins that must be added. It therefore makes some sense to strive to add the least number of types necessary.

While modern HPSG type systems are never MSLs in practice, they are always *almost* MSLs, in a sense that can be made mathematically precise, which we do here for the first time. Converting an HPSG type system to an MSL would be horrendously slow if it were not the case that HPSGs were almost MSLs already, because an exponential number of types need to be added in the worst case. There is another cost hidden in this method, furthermore, at least when we strive to add the least number of extra types necessary. In this case, *naming* these types is also a challenge. Figure 1(a), for example, shows an input type hierarchy that is not an MSL. In Figure 1(b), it has been converted into an MSL by adding one extra type. Ideally, we would like to name this type in a manner that reflects its usage in the grammar. Two possibilities that are immediately evident are $e \vee f$ or $a \wedge b \wedge c \wedge d$. Neither of these are ideal because they do not attest to a precise pair of types that the system needed to unify during parsing, and which therefore gave rise to the need for this extra type. This is extremely useful for debugging understanding feature structure outputs with large grammars. Grammar writers instantly know what user-defined types had been combined.

The key to the alternative introduced here is that it actually costs *less* time in practice to compute with a *larger* type system provided that joins are added on-line when necessary. This is achieved by doing a small amount of extra compilation off-line — small in practice again because of a specific mathematical property that practical HPSGs possess - and using the data structure that it creates to add many more types during parsing than the absolute minimum necessary for MSL-hood. In the limit, our method creates a type hierarchy more like a *conjunctive lattice,* but it only adds types as it needs them. Figure 1(c) is what it creates from Figure 1(a). From the standpoint of naming conventions, this type system is ideal, because every added type is named for the set (pair or larger) of types that required it.

[1] Some of the HPSG community draw these subtypes below their supertypes in graphical representations of type hierarchies, but still use the name *join*, even though the correct term is *meet* in this orientation. We will also use the term, *join*, but will depict type hierarchies in the opposite orientation, in which more specific subtypes appear above their more general supertypes.

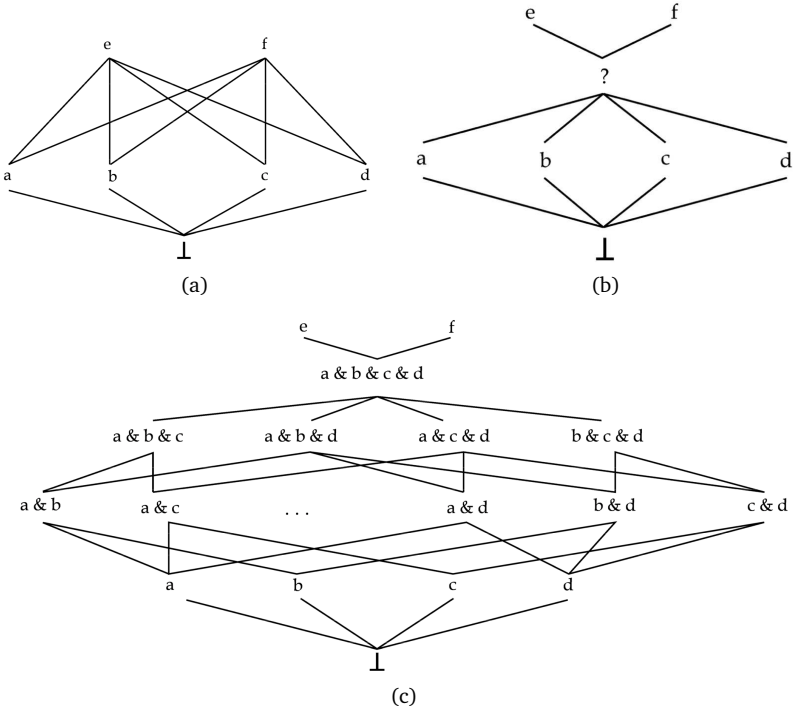

Figure 1: (a) A non-MSL type hierarchy, (b) its MSL completion based on the Dedekind-MacNeille completion, and (c) its conjunctive lattice.

Section 2 discusses the mathematical background necessary to understand the conversion that yields Figure 1(b). Section 3 presents a precise way of appreciating what we mean by a "near-meet-semilattice," through quantifying the size and number of a special kind of subset of types called *prime sets*. Section 4 then introduces another special kind of subset that can be used to efficiently compute the prime sets of a type hierarchy. Section 4.1 describes how joins are computed with the new method, and what the compiler computes to achieve this. Section 6 then presents an evaluation which shows that the new method has nearly the same performance at run-time (5.4% slower) as parsing with precompiled MSLs directly, but without the compile-time cost of the latter. We assert that in the context of grammar design, 5% is worth less compilation time along with the better naming conventions that naturally ensue from this method. Irrespective of compiling and parsing speed, the formal treatment of this subject also provides a more refined theory for analyzing the structure of type hierarchies in large-scale grammars than a binary MSL/non-MSL distinction.

2 Dedekind-MacNeille Completions

Let P be a partially ordered set, and $S \subseteq P$. The set of upper bounds of S, written S^u, is the set of all $x \in P$ such that for all $s \in S, s \leq_P x$. The lower bounds, S^l, are all of the $x \in P$ such that for all $s \in S, x \leq_P s$. The *Dedekind-MacNeille completion* of P ($DM(P)$) is the set of all $A \subseteq P$ such that $A^{ul} = A$. All of the singleton subsets of P are included in $DM(P)$, so informally we can say that P is included in $DM(P)$. $DM(P)$ is the smallest set that both includes P and is an MSL (Davey and Priestley, 2002).

The computer science literature on lattice theory has tended to emphasize $DM(P)$ as either a theoretical device for understanding (but not computing) joins even when they are not present (e.g., Aït-Kaci et al., 1989), or a goal to aim for when adding joins incrementally, each as it becomes necessary (e.g., Bertet et al., 1997). Using $DM(P)$ is supposed to provide us with some sort of reassurance about the maximum amount of extra work that must be performed to embed P into an MSL, at least if the results are pre-compiled or cached. Because $|DM(P)|$ is exponential in $|P|$ in the worst case, however, this does not provide much solace by itself. What matters in the end is the actual amount of overhead accrued for working with a non-MSL type hierarchy. This is true even if $DM(P)$ is not used.

That overhead can be paid either all at once during an initial compilation stage, or in small amounts over time, with the hope that some completion types will never be needed by the user's queries. Obviously, we do not want to compute any completion larger than $DM(P)$ at compile-time if we can help it. The prospect of incrementally computing completion types in a larger lattice is still available, however, as long as the overhead is still acceptable in practice. It is also worth noting that the incremental algorithm of Bertet et al. (1997) includes a line which stops execution for every type that is added and prompts the user to name it. The problem of naming in the Dedekind-MacNeille completion extends well beyond applications to computational linguistics.

3 Prime Sets

What remains then is to find a new source of reassurance about on-line cost that depends upon structural properties of the input type hierarchy rather than upon the size of the worst-case lattice using a given completion strategy. The best structural property of all is for P to be an MSL already. In this case, $DM(P)$ consists only of singleton sets plus possibly a new top-most element (which is usually discarded anyway), and so $|DM(P)| \leq |P| + 1$.

Paradoxically, even if P were not an MSL, finding the upper bound of a set of arguments $S \subseteq P$ in many cases is as easy as combining every type of S in succession, according to some arbitrary linear ordering of its elements. At each step, we compute the join of the current element and a running accumulator type, or fail if they have no upper bounds in common. That is still linear time in $|S|$, even if non-linear in other variables, as is the case when P is an MSL. It is difficult to imagine doing any better in this particular dimension.

The trouble is that this linear-time incremental method does not always work, because of subsets of S (or P) that we will call *prime sets*.[2].

Definition 1. *Let P be a partially ordered set, and $S \subseteq P$. S is an anti-chain iff for all $x, y \in S$, neither $x \leq_P y$ nor $y \leq_P x$.*

[2]These should not be confused with prime ideals or filters nor the prime elements that generate them (see section I-3 of Gierz et al., 2003)

Definition 2. *Let P be a partially ordered set, and $S \subseteq P$. S is a prime set of P iff $|S| > 1$, S is an anti-chain, and, for all non-empty $T \subseteq S$, T has a join iff $|T| = |S|$ or $|T| = 1$.*
Proposition 3. *A partial order is a meet-semi-lattice iff its maximal prime sets are of size 2.*

No non-trivial proper subset of a prime set has a join. When $|S| > 2$ and S is prime, considering pairs of elements in succession will not work for any linear ordering of S. In Figure 2(a), for example, $S = \{a, b, c\}$ is a prime set because it has a join and none of its 2-subsets does. One needs to consider all three at once to see the join.

Candidate sets S of size larger than 2 are important because they naturally result from delaying the computation of joins. A very natural strategy for performing unification in a non-MSL is to use joins where they exist, and the union of the sets of types to be unified otherwise, hoping that the latter will eventually be resolved to a join by the addition of some other element later in the computation. This strategy implicitly uses the conjunctive lattice of P to support its computations, but does not compute it. It is also the strategy that we will adopt. The only thing we need to remember is that we should never refer to a set or subset of types when that set has a join in P that we could refer to instead. That amounts to using the user's names for conjunctions vis-a-vis the subtyping relation where they exist, and explicit conjunctions elsewhere. Operationally, it reduces unification to searching for prime sets and prime subsets.

In a nutshell, the reason that $DM(P)$ can be exponentially larger than P is that the prime sets of P can grow in size linearly with $|P|$, as will be proven in the next section. Better still, tabulating the number of prime sets of each size indicates how "MSL-like" a type hierarchy is. It gives us a spectral view of the basic subsets that every large set decomposes into during unification.

While most large HPSGs are not MSLs in practice, they do not avail themselves of the possibility of having large prime sets either. This is evident in their spectra, and it means that it is relatively inexpensive to enumerate all of the prime sets.

4 Pseudo-prime Sets

A close variant of prime sets turns out to be even more useful:
Definition 4. *$S \subseteq P$ is a pseudo-prime set of P iff $|S| > 1$, S is consistent, and, for all non-empty $T \subseteq S$, T has a join iff $|T| = 1$.*

A pseudo-prime set is as close as a set with no least upper bound can get to being a prime set. The number of pseudo-prime sets is also an upper bound on the potential number of new types added by a completion, because every completion type in $DM(P)$ corresponds to the set of upper bounds of some pseudo-prime set (Penn, 2000, though stated in different terms).

In Figure 2(a), $\{a, b\}, \{a, c\}$ and $\{b, c\}$ are all pseudo-prime sets, for example.

Pseudo-prime sets stand in a very special relationship to prime sets and to each other:
Proposition 5. *Every k-subset of a pseudo-prime set with $k > 1$ is a pseudo-prime set.*
Proposition 6. *Every proper k-subset of a prime set with $k > 1$ is a pseudo-prime set.*

This means that we do not have to search through all $\binom{|P|}{k}$ possible k-subsets of P to find the size-k prime sets of P. Instead, we can merely focus on the size $k-1$ pseudo-primes,

```
Data: A finite poset of types P = ⟨T,⊑⟩
Result: All the pseudo-prime PsPrime(P) and prime sets Prime(P) of P
1  begin
2      init: Prime(P) ← {}, PsPrime(P) ← {} ;
3      forall the consistent types t1,t2 ∈ T do
4          Mins ← FindMinimal({t1,t2}^u);
5          if Mins has only one element then                    // There is a least upper bound
6              Add {t1,t2} to Prime(P) ;
7          else// There is no join
8              Add {t1,t2} to PsPrime(P) ;
9          end
10     end
11     if if there is no set in PsPrime(P) with size 2 then
12         return PsPrime(P) and Prime(P) ;
13     else// P is not an MSL: search for primes and pseudo-primes of size greater than 2
14         size := 2 ;
15         repeat
16             forall the pp1,pp2 ∈ PsPrime(P) do
17                 Cand ← pp1 ∪ pp2;
18                 if |Cand| is size + 1 then
19                     Mins ← FindMinimal(Cand);
20                     if Mins has only one element then
21                         Prime(P) += Cand;
22                     else
23                         PsPrime(P) += Cand;
24                     end
25                 end
26             end
27             size = size + 1;
28         until (there is no pseudo-prime set of size);
29         return PsPrime(P) and Prime(P) ;
30     end
31 end
```

Algorithm 1: Algorithm for finding prime and pseudo-prime sets of a poset.

one of which must live inside every prime set. The size $k-1$ pseudo-primes in turn can be constructed from $k-2$-pseudo-primes, etc., with the 2-pseudo-primes being the pairs of types that attest to the non-MSLhood of P. This recursive search procedure is given in Algorithm 1. Any procedure that enumerates prime sets or pseudo-prime sets is exponential in the worst case, but this algorithm makes efficient use of the relationship between primes and pseudo-primes to achieve efficiency when the largest prime sets are of low cardinality.

Pseudo-primes are also the key to bounding the size of prime sets:

Proposition 7. *The maximum size attainable by a prime subset of a poset P is $\lfloor \frac{|P|-1}{2} \rfloor$.*

Proof. Let Ψ be any prime subset of P. Let $n = |P|$ and $p = |\Psi|$. Consider the p distinct subsets of Ψ of size $p-1$ (i.e. $K_1, ..., K_p \subseteq \Psi$ such that $|K_1| = ... = |K_p| = p-1$). Let $m = |\bigcup_{1 \le i \le p} \mu(K_i)|$ where $\mu(S) = \{x \in S^u \mid \nexists\, u \in S^u \text{ s.t } u \le x\}$, the set of all minimal upper-bounds of S. For all i, $|\mu(K_i)| \ge 2$ because $K_1, ..., K_p$ are all pseudo-prime sets. For the same reason, $|\mu(K_i) \cap \mu(K_j)| \le 1$ when $i \ne j$, because then $K_i \cup K_j = \Psi$. In fact, $\mu(K_1), ..., \mu(K_p)$ are either all pairwise disjoint or all agree on the same one element, so there are only two cases:

Case A: $\bigcap_i \mu(K_i) = \emptyset$ Then P must have at least $p+m$ elements and one extra element for the join of Ψ that must exist above all the m elements in $\bigcup_{1 \le i \le p} \mu(K_i)$. So, (i) $n \ge p+m+1$. Conservatively, we must choose p disjoint antichains of size at least 2 from the m elements, thus we have (ii) $p \le \lfloor \frac{m}{2} \rfloor$. Therefore, from (i) and (ii), if m is even then $n \ge 2p+1$, and if m is odd then $n \ge 3p+2$. Since $2p+1 \le 3p+2 \le n$, then $p \le \frac{n-1}{2}$.

Case B: $\bigcap_i \mu(K_i) \neq \emptyset$. In this case, $n \geq p + m$ and $p \leq m - 1$, subtracting for the one upper bound that all of the K_i have in common. Therefore, $n \geq p + m \geq 2p + 1$ and consequently $p \leq \frac{n-1}{2}$.

□

There are also simple examples in which this bound can be attained, so this is tight.

A spectral decomposition of pseudo-primes is also somewhat interesting because of its relationship to the size of $DM(P)$, and to prime sets — the largest prime set cannot be more than one element larger than the largest pseudo-prime, but in practice it is much less. Figure 3 shows the decompositions for both primes and pseudo-primes for both a 1999 pre-release of the English Resource Grammar (ERG Flickinger, 1999) and Berligram (Müller, 2007). The first thing that we can observe is the very small size of all of the pseudo-primes and primes in both grammars — at most 9 in the ERG, and 6 in Berligram. It took 27 seconds [3] to find all the primes and pseudo-primes in the ERG, and less than 1 second to find them in Berligram. By contrast, it takes the LKB 4 seconds to compute $DM(P)$ for the ERG. We can also see a greater difference between the largest prime and the largest pseudo-prime in the ERG (9-4=5) than we can in Berligram (6-4=2). Pseudo-primes lay the groundwork for primes, so when a prime set nevertheless does not occur, this is significant. Finally, we can observe that, although the ERG is nearly 10 times the size of Berligram in its total number of types, it has about 25 times as many primes of cardinality 3 or greater, and of the same maximum size (4).

A large number of primes, a skewed distribution of primes towards small cardinalities, a large number of pseudo-primes, and a large difference between the size and/or number of pseudo-primes and primes are all strong indicators that a type hierarchy is more MSL-like when interpreted relative to the total number of types. The total number of types is not a good indicator, nor is "join density," which is common to formal concept analysis (Besson et al., 2005).[4] The (relative to P) size of $DM(P)$ is not bad, but it fails to indicate just how far the tails of these distributions extend. A type hierarchy with 10^6 pseudo-primes of size 2 is more MSL-like than one with 10^5 pseudo-primes of size 9, and simple counts of $|DM(P)|$ often cannot tell the difference, especially with high join densities.

One conclusion to draw from this particular comparison is obviously that the ERG is more MSL-like, which implies that it is more conservative in its structure, and would be easier to compute with than many other potential 3414-type hierarchies. On the other hand, the sheer number of types may make finding the right part of the type hierarchy to modify more difficult than it needed to have been. Another way to look at it is that Berligram makes more efficient use of the amount of information that a 434-type hierarchy can carry. There is more information embedded in its structure relative to its size, but that information may make it more difficult to predict the consequences of type unification than in some other hierarchies of its size. The ERG and Berligram do not have the same number of types, nor

[3] All the timing results reported in this paper were obtained on an Intel®-based system with a 3.6 GHz Xeon™ processor and 3 GB of RAM running the Ubuntu 6.06.2 Linux operating system.

[4] Join density, in terms of our partial orders, is calculated as the ratio of the size of the extension of the (transitively and reflexively closed) subtype relation to the square of $|P|$. The join density of the ERG is .001; that of Berligram is .006.

do they attempt to account for the same constructions, nor even the same language, so we can only speculate here. But prime sets and pseudo-primes can illuminate these issues.

4.1 Building an Automaton-based Index

The final application of prime and pseudo-prime sets considered here is to unification itself. As mentioned above, it is possible to maintain argument sets of types from a non-MSL as argument sets even after unification, provided that all of the prime subsets are replaced with their joins. For the unifier not to perform this replacement is tantamount to it simply handing back a candidate pair of types from an MSL ununified.

If we use topologically sorted lists (as induced by the subtype relation) as our representations of prime sets, pseudo-prime sets and argument sets, then Propositions 5 and 6 will allow us to use a simple automaton-based index to perform this replacement. The index has a linear number of states relative to the number and size of the pseudo-primes, because each state corresponds to a prefix of one or more pseudo-primes in topological order. It has two kinds of edges: *suffix edges* and *redex edges*, and both kinds of edges are labelled with elements of pseudo-prime or prime sets.

All of the pseudo-prime sets can be arranged into a tree such that every path through the tree from the root to any node corresponds to a pseudo-prime or a singleton set. Paths from the root to a leaf correspond to maximal pseudo-primes — no pseudo-prime contains them. These trees are connected with suffix edges, each of which is labelled with the k^{th} element that extends a $k-1$-length prefix of one or more pseudo-primes to a k-length prefix. On top of this skeleton, we add the redex edges, which map a pseudo-prime prefix, X, that contains a $k-1$-length prefix of a size-k prime set to the result of replacing that prime set within X by its join, transitively closed under all possible further replacements. The redex edge is labelled with the k^{th} element that completes the prime set.

The index for Figure 2(a), for example, is shown in Figure 2(b). Its pseudo-prime sets are: $\{\{a,b\}_{12}, \{a,c\}_{13}, \{a,z\}_{14}, \{b,z\}_{15}, \{b,c\}_{16}, \{d,z\}_{17}, \{c,z\}_{18}, \{g,z\}_{19}, \{f,z\}_{20}, \{e,z\}_{21}, \{h,z\}_{22}, \{a,b,z\}_{23}, \{a,c,z\}_{24}, \{b,c,z\}_{25}$; and its prime sets are: $\{a,f\}$, $\{b,g\}$, $\{d,c\}$, $\{d,g\}$, $\{d,f\}$, $\{d,e\}$, $\{g,f\}$, $\{g,e\}$, $\{f,e\}$, $\{a,b,c\}$.[5] Suppose $\{a,b,c,z\}$ is of interest. The automaton consumes a and b, which is a pseudo-prime (12) and the prefix of the pseudo-prime, $\{a,b,z\}_{23}$, but upon seeing c traverses a redex edge that reduces the prime set $\{a,b,c\}$ to its join, e, which is a singleton and therefore not subject to further replacement. Consuming z next leads to the pseudo-prime, $\{e,z\}_{21}$. So if the union of the argument sets provided to the unifier is $\{a,b,c,z\}$, what the unifier should return is $\{e,z\}$, which should be interpreted as the conjunctive type, $e\&z$. This is as close to the grammar writer's idioms as we can come in describing this result, given that the type hierarchy is not an MSL.

Having constructed the automaton directly from the pseudo-prime and prime sets, it can then be pruned by eliminating states that correspond to singletons with no outgoing suffix edges and no outgoing or incoming redex edges. Singleton sets clearly do not need to be fed to the automaton. In the example in Figure 2(b), states 9, 10 and 11 would be pruned.

Some statistics for the automata constructed for the ERG and Berligram are presented in

[5] These sets are sorted according to the following topological order (subscripts are topological ordinals): $\bot_0 < a_1 < b_2 < d_3 < c_4 < g_5 < f_6 < e_7 < h_8 < z_9 < y_{10} < x_{11}$.

Table 1. Our implementation of the automaton compiler has been written in Prolog and

	Before pruning		After pruning	
	ERG	Berligram	ERG	Berligram
# of suffix edges	9508	1425	7058	1205
# of redex edges	2296	554	2296	554
Total # of edges	11804	1979	9354	1759
Total # of states	8967	1314	6517	1094

Table 1: Statistics related to the constructed automaton-based index for type hierarchies of the ERG (Flickinger, 1999) and Berligram (Müller, 2007).

generates the automaton as Prolog clauses, too, which are then also compiled. The two stages of compilation together consumed 30 milliseconds for Berligram and 2.2 seconds for the ERG, which is well within the range of compilers that add joins on-line. Further speed improvements are doubtlessly possible, since the automaton can in principle be constructed incrementally as Algorithm 1 is being executed.

5 Unification

Having constructed the automaton directly from pseudo-prime and prime sets, we are implicitly assuming that every input set to the automaton is an anti-chain. The algorithm for unification, given as Algorithm 2, shows how the result should look.

Data: $P = \langle T, \sqsubseteq_P \rangle$;
two sets of types $A, B \subseteq T$;
the automaton-based index $\mathscr{M}_P$;
ψ: the topology of P used for construction of $\mathscr{M}_P$;
Result: minimal upper bound of A and B or failure

```
1 begin
2     Feed ← AntiChainReduce(P, ψ ,A∪B);
3     if Feed has only one element then
4         return Feed;
5     else
6         AutResult ← Aut(start state of M_P , Feed);
7         return AutResult;
8     end
9 end
```

Algorithm 2: The algorithm for unification of two sets of types.

`AntiChainReduce` reduces an input argument set to the topologically sorted, maximally specific anti-chain that contains it. This can be accomplished in quadratic time as a function of the size of the input set, simply by considering every pair of types and replacing the pair with the higher of the two if they are ordered.

6 Parsing Evaluation

To evaluate how this unification algorithm performs in practice, we evaluated three systems on a common grammar and corpus of sentences. The grammar was the ERG, and the corpus, called the FUSE corpus, has 2354 sentences, ranging from 1 to 50 words in length, 192 of which are ungrammatical according to the ERG. All three of the systems that we

tested had memory allocation problems while parsing this corpus, so every sentence that resulted in at least one system running out of memory was excluded, leaving a remainder of 1727 sentences, 159 of which were ungrammatical.[6] We also imposed a maximum of 8000 chart edges after which parsing was terminated. The excluded sentences were those that exceeded the memory available to one of the processes with that cap in place. The three systems were:

(1) ALE version 4.0 beta, running on the Dedekind-MacNeille completion of an ALE port of a 1999 pre-release version of the ERG, with 45 rules, 155 features, 1314 lexical entries, no lexical rules and 3412 types, plus a most general type, $\bot$, plus a built-in type for strings. $DM(P)$ added another 893 types to the system. We compiled ALE with SICStus Prolog 3.12.10 (compact code). [7]

(2) the LKB, version as at March, 2009: This system allows non-MSL grammars as input, but it automatically computes the Dedekind-MacNeille completion on their type systems at compile-time, naming newly added types with a number. The 1999 pre-release of the ERG no longer runs on the LKB because of non-backwards-compatible changes in the system over the last 10 years. Porting an LKB grammar to ALE is very tricky because the LKB's input syntax is very heavily overloaded. So instead of porting the current ERG to ALE, we reported our existing port of the 1999 pre-release of the ERG back to this version of the LKB. We have verified that these two ports generate exactly the same edges on the non-excluded sentences of this corpus. We compiled the LKB with Allegro Common Lisp Enterprise 8.0.

(3) an experimental system, obtained by replacing ALE 4.0's type unifier with the one described in this paper. This system generates the same object code as ALE 4.0 when the input grammar's type system is an MSL. We ran this on the 1999 pre-release of the ERG without computing the Dedekind-MacNeille completion, which thus results in different object code.

The results are shown in Figure 6. These are log-linear graphs, so the roughly even separations attest to a nearly constant factor of speed-up, not a constant difference in milliseconds. The LKB is approximately 1.82 times slower than ALE 4.0, and the experimental version implemented for this study is approximately 1.054 times slower than ALE 4.0. Thus the experimental system produces a run-time parser that is 5.4% slower than ALE after having compiled out the Dedekind-MacNeille completion in advance, but is still more than 40% faster than the LKB, a commonly used system that caches them on-line.

The figure of 5.4% obtains with an experimental system that does not cache the results of prime-set reduction on previously seen argument sets. Caching is best implemented by caching not only previously seen argument sets that are consistent, but also previously seen argument sets that are inconsistent. As shown in Figure 6(d), however, the difference is not large. In the latter case, one obtains a system that is an average of 5.7% slower than parsing with precompiled MSLs on a first pass of parsing, but only 2.7% slower on a second pass through the same corpus of sentences (for which all of the cache entries are in place). We used the built-in SICStus `term_hash/2` predicate to hash argument sets, which gave us a perfect hash (one set per hash). Here again, a comparison with the LKB is informative in that argument set caching behaves surprisingly like the LKB's lexicon caching: while we

[6] The test sentences and results are available at `http://www.cs.toronto.edu/~rouzbeh/resources.html`.
[7] The MSL-ERG in ALE syntax is available at `http://www.cs.toronto.edu/~rouzbeh/resources.html`.

might naturally expect to see a steady stream of new words throughout the parsing of a corpus of this size, we also see a steady stream of new argument sets, even though the number of types and their relative ordering are held constant throughout the experimental parsing runs. As a result, it would take a much larger sample to witness a convergence of the second pass with the first. This suggests that argument set caching is only worthwhile over much longer timespans of use with the same type system.

7 Conclusion

We introduced two new mathematical constructions, prime sets and pseudo-prime sets, and showed that they provide a reasonable alternative to the Dedekind-MacNeille completion, by providing a means for manipulating conjunctive sets of types at very low overhead. These sets provide better naming conventions for newly added types than any implementation based on Dedekind-MacNeille could hope to do because they effectively allow for a trace of partial unifications of a set of arguments. Prime and pseudo-prime sets also form the basis of a more refined method for analyzing the upper bounds of a type system than simply calling it an MSL or non-MSL. This is of independent value to grammar designers.

We have not yet looked at the frequency distributions of primes and pseudo-primes encountered during parsing with the ERG over the FUSE corpus, for example. Both our compilation strategy and the spectral decomposition method would benefit from taking this information into account, because some portions of a completed lattice are clearly more important than others, simply as a result of certain types being used more often in parsing representative corpus input than others.

Some additional work on the combinatorial properties of prime and pseudo-prime sets also remains. Although we have identified a tight upper bound on the possible sizes of prime sets, the only known bounds on the numeracy of prime and pseudo-prime sets are based on the classical problem (the so-called *Dedekind Problem*), of finding the number of anti-chains of a given poset. The field had settled on a fairly stable bound until recently (Korshunov and Shmulevich, 2000).

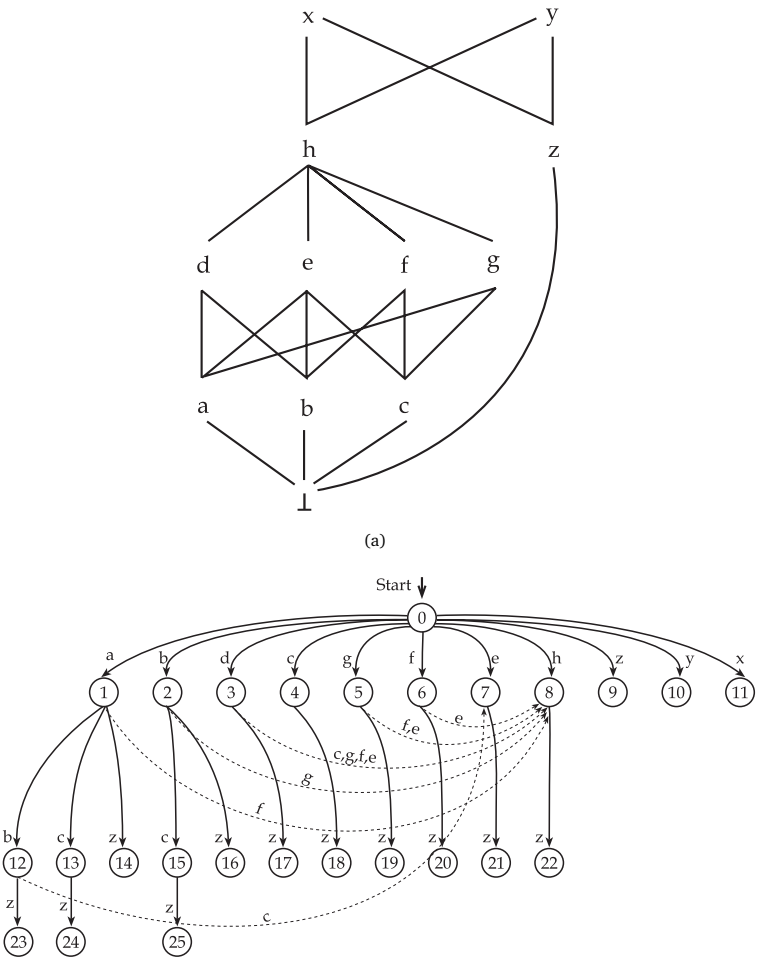

Figure 2: (a) A non-MSL type hierarchy and (b) its automaton-based index). The redex edges are depicted as dotted arcs; if those eliminated from the automaton, a suffix tree is obtained.

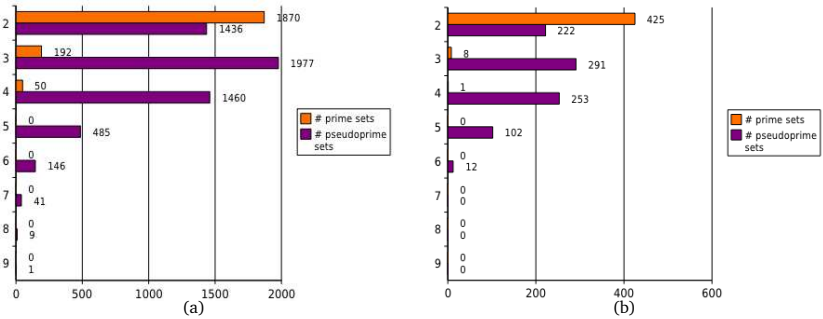

Figure 3: Number and size of the prime and pseudo-prime sets of (a) the English Resource Grammar (3412 types in total), and (b) the German Berligram (434 types). The horizontal and vertical axes show the number and size of the sets, respectively.

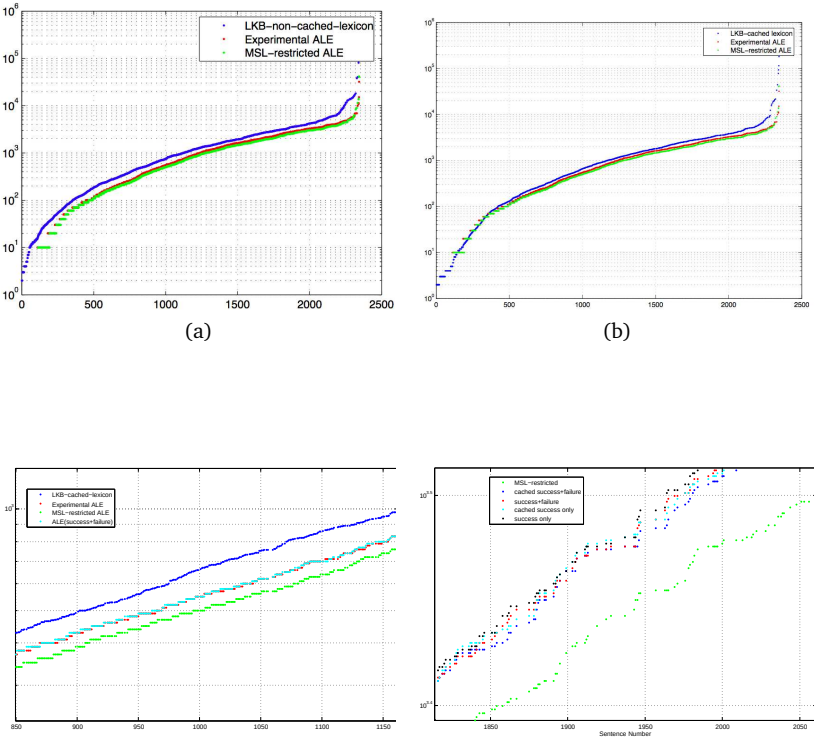

Figure 4: Evaluation of the `MSL-restricted ALE`, `Experimental ALE` and the LKB on FUSE. The LKB caches the lexicon as it parses, so each sentence was parsed twice in succession. The parsing time of the first parse is given in (a) and that of the second in (b). Figure (c) is a close-up of a portion of Figure (b), along with Experimental ALE plus caching of consistent and inconsistent argument sets (first pass). Figure (d) shows the effect of caching in close-up detail.

Stacking of Dependency and Phrase Structure Parsers

Richárd Farkas and Bernd Bohnet
Institute for Natural Language Processing
University of Stuttgart
{farkas,bohnetbd}@ims.uni-stuttgart.de

ABSTRACT
We investigate the stacking of dependency and phrase structure parsers, i.e. we define features from the output of a phrase structure parser for a dependency parser and vice versa. Our features are based on the original form of the external parses and we also compare this approach to converting phrase structures to dependencies then applying standard stacking on the converted output. The proposed method provides high accuracy gains for both phrase structure and dependency parsing. With the features derived from the phrase structures, we achieved a gain of 0.89 percentage points over a state-of-the-art parser and reach 93.95 UAS, which is the highest reported accuracy score on dependency parsing of the Penn Treebank. The phrase structure parser obtains 91.72 F-score with the features derived from the dependency trees, and this is also competitive with the best reported PARSEVAL scores for the Penn Treebank.

KEYWORDS: parsing, stacking, dependency parsing, phrase structure parsing.

Proceedings of COLING 2012: Technical Papers, pages 849–866,
COLING 2012, Mumbai, December 2012.

1 Introduction

Both phrase structure and dependency parsers have developed considerably in the last decade, cf. (Nivre et al., 2004; McDonald et al., 2005b; Charniak and Johnson, 2005; Huang, 2008). The development has taken rather different directions as phrase structure parsers and dependency parsers employ different techniques to parse sentences. Phrase structure parsers usually apply probabilistic context free grammars and focus on the relationships among phrases. Dependency parsers use edge factored models for parsing that primarily model the interaction between the a head word and a dependent word. Second order graph-based parsers consider in addition for the decision on a dependency edge the interaction with siblings and grandchildren. Phrase structure and dependency parsers have both shown to be efficient and to provide accurate parsing results. Different parsing approaches have different strengths on distinct linguistic constructions, cf. (Nivre and McDonald, 2008).

In this paper, we exploit the difference of the representations of dependency and phrase structure parses and the divergence in the parsing techniques. We use features derived from the 1-best automatic phrase structure parse to augment the feature set of the dependency parser and vice versa. This way of combining parsers proved to be effective and provides a substantial accuracy gain for both parsing approaches.

Our ultimate objective is to advance one parser by a second one. This motivation is different from previous approaches for combining phrase-structure and dependency parsers (cf. (Klein and Manning, 2003; Carreras et al., 2008; Rush et al., 2010)) which aimed to achieve a joint optimum of the two approaches. Our proposal has three advantages over previous work. (i) Our approach is simple to implement by defining new feature templates, yet very effective. (ii) It does not require a joint representation of different parse structures. (iii) The participating dependency and phrase-structure parsers can be easily replaced, and each can be developed and optimized independently.

In our experiments both parsers utilize the same (training) data set – having two different representations – without having access to external information. Thus, our results indicate that state-of-the-art parsers can be still further improved without additional data and that there may be approaches that reach even higher accuracy levels in a single pass. At the dependency parser framework, we also investigated whether our approach retains its added value over other extensions and we answer the research questions: Is there a significant improvement still possible with two stacked dependency parsers? What is the impact on top of the results which utilize external information?

We also describe the findings of a manual contribution analysis of the second parser. This discussion identifies linguistic constructions which are responsible for the improvements and it brings up ideas how the parser approaches themselves can be improved.

The contributions of this paper are as follows:

- We propose the stacking of dependency and phrase-structure parsers.
- We report outstanding scores on the Penn Treebank and on the German Tiger Treebank for stacking a phrase structure parser on and a dependency parser and vice versa. The added value of the approach in the dependency parsing environment is still considerable in the presence of other extensions.
- We give explanations why the proposed stacking approach works.

2 Related Work

A number of studies have addressed feature-rich dependency and phrase structure parsing, cf. (Nivre et al., 2004; McDonald et al., 2005b; Charniak and Johnson, 2005; Huang, 2008).

The two main approaches to **dependency parsing** are transition-based dependency parsing (Yamada and Matsumoto, 2003; Nivre, 2003; Titov and Henderson, 2007), and graph-based dependency parsing (Eisner, 1996; McDonald et al., 2005a; Carreras, 2007; Rush et al., 2010).

The most successful supervised **phrase structure parsers** are feature-rich discriminative parsers which heavily depend on an underlying PCFG (Charniak and Johnson, 2005; Huang, 2008). These approaches consist of two stages. At the first stage they apply a PCFG to extract possible parses, then at the second stage select the best parse from the set of possible parses (i.e. rerank this set) employing a large feature set (Collins, 2000; Charniak and Johnson, 2005).

There is little related work on **combining the two approaches**. Some generative parsing approaches have exploited the differences between phrase structure and dependency parsers. For instance, Klein and Manning (2003) introduced an approach where the objective function is the product of the probabilities of a generative phrase structure and a dependency parser. Model 1 of Collins (2003) is based on the dependencies between pairs of head words. On the other hand, the related work on this topic for discriminative parsing is sparse, and we are only aware of the following works. Carreras et al. (2008) and Rush et al. (2010) introduced frameworks for joint learning of phrase and dependency structures, and showed improvements on both tasks for English. These frameworks require special formulation of – one or both – parsing approaches while our approach allows the usage of arbitrary dependency parsers and any feature-based phrase structure parser.

Our motivation differs from these solutions as we focus on advancing one approach rather than achieving a joint optimum. Our approach can be regarded as a special stacking procedure (Nivre and McDonald, 2008), specifically, the stacking of a phrase structure parser with a dependency parser. In our previous work (Farkas et al., 2011), we reported results with a stacking approach for phrase structure parsing evaluated on a German corpus. We focus herein on the reverse direction as well, i.e. we define features for dependency parsers, we report performance outstanding scores on English for both directions, compare to the state-of-the-art results and carried out a detailed analysis of the stacking's contributions.

Wang and Zong (2010) introduced a procedure that exploits dependency parses to improve a phrase structure parser. They used automatic dependency parses for pruning the chart of a phrase structure parser and reported a significant improvement. One of our feature templates for the phrase structure parser can be regarded as a generalization of this approach.

3 Dependency Parser Exploiting Phrase Structure Parses

In this study we focus on graph-based parsers, however, our features from the phrase structures can also be adapted to a transition-based parser. **Graph-based dependency parsers** decompose the dependency structure into *factors*. Each factor of the first order graph-based parser corresponds to a dependency edge. McDonald et al. (2005a) first used second order factors which incorporates siblings of the head and dependent.

The second order algorithm of Carreras (2007) uses three second order factors: the sibling, the leftmost and rightmost grandchildren. The edge labeling is an integral part of the algorithm, which requires an additional loop over the labels. This algorithm has a complexity of $O(n^4L)$.

Koo and Collins (2010) presented a parser that can evaluate factors of three edges.

In this paper, we utilize the state-of-the-art parser of Bohnet (2010), a graph-based parser which employs online training with a perceptron which employs the MIRA update (Crammer and Singer, 2003). The parser contains a feature function for the first order factor, one for the sibling factor, and one for the grandchildren. We integrated in each of the functions features representing information on the phrase structure.

3.1 Features Defined on Phrase Structure Parses

We explore new feature templates to include features from the phrase structures. These templates are defined on the phrase structures themselves which is an important difference compared to previous work on joint parsing. Joint parsing requires a joint representation of phrase and dependency structures and is traditionally carried out by – explicitly or implicitly – converting the phrase structures into bilexical dependencies. For a comparative analysis of these two approaches please refer Section 6.3. Here we introduce our feature template utilizing the original phrase structures.

The feature templates provide information for the dependency parser about the embedding of the nodes in the phrase structure. A first order factor consists of the head and the dependent. A second order factor comprises of two connected edges, which additionally consist of a sibling or grandchild. The feature templates represent the location of the nodes in the phrase structure and the label of the phrase involved. We use the following abbreviations to define the feature templates: `L` represents the edge label; `hP`, `dP`, and `xP` the part-of-speech tag of the head, that of the dependent and the sibling or grandchild. The `hPoPS`,`dPoPS`, `xPoPS` denote the part-of-speech tag provided by the phrase structure parser for the head, dependent, and sibling or grandchild, respectively.

`hPS`, `dPS`, `xPS` denote the label of the phrase where the corresponding terminal node is embedded, respectively. `hPPS`, `dPPS`, `xPPS` denote the phrase that contains the phrase of the corresponding terminal of the head, dependent and sibling/grandchildren, respectively. The **r**elative **l**ocation, `rl`, of the head and dependent in the phrase structure: `rl=Phd`, if the head and dependent are terminals of the same phrase; `rl=Ph->Pd`, if the dependent is in a subphrase of the phrase of the head; `rl=Pd->Ph` denotes the inverse relation; otherwise `rl=Pd?Ph`. `rlx` stands for the relative location of the head and dependent, grandchild or sibling in the sentence, e.g. if the head is before or after the dependent in the sentence `rlx=h<d` or `rlx=d>h`. We count all pairwise combinations of the above nodes.

1. first order features:
   `L+hP+dP+hPS+rl`, `L+hP+dP+dPS+rl`, `L+hP+dP+hPS+dPS+rl`,
   `L+dP+hPS+hPPS+dPS+rl`, `L+dP+hP+dPPS+hPS+rl`, `L+hPoPS+dPoPS`.
2. sibling features:
   `L+hP+dP+xP+hPS+rlx`, `L+hP+dP+xP+dPS+rlx`, `L+hP+dP+xP+xPS+rlx`,
   `L+hPS+dPS+xPS+rlx`, `L+xP+hPS+dPS+xPS+rlx`, `L+xP+hPS+dPS+xPS+xPPS+rlx`,
   `L+xP+hPPS+dPS+xPS+rlx`, `L+xP+hPPS+dPS+xPS+xPS+rlx`,
   `L+hPoPS+dPoPS+xPoPS`.
3. We use as grandchildren features the same feature set as for the sibling features and replace x by the grandchild.

4 Phrase Structure Parser Exploiting Dependency Parses

Phrase structure parsers use a PCFG to extract possible parses. The full space of possible parses cannot be iterated through in practice, and they are usually pruned as a consequence. The *n-best list parsers* keep just the 50-100 best parses according to the PCFG (Charniak and Johnson, 2005). Other methods remove nodes and hyperedges whose posterior probability is under a pre-defined threshold from the forest (chart) (Huang, 2008). The task of the second stage is to select the best parse from the set of possible parses (i.e. rerank this set). These methods employ a large feature set (usually a few millions features) (Collins, 2000; Charniak and Johnson, 2005). The n-best list approaches can straightforwardly employ local and non-local features as well because they decide at the sentence-level (Charniak and Johnson, 2005) while involving non-local features is more complicated in the forest-based approaches and studies show only a minor empirical advantage of the latter approach (Huang, 2008; Wang and Zong, 2011). In this study, we experiment with n-best list reranking using a Maximum Entropy machine learning model and our goal is to investigate the extension of the standard feature set of these models by features extracted from the automatic dependency parse of the sentence in question.

4.1 Features Defined on Dependency Parses

The objective of the features defined for phrase structure parsing is to characterize the divergence/similarity of constituents with the corresponding part of the automatic (1-best) dependency parse of the sentence in question. We defined three feature templates for representing hyperedges (i.e. CFG rules applied over a certain span of words). We illustrate them on two possible subparses of Figure 1.

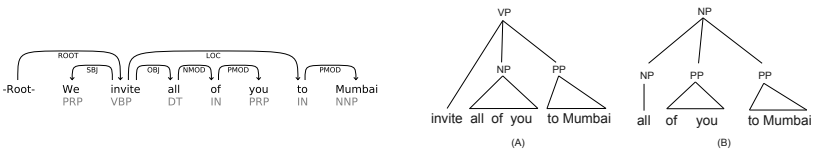

Figure 1: A dependency parse and two hyperedges (*A* and *B*) of the phrase structure chart for the introduction of feature templates.

outArc features are counting the dependency arcs which "go out" from the constituent in question. More precisely we count the words within the span whose parent in the dependency tree lays outside the span of words in question. We use the absolute count and the ratio of outArcs among the words of the span. The more arcs go out, the further away is the dependency subtree over the words of the constituent from a dominating subtree. Hence, these features try to capture the "phraseness" of the span of words in question based on the dependency tree. The example *A* in Figure 1 gets `outArc=1` and `outArcRatio=1/6` as only the parent of *invite* lays outside the constituent. For *B* we have `outArc=2` and `outArcRatio=2/5` because of *all* and *to*.

POSRel features indicate the dependencies which occur in the dependency parse (explicitly) as well as in the phrase-structure parse (implicitly). For this we gather the daughter constituents whose lexical head is linked in the (undirected) dependency tree to the head of the parent constituent. We define features from them using the pair of the two heads' POS tag and a

triplet using the POS tags and the corresponding dependency label. For *A* we have the following binary valued features: `VBP-DT`, `VBP-DT-OBJ` (from *invite–all*), `VBP-IN`, `VBP-IN-LOC` (from *invite–to*) as both daughter attachments have the corresponding arcs in the dependency tree. For *B* we do not extract features for the second PP daughter attachment as the lexical head of the parent (*all*) and the lexical head of the daughter (*to*) are not linked in the dependency parse.

ConstRel features are similar to `POSRel` but use the constituent labels rather than the POS tags of the heads. Thus, for *A* we have `VP-NP`, `VP-NP-OBJ` (from *invite–all*), `VP-PP`, `VP-PP-LOC` (from *invite–to*).

We also investigated the role of case and grammatical functions of the phrase structure parser in German and extended the `POSRel` and `ConstRel` feature sets by adding this information to the labels.

Note that the value of `outArc` is 1 iff the word span in question has a dominating dependency subtree in the automatic parse. Wang and Zong (2010) prune hyperedges with `outArc`$\neq 1$ thus this feature can be regarded as a generalization of their approach.

These features are similar in nature to the lexical head-based features of Charniak and Johnson (2005) and Versley and Rehbein (2009) but their role is different. Those dependency-like features try to describe the local hyperedges using the internal state of the parsing approach while we exploit here a globally (i.e. sentence-level) optimized dependency parse tree which represents external knowledge to the parser.

5 Experimental Setting

5.1 Data Sets

We used the Penn Treebank (section 23 served as test set and section 22 and 24 were used as development set in the phrase-structure and dependency experiments, respectively) with the Penn2Malt converter, and the head-finding rules of Yamada and Matsumoto (2003) for our experiments on English because most of the published state-of-the-art results were obtained on these datasets and conversion. For German, we used the Tiger Treebank and followed the split of the Parsing German (PaGe) shared task (Kübler, 2008) for phrase structure parsing. For dependency parsing, we used the dependency corpora of the CoNLL-2009 shared task, cf. (Hajič et al., 2009) (which consists of automatically converted trees from a part of the Tiger Treebank).

The phrase structure parsers traditionally conduct POS tagging during parsing (the different POS alternatives are on the chart). For obtaining POS tags for the dependency parsing experiments, we jackknifed the training data 10 fold, i.e. we trained the POS tagger on nine folds and tagged the tenth fold. On the English training set, the POS tagger of Toutanova et al. (2003) achieves an accuracy of 97.1, on the development set, 97.2 and the test set, 97.3. For German, we used a SVM-based tagger and we obtained on the training set an accuracy of 97.2, on the development set, 97.5 and on the test set, 97.4.

We followed the same jackknifing procedure in the stacking experiments in order to obtain the parses from which the features are extracted. We generated the dependency and constituent parses of the training corpus by training the respective parser on nine folds and parsing the tenth fold. During parsing the test set and development set we utilized the parses from the second parser which was trained on its entire training corpus.

5.2 Implementation Details

For our experiments, we utilize the second-order graph-based parser of the **dependency parsers** of Bohnet (2011)[1]. The second-order parser employs online training with a perceptron (Crammer and Singer, 2003) and it is based on a Hash Kernel. We employed this parser since it is quick to train, provides useful labeled dependency trees and achieves state-of-the-art accuracies. We used the transition-based parser that is included in the same package for our experiments as well.

For the **phrase structure parsing** experiments, we also employed state-of-the-art parsers. We used the first-stage parser of Charniak and Johnson (2005) for English and Bitpar (Schmid, 2004) for German. The latter employs a grammar engineered for German (Farkas et al., 2011). At the second stage, we used the 50 and 100-best parses to rerank and filtered out rare features (which occurred in less than 5 sentences). We employed the ranking MaxEnt implementation of the MALLET package (McCallum, 2002) and optimized the L2 regularizer coefficient on the development set.

5.3 Baseline Feature Sets

For conducting baseline **dependency parsing** experiments, we employed the feature set of Bohnet (2010). For the stacking of graph-based and transition-based dependency parsers, we used the feature template definitions from Nivre and McDonald (2008) which was extended by grandchildren factors (similarly to Torres Martins et al. (2008)).

For **phrase structure reranking** we utilized the features of Charniak and Johnson (2005) and for German we reimplemented the feature templates of Versley and Rehbein (2009) as baseline feature sets. The latter is the state-of-the-art feature set for German, which consists of features constructed from the lexicalized parse tree and its typed dependencies along with features based on external statistical information (like the clustering of unknown words according to their context of occurrences and PP attachment statistics gathered from the automatic POS tagged DE-WaC corpus, a 1.7G words sample of the German-language WWW).

5.4 Evaluation Metrics

For the evaluation of the dependency parses, we use the standard labeled (LAS) and unlabeled attachment scores (UAS) excluding punctuation for English and including punctuation for German. We use the predicted POS tags everywhere thereafter.

We use the standard `evalb` implementation of PARSEVAL on every sentence without length limitation as evaluation metric for phrase structure parsers. As the grammatical functions of constituents are important for downstream applications – especially in German –, we also report PARSEVAL scores on the conflation of constituent labels and grammatical functions (the scores in brackets in Table 3). We have to mention that our F-values are not directly comparable to the official results of PaGe Shared Task – which was our original goal – because the evaluation metric had a special implementation for calculating the F-measure (which differs from `evalb` for example in handling punctuation marks) and it used gold-standard POS tags in the input (which we thought to be unrealistic).

6 Results

6.1 Oracle Experiments

In order to validate the value of our new feature templates, we carried out the following oracle experiment. We used the gold standard parse trees from the second parser for training and parsing, i.e. we extracted features from the gold standard phrase structure parses for dependency parsing and vice versa. Our dependency parser achieved an UAS of 98.52 and LAS of 98.17 on the English test set. The re-ranking phrase structure parser achieved 95.78 where the oracle score – i.e. selecting the best candidate from the candidate list – is 96.83. Hence using the gold standard trees of the second parser yield scores close to the theoretical upper bound, which empirically proves that our new feature templates can effectively capture the information present in the other syntactic representation.

6.2 Dependency Parsing Results

Table 1 shows the results achieved on the test and development sets of English and German.

Our baseline parsers here are the transition-based parser (baseline T) and graph-based parser (baseline G) of (Bohnet, 2011). The row "G+T features" presents stacking results for the transition-based and graph-based parser. In this setting, the graph-based parser uses the output of the transition-based parser. This setting shows already a high accuracy improvement of 0.44 and obtained an unlabeled accuracy score of 93.5 in English. This result shows that the stacking idea of Nivre and McDonald (2008) works well on this higher accuracy level obtained with the offspring of their parsers.

The row "G+P features" shows the results when the graph-based parser exploits the features extracted from the phrase structure parser. The unlabeled accuracy score achieved the current best results for this data set with 93.95 UAS. When we use the output of the transition-based parser and the phrase structure parser as input to the graph-based parser (G+P+T features), we are able to obtain an even higher accuracy score of 94.04. Exploiting phrase structure parses achieves a gain in UAS of 0.89 and 0.54 employing them as an extension of the graph-based and the stacked dependency parser G+T. The added value of the features from the transition-based dependency parses on top of the extended feature set (i.e. the difference between G+P and G+P+T) is minor – and there is a decrease at 2 out of the 8 settings. These results indicate that the features gathered from the phrase structure parse contain almost all of the information which can be gathered from the transition-based dependency parse.

The two last rows show scores when we use in addition cluster-based features similarly to Koo et al. (2008). The cluster-based feature provided an improvement of 0.17 on top of the results of the graph-based parser (G+C features). The last row (G+P+T+C features) shows the scores for the features from all sources where we finally obtain 94.14 UAS.

Similarly to the results for English, we can also report large improvements for the German Tiger Treebank. With the G+T features, we gain 0.24 UAS and 0.71 with the "G+P features" compared with the "baseline G". When we utilized each feature set, the parser achieved 91.88 UAS and 89.90 LAS (0.81 improvements in UAS), which is the highest reported accuracy score for this data set.

	English		German	
	Devel.	Test	Devel.	Test
baseline T	91.46/90.10	92.71/91.56	90.27/87.76	90.39/88.05
baseline G	92.09/90.81	93.06/91.95	90.37/88.01	91.02/88.81
G+T features	92.34/90.96	93.50/92.53	90.45/88.29	91.26/89.13
G+P features	92.81/91.71	93.95/92.99	90.64/88.47	91.73/89.50
G+P+T features	92.83/91.70	94.04/93.10	90.70/88.54	91.69/89.69
G+C features	92.14/90.87	93.23/92.15	90.53/88.31	91.40/89.19
G+P+T+C features	92.96/91.80	94.14/93.17	90.73/88.50	91.88/89.90

Table 1: Dependency parsing results achieved by the enriched feature sets. The accuracy scores are statistically significant between the baseline G and G+T, G+P, and G+P+T+C with $p < 0.001$ and between G+P and G+P+T+C with $p<0.05$. We used two sample t-test.

6.3 Stacking of Converted Parses

An alternative approach for stacking phrase structures into a dependency parser is to convert the phrase structures into dependency trees and extract features from this representation. We investigated this approach on the English dataset[2]. We used the Penn2Malt converter on the automatic phrase structure parses and then employed the same dependency stacking features which were used for "G+T features" and were described in Section 5.3. Table 2 repeats the scores from Table 1 achieved by the baseline parser and by the feature templates defined directly on phrase structures and compares these scores with the results achieved by the conversion-based stacking.

	English	
	Devel.	Test
baseline G	92.09/90.81	93.06/91.95
G+P converted	92.48/91.23	93.74/92.73
G+P direct	92.81/91.71	93.95/92.99

Table 2: Results achieved by utilizing features defined directly on phrase structures vs. defined on converted trees. The accuracy scores are statistically significant between the two approaches with $p<0.05$. We used two sample t-test.

6.4 Phrase Structure Parsing Results

Table 3 summarize the results achieved by phrase structure parsers[3]. In the reranking approach we used 50-best lists for English and 100-best lists for German as it is standard in previous work.

The "generative" row stands for the results achieved by the first-stage parsers. The "oracle" score is the highest available score in the 50-best and 100-best lists, thus serve as an upper

[2]Unfortunately, we do not have access to the conversion scripts for German. As the conversion in the reverse direction (i.e. converting dependency parses into phrase structures) is not straightforward we restricted ourself to phrase structure to dependency conversion and the English dataset.

[3]Note that the difference in German scores between this table and the scores reported in our previous study (Farkas et al., 2011) is because we report score on each sentences – and compare our results here against re-trained baseline parsers – while we limited the evaluation to sentences shorter than 40 tokens in the previous study – in order to be able to compare those results against previously published scores on the same corpus.

bound for rerankers. The last three rows contain the results of reranking on top of first-stage parsers employing the baseline[4], only the new features defined from dependency parses (dep) and their union (bl+dep).

	English		German	
	Devel.	Test	Devel.	Test
generative	88.86	89.71	77.83 (66.88)	76.81 (65.76)
oracle	95.90	96.83	86.18 (76.10)	83.37 (73.07)
baseline features	90.59	91.38	79.76 (67.99)	78.41 (67.05)
dep features	89.90	90.66	79.82 (69.28)	78.01 (67.46)
bl+dep features	90.92	91.72	80.90 (70.39)	79.45 (68.73)

Table 3: Phrase structure parsing PARSEVAL scores achieved by utilizing various feature sets. The figures in brackets for German are PARSEVAL scores including grammatical functions. The accuracy scores are statistically significant between "baseline features" and "bl+dep features" with $p<0.05$. We used two sample t-test.

As Table 3 shows, the reranking parser using only our features constructed from the automatic dependency parse of the sentence achieved a 1.0 improvement on the English development and test sets, respectively and they added a value of 0.3 over the baseline feature set as well.

The results for German are even more convincing. The simple dependency parse-based features are competitive with the German-specific feature set of Versley and Rehbein (2009). Moreover these two feature sets have a certain level of diversity as their union could achieve significantly better results (over 1.0 point of improvements), than any of them alone. The added value of the dependency parse-based features is higher if we consider the evaluation metric which also takes into account the grammatical function labels as well.

6.5 Comparison to previous work

Table 4 shows labeled and unlabeled accuracy scores of previous work reported for the Penn2Malt conversion with the head finding rules of Yamada and Matsumoto (2003). Carreras et al. (2008) (CCK) combine a dependency parsing decoder with parsing based on TAG. Koo and Collins (2010) (Koo'10) used a parser with third order factors and obtained an unlabeled accuracy of 93.04. Martins et al. (2010) introduced a parser (Turbo) with even higher accuracy (93.26 UAS), which is one of the highest accuracy scores for a parser that does not employ additional sources of information.

The following approaches use additional sources of information. Suzuki et al. (2009) (SICC) use a second order dependency parser that employs siblings and grandchildren factors. They apply the semi-supervised learning approach of Suzuki and Isozaki (2008) to dependency parsing and include additionally the cluster-based features of Koo et al. (2008) (KCC).

The improvement of the accuracy achieved by our stacking approach is surprisingly high. We achieved an error reduction of 16.5% (an absolute gain of 1.1 percentage points) over our baseline and it outperforms the best reported scores with combining dependency and phrase structure parses (Carreras et al., 2008) by 0.6.

[4]The small difference between the original Brown parser and reranking with baseline features is due to the different MaxEnt implementations employed.

	English (UAS)			German (LAS)	
	Devel.	Test		Devel.	Test
CCK'08	92.5	93.5	GHPT'09		87.28
Koo'10		93.04	B'10		88.06
Turbo'10		93.26			
This work (G+P+T)	92.14	94.04		88.54	89.69
KCC'08	91.85	93.16			
SICC'09		93.8			
This work (G+P+T+C)	92.96	94.14		88.50	89.90

Table 4: Comparison to previous work. We report UAS only for the English Penn Treebank since usually unlabeled scores were published and labeled attachments scores only for the German Tiger Treebank since in the CoNLL shared task 2009 only labeled attachment scores were reported.

For German the two top scoring parsers of the CoNLL 2009 shared task on Syntactic and Semantic Dependency parsing were the parser of Gesmundo et al. (2009), who had the best overall scores and the parser of Bohnet (2010), which performed best on English and German. However we note that directly comparing these results to our ones is not fully fair since the POS tagging accuracy of the data sets were lower than 95.5 at the CoNLL 2009 shared task.

Table 5 sketches the **phrase-structure parsing** results in the context of previously published results. We retrained the current version of the Charniak and Johnson (2005) parser[5] (C&J) for English. We also cite the scores reported by Rush et al. (2010) who also exploited phrase structure and dependency parsers together. Our final scores are competitive with the best reported supervised PARSEVAL score in the Penn Treebank by (Huang, 2008) who also extended the feature set of Charniak and Johnson (2005) and applied forest-based reranking.

	English			German	
	Devel.	Test		Devel.	Test
C&J	90.60	91.36	Berkeley	76.60 (65.25)	76.05 (64.00)
Rush'10	–	90.7	PyNLP	76.76 (66.29)	76.27 (65.21)
Huang'08	–	91.69			
This work (bl+dep)	90.92	91.72		80.90 (70.39)	79.45 (68.73)

Table 5: Comparison to previous work. Our method significantly outperforms state-of-the-art systems.

For German, we trained the current version of the Berkeley parser[6] (Petrov et al., 2006) and PyNLP[7] parsers (Versley and Rehbein, 2009). Note that the results of the generative Berkeley parser is competitive with the PyNLP parser which utilizes reranking, while the first-stage parser, which we employ here – using a fine-tuned German-specific tree annotation schema – outperforms both of them. The discriminative approach with the baseline feature set we employed gave an improvement of 2 percentage points over the first-stage parser and the features gathered from dependency parsers could add an additional 1 point to this.

7 Discussion

We manually analyzed the outputs of the parsers in order to identify linguistic constructions where one or another parser performed better. Our findings help understand the reasons why the approach works and they might suggest ways of improving data-driven parsers as well.

7.1 Why did the phrase structures help dependency parsing?

In order to find the explanation why phrase structure parse-based features help the dependency parser we manually investigated the sentences of the English development set where the parsers with and without these features gave different output.

We found that the most frequent error fixing categories are related to longer phrases, typically noun phrases and named entities. For example, the phrase structure parser could recognize the phrase boundaries of *US Today 's total paid ad pages* and *St. Therese , Quebec* and with the phrase structure-based features the dependency parser was able to fix its errors here. Note that in the latter example if the parser analyses the entity as two separated entities *St. Therese* and *Quebec*, it introduces 3 attachment errors (for *Therese*, for the comma and for *Quebec*). Besides noun phrases the parses of institutionalized phrases like *with or without* and *rather than to* were also considerable improved. These improvements can be probably attributed to the phrase-based thinking of the second parser.

Phrase structure-based features improved considerably the accuracy of coordinations. It is a known issue that the representation of coordination in the dependency structure has an impact on the accuracy. The Penn2Malt converter builds dependency structures where the conjunction is the head. Nilsson et al. (2007) showed that this representation of coordinations yields a lower parsing accuracy – across four languages – than a representation where the conjunction and the members of the coordination form one chain. Our features defined on the phrase structure trees can be regarded as a third type of representation of coordination. Although these features help in the current setting we expect a smaller contribution if a different dependency representation (like the chain type) is targeted.

The counting of the errors – or error fixes – related to coordination is not straightforward because besides the wrong attachment of a `CC` it introduces several attachment errors in the construction. For instance, we observed several article attachment errors related to this as well. For example in *the agreement and consent decree* the article can be attached to the *agreement* or to the *decree* according to the analysis of the coordination.

The rest of the improvements is heterogenous but we observed two other quite frequent error types. The first one is the attachment to a verb if multiple verbs are present in the sentence, most typically the choice between the auxiliaries and the main verbs. For instance in *having just passed* the dependency parser attached *just* to the main verb while was able to correctly attach it to the auxiliary with the help of phrase structure-based features. We counted down the attachment errors of the dependency parser where it chose a wrong verb. The phrase structure-based features could eliminate 245 such errors while introduced 117 new attachment errors.

A related interesting issue is that the incorporation of the phrase structure-based features into the graph-based parser improves the selection of the sentence's root by almost 1 percentage point (the F-score of the `ROOT` label increased from 96.24 to 97.1). This might be an artifact of the two-stage approach of the phrase structure parser, i.e. the reranking second stage could

choose from candidates having different roots. We intend to more deeply investigate this issue in the future as it seems to be promising to design a reranking phase for dependency parsers which can select from parses with different roots.

7.2 Why did the dependency structures help phrase structure parsing?

We followed the methodology of contribution analysis for phrase structure parses and we manually investigated the sentences of the English development set where the discriminative parsers with and without these features gave different output. We identified two categories of improvement. The first one is the "attachment" of adverbs and adjectives, especially in the case of collocational modifiers like *more like* and *many more*. The second phenomenon where the dependency parse-based features could eliminate a considerable amount of errors – much more than was introduced – is PP attachment. The explanation for both of these contributions might be the "lossless" lexicalization of the dependency parsers. Although the PCFG parser of Charniak (2000) is lexicalized[8] and the re-ranking stage is deeply lexicalized, using only 50 candidate parses and a frequency-based feature pruning implies some extent of information loss while dependency parsers can exploit very rare lexical cues.

7.3 What is the difference between stacking directly and stacking after conversion?

We also manually compared the parses of the two stacking approaches, i.e. the one where the features are defined directly on phrase structures versus the other where the features are defined on a dependency tree which were automatically converted from the phrase structures (see Section 6.3). Although the difference between the two approaches is significantly different we cannot conclude that the first one is clearly better than the second one. There are 214 sentences in the development set where the direct appraoch achieves higher attachment scores than the other while there are also 197 sentences where its scores were worse.

Interestingly, the most frequent linguistic constructions which are responsible for these differences are related to conjunctions at both the directions. We found that in the case of noun phrase coordinations, the features defined directly on the phrase structures are more useful than after conversion. This further supports our earlier discussion that our features as a representation type of coordination is more useful than the "conjunct is the head" representation used in the Penn2Malt conversion.

On the other hand, in the case of compound sentences (i.e. the conjunction of independent clauses) the converted parses contributed frequently more than features directly defined on the phrase structures (this is expressed also by the F-score of the `ROOT` label which is 0.3 higher in the first case). The cause for this effect is that the phrase structure puts the two (or more) independent clauses to same level while the dependency tree – at least in the Penn2Malt conversion – has to label a single token as the root of the sentence. The root selection among the heads of the independent clauses follows a deterministic rule during the conversion process, thus the converted trees do not face the problem of root ambiguity in these compound sentences.

8 Conclusions

We proposed here the stacking of dependency and phrase structure parsers. We introduced a feature set for describing phrase structures for data-driven dependency parsers and dependency

[8] However, it utilizes just the head of the parent instead of bi- (or higher order) lexicalization.

parses for discriminative phrase structure parsers. We investigated the performance of our stacking approach on English and German and we reported a significant improvement over the state-of-the-art parsers in both directions. We believe that the key factor of this success is that we designed our framework to advance one parser exploiting the other, rather than optimizing a joint objective function.

In our experiments both parsers utilize the same (training) data set without having access to external information. We argue that our results – especially the gain at dependency parsers – indicate that state-of-the-art parsers can be still further improved without additional data. To facilitate these further developments, we manually analyzed several parses of different approaches and identified linguistic phenomena where the gain was considerable. For instance, for the dependency parsers these phenomena are named entities, longer noun phrases, coordination and root selection. Investigating them more deeply could probably reveal parsing techniques which can yield considerable added value to current procedures.

ABSTRACT
In this paper, we propose a novel semantic cohesion model. Our model utilizes the predicate-argument structures as soft constraints and plays the role as a reordering model in the phrase-based statistical machine translation system. We build a translation system with GALE data. Experimental results on the NIST02, NIST03, NIST04, NIST05 and NIST08 Chinese-English tasks show that our model improves the baseline system by 0.93 BLEU 0.98 TER on average. We also compare our method with a syntax-augmented model (Cherry, 2008), and demonstrate the importance of predicate-argument semantics in machine translation.

KEYWORDS: statistical machine translation, semantic role labeling.

Proceedings of COLING 2012: Technical Papers, pages 867–878,
COLING 2012, Mumbai, December 2012.

1 Introduction

In recent years, there are growing interests in incorporating semantics into statistical machine translation (SMT) (Wu and Fung, 2009; Liu and Gildea, 2010; Gao and Vogel, 2011; Baker et al., 2012). Among all existing semantic representations, semantic role labeling (SRL) aims at automatically analyzing predicate-argument structures and can capture essential meaning of sentences. Since the seminal work of (Gildea and Jurafsky, 2002), quite a few researchers concentrate on resolving SRL with different machine learning methods. Nowadays, good SRL systems can be built based on accurate syntactic parsers for English, as well as many other languages.

In this paper, we explore predicate-argument analysis of source sentences to improve phrase-based SMT systems. On one hand, the predicate-argument event layer of SRL captures global dependencies which is crucial for the MT output quality. On the other hand, the semantic role information contained in SRL also provide a good clue to the appropriateness of a phrase segment chosen by a translation system. Compared to the syntactic representation in both constituency and dependency formalisms, SRL focuses more on modeling the skeleton of a sentence.

To exploit the two attributes of SRL, we propose two types of constraints which are implemented as two models in the decoder. The first model restrains the translation process so that it is consistent with the global dependency in the source sentence. The second model inspects the source sentence segmentation so that each source phrase is consistent with the semantic roles.

We conduct experiments on the NIST02, NIST03, NIST04, NIST05 and NIST08 Chinese-English tasks. Experimental results show that our model improves the baseline system by 0.93 BLEU 0.98 TER on average. We also compare our method with a syntax-augmented model (Cherry, 2008), and demonstrate the importance of predicate-argument semantics in machine translation.

The remainder of this paper is organized as follows: Section 2 describes the semantic soft constraints proposed for translation system. Section 3 introduces a related work (Cherry, 2008) as we compare our method with it. Section 4 provides the experimental configuration and results. Section 5 briefly summarizes recent work on employing different semantics related techniques. Conclusions will be given in Section 6.

2 Semantic Cohesion Model

In this section, we describe the proposed idea. Firstly, we will briefly describe the basement of this research: the principle of statistical machine translation. Secondly, the SRL framework will be given. Thirdly, we demonstrate how the semantic role information can be used for translation.

2.1 Principle

In statistical machine translation, we are given a source language sentence $f_1^J = f_1 \dots f_j \dots f_J$. The objective is to translate the source into a target language sentence $e_1^I = e_1 \dots e_i \dots e_I$. The strategy is among all possible target language sentences, we will choose the one with the highest probability:

$$\hat{e}_{\hat{i}}^{\hat{I}} = \arg\max_{I, e_1^I} \{Pr(e_1^I | f_1^J)\} \quad (1)$$

We model $Pr(e_1^I|f_1^J)$ directly using a log-linear combination of several models (Och and Ney, 2002):

$$Pr(e_1^I|f_1^J) = \frac{\exp\Big(\sum_{m=1}^{M} \lambda_m h_m(e_1^I, f_1^J)\Big)}{\sum_{I', e'^{I'}_1} \exp\Big(\sum_{m=1}^{M} \lambda_m h_m(e'^{I'}_1, f_1^J)\Big)} \quad (2)$$

The denominator is to make the $Pr(e_1^I|f_1^J)$ to be a probability distribution and it depends only on the source sentence f_1^J. For search, the decision rule is simply:

$$\hat{e}_{\hat{i}}^{\hat{I}} = \arg\max \Big\{ \sum_{m=1}^{M} \lambda_m h_m(e_1^I, f_1^J) \Big\} \quad (3)$$

The model scaling factors λ_1^M are trained with Minimum Error Rate Training (MERT).

In this paper, the phrase-based machine translation system is utilized (Och et al., 1999; Zens et al., 2002; Koehn et al., 2003). The translation process consists in segmentation of the source sentence according to the phrase table which is built from the word alignment. The translation of each of these segments is then just extracting the target side from the phrase pair. With the corresponding target side, the final translation is the composition of these translated segments. In this last step, reordering is allowed.

2.2 Semantic Role Labeling

In the last decade, there has been an increasing interest in SRL on several languages, which consists of recognizing arguments involved by predicates in a given sentence and labeling their semantic types. Typical semantic classes include *Agent*, *Patient*, *Source*, *Goal*, and so forth, which are core arguments to a predicate, as well as *Location*, *Time*, *Manner*, *Cause*, and so on, which are adjuncts. In order to indicate exactly what semantic relations hold among a given predicate and its associated participants and properties, the role-bearing constituents must be identified and their correct semantic role labels assigned.

Such sentence-level semantic analysis of text is concerned with the characterization of events and is therefore important to understand the essential meaning of the original input language sentences – *who* did *what* to *whom*, for *whom* or *what*, *how*, *where*, *when* and *why*? Different from many other semantic representation formalisms, this shallow semantic interpretation abstracts important predicate-argument structural information away from syntactic structure and may potentially benefit machine translation, as well as many other NLP applications.

2.3 Semantic Cohesion for Translation

We now explain how the SRL is utilized in the decoder. Suppose the source language is temporarily English, we detect and classify semantic roles of all predicates for the source sentence before translation. The Figure 1 is an example with Propbank-style annotations. Figure 1 consists of four rows. The first row is the orginal source sentence. The next three rows demonstrate the event layers of the sentence. Each event layer has one predicate and corresponding arguments. The source sentence in Figure 1 has three predicates. The first predicate *make* and second predicate *distribute* governs two arguments A0 (namely proto-Agent) and A1 (namely proto-Patient) respectively; third predicate *base* possesses two semantic

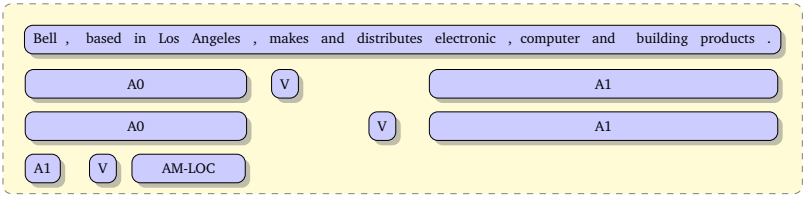

Figure 1: An example of SRL. The source sentence is given at top.

roles A1 and AM-LOC (namely location). Then a model will be added into the decoder as a new feature of the log-linear framework (Equation 2). The algorithm is as follows:

Given the source sentence and its predicate-argument structural information, during the translation process, every time one hypothesis is extended, the added model checks if the source semantic analysis contains one structure S such that:

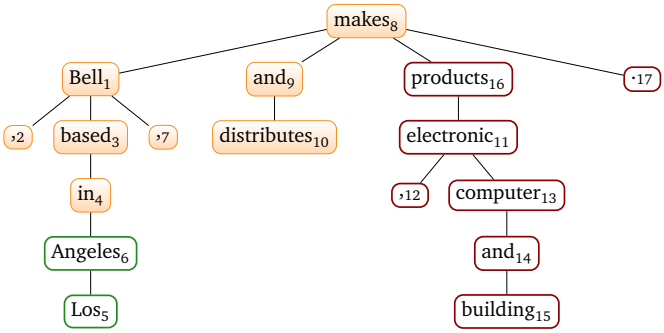
- Its translation is already started (at least one word is covered)
- It is interrupted by the new added phrase (at least one word in the new source phrase is not in S)
- It is not finished (after the new phrase is added, there is still at least one uncovered source word in S)

If so, we say this hypothesis violates the structure S, and the model returns the number of structures that this hypothesis violates.

We use two kinds of structures. In other words, we add two models/features into the log-linear framework. The structure of the first model (we name it SRL1) is the whole predicate-argument structure, i.e. event layer. The SRL1 feature will report how many event layers that one search state violates. For the second model (we name it SRL2), the structure is semantic role. The SRL2 feature will calculate the amount of semantic roles that one search state violates. In Figure 1, there are three event layers and six semantic roles. Suppose currently only the first source word *Bell* is already covered/translated, and then the decoder decides to translate the source word *computer*. Then the feature SRL1 will give penalty 1. Because this decision violates the third event layer in Figure 1. The third event layer was starting to be translated (*Bell* is covered), however, the decoder jumps to *computer* before it finishes current event layer(A1 and AM-LOC have not been translated yet). The feature SRL2 will give penalty 2 because the two semantic role A0 have been violated. During search, we have the access to the coverage vector which stores those source words that have been translated. So based on the source sentence semantic analysis and current coverage vector, the two feature values can be easily computed.

3 Syntactic cohesion model

We now introduce a related work as comparison will be presented later in this paper. (Cherry, 2008) proposed a syntactic cohesion model. The core idea is that the syntactic structure of the source sentence should be preserved during translation. This structure is represented by a source sentence dependency tree. To keep syntactic cohesion, the decoding process should not break



[Bell , based in Los Angeles , makes and distributes electronic , computer and building products .]

Figure 2: A dependency tree example. The source sentence is given at bottom.

this dependency structure. (Cherry, 2008) used his model as a new feature of the log-linear decoding framework and showed improvement on English-French direction. We implement this model in the phrase-based decoder and report results on Chinese-English translation.

To illustrate the method, we use the Figure 2 as an example. Figure 2 is a dependency tree (again, suppose the source language is now English) . Every node represents a word. We also put the position of the word in the node. So $Bell_1$ means $Bell$ is the first word of the sentence. The algorithm is as follows:

Given the source sentence and its dependency tree, during the translation process, once a hypothesis is extended, check if the source dependency tree contains a subtree T such that:

- Its translation is already started (at least one node is covered)
- It is interrupted by the new added phrase (at least one word in the new source phrase is not in T)
- It is not finished (after the new phrase is added, there is still at least one free node in T)

If so, we say this hypothesis violates the subtree T, and the model returns the number of subtrees that this hypothesis violates.

In Figure 2, nodes filled with yellow means the words have been already covered/translated. Now suppose the length of the new added phrase is 1, then according to the above algorithm only position 5 and 6 (green rectangle) are good candidates. Choosing other source words (red rectangle) to translate will violate the subtree $in_4 - Los_5 - Angeles_6$.

4 Experiments

4.1 Experimental Setup

Our baseline is a phrase-based decoder, which includes the following models: an n-gram target-side language model, a phrase translation model and a word-based lexicon model. The

latter two models are used for both directions: $p(f|e)$ and $p(e|f)$. Additionally we use phrase count features, word and phrase penalty. The reordering model for the baseline system is the distance-based jump model which uses linear distance. This model does not have hard limit. We list the important information regarding the experimental setup below. All those conditions have been kept same in this work.

- lowercased training data (Table 1) from GALE task
  alignment trained with GIZA++
- tuning corpus: NIST06 test corpora: NIST02 03 04 05 and 08
- 5-gram LM (1 694 412 027 running words) trained by SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing
  LM training data: target side of bilingual data.
- BLEU (Papineni et al., 2001) and TER (Snover et al., 2005) reported
  all scores calculated in lowercase way.
- Stanford Parser (Levy and Manning, 2003) used to get the Chinese constituent tree for the SRL and the dependency tree for the syntactic cohesion model

	Chinese	**English**

4.2 A Full Parsing Based Chinese SRL System

4.2.1 Background

SRL methods that are successful on English are adopted to resolve Chinese SRL (Xue, 2008; Sun, 2010). Previous work indicates that syntactic information is very important for SRL and full parsing based approaches are considerably better than shallow parsing based ones. Based on a phrase-structure parsing, SRL is usually formulated as a constituent classification problem. In particular, SRL is divided into three sub-tasks: 1) pruning with a heuristic rule, 2) argument identification (AI) to recognize arguments, and 3) semantic role classification (SRC) to predict semantic types. To efficiently excluded non-arguments, a pruning procedure is executed to filter out constituents that are highly unlikely to be semantic roles of a predicate p. In the AI sub-task, for every candidate constituent c, a binary classifier is employed to determine whether c is an argument of p. In the SRC sub-task, all arguments recognized in the AI step are assigned detailed semantic types by a multi-class classifier. Distinct from the constituent classification method introduced above, we use a constituent chunking based method to acquire predicate-argument structures in this paper.

4.2.2 Semantic Chunking Based SRL

SRL is performed on the output of a syntactic parser, and only phrases in the parse tree are taken as possible candidates. If there is no phrase in the parse tree that shares the same text

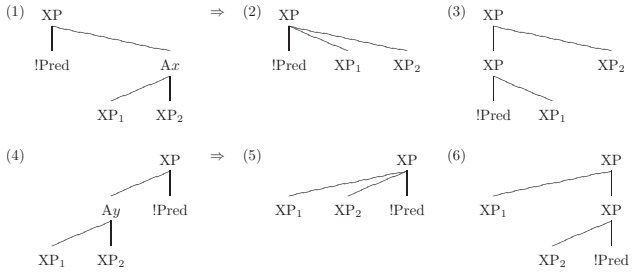

Figure 3: Parsing errors that can be tolerated by full parsing based constituent chunking.

span with an argument in the manual annotation, the system cannot possibly get a correct prediction. In other words, the best the system can do is to correctly label all arguments that have a counterpart node in the parse tree.

In this paper, we implement a semantic chunking method which can tolerate some syntactic parsing errors. First, our system collects all c-commanders[1] and puts them in order. Because c-commanders of a predicate are not overlapped with each other and compose the whole sentence, we can take this step as a sequentialization procedure. Sun et al. (2008) present a theoretical analysis about argument positions and suggest that an argument should c-command a predicate. Therefore, our sequentialization precedure keeps most semantic roles. On basis of sequentialized constituents, we define semantic chunks which do not overlap nor embed using IOB2 representation (Ramshaw and Marcus, 1995) and transfer the SRL problem as a **constituent tagging** problem. Our definition of semantic chunks is described below.

- Constituent outside an argument receive the tag *O*.
- For a sequence of constituents forming a semantic role of *Ax*, the first constituent receives the semantic chunk label *B(egin)-Ax*,
- and the remaining ones receive the label *I(nside)-Ax*.

Developing features has been shown crucial to advancing the state-of-the-art in SRL. To achieve good Chinese SRL results, we utilize rich syntactic features introduced in (Sun, 2010). For sequential tagging, we use a first order linear-chain global linear model and estimate parameters with structured preceptron (Collins, 2002).

Our semantic chunking method can tolerate two types of parsing errors that are shown in Figure 3. Assume tree structures (1 and 4) on the left hand side are the correct syntactic analysis, while tree structures (2, 3, 5 and 6) on the right hand side are some wrong analysis. Though a constituent classification system, the arguments Ax and Ay can not be recovered since there is no node to express them. In our constituent chunking system, however, when these errors occur, the arguments can still be found, if XP$_1$ is assigned a label *B-Ax* or *B-Ay* and XP$_2$ is assigned a label *I-Ax* or *I-Ay*.

[1]C-command is an concept in X-bar theory. Assuming α and β are two nodes in a syntax tree: α C-commands β means every parent of α is ancestor of β.

The full parsing based semantic chunking system was first introduced in (Sun, 2012). To learn more empirical evaluation results of this system as well as a comparative study of full and shallow parsing based SRL, readers can refer to (Sun, 2012).

4.2.3 An Example

An example is illustrated in Figure 4, where the predicate is the verb "调查/investigate". To find all arguments and adjuncts, our system first employs Stanford parser to obtain a phrase-structure analysis. Based on the syntactic tree, our SRL system then collects all c-commanders of the predicate, including all square nodes. Finally, a sequence classifier is applied to assign these candidate nodes chunk labels *B-A0*, *B-TMP*, *B-MNR* and *B-A1*. Based on these labels, we can know the event structure, e.g. the proto-Patient is the NP "事故原因/accident cause".

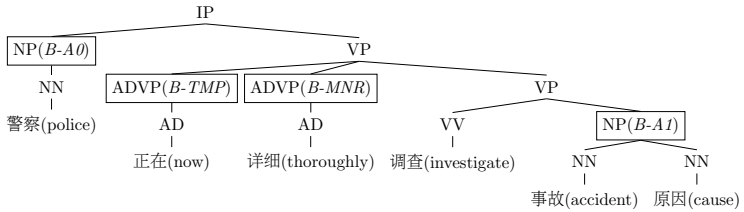

Figure 4: An example sentence: *The police are thoroughly investigating the cause of the accident*.

4.3 Results

Experimental results are presented in Table 2. Besides the five test corpora, we add a column **avg.** to show the average improvements. We also add a column **Index** for score reference convenience. **SRL1** and **SRL2** are the two features described in Section 2.2. **SC** is the syntactic cohesion model described in Section 3.

From Table 2 we see that our proposed feature **SRL1** is able to improve the baseline by 0.57 BLEU and 0.71 TER. **SRL2** improves the baseline by 0.75 BLEU and 0.77 TER. When **SRL1** and **SRL2** are used together, further improvements have been observed. In general, the semantic analysis information improves the baseline system by 0.93 BLEU and 0.98 TER (line 4 and 9). For the comparison with **SC** model, we see their performance is very close. Both **SRL1+SRL2** and **SC** refine the baseline. **SRL1+SRL2** is slightly better at BLEU (compare line 4 and 5) while **SC** is slightly better with TER (compare line 9 and 10).

SRL abstracts important event structures away from syntactic parses. Compared to full parsing model **SC**, **SRL1+SRL2** only concentrates on modeling the skeleton of a sentence, and provide much less information. Nevertheless, our experiments suggest that SRL achieves an equivalent contribution (as constraints) to a phrase-based MT system.

5 Previous Work

(Wu and Fung, 2009) propose a Hybrid two-pass model to use semantics for SMT. The first pass is a conventional phrase-based SMT decoder. The second pass generate a set of candidate re-ordered translation hypotheses by iteratively moving constituent phrases whose predicate or semantic role label was mismatched to the source sentence. The output of the second pass

Systems	NIST02	NIST03	NIST04	NIST05	NIST08	avg.	Index
			BLEU scores				
baseline	33.60	34.29	35.73	32.15	26.34	-	1
baseline+SRL1	34.50	34.76	36.21	32.75	26.77	0.57	2
baseline+SRL2	34.73	34.88	36.60	32.83	26.82	0.75	3
baseline+SRL1+SRL2	35.05	34.93	36.71	33.22	26.89	0.93	4
baseline+SC	34.96	34.52	36.37	33.35	26.90	0.79	5
			TER scores				
baseline	61.36	60.48	59.12	60.94	65.17	-	6
baseline+SRL1	60.44	59.58	58.61	60.01	64.88	0.71	7
baseline+SRL2	60.28	59.49	58.14	60.20	65.11	0.77	8
baseline+SRL1+SRL2	60.05	59.55	58.14	59.69	64.74	0.98	9
baseline+SC	59.90	59.37	58.27	59.69	64.44	1.08	10

Table 2: Experimental results

is the re-ordered translation hypothesis with the maximum match of semantic predicates and arguments. In essence, the paper proposes a semantics-based postprocessing or a semantics-based post reordering technique, where the usage of semantic information is limited due to the fact that the lexical choice has been fixed. The second pass can only do some permutation of the output of the phrase-based decoder.

(Liu and Gildea, 2010) implement two semantic role features in their tree-to-string machine translation system. First feature is named semantic role reordering which describes reordering of the source side semantic roles in the target side. Second feature is named deleted role which can penalize the deletion of source side semantic roles. They show improvement over a small FBIS English-to-Chinese system.

(Gao and Vogel, 2011) present an approach of utilizing target side SRL information to improve the hierarchical phrase-based machine translation. They extract SRL-aware Synchronous Context-Free Grammar (SCFG) rules together with conventional Hiero rules. Instead of adding additional features in the decoder, special conversion rules are applied during rule extraction procedure to ensure that when SRL-aware SCFG rules are used in derivation, the decoder only generates hypotheses with complete semantic structures.

(Baker et al., 2012) build a modality/negation (MN) annotation scheme in the target side. They define modality as an extra-propositional component of meaning and negation as an inextricably intertwined component of modality. A MN lexicon is created in a semi-supervised way. Using this lexicon a MN tagger is designed to identify the substrings that are related to MN. After the target side MN annotation, they incorporate the MN into a small Urdu-English translation task. Their baseline is a Syntax Augmented Machine Translation (SAMT) system. By using a tree grafting approach, the original syntactic tags enriched with new MN annotations are assigned to the parse trees of target side training data.

The main characteristics (also the differences to the above work) of this paper are as follows: we utilize the source side SRL information as soft constraints to improve the phrase-based machine translation system; the two models/features are implemented in the log-linear framework so that SRL information can directly act on the translation process; the experiments are carried out with a large scale Chinese-to-English NIST task; a comparison with (Cherry, 2008) which

uses dependency tree as soft constraints has been conducted.

6 Conclusion

In this paper, we proposed a method to utilize the source side semantic analysis for SMT. Two models have been created. The first model SRL1 captures the global semantic dependency in the source sentence; the second model SRL2 makes sure that the local semantic coherence is kept during search. From SMT perspective, SRL1 is a long distance reordering model; SRL2 is a local reordering model and a phrase model (it encourages the decoder to choose those phrases that keep semantic coherence). The SRL is able to improve the baseline 0.93 BLEU and 0.98 TER. We also did comparative study with SC model. Results show that the performance of the two methods is similar. SRL is 0.14 BLEU better than SC while SC is 0.1 TER better than SRL.

ABSTRACT
There is a demand for taxonomies to organise large collections of documents into categories for browsing and exploration. This paper examines four existing taxonomies that have been manually created, along with two methods for deriving taxonomies automatically from data items. We use these taxonomies to organise items from a large online cultural heritage collection. We then present two human evaluations of the taxonomies. The first measures the cohesion of the taxonomies to determine how well they group together similar items under the same concept node. The second analyses the concept relations in the taxonomies. The results show that the manual taxonomies have high quality well defined relations. However the novel automatic method is found to generate very high cohesion.

TITLE AND ABSTRACT IN BASQUE

Dokumentu bildumak antolatzeko taxonomien arteko alderaketa

Dokumentu bildumak kategorietan sailkatzea oso erabilgarria da, dokumentuak arakatzeko eta aztertzeko aukera berriak eskaintzen duen heinean. Hori horrela izanik, dokumentu bilduma handiak sailkatzeko taxonomien behar handia dago. Artikulu honetan eskuz sortutako lau taxonomia aztertzen dira, taxonomiak automatikoki sortzen dituzten bi metodorekin batera. Taxonomia hauek ondare kulturaleko bilduma handiak antolatzeko erabili ditugu. Taxonomien ebaluazioa egin dugu galdetegietan oinarritutako bi metodo erabiliaz. Lehenbizikoak taxonomiaren kohesioa neurtzen du, hau da, antzeko itemak kontzeptu beraren azpian zein ondo taldekatzen diren. Bigarrenak taxonomiako kontzeptuen arteko erlazioak aztertzen ditu. Emaitzek erakusten dute eskuzko taxonomien erlazioen kalitatea, baina metodo automatiko berri batek lortzen du kohesio handiena.

1 Introduction

With increasingly large sets of diverse collections of documents available online a key challenge is organising and presenting these items effectively for information access. To enable the navigation and exploration of collections, content providers typically provide users with free-text search functionalities, along with some form of browsable subject categories or taxonomy, also useful in organising documents. Providing multiple mechanisms for accessing documents enables users to conduct various modes of information seeking activity, from locating specific documents to more exploratory forms of searching and browsing behaviour (Hearst, 2009; Marchionini, 2006; Wilson et al., 2010).

In this paper we focus on evaluating different taxonomies that could be used to organise and navigate content from Europeana[1], an online cultural heritage collection. This collection comprises many subcollections taken from different providers, and thus contains a very diverse set of cultural heritage *items*[2]. Some of the subcollections are linked to bespoke taxonomies; however, many are not. This therefore represents a very challenging dataset to organise in a consistent and uniform manner. We focus on two main approaches for organising content: the first is to map items from Europeana onto existing manually-created taxonomies; the second is to use data-driven approaches to automatically derive taxonomies from the collection. This requires being able to successfully group items into categories and generate suitable category labels. A note on definitions: the term 'taxonomy' is used in this paper as a general term meaning a conceptual hierarchy. A taxonomy does not necessarily have to be a subsumption hierarchy (where each child concept is subsumed by its parent concept). Some of the taxonomies described here are subsumption hierarchies and some are not.

There are many different ways of evaluating taxonomies (Snow et al., 2004; Malaisé et al., 2006; Yi, 2008; Nikolova et al., 2010; Ponzetto and Strube, 2011). Here we focus on two approaches which capture different qualities of the taxonomies. The first evaluation measures the *cohesion* of the taxonomies; how well they group together similar items into the same concept node. The second analyses the *relationships* between concept nodes in the taxonomies and whether people can understand the concept labels. We believe this is the first time that such evaluations have been applied to such taxonomies over large collections of data items.

This paper provides three main contributions: (1) the systematic comparison of different taxonomies for organising a large cultural heritage collection; (2) a novel data-driven approach based on using Wikipedia article links as concept nodes in the taxonomy; and (3) the evaluation of cohesion and relationship type between concepts using an approach based on crowdsourcing. The rest of the paper comprises the following. Section 2 describes related work in this area. Section 3 gives a brief overview of the key data resources and tools referenced and Section 4 describes the taxonomies and item-to-resource mapping approaches used in the experiments. Section 5 describes the cohesion and relatedness experiments and the results obtained.

2 Related work

There are many category systems or taxonomies available, some of which are domain specific; others aimed at covering more general subjects. For example, one of the most popular and commonly used resources is the Library of Congress Subject Headings (LCSH)[3]. LCSH provides

[1] `http://www.europeana.eu`

[2] An item is defined here as a online record of a cultural heritage artifact (usually an image), together with associated metadata, such as title, subject, description etc.

[3] `http://www.loc.gov/aba/cataloging/subject/`

a controlled vocabulary of keywords (or subject headings), which are widely used in libraries to catalogue materials and facilitate information access. Similarly, in the medical domain MeSH[4], created and maintained by the National Library of Medicine, provides a controlled vocabulary of medical subject headings. In computational linguistics, WordNet (Fellbaum, 1998) is a commonly used lexical knowledge base that links concepts in various ways. WordNet has been expanded with WordNet domain labels which group together words from different syntactic categories and different senses (Bentivogli et al., 2004). These domain labels are organised into a hierarchical structure.

There is a body of previous work on automatically deriving taxonomies and relations from free text. Hearst (1992) was perhaps the earliest significant effort to derive hyponym-hypernym relations from free text using the now eponymous Hearst patterns which code common syntactic forms of the hyponymy pattern (e.g. 'Vehicles such as Cars'). These patterns were hand-crafted. More recently Snow et al. (2004) developed on this work by using an existing knowledge base to automatically derive lexico-syntactic patterns containing the hyponym-hypernym pairs.

An alternative to creating hierarchies of concepts from the pattern-based methods is to use statistical methods. Sanderson and Croft (1999) used an approach to automatically build a hierarchy of terms or concepts (nouns and noun phrases) based on term co-occurrences within a set of documents. To order the concepts a statistical relation called *subsumption* was used to determine which of a co-occurring pair of concepts was most likely to be the parent. Griffiths and Tenenbaum (2004) uses Bayesian methods and LDA (Latent Dirichlet Allocation) to derive topic clusters and create a topic hierarchy. Recent work has exploited the information in Wikipedia to create taxonomies. Ponzetto and Strube (2011) uses the category hierarchy along with lexical matching methods to create a taxonomy which compares well with manually created resources. DBpedia (Auer et al., 2007) also uses the Wikipedia category hierarchy but also additionally links in the articles into the hierarchy.

One key problem is how to evaluate taxonomies effectively. This is a complex problem since there are many aspects to consider. We can consider how users would rate various aspects of their experience using a questionnaire. However this subjective study can be misleading since people can underrate or overrate their experience. A more objective approach is to log user interactions and then infer from these how effective the taxonomy is i.e. time spent on a task, how much of the domain was covered and so on. There have been user studies of taxonomies which have used combinations of both of these approaches (Malaisé et al., 2006; Yi, 2008; Nikolova et al., 2010). There is also an important distinction to be made between the data content of a taxonomy and the methods used for visualisation. There have been user studies which have focussed on evaluation different visualisations while keeping the data constant (Katifori et al., 2007). In this paper we are considering only the data content, the concepts and relations, so visualisations are kept constant.

User studies are certainly important. However these studies often don't answer certain questions about the taxonomy. We can measure aspects of their experience but we might not have a fine-grained understanding of which aspects of the taxonomy were positively or negatively perceived. Also such studies require users to be physically present at a machine specially set up for logging. This can make such studies expensive and time-consuming. A different approach is to use intrinsic evaluations. Yu et al. (2007) present a wide range of ontology evaluation approaches as applied to variations of the Wikipedia category structure such as

[4] http://www.nlm.nih.gov/mesh/

fanout, tangledness, relationship richness, class richness, importance connectivity and cohesion. Cohesion attempts to measure the degree to which similar items are clustered together under a single node in the taxonomy. This was initially proposed by (Boyd-Graber et al., 2009) and has also recently been applied to cultural heritage (Hall et al., 2012).

Another evaluation is to measure the accuracy of the child-parent pairs from the taxonomies by asking evaluators to classify them as either *isa* or *notisa* relations (Snow et al., 2004; Ponzetto and Strube, 2011). A similar method is used here but expanded to give a more detailed understanding of the types of the relations found in the different taxonomies.

3 Resources and tools

This section lists some key resources and tools that are used in this paper.

3.1 Wikipedia Miner

The Wikipedia Miner (Milne and Witten, 2008) tool is used in this paper both as a tool to help map items into existing taxonomies and as a way to generate a novel taxonomy from scratch. Wikipedia Miner is a Wikification tool which adds inline links to Wikipedia articles into free text. The software is trained on Wikipedia articles, and thus learns to disambiguate and detect links in the same way as Wikipedia editors. Disambiguation of terms within the text is performed first. A machine-learning classifier is used with several features. The main features used are *commonness* and *relatedness*, as in Medelyan et al. (2008). The commonness of a target sense is defined by the number of times it is used a destination from some anchor text e.g. the anchor text 'Tree' links to the article about the plant more often than the mathematical concept and is thus more common. Relatedness gives a measure of the similarity of two articles by comparing their incoming and outgoing links. The performance achieved using their approach is currently state of the art for this task. The Wikipedia Miner software is freely available[5].

3.2 Europeana cultural heritage collection

Cultural heritage items from Europeana are used for the evaluation. Europeana is a large online aggregation of cultural heritage collections from across Europe. In this paper a snapshot of the English subset of the data from March 2011 is used. This comprises 547780 items in total. Each item consists of an XML metadata record. This comprises a number of fields the most informative of which are `dc:title`, `dc:subject`, `dc:description` which contain the title, subject keywords and a textual description of the item. About 74% of the items have an associated image which is displayed on the portal website. A difficulty with this collection is that a significant number of the items have very little associated metadata. In the worst case some items have only a one-word title, with no subject or description. This problem is dealt with implicitly in the methods described below, where such sparse records are effectively filtered out in the mapping and taxonomy generation stages and are not included in the evaluations.

4 Taxonomies and mappings

Six taxonomies were tested in these experiments. Four of these were based on existing taxonomies which have been mostly manually created: the Library of Congress Subject Headings, WordNet Domains, Wikipedia Taxonomy and DBpedia. The remaining two taxonomies were automatically derived from the metadata present for the items in the collections: WikiFreq and

[5] `http://wikipedia-miner.cms.waikato.ac.nz/`

LDA topics. This section gives a description of each of these taxonomies and how the items in the collection were mapped into them. Statistics for each taxonomy are presented at the end of this section.

4.1 Manually created taxonomies

4.1.1 Library of Congress Subject Headings (LCSH)

The LCSH comprises a controlled vocabulary maintained by the United States Library of Congress for use in bibliographic records. They are used in many libraries to organise their collections as well as for organising materials online.

The text from the `dc:subject` field in the Europeana item are used for the mapping. The text is lemmatized using Freeling (Padró, 2011). The text is compared to the category labels for the LCSH concepts. If the text contains any of the category labels then the item is matched to these categories. If more than one matching label is found, then the longest matching label is used for the mapping.

4.1.2 WordNet domains

The WordNet hierarchy is a fine-grained classification which is too detailed for browsing, with more than a hundred thousand nodes and concepts like *entity, natural phenomenon* and *body of water*. Instead *WordNet domains* organises the WordNet concepts into a smaller hierarchy, with only 164 domain labels which are easily understood by a general user. The domain labels have been semi-automatically applied to each of the synsets in WordNet. Each synset is annotated with each one label from a set of about two hundred. The information provided by the domain labels is complementary to the data existing already in WordNet. The domain labels group together words from different syntactic categories (e.g. nouns and verbs), and also may group together different senses of the same word and thus reduce polysemy.

WordNet domains lists the domain labels for all open class words in WordNet, but it only contains a few proper nouns. Given the large concentration of proper nouns in Europeana, we extend the list of words using Yago2. Yago2 (Hoffart et al., 2011) is a knowledge base derived from Wikipedia with more than 10 million entities, and each entity in Yago2 is linked to a WordNet 3.0 synset. We also used a mapping from WordNet 3.0 synsets to WordNet Domain labels as provided by the Multilingual Central Repository (MCR) (Atserias et al., 2004). To perform the mapping, the first step is again to use the `dc:subject` field to link Europeana items to Yago2 entities (using lemmatization and finding the longest possible match). These are then mapped to the WordNet Domain labels via the Yago2 entity-to-synset and the MCR synset-to-WordNetDomain mappings.

4.1.3 Wikipedia Taxonomy

Wikipedia Taxonomy (Ponzetto and Strube, 2011) is a taxonomy derived from Wikipedia categories. The authors create the Wikipedia Taxonomy by keeping the isa relations between Wikipedia categories and discarding the rest. We first apply Wikipedia Miner (see Section 3.1) over the Europeana items to find the relevant Wikipedia entities in the the `dc:subject` field. Then, we link the Europeana item to all Wikipedia Taxonomy categories which are related to these entities.

4.1.4 DBpedia ontology

The DBpedia ontology (Auer et al., 2007) is a small, shallow ontology manually created based on information derived from Wikipedia. Contrary to the previous vocabularies described above, the DBpedia ontology is a formalised ontology, including inference capabilities. The authors provide the instances of each ontology class, i.e. the set of Wikipedia entities pertaining to this class. For mapping Europeana items to DBpedia ontology classes, we first apply Wikipedia Miner to find the relevant Wikipedia entities to the item, and then link the item to the classes these entities belong.

4.2 Automatically created data-driven taxonomies

4.2.1 LDA topic modelling

Latent Dirichlet Allocation (LDA) is a state-of-the-art topic modelling algorithm, that creates a mapping between a set of topics T and a set of items I, where each item $i \in I$ is linked to one or more topics $t \in T$. Each item is input into LDA as a bag-of-words and then represented as a probabilistic mixture of topics. The LDA model consists of a multinomial distribution of items over topics where each topic is itself a multinomial distribution over words. The item-topic and topic-word distributions are learned simultaneously using collapsed Gibbs sampling based on the item - word distributions observed in the source collection (Griffiths and Steyvers, 2004). LDA has been used to successfully improve result quality in Information Retrieval (Azzopardi et al., 2004; Wei and Croft, 2006) tasks and is thus well suited to support exploration in digital libraries.

To turn the flat LDA topic model into a navigable hierarchy, Griffiths and Tenenbaum (2004) describe a hierarchical LDA approach. However this was found to be prohibitively time consuming given our large data-set. Instead a recursive divide and conquer approach was used, which was much more efficient. The number of topic groups at each stage was limited to a maximum of 9 to make the hierarchy manageable for users to navigate. The algorithm is outlined below.

1) Run LDA over the corpus to determine the document-topic probabilities. The number of topics $topic\_n$ to generate is automatically determined using this equation:

$$topic\_n = \min(9, \frac{\left|documents\_in\_corpus\right|}{30}) \quad (1)$$

2) For each topic used the document-topic probabilities that LDA outputs to identify the set of documents associated with that topic. Each document is assigned only to its highest-probability topic. While this removes some of the power inherent in the LDA topic model, we believe that from a navigational perspective it is better if each document is located at only one point in the hierarchy and not at multiple points. To give each topic a label, we simply selected the highest-probability word from each topic's topic-word distribution.

3) If a topic set has less than 60 items then stop. Otherwise go back to 1) using the set of items identified in 2) as the corpus.

4.2.2 Wikipedia link frequencies

This is a novel method for taxonomy creation which uses Wikipedia article links as the concept nodes in the taxonomy. The first step is to add inline article links to all the item texts in the collection using Wikipedia Miner (see Section 3.1). A confidence threshold of 0.5 was used to help ensure the links were of high quality - that is they are correctly disambiguated and relevant to the topic of the item.

The first step is to find the frequency counts of all article links that occur in the items. Let L be the set of all links found in the items. Then the frequency function $F : L \rightarrow \mathbb{N}$ gives the global frequency count for occurrences of the link in all items.

The following procedure is then used for each item to create and populate the taxonomy. Let $S \subset L$ be the set of links found in that item. The links are ordered in S by order of frequency according to the F function (most frequently occuring first) to give an ordered list of links $a_1, a_2, a_3 \cdots a_n$. The item is then inserted into the tree under the branch $a_1 \rightarrow a_2 \rightarrow a_3 \cdots \rightarrow a_n$, with a_1 at the top level in the tree and the item appearing under the node a_n. If this branch does not already exist in the tree then it is created.

It was found that using this approach the branching factor was very high at some levels so the number of child nodes at each level was limited to at most 20. Furthermore only items with at least 2 links were used to prevent a large number of single-linked items appearing at the top level. Concepts with less than 20 items were also filtered out.

This method is labelled WikiFreq in the remainder of the paper.

4.3 Taxonomy statistics

Table 1 shows some statistics for each taxonomy:

- The number of items that are mapped into the taxonomy.
- The average number of parents for each item.
- The average depth from the root node to an item.
- The number of top level nodes in the taxonomy.

A problem with some of the manual taxonomies is the very high number of top level nodes, which makes it difficult for users to browse. However there is no obvious way to select suitable top level nodes in these taxonomies. Additionally some of the taxonomies assign items to many parent nodes - this means that the data is repeated across the taxonomy. This is not a problem in itself, but is likely to mean that items may often be assigned to incorrect nodes.

5 Experiments

Two evaluations were performed on the taxonomies. The first measured the cohesion of the item clustering, and the second gathered human judgements of the relations that were found between child-parent concept pairs in the taxonomy. For both evaluations online surveys were created using an in-house crowdsourcing interface. Links to the surveys were sent out to a mailing list comprising thousands of students and staff members at the University of Sheffield.

Type	Taxonomy	Items	Nodes	Avg. parents	Avg. Depth	Top nodes
Manual	LCSH	99259	285238	1.8	1.97	28901
	DBpedia	178312	273	4.2	2	30
	Wiki Taxonomy	275359	121359	11.7	1.13	10417
	WN domains	308687	170	7.1	7.1	6
Automatic	LDA topics	545896	22494	1	7.3	9
	Wiki Freq	66558	502	1	3.39	24

Table 1: Statistics for each taxonomy

5.1 Cohesion

A cohesive cluster is defined as one in which the items are similar while at the same time clearly distinguishable from items in other clusters (Tan et al., 2006). To measure the cohesiveness of the taxonomies we use the *intruder detection* task originally devised in Boyd-Graber et al. (2009) and recently used for cultural heritage items in Hall et al. (2012). The idea of this is to present 5 items to an evaluator. Four of these are taken from one concept node in the taxonomy and the other (the *intruder*) is randomly picked from elsewhere in the taxonomy. The more cohesive the concept in the taxonomy the more obvious it should be which is the intruder item. Each *unit* was displayed as a list of five images along with the titles of the items. An example[6] of a cohesive unit is shown in Figure 1. To generate good quality units for the evaluation the *informativeness* of items was calculated as follows:

$$\begin{aligned} informativeness(item) = \quad & length(item_{title})/avgL_{title} * log(N/count(item_{title})) \\ & + length(item_{desc})/avgL_{desc} * log(N/count(item_{desc})) \\ & + length(item_{subj})/avgL_{subj} * log(N/count(item_{subj})) \end{aligned}$$

where $title, desc, subj$ refer to the title, description and subject fields of the metadata, $avgL_X$ is the average length of field X over the whole collection, $length(item_X)$ is the length of that item field text, and $count(item_X)$ gives the frequency of that item field text over the whole collection. The higher the resulting value the more informative the item is. Note that as well as taking into account the length of the fields, this also weights by the inverse document frequency (idf) value, so very frequently occuring terms will be downweighted.

The most informative items were selected for each category. This helped to ensure that the users were presented with informative items, allowing them to have enough information to decide which was most likely to be the intruder. The same also applies to the taxonomy mappings being evaluated; it is difficult to correctly map items with very little information in the metadata. The procedure for selecting the sample units was as follows:

[6] Images reproduced from Wikipedia and subject to relevant licenses.
http://en.wikipedia.org/wiki/File:York_Minster_close.jpg.
http://en.wikipedia.org/wiki/File:Wells_Cathedral,_Wells,_Somerset.jpg.

http://en.wikipedia.org/wiki/File:Sfec-durham-cathedral-2007-263.JPG

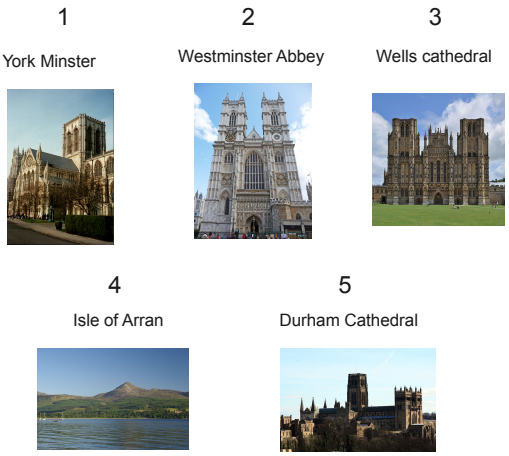

Figure 1: Example of a cohesive unit. Here the intruder item is number 4.

1. Select categories at random that have at least 4 items.

2. For each category:

   (a) Return the 4 items in the category which were most informative.

   (b) To find the intruder item, select 100 items at random from the whole collection and return the most informative item.

Six units were shown on each page, one of which was always a control unit. The control units were manually chosen to be examples where the intruder was very obvious. The purpose of the control units was to ensure the quality of the judgements, since if a participant got the control unit wrong it was an indication that they were not taking the task seriously.

Thirty non-control units were created from each taxonomy. Altogether 134 people attempted the survey. 23 of the users evaluated at least one control unit wrong, or evaluated less than 5 units in total, and so their answers were excluded. The remaining 111 participants contributed a total of 1255 answers. Each unit received a minimum of 5 answers and an average of 6.97 answers. A unit was judged as cohesive if more than 80% of the annotators agreed on the same intruder.

Type	Taxonomy	Coherent units	Percentage
Manual	LCSH	19	63.3
	DBpedia	17	56.7
	Wiki Taxonomy	18	60.0
	WN domains	15	50.0
Automatic	LDA topics	17	56.7
	Wiki Freq	**29**	**96.7**

Table 2: Number of coherent units (out of 30) for each of the taxonomies.

The results (Table 2) show that most of the taxonomies achieved roughly the same level of cohesion for the clusters, roughly between 50 and 63%. However the WikiFreq taxonomy performed far better, with only one unit of the 30 judged as not coherent. This success shows that the Wikipedia links are very effective as a means of grouping together similar items. This might be explained by considering that items grouped together under the same node will share a number of keywords which link to the same Wikipedia articles which would ensure that the items are very similar. In contrast the Wikipedia taxonomy and DBpedia ontology use categories rather than articles in Wikipedia as the concept nodes. These are much more loosely defined; each article in Wikipedia can belong to many categories and each category contains many articles. The results also indicate that Wikipedia articles as entities are much more clearly defined than the LDA topic keywords and thus work much better at grouping together the similar items.

5.2 Relation classification

Previous work has evaluated taxonomies by presenting child-parent pairs of concept nodes to evaluators and asking them a simple boolean question - does the pair represents a valid hypernymic relation, i.e. is it true that "ChildNode isa ParentNode"? (Ponzetto and Strube, 2011; Snow et al., 2004). We would expect the manually created taxonomies to perform well here. The automatic methods also intend to create a hierarchical structure, with more general concepts at the top nodes going to more specific in the lower nodes.

Here we conduct a slightly deeper analysis of what kinds of relations were present in these taxonomies. Instead of a simple boolean question a two-part question was used. Given a child-parent pair A, B the evaluators were asked two questions:

1. Are the two concepts A and B related? (Yes/No/I don't know) The evaluators were asked to judge the relation within the context of the cultural heritage taxonomy. A positive example was presented: Westminster and London, which were related because Westminster is in London. A negative example was Fish and Bicycle which were unrelated and would not be a useful pair to include in a taxonomy.

2. If Yes, then how would you best define the relationship? Is A more specific than B, less specific than B, neither, or don't know? Examples were also given to help with this question. Westminster is *more* specific than London since Westminster is within London. The term Scientist is less specific than Physicist, since while all Physicists are Scientists, not all Scientists are Physicists (they could be biologists or chemists for example). For

Type	Taxonomy	Child (A)	Parent (B)
Manual	LCSH	Work	Human Behaviour
		Braid	Weaving
		Time	Geodetic Astronomy
	DBpedia	Mountain Range	Place
		Fern	Plant
		Congressman	Politician
	Wiki Taxonomy	Mammals of Africa	Wildlife of Africa
		Schools in Wiltshire	Schools in England
		British Culture	European Culture
	WN domains	vehicles	transport
		mechanics	engineering
		home	applied science
Automatic	LDA topics	earthenware	dish
		view	church
		tunnel	chapel
	Wiki Freq	Corrosion	Coin
		Interior Design	Industrial Design
		Towpath	Waterscape

Table 3: Some examples of child-parent pairs from each taxonomy.

the 'neither' option consider Physicist and Biologist. The concepts are related (both are scientists) but neither is more specific than the other.

Forty non-control pairs from each taxonomy were presented to the evaluators giving a total of 240 pairs. Examples of concept pairs from each taxonomy are shown in Table 3. As for the previous experiment control pairs were manually identified where the answer should be obvious. Five pairs were shown on each page of which one was always a control pair.

Altogether 270 people attempted this survey. 97 people evaluated more than half the control pairs wrong or evaluated less than 5 pairs in total, and so their answers were excluded. Of the 173 remaining participants, a total of 3826 evaluations were made for each pair. A minimum of 8 evaluations and an average of 15.94 evaluations were made for each instance.

Type	Taxonomy	Yes	No	Don't know	Agreement
Manual	LCSH	74.2	8.8	17.0	79.1
	DBpedia	86.6	11.2	2.2	88.4
	Wiki Taxonomy	**96.1**	1.7	2.3	**95.9**
	WN domains	77.1	14.5	8.4	83.9
Automatic	LDA topics	30.3	**50.3**	19.3	71.6
	Wiki Freq	47.6	16.5	**35.8**	70.9

Table 4: Are *A* and *B* related?

The results for the relatedness question (Table 4) show a clear pattern. The manually created taxonomies are markedly more likely to contain clearly related pairs of concepts. The Wikipedia

taxonomy hierarchy is the highest performing in this regard which suggests that the user-created category hierarchy is of high quality and has easily understood concepts and relations. DBpedia scores slightly lower. This difference might be explained due to DBpedia containing article entities as well as categories. The lower score suggests either that articles are not always placed in the best categories, or that it is harder for users to identify article-category relationships. WordNet domains scores lower. This may be due to the domain concepts being sometimes quite general and possibly harder for general users to understand (for example one pair of concepts was 'color' and 'factotum'). LCSH scored surprisingly low considering that it is a manually created taxonomy. This suggests that the concepts and relations in this hierarchy are even harder for users to understand or identify. Finally the two data derived taxonomies score lower still. For the WikiFreq taxonomy a high percentage of the relations were classified as 'Don't know'. This may be because a high number of the article links are about quite obscure concepts which most people would not know about. Finally the LDA topics produced the highest number of definite 'No' judgements which shows that the taxonomy may be difficult or confusing for users to navigate.

Type	Taxonomy	$A < B$	$A > B$	Neither	Don't know	Agreement
Manual	LCSH	65.4	8.7	23.4	2.5	68.7
	DBpedia	76.2	4.9	18.1	0.7	78.9
	Wiki Taxonomy	**78.3**	4.7	16.0	0.9	**82.8**
	WN domains	63.6	6.3	28.0	2.0	67.6
Automatic	LDA topics	21.4	14.8	**62.1**	1.6	61.0
	Wiki Freq	30.9	**22.6**	43.6	**2.9**	67.0

Table 5: Specificity of the pairs, with A the child node, and B the parent node. $A < B$ means A is more specific than B.

The results for the specificity question are shown in Table 5. These follow a roughly similar pattern to the relatedness. The $A < B$ case is the most desirable for the taxonomies since we would prefer the most general concepts at the top of the hierarchy narrowing down into more specific concepts. The Wikipedia taxonomy and DBpedia both score relatively highly here, although both contain a surprisingly high number of cases where neither A or B was identified as more specific than the other (16.0 and 18.1% respectively). For the Wikipedia taxonomy this shows that although almost all child-parent pairs are considered to be related concepts, they are not always easily identified with the child as more specific than the parent. Both WordNet domains and LCSH fare worse, again with more relations identified as 'neither'. The WikiFreq taxonomy contains a more mixed set of results with quite a high proportion of relations the 'wrong way round' with A deemed to be less specific than B, although the highest number falls into the 'neither' category. This result is a reflection of the nature of the links within the items. The taxonomy is ordered with the most frequent occuring links at the top going down towards the least. Clearly this is not enough to create the kind of general-to-specific relationships which are desirable. Finally the results for the LDA topics show that the majority are defined as 'neither' - the concepts are topically related but mostly without any specificity ordering.

Conclusion and perspectives

Developing effective taxonomies for the purpose of organising large number of data items is a complex task. Existing manually created taxonomies might be accurate and well structured but may not be adequate for a specified domain or may be hard for users to navigate. Automatic methods for deriving taxonomies have the advantage of closely reflecting the nuances of the data - but organising the derived concepts into meaningful relations remains a problem.

The experiments in this paper shows some surprising results. The LCSH taxonomy has been manually created for the purpose of organising library collections and so might be the obvious choice to organise CH data online. However the results show that the relations within LCSH are defined less clearly than that of the Wikipedia derived taxonomies. WordNet domains performs at a similar level to the LCSH in terms of the quality of the relations. The LDA topic hierarchy gave poor results in terms of the identified topics. The topic pairs were often unrelated, and had no general-to-specific structure as would be desirable for this application.

The WikiFreq hierarchy performed slightly better in this regard. Just over half the concept pairs were judged to be related. Just under a third were labelled as 'Don't know' which may reflect the obscurity of the concept nodes identified. It was hoped that organising the frequency counts of the links would organise the hierarchy into a general-to-specific direction. This was not achieved, although the hierarchy does have the benefit of providing the user with an overview of the collection by immediately seeing which kind of items are most prevalent.

In terms of cohesion all the taxonomies achieved similar results except for the WikiFreq taxonomy which achieved almost perfect cohesion. This shows how effective the Wikipedia links are in grouping together similar items.

It is also worth noting that WikiFreq and LCSH map significantly fewer items into the taxonomy.

Future work will continue with different evaluation approaches, such as domain/task coverage and accuracy of the mappings. We also aim to expand the evaluations to include user studies; a key question is how well these taxonomies assist users when used for browsing large collections, such as Europeana. The aim is to see if there is a correlation between the intrinsic results that were found here with the extrinsic quality judgements when used in real life applications. A promising line of work will be to build on the WikiFreq approach by integrating with the high quality Wikipedia taxonomy knowledge base. The hope is that using this approach will generate highly coherent units along with a well structured conceptual tree.

ABSTRACT
Manual corpus annotation is getting widely used in Natural Language Processing (NLP). While being recognized as a difficult task, no in-depth analysis of its complexity has been performed yet. We provide in this article a grid of analysis of the different complexity dimensions of an annotation task, which helps estimating beforehand the difficulties and cost of annotation campaigns. We observe the applicability of this grid on existing annotation campaigns and detail its application on a real-world example.

KEYWORDS: manual corpus annotation, annotation campaign management, annotation campaign cost estimate.

Proceedings of COLING 2012: Technical Papers, pages 895–910,
COLING 2012, Mumbai, December 2012.

1 Introduction

With the development of NLP applications, the annotation campaigns are becoming more numerous and more varied. Annotated corpora are used for acquiring knowledge as well as for testing theories, models and tools. They can be directly used in end-applications or for specific internal tasks.

Manual annotation is actually a widespread practice in NLP. It consists in adding labels of linguistic nature or reflecting the usage of NLP technologies on some oral or written discourse. This corresponds to a great diversity of phenomena, as these annotations vary in nature (phonetic, morpho-syntactic, semantic or task-oriented labels), in the range they cover (they can concern a couple of characters, a word, a paragraph or a whole text), in their degree of coverage (all the text is annotated or only a part of it) and in their form (atomic value, complex feature structures or relations and even cross-document alignment relations).

It has been a long road since the big pioneer annotation campaigns like the Penn Treebank (Marcus et al., 1993), but one problem remains: manual annotation is expensive. Various strategies have been implemented to reduce or control annotation costs. Tools have been developed to assist and guide the work of annotators. Automatic annotation methods, sometimes based on machine learning, have been introduced to relieve the annotator of the most trivial and repetitive work and to allow him/her to focus on the hardest annotation tasks where human interpretation is critical. For simple tasks, the use of crowdsourcing is developed with the idea of dividing up tedious work and exploiting the number of annotators to compensate for the heterogeneity of their competence and reliability. Significant efforts have also been made to develop evaluation protocols and to measure intra and inter-annotator agreements, which allow for a better control of the quality of the produced annotated data.

Despite all this work and the experience gained in annotation, we lack a global picture or an overall methodology to *a priori* determine the various costs of an annotation campaign (task definition, data preparation, recruitment and management of annotators, annotation itself, quality control, etc.), make the necessary compromises and choose the appropriate solutions to alleviate the annotators' work.

This article relies on the analysis of many annotation campaigns, which are described in the state of the art or were managed by the authors. It does not offer a tool or a ready-made solution to tell you "how to build your next annotation campaign". Instead, we propose an analytical framework, a grid of analysis, to understand the complexity of annotation tasks. It is based on a decomposition of these tasks into elementary ones and a decomposition of complexity into 6 dimensions that are orthogonal to each other except for one. We also provide concrete metrics to measure the complexity of annotation tasks, *a priori* when possible, from already annotated samples or by comparison with similar annotation tasks. Our approach is pragmatic, as our aim is to provide practical tools to analyze the complexity in all its dimensions. Obviously, it gives a simplified view of complex annotation tasks, but it enables to compare different campaigns on a common basis.

This article is as follows. Section 2 shows that the notion of complexity is present in many works in the state of the art but that no comprehensive analysis has been proposed so far. The third section presents our analysis of the complexity dimensions of annotation. Section 4 illustrates the practical benefit of this method of analysis and shows how to apply it on a complex task.

2 An important but implicit issue

If the question of the complexity of annotation tasks has deserved little attention as such, it is implicitly present in most of the issues related to annotation.

2.1 Feedback on large-scale campaigns

An effort has been made to document large-scale projects and encountered issues. For example, concerning the Penn Treebank, (Marcus et al., 1993) explains that the POS tagset has been largely reduced as compared to that of the Brown corpus, in order to eliminate the categories that could be deduced from the lexicon or the syntactic analysis. It is also noted that reducing the size of the tagset allows to reducing inconsistencies. Finally, in order to "avoid arbitrary decisions", the annotators were allowed to associate several categories to a same token. The same principle was used for the syntactic layer, allowing multiple binding in case of ambiguity. For the same reason, no distinction was made between arguments and circumstants. (Abeillé et al., 2003) presents the main issues encountered during the French Treebank annotation and the found solutions. One difficulty concerns multi-word expressions that the campaign managers finally chose to annotate both as multi-word expressions and as distinct elements to avoid "linguistic debates". Another interesting issue concerns the hierarchical structure of the tagset. It allows to simplify the annotation as most of the sub-categories end up being unambiguous once the main category is selected. In the speech domain, the MEDIA annotation campaign gave rise to an in-depth reflexion on the methodology (Bonneau-Maynard et al., 2005), but is addresses the management of annotation campaigns rather than the analysis of annotation tasks.

2.2 Good practices in manual annotation

Good practices have progressively emerged to tackle various aspects of annotation tasks. They have been, in particular, inherited from corpus linguistics. (Leech, 1993, 2005) present a list of what a specification for annotation should contain. It represents an effort toward the identification of several levels of difficulty encountered when making decisions during the manual annotation of a corpus: segmentation, inclusion of units (words or phrases) within other units (clauses or sentences), assigning categories to some textual fragments.

Annotation formats Recommendations were published within the framework of the standardization effort of the annotation formats, in particular in (Ide and Romary, 2006), that finally gave birth to the ISO 24612 standard. In this view, the authors are little concerned by manual annotation difficulties as such but, to represent annotations they identify complex structuring elements which are of interest here : segmentation (identification of continuous or discontinuous sequences of characters), several layers of annotations (for example morpho-syntactic, then syntactic), relations between these layers, overlapping issues.

Organization of annotation campaigns An overall schema of the organization of annotation campaigns has also emerged. It involves several actors, among which the client (who can, for example, be the organizer of an evaluation campaign), the annotation manager, that is the person who is going to write the annotation guide from a (clearly) expressed need, and the annotators themselves, who proceed from the annotation guide. The increasing use of so-called "non-experts", through crowdsourcing for example, introduced a further distinction between expert annotators (editors/curators in GATE Teamware (Bontcheva et al., 2010)) and annotators themselves. The multiplication of actors contributes to the difficulty to organize an annotation campaign but not to that of the annotation task *per se*. Note also that the analysis we propose here applies whatever the level of expertise of the annotators. Besides, the annotation guide is recognized as the keystone of annotation campaigns, as it defines what should be annotated. Here, we consider that the need is clearly defined and known from all the participants.

Annotation evaluation Studies concerning the evaluation of the quality of manual annotation allowed to identify some factors influencing inter- and intra-annotator agreements. (Gut and Bayerl, 2004; Bayerl and Paul, 2011) demonstrated that the inter-annotator agreement and the complexity of the annotation task are correlated (the larger the number of categories, the lower the inter-annotator agreement) and that the categories prone to confusions are in limited number. This brings out two complexity dimensions related to the number of categories and to the ambiguity between some categories. This ambiguity-related complexity dimension also appears in (Popescu-Belis, 2007). In the study of the inter-annotator agreements, (Krippendorff, 2004) identified a step of identification of the elements to annotate that is called "unitizing". Similarly, in the Proposition Bank project (Palmer et al., 2005), the organizers separated role "identification" from role "classification" to compute the inter-annotator agreement, in order to "isolate the role classification decisions" from the (supposedly easier) identification.

2.3 Insights from Cognitive Science

Few publications focus on the difficulties of manual annotation. In (Tomanek et al., 2010), the authors used an eye-tracking device to analyze and model the annotation cognitive complexity. Their experiment was carried out on a simple named-entity annotation task (persons, locations and organizations), with some pre-identification of complex noun phrases containing at least one potential named entity. They measured the influence of the syntactic and semantic complexities[1] as well as the size of context that was used by the annotators. The results show that the annotation performance tends on average to "correlate with the [semantic] complexity of the annotation phrase" and less so with its syntactic complexity, and that the size of the needed context also depends on the semantic complexity of the annotation phrase. However interesting, their conclusions only apply to simple named entity annotation task.

3 Measuring the complexity of an annotation task

Manual annotation requires the annotator to determine which units should be annotated and how. Measuring the complexity of an annotation task requires a detailed analysis of these localization and characterization operations.

We propose to analyze the complexity of elementary annotation tasks according to six dimensions: the first two (discrimination and delimitation) relate to the localization of annotations, while the next three concern their characterization (expressiveness, tagset dimension and ambiguity degree). The context is a sixth factor of complexity that impacts annotation decisions: it is presented here as a separate dimension for the sake of simplicity, even though it simultaneously affects discrimination, boundaries delimitation and disambiguation.

Analyzing a task along those six dimensions is artificial in the sense that annotators do not make separate decisions, but this analytic approach is meant for the management of annotation. It is independent from both the volume of annotations to be added and the number of annotators involved: these values participate in the cost of a task but not in its complexity, which is important to evaluate as early as possible in the annotation process.

3.1 Decomposition of annotation tasks

In an annotation task, one or several human annotators are asked to explicit how they interpret a source signal. The guidelines usually explain what kind of interpretation is expected and for which purpose. Depending on the task, the annotators are provided with a closed tagset or

[1] Respectively measured as the "number of nodes in the parse tree" and the "inverse document frequency of the words in the phrase according to a reference corpus".

are allowed to introduce any tag they find relevant. The annotators have to read the source document and tag some or all of its segments with one or several tags.

Instead of decomposing annotations tasks into *levels* or *layers* (Goecke et al., 2010), in order to analyze the task complexity, we propose to decompose a campaign into *elementary annotation tasks* (EATs). The complexity of the various EATs is computed independently and the complexity of a whole campaign is computed as the combination of the complexity of the elementary tasks. We consider that an annotation task can be decomposed into two or more EATs if the tagset itself is made of smaller independent ones. [2] This decomposition in EATs is formal in the sense that it is independent of the pragmatic organization of the work: the annotators can handle different EATs as separate steps on the source signal or all at once depending on the specific nature of the work and the tools they use. The decomposition in EATs does not result in a simplification of the original task as it is often the case for the Human Intelligence Tasks (HITs) to be performed by Turkers (workers) in Amazon Mechanical Turk (Cook and Stevenson, 2010).

To take a simple example, the annotation of gene renaming relations can be analyzed as a combination of two EATs. The first one identifies the gene names in the source signal. The second one relies on the first level of annotation and indicates which of the genes hold in a renaming relation. Obviously, the annotators can add both types of annotations at the same time, but the tagsets are independent and it is easier, from a formal point of view, to analyze the annotation task as a combination of two EATs than as a unique, but complex one.

3.2 What to annotate?

Localizing the units to be annotated consists in distinguishing what is to be annotated from what is not, and potentially adjusting the boundaries of the identified units.

3.2.1 Discrimination

In some annotation experiments, the question of "what to annotate" is straightforward, for instance when the units to annotate have already been marked in an automatic pre-annotation phase or when all the units are to be annotated, as in a POS-tagging task. However, for the annotators, the corpus is often a haystack within which they must find what to annotate, and discriminating what should be annotated from what should not is a complex task.

Identifying the units on which the annotation work should focus is all the more complex as the units to consider are heterogeneous. (Erk et al., 2003) emphasizes that semantic role annotation and discourse annotation mix several levels of segmentation (from less than a word to more than a sentence). As a simple example, it is easier to identify in a text negatively connoted adverbs, in particular, than all the negative expressions, as the latter can be words, phrases, or even entire parts of a text. In the second case several segmentation levels are actually to be considered. This gives a first scale of difficulty. An annotation task is considered difficult to the extent that the discrimination factor, defined by the following formula, is high:

$$Discrimination_a(F) = 1 - \frac{|A_a(F)|}{\sum_{i=1}^{n} |D_i(F)|}$$

where F is the flow of data to annotate, a is an annotation task, n is the number of segmentation levels that are potentially relevant, $|D_i(F)|$ is the number of units obtained during the

[2] Independence, here, means that the tags of two different tagsets are globally compatible (even if some specific combinations may be forbidden), whereas the tags of a single tagset are mutually exclusive (except for encoding ambiguity).

segmentation of F at level i and $|A_a(F)|$ is the number of units to be annotated in the relevant annotation task.

Intuitively, this measure indicates that the discrimination weight is high when the units to annotate or mark are "submerged" within others, and when the proportion of what is to be annotated ($|A_a(F)|$) as compared to what could be annotated or is "markable" ($\sum_{i=1}^{n} |D_i(F)|$) is low. The identification factor is 0 when all the units of the flow are to be annotated, and approaches 1 when only a few units are actually to be annotated while many could be annotated.

For the classification of pronouns as anaphoric or impersonal, the discrimination factor is 0 if all the occurrences of pronouns have been identified beforehand. By contrast, for gene renaming relations, the discrimination factor is high because only a small proportion of gene name couples participate in a renaming relation and are to be annotated as such.[3]

It is generally easy to estimate the number of units to be annotated – from the definition of the annotation task, on a sample of the relevant corpus or by reference to comparable tasks – but more difficult to estimate what could be annotated. This requires the choice of a reference segmentation that divides the flow to annotate into units, of which some are to be annotated, and others not. This reference segmentation can be chosen in different ways:

1. The simplest solution is to rely on an obvious segmentation which can be automatically computed or which is intuitive for the annotator, even if it implies reviewing the boundaries of the units to be annotated which do not correspond to this segmentation. For example, with named entities, starting from a segmentation into words leads to consider compound named entities as "modified" units. This strategy reduces the discrimination weight, but increases the issue of boundary delimitation (see section 3.2.2 below).

2. When the units to annotate are too heterogeneous, several reference segmentations can be considered ($n > 1$ in the preceding formula): this increases the number of "markables", but avoids the need to modify many boundaries. In the case of named entities annotation, one could for instance consider all the words and all the phrases as "markables". This approach must be used if it seems less costly than the previous one.

3. Finally, the annotation task can be decomposed into several layers, corresponding to distinct EATs. In that case, the discrimination weights of the layers are computed independently, each one with a specific reference segmentation. Such a decomposition is needed only when the different types of "markables" resulting from the various segmentations are annotated differently. It would be artificial for instance to decompose the task of named entities annotation into several EATs if the same tagset is used for words and phrases.

3.2.2 Boundary delimitation

Identifying points of interest in the flow of data is not enough, as the elements to be annotated are often data segments. To identify what to annotate, one should also delimit the boundaries of the segment to be annotated.

Here again, the task is easy when a reliable reference segmentation can be computed. However, segmentations that can be computed automatically are often approximations and the annotator must locally modify the boundaries of the discriminated units: for instance, if one starts with a segmentation into words to annotate named entities or terms, the segmentation must be

[3] We assume here that the gene names are pre-annotated (or identified in a different EAT) and that all gene name couples in the same abstract are "markable", *i.e.* subject to expressing a renaming relation.

corrected for all the multi-word expressions. In most cases, delimiting the boundaries consists in enlarging or reducing the discriminated unit based on the reference segmentation, but there are also cases in which a discriminated unit should be decomposed in several units or where several contiguous discriminated units are grouped together into one annotation.[4]

Delimitation of boundaries represents a second complexity factor, $Delimitation_a(F)$, which is computed by comparing the segmentation obtained after the annotation to the reference segmentation. This factor is inspired from the slot error rate (Makhoul et al., 1999), a metric that is used in named entities recognition and classification and which takes boundary errors into account. Once the discriminated units before and after the boundary delimitation are optimally aligned, we can compute the following discrimination rate:

$$Delimitation_a(F) = min(\frac{S+I+D}{|A_a(F)|}, 1)$$

where $|A_a(F)|$ is the final number of discriminated units, I the number of inserted units, obtained by initial units decomposition, D the number of units deleted when grouping some of the initial units, and S is the number of substitutions, *i.e.* the number of discriminated units that underwent a change in their boundaries other than that of the previous decomposition and grouping cases.

This delimitation factor is worth 0 when no discriminated unit has been modified and it rises with the number of decompositions, groupings and boundary modifications performed by the annotator with respect to the reference segmentation. The value is limited to 1 to keep the same interval $[0, 1]$ for the six complexity factors.

The delimitation cost is measured *a posteriori*, but it can be estimated based on a sample of annotated corpus or by comparison with a similar task.

3.3 How to annotate?

Once the units have been discriminated and delimited, they have to be characterized.

3.3.1 Expressiveness of the annotation language

We distinguish between three types of annotation languages: type, relational and higher order languages.

In the simplest case, annotation consists in associating a type with a data segment, *i.e.* in labeling it. Many annotation tasks rely on such a type language: words of a text are associated with part-of-speech, speech turns are associated with interlocutors or with rhetorical functions, phrases are associated with named entities types. In some cases, the label that is used is itself structured, as with morpho-syntactic labels associating a part-of-speech with a lemma and its morpho-syntactic features, but such structuring increases the size of the tagset (see section 3.3.2) without changing the expressiveness of the annotation language.

Establishing relations between units is also a common task, but it is more complex. The complexity of relational annotations should not be underestimated: even if annotators do not always proceed in exactly this way, they have to locate and type the arguments of the relation, discriminate the couples, triplets, and more generally the n-uplets of segments to annotate among the set of n-uplets that are markable, and finally type the relation existing between the elements of the n-uplet.

[4] We neglect here the case of discontinuous units, which are often not annotated as such and which are not numerous enough to impact the present analysis.

A higher-order language is used when annotations are added to other annotations, but the complexity of this type of language, which is difficult to formalize and manipulate, is such, that it is often reduced to a simpler language. For example, to qualify an annotation as uncertain, the generally preferred option is to increase the tagset size so as to add the qualifier as an attribute associated with a main type. Alternatively, the decomposition of an annotation task into EATs also allows to qualify or relate, in a later step, annotations added in a previous one: you obtain several EATs, each one relying on a first order annotation language.

The degree of complexity entailed by the expressiveness of the annotation language is naturally represented by an ordinal qualitative scale, but for the sake of homogeneity with the previous factors, described by numeric values, we associate the different levels of expressiveness with graduations on a numeric scale from 0 to 1. In this scale, 0.25 corresponds to type languages, 0.5 and 0.75 to relational languages, respectively of arity 2 and higher than 2, while the maximal value, 1, is dedicated to higher-order languages.

3.3.2 Tagset dimension

The annotator generally selects the value of an annotation in a predefined tagset that is presented in the annotation guide and this choice is all the more difficult to make as it is open. The size of the tagset is therefore a new factor of complexity.

In the simplest case, the choice is boolean and annotating amounts to assigning the discriminated units into two categories:[5] sentences may be marked as relevant or not; the occurrences of the *it* pronoun are marked as anaphoric or impersonal.

However, the choice is often more open, for instance for representing the diversity of morpho-syntactic units, annotating syntactic dependencies or typing named entities. For the richest annotations, structured labels are often proposed: the annotator adds several labels on a single given unit, the combination of which forms the final annotation (Dandapat et al., 2009).

Finally, there are annotation tasks for which the choice of a label is entirely left to the annotator, as in speech transcription, where there may be as many labels as words. In such cases, we consider that we have a huge tagset, even though the annotation effort is probably of a slightly different nature for the annotator.

If an annotation A is formed of a sequence of m labels ($A = E_1 E_2 \ldots E_m$) and each label E_i can take n_i different values, the complete tagset theoretically contains n different labels, with $n = n_1 * n_2 * \ldots * n_m$. However, in practice, constraints are defined which reduce the number of combinations: the annotator does not have to choose one label from n at once, but instead first select 1 label among n_1 labels, then 1 among at most n_2, etc. up to 1 among at most n_m. The size of the tagset does not depend on the total number of possible labels but on the degrees of freedom of the successive choices that the annotator has to make. The total degree of freedom ν for the choice of m labels is given by the following formula:

$$\nu \leq \nu_1 + \nu_2 + \ldots + \nu_m$$

where ν_i is the maximal degree of freedom the annotator has when choosing the i^{th} label ($\nu_i = n_i - 1$).[6] For instance, the tagset for the POS part of the Penn Treebank contains 36

[5] This boolean annotation is similar to the discrimination task, though the units to be annotated should be not only located but labeled.

[6] The formula gives a high boundary of the global degree of freedom because the choice of the i^{th} label is often constrained by the labels already added, so the annotator has in practice a degree of freedom that is less than $(n_i - 1)$, if n_i is the number of available labels at this point.

tags (Santorini, 1990), so v equals 35, but as some tags are subtypes of others (like JJR and JJS for JJ) there are 21 in fact tags corresponding to main categories, and, as the maximum number of subtypes is 6 (for verbs), we may consider that $v = 20 + 5 = 25$.

The tagset dimension can be computed using the following formula:

$$Dimension_a(F) = min(\frac{v}{\tau}, 1)$$

where v is the global degree of freedom the annotator has when choosing a label for an annotation task a within a flow of data F, and τ is the threshold from which we consider the tagset as arbitrarily large. In the experiments detailed below, τ is worth 50, based on the feedback of the annotators.

The tagset dimension is worth 0 for the binary tagsets presenting a degree of freedom of 1 and it increases with the size of the tagset and the correspondingly increasing degree of freedom. It is worth 0.5 for the Penn Treebank POS tag annotation (0.7, if we consider the tagset as flat). It reaches a ceiling at 1. Annotation tasks with large tagsets ($> \tau$) are very difficult to manage.

3.3.3 Degree of ambiguity

The need to disambiguate the units to annotate introduces a fifth complexity factor, which is more difficult to estimate than the previous ones. As the role of the annotator is precisely to resolve ambiguous cases whenever possible, ambiguities are difficult to observe. Still, we can evaluate the ambiguity degree the annotator must resolve for a given task in two ways.

The first method consists in measuring the residual ambiguity degree by observing the traces left by the annotator during the annotation: the annotation protocol may allow the annotator to annotate with several labels in case of ambiguity, to use an under-determined label, or even to add an uncertainty feature to the chosen label. This allows measurement of the degree of residual ambiguity:

$$Ambiguity_{Res,a}(F) = \frac{|Annot_A|}{|Annot|}$$

where a and F are the annotation task and the flow of data to be considered and where $|Annot_A|$ and $|Annot|$ are respectively the number of annotations bearing an ambiguity mark and the total number of annotations added to F. By definition, this residual degree of ambiguity can only be measured *a posteriori*, once the annotation has been performed, or from a sample of it.

The degree of residual ambiguity is worth 0 when no ambiguity mark was added by the annotator and would be worth 1 in the case (in real life, absurd) where all the annotations were marked as ambiguous, in one way or another. Obviously, depending on the traces which are used to compute it and on the directions given to the annotators, this metric can be more or less reliable and it should be associated, whenever possible, with results from another method.

This second method consists in measuring the theoretical degree of ambiguity for the tasks where several occurrences of the same vocables (vocabulary units) are annotated: this method applies to morpho-syntactic annotation or to semantic disambiguation but not to speech turn analysis or gene renaming relations. This metric relies on the idea that ambiguous vocables have occurrences that are annotated differently at different locations in the flow of data. The ambiguity factor is given by the proportion of units to be annotated that correspond to ambiguous vocables. The theoretical ambiguity can be measured from a dictionary that lists the possible labels for all the vocables, if the annotation relies on such a dictionary or, directly,

on a sample of annotated text. The theoretical ambiguity also depends on the frequency of ambiguous vocables in the flow of data to be annotated. It is computed in the following way:

$$Ambiguity_{Th,a}(F) = \frac{\sum_{i=1}^{|Voc(F)|} (Ambig_a(i) * freq(i,F))}{|Units_a(F)|}$$

with

$$Ambig_a(i) = \begin{cases} 1 & \text{if } \quad |Labels_a(i)| > 1 \\ 0 & \text{else} \end{cases}$$

where Voc is the vocabulary of the units of the flow of data F, $|Voc(F)|$ the size of the vocabulary, $freq(i,F)$ the frequency of the vocable i in F, $|Units_a(F)|$ the number of units to annotate in F and $|Labels_a(i)|$ the number of labels available for the vocable i for the annotation task a.

When there is no ambiguous vocable, $|Labels_a(i)|$ is worth 1 and $Ambig_a(i)$ is worth 0 for every i, the annotation task is trivial and can be easily automated by projecting on the flow of data a dictionary establishing the correspondence between the vocables and their labels. In this case, $Ambiguity_{Th,a}(F)$ is worth 0. Conversely, if all the vocables are ambiguous, $Ambiguity_{Th,a}(F)$ is worth 1. Note that the weight of an ambiguous vocable influences the degree of theoretical ambiguity in proportion to its frequency.

Theoretical ambiguity tends to overestimate the weight of the ambiguity for the annotator as some ambiguities are probably trivial to solve.

3.4 The weight of the context

The weight of the context is a sixth complexity factor. Even though it is not independent from the previous factors as they were from each other (it makes discrimination, delimitation and disambiguation more complex for the annotator), we represent it here as such, for the sake of simplicity.

The complexity of an annotation task increases with the size of the window to take into account around the unit to annotate and with the number of knowledge elements to be rallied. While it is difficult to determine the number of words participating in the resolution of an annotation task and *a fortiori* the number of knowledge elements at issue[7], we can identify two qualitative scales: the size of the data to be taken into account around the unit to be annotated and the degree of accessibility of the sources of knowledge that are consulted.

For the sake of homogeneity with the previous complexity factors, we translate the two preceding qualitative scales into a common discreet scale from 0 to 1:

- 0 corresponds to cases where no data around the unit to be annotated and no additional knowledge come into play. This is a theoretical case, since an annotation task where no context whatsoever is needed should actually be automated.
- Conversely, 1 is for the most complex cases, where the whole data flow and exterior sources of knowledge are necessary to annotate the units. The gene renaming relations annotation is one such, as the renaming relation, often hardly noticeable in the data flow, can often be confused with an isotopy (resemblance) relation or the membership in a common family. One must read the whole abstract to determine the semantics of the relation and sometimes the annotators must refer to an external source to better understand the properties of the genes and support their decision.

[7] Assuming that the elements of knowledge are countable, which is obviously an oversimplification.

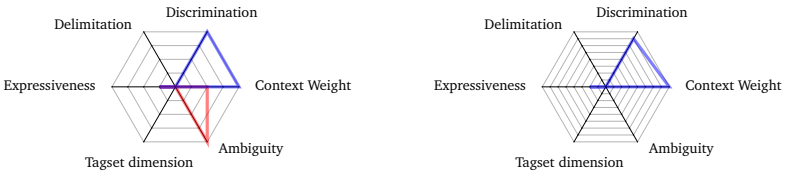
- We estimate at 0.25 the weight of the context in two cases: 1) if the annotation depends on the immediate environment of the unit to be annotated, or 2) if only provided sources, such as annotation guidelines, are to be consulted.
- The complexity is evaluated at 0.5 in three cases: 1) if the two previous difficulties combine; 2) if a larger part of the data is needed; or 3) if a well-identified exterior source of knowledge is to be consulted.
- Finally, the complexity is evaluated at 0.75 in three cases: 1) if the annotator must read the whole sentence and consult exterior sources to add annotations; 2) if s/he must take the entire flow of data into account; 3) if s/he must look for new knowledge sources.

This scale is obviously oversimplifying, but it is important to take that factor into consideration when planing an annotation campaign and the above criteria are meant for guiding the analysis and facilitating the comparison between complexity dimensions.

3.5 Synthesis

Since the six complexity factors are normalized on the same scale, once the complexity of different tasks is analyzed, it is easy to represent the various dimensions on a spider graph.[8]

Let us consider for instance the simple task, already mentioned, that consists in classifying pronoun occurrences as impersonal or anaphoric (REF OMITTED). Since the pronouns are previously tagged, both discrimination and delimitation are worth 0. The tagset being composed of two tags, this dimension is also at 0 and the expressiveness of the annotation language is 0.25 (type language). However, the ambiguity degree is high (1) as all occurrences are ambiguous. From our personal experience of annotation, we know that the context is worth 0.5 (or more) as the whole sentence must be considered to understand the role of the pronouns. The complexity of this task is represented on Figure 1a.



(a) Synthesis of the complexity dimensions of the pronouns classification (red) and gene names tagging (blue) campaigns

(b) Synthesis of the complexity dimensions of the whole gene names renaming campaign (2 EATs, double scale)

Figure 1: Two synthesis examples

The case of gene renaming (Jourde et al., 2011) is a little bit more complex and it is best analyzed as a combination of two EATs. Representing each EAT on a separate spider graph gives no idea of the whole task. We rather recommend to represent all EATs of a task in a single graph, which scale must be enlarged in proportion (from 0 to 2), as in Figure 1b. In the present case, the first EAT is the tagging of gene names in the sequence of words that composes the text. The discrimination factor is high (0.9), as only few words are gene names. Delimitation is 0, as

[8]The results presented in all the graphs in the article are rounded up/down to the nearest integer.

gene names, in our example, are simple tokens. On the contrary, the characterizing factors are low: the tagset is boolean (Dimension=0), a type language is used (Expressiveness=0.25) and ambiguity is very low as only few gene names are also common names (theoretical ambiguity can be approximated at 0.01[9] and residual ambiguity is on average of 0.04 for two annotators). In this case, the context is the highest factor as it is often necessary to read the whole PubMed abstract to understand the role of a mentioned entity and as annotators sometimes consult external resources (context weights 1) (Fort et al., 2010).

This first EAT is represented on the same graph as the pronoun classification, thus enabling the comparison of the two tasks (see Figure 1a). If they both show little complexity on three dimensions (delimitation, expressiveness, tagset dimension), the first one (pronouns) presents a high ambiguity dimension and no discrimination problem, while the second one (gene names) shows high complexity levels on the discrimination and context dimensions and no ambiguity. The solutions to alleviate the costs of these campaigns should therefore be adapted (pre-annotation and easy access to context for gene name tagging, and probably a carefully designed documentation for the pronoun classification).

Gene renaming consists in linking the gene name occurrences that hold a renaming relation. The whole task therefore comprises a second EAT, which consists in marking the renaming relations or its absence on any couple of gene names co-occurring in the same abstract. In that case, the discrimination is high (0.95) as only few gene couples are actually renaming each other. Delimitation is null since the gene names have already been annotated. The tagset is composed of 3 tags as the renaming relation is oriented (Dimension=0.04). Even if the annotations carry relational information, the language is a type language (a couple of gene names bears a tag, which expresses the direction of the relation). Ambiguity is very low (residual ambiguity is on average of 0.02 for the two annotators), but the context is high, as in the previous case. Figure 1b shows how the two EATs are combined to provide an analysis of the complexity of the whole task, which proves to be focused on discrimination and context.

4 Validation and illustration

4.1 Experimental validation

Although, as we showed in section 2, this grid of analysis has never been identified as such, some existing results or experiments confirm its applicability.

One first example of this is related to discrimination. In experiments led on the effects of pre-annotation on POS-tagging, the authors of (Fort and Sagot, 2010) showed that if the automatic pre-annotation is of very good quality, *i.e.* if only few tokens disseminated within the text have to be corrected, very good annotators can end up with less good annotation results, due to lapses in their concentration. This corresponds directly to the discrimination dimension we present here, which tends to get higher if the annotations to perform are submerged within the text.

Also, it has been observed that the quality of the annotation decreases with the number of tags involved (Bayerl and Paul, 2011). Structuring the tagset allows to reduce the degree of freedom at one point of choice and an appropriate annotation tool can help efficiently dealing with the hierarchy of tags (Dandapat et al., 2009).

Such an annotation tool can also help with complex language types, like relations, providing a graphical, user-friendly way to annotate them, like with Knowtator (Ogren, 2006). However, the number of manipulations involved is still higher than for simple type languages.

[9] To obtained this, we checked how many of the tagged gene names could also be tokens from the Brown corpus.

From the ambiguity point of view, the most obvious way to reduce it is to identify and remove the cases which are problematic. In the syntactic part of the Penn Treebank annotation, significant time was saved by reducing the ambiguity causes: "It proved to be very difficult for annotators to distinguish between a verb's arguments and adjuncts in all cases. Allowing annotators to ignore this distinction when it is unclear (attaching constituents high) increases productivity by approximately 150-200 words per hour." (Marcus et al., 1993). The analysis we propose here should help identifying these cases sooner in the process.

In the context of the gene renaming annotation campaign, we discovered that in some cases, the annotators needed the whole text to make their final decisions, and not only the abstract they had to annotate, as it was initially planned. If this need could have been identified beforehand, it would have been taken into account and the annotation tool would have been parameterized to give an easy access to the whole documents to annotators.

4.2 Example: structured named entities

We applied this analysis on a structured named entity annotation campaign for French described in (Grouin et al., 2011).

Structured named entities Within the Quaero program[10], a new definition of structured named entities was proposed. This new structure relies on two principles: the entities are both hierarchical and compositional. An entity is then composed of two kinds of elements: the 7 types (and 32 subtypes) which refer to a general segmentation of the world into major categories and the 31 components which allow to tag every word of the entity expression. Following this definition, the annotation campaign can be decomposed into two EATs: types and components. Figure 2 illustrates this definition on a French phrase. The types (EAT 1) are shown in red tags and the components (EAT 2) in blue tags.

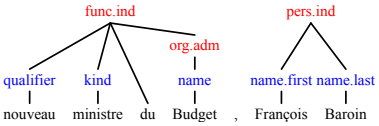


Figure 2: Multi-level annotation of entity types (red tags) and components (blue tags): *new minister of budget, François Baroin*.

Analysis For this illustration, we used the French spoken data provided by the mini-reference corpus (see (Grouin et al., 2011)) comprising 11,532 tokens, 1,161 entity types and 1,778 components.[11] Figure 3 represents the overall scores for this task using a spider graph.

The discrimination score is of 0.90 for the annotation of the types and 0.14 for the annotation of the components. To compute a delimitation score on such data, we first replaced in the annotated file every tag with a simple tag (*annot*) and in the same, but unannotated, file (as a reference file, under the hypothesis where tokens constitute the normal delimitation) we added the same tag around each token. Then we computed a slot error rate (SER) between these two files. The SER for types is over 100% (Delimitation=1) and the SER for components is 30% (Delimitation=0.3).

[10] www.quaero.org

[11] This mini-reference corpus is a sub-part of the whole corpus, that contains 1,291,225 tokens, 113,885 types and 146,405 components.

The annotation language is a type language, the degree of expressiveness is therefore of 0.25 for each of the EATs. Taking into account the types and sub-types structure, the total degree of freedom v for the annotation of the different types (EAT 1) is 10. The dimension score is then of 0.2. Concerning the components EAT, the total degree of freedom is 30 and the dimension score of 0.6. The theoretical ambiguity is computed for each EATs. The score is of 0.15 and 0.12 for the types and components respectively. These scores are low and the tasks do not seem very complex from the point of view of this dimension. The sample size is probably to blame here, as, if we compute this score *a posteriori* using the overall corpus (which is of course not possible in a real situation) the scores are of 0.49 for the components and of 0.36 for the types. Additional experimental results are necessary to take this scaling factor into account in the measure of ambiguity.

Concerning the weight of the context we estimate it at 0.75 because the annotators had to take into account the entire flow of data (the entity definition is contextual). Moreover, it was sometimes necessary to validate a choice by exploring external data (such as Wikipedia).

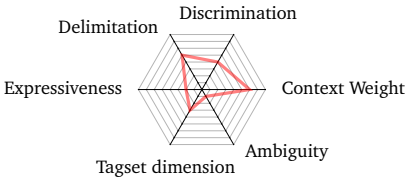

Figure 3: Synthesis of the complexity for the structured named entities campaign (2 EATs, double scale)

This analysis validates the choice of the hierarchical tagset that has been done for the annotation campaign described in(Grouin et al., 2011). Had a flat tagset been chosen, the dimension score would have been 1 ($v = 61$). Moreover, this analysis is in line with what was observed concerning the context weight within the campaign(Rosset et al., 2012). Of course, it presents some limits as it has been shown for the ambiguity score computation.

Conclusion

The grid of analysis we propose here should be used as part of the preparatory work of any annotation campaign, large or small. Obviously, when done *a priori*, on a small sample of annotations, the results will be approximate, but we believe that the analysis itself helps asking the right questions and finding the appropriate solutions.

Obviously, this pre-campaign work should be supported by an appropriate tool, so that this grid of analysis is computed more or less automatically. We are writing specifications for such a module, intended to be plugged into annotation management tools like Slate (Kaplan et al., 2010) or GATE Teamware (Bontcheva et al., 2010).

ABSTRACT
We present a new method to generate extractive multi-document summaries. The method uses Integer Linear Programming to jointly maximize the importance of the sentences it includes in the summary and their diversity, without exceeding a maximum allowed summary length. To obtain an importance score for each sentence, it uses a Support Vector Regression model trained on human-authored summaries, whereas the diversity of the selected sentences is measured as the number of distinct word bigrams in the resulting summary. Experimental results on widely used benchmarks show that our method achieves state of the art results, when compared to competitive extractive summarizers, while being computationally efficient as well.

KEYWORDS: Text Summarization; Integer Linear Programming; Support Vector Regression.

1 Introduction

A multi-document summarization system aims to generate a single summary from an input set of documents. The input documents may have been obtained, for example, by submitting a query to an information retrieval engine and retaining the most highly ranked documents, or by clustering the documents of a large collection and then using each cluster as a set of documents to be summarized. Although evaluations with human judges also examine the coherence, referential clarity, grammaticality, and readability of the summaries (Dang, 2005, 2006; Dang and Owczarzak, 2008), and some of these factors have also been considered in recent summarization algorithms (Nishikawa et al., 2010b; Woodsend and Lapata, 2012), most current multi-document summarization systems consider only the importance of the summary's sentences, their non-redundancy (also called diversity), and the summary length (McDonald, 2007; Berg-Kirkpatrick et al., 2011; Lin and Bilmes, 2011).

An *extractive* multi-document summarizer forms summaries by extracting (selecting) sentences from the input documents, without modifying the selected sentences. By contrast, an *abstractive* summarizer may also shorten or, more generally, rephrase the selected sentences. In practice, the additional processing of the selected sentences may only marginally improve or even reduce the perceived quality of the resulting summaries (Gillick and Favre, 2009), though recent work has produced abstractive summarization methods that perform better than extractive ones (Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012). Nevertheless, the difference in the performance of extractive and abstractive summarizers is often small, and abstractive summarizers typically require more processing time, as well as tools and resources (e.g., reliable large coverage parsers, paraphrasing rules) that are often not available in less widely spoken languages. Hence, it is still worth trying to improve extractive summarizers, at least from a practical, application-oriented point of view.

Many multi-document summarizers, especially extractive ones, adopt a greedy search when constructing summaries. For example, they may rank the sentences of the input documents by importance, and then iteratively add to the summary (and remove from the ranked list of input sentences) the sentence with the highest importance score, until the maximum allowed summary length has been reached, possibly discarding sentences that are too similar to sentences already included in the summary. Recent work has shown that adopting more principled optimization methods based on Integer Linear Programming (ILP), instead of greedy search, can lead to summaries that are better or at least comparable to those of state of the art summarizers (McDonald, 2007; Gillick and Favre, 2009; Nishikawa et al., 2010a).

In this paper, we introduce a new extractive multi-document summarization method that uses ILP to jointly optimize the importance of the summary's sentences and their diversity (non-redundancy), also respecting the maximum allowed summary length. Our method is more efficient than the seminal ILP-based summarizer of McDonald (2007), because of its simpler ILP model. The main competitor of our method, if we exclude abstractive summarizers, is the extractive version of Berg-Kirkpatrick et al.'s (2011) summarizer, which has the best previously reported results in extractive multi-document summarization. Inspired by Berg-Kirkpatrick et al.'s work, we include in the objective function of our ILP model the number of distinct word bigrams (of the input documents) that occur in the summary, but we use that number to measure diversity, unlike Berg-Kirkpatrick et al.'s work, where bigrams are weighted to measure importance. To obtain an importance score for each sentence, we use a Support Vector Regression (SVR) model (Vapnik, 1998), which has no direct counter-part

in Berg-Kirkpatrick et al.'s method. We show that our ILP method achieves state of the art ROUGE scores (Lin, 2004) on widely used benchmark datasets, when compared to Berg-Kirkpatrick's and other competitive extractive summarizers, also outperforming two greedy baselines that use only the importance scores of the SVR. For completeness, we also discuss and compare against the abstractive version of Berg-Kirkpatrick et al.'s summarizer, and the state of the art abstractive summarizer of Woodsend and Lapata (2012).

Section 2 below discusses previous work on ILP methods for summarization. Section 3 presents our own ILP model, after first introducing the SVR model of sentence importance and the greedy baselines. Section 4 presents the experiments that we conducted and discusses their results. Section 5 concludes and proposes directions for further research.

2 Related work

The first ILP method for summarization was proposed by McDonald (2007). It constructs summaries by maximizing the importance of the selected sentences and minimizing their pairwise similarity, as shown below. No sentence ordering is performed.

$$\max_{x,y} \sum_{i=1}^{n} imp(s_i) \cdot x_i - \sum_{i=1}^{n} \sum_{j=i+1}^{n} sim(s_i, s_j) \cdot y_{i,j} \tag{1}$$

subject to:

$$\sum_{i=1}^{n} l_i \cdot x_i \leq L_{max} \tag{2}$$

and (for $i = 1, \ldots, n$ and $j = i+1, \ldots, n$):

$$y_{i,j} - x_i \leq 0 \tag{3}$$

$$y_{i,j} - x_j \leq 0 \tag{4}$$

$$y_i + x_j - y_{i,j} \leq 1 \tag{5}$$

Here, n is the number of sentences in the input documents; $imp(s_i)$ is the importance score of sentence s_i; l_i is the length of s_i; $sim(s_i, s_j)$ is the similarity of sentences s_i and s_j; and L_{max} is the maximum allowed length. The x_i variables, jointly denoted x, are binary and indicate whether or not the corresponding sentences s_i are included (selected) in the summary. The $y_{i,j}$ variables, jointly denoted y, are also binary and indicate whether or not both s_i and s_j are included in the summary. Constraint 2 ensures that the maximum total length is not exceeded. Constraints 3–5 ensure that the values of x_i, x_j, and $y_{i,j}$ are consistent (e.g., if $y_{i,j} = 1$, then $x_i = x_j = 1$; and if $y_{i,j} = 0$, then $x_i = 0$ or $x_j = 0$).

McDonald showed experimentally that the ILP model above achieves better ROUGE scores (Lin, 2004) than a greedy method that attempts to maximize the same objective (1). However, McDonald also showed that the ILP model above corresponds to an NP-hard problem and is, therefore, intractable for a large number of sentences. A set of experiments by McDonald confirmed that the model does not scale up well in practice, mostly because of the $O(n^2)$ $y_{i,j}$ variables that are used to model the redundancy between sentences. Furthermore, the ROUGE scores of McDonald's ILP model were not always better than those obtained using a modified version of the Knapsack dynamic programming algorithm (Cormen et al., 2001).

In a more recent approach, Berg-Kirkpatrick et al. (2011) presented an ILP method based on the notion of 'concepts', a notion initially introduced by Gillick and Favre (2009). The

so called 'concepts' are actually word bigrams, all the word bigrams of the documents to be summarized. Each bigram has a weight w_i that indicates its importance. The ILP objective (6) of Berg-Kirkpatrick et al. prefers summaries with many important concepts, i.e., summaries whose bigrams have a large sum of weights w_i; below b_i are binary variables indicating which bigrams ($|B|$ in total) are present in the summary. An additional constraint, not shown here, ensures that the maximum allowed summary length is not exceeded.

$$\max_{b,c} h(b,c) = \max_{b,c} \sum_{i=1}^{|B|} w_i \cdot b_i + \sum_{i=1}^{|C|} u_i \cdot c_i = \sum_{i=1}^{|B|} (W^T \cdot \Phi_i) \cdot b_i + \sum_{i=1}^{|C|} (U^T \cdot \Psi_i) \cdot c_i \qquad (6)$$

Berg-Kirkpatrick et al.'s model also takes into account the possible subtree cuts (deletions) of the parse trees of the sentences of the input documents. The cuts give rise to different compressions (shortenings) of the sentences; hence, Berg-Kirkpatrick et al.'s summarizer is an abstractive one. In the objective (6), u_i are the weights of the possible subtree cuts of all the sentences of the input documents, and c_i are binary variables indicating which cuts ($|C|$ in total) are used. Additional contraints, not shown above, ensure that the values of b_i and c_i are consistent. Overall, Berg-Kirkpatrick et al.'s method aims to produce summaries that contain many important bigrams, while also performing many desirable subtree cuts.

The weights w_i and u_i are themselves estimated as weighted sums of features, i.e., $w_i = W^T \cdot \Phi_i$, where Φ_i is a feature vector describing the bigram of the binary variable b_i, and W is a vector of feature weights; similarly, $u_i = U^T \cdot \Psi_i$, where Ψ_i is a feature vector describing the subtree cut of the binary variable c_i, and U is a vector of feature weights.[1] The feature vector Φ_i includes, for example, the frequency of the corresponding bigram in the documents to be summarized, and the minimum sentence position (e.g., 3rd sentence in a document) of the sentences that contain that bigram in the input documents. The features of Ψ_i show, for example, if a relative clause or a temporal phrase was cut.

Berg-Kirkpatrick et al. use a structured Support Vector Machine (SVM) (Vapnik, 1998; Tsochantaridis et al., 2004) that assigns to each candidate summary the score $h(b,c)$ of the objective function (6), given W and U. During training, the SVM searches for the values of W and U that allow it to prefer the gold summary (of each training set of input documents) to all the other possible summaries (of the same input documents) by a margin determined by a loss function. Berg-Kirkpatrick et al. use a bigram recall loss function similar to ROUGE-2 (Lin, 2004). The loss function causes more emphasis (larger margin) to be placed on preferring the gold summaries to other summaries that share many bigrams with the gold ones. The learnt W and U are then used in the objective (6).

Berg-Kirkpatrick et al. report that their full method achieves higher ROUGE scores than an extractive version of their method (without the subtree cuts, i.e., without sentence compression) with no significant decrease in grammaticality (when sentence compression is used), unlike other work (Gillick and Favre, 2009), where sentence compression was found to reduce grammaticality. The extractive version of Berg-Kirkpatrick et al.'s method omits the second term of Formula (6), as in the previous work of Gillick and Favre (2009). As already noted, the extractive version of Berg-Kirkpatrick et al.'s method has the best previously published results in extractive multi-document summarization.

[1] Berg-Kirkpatrick et al. (2011) use different terminology. A minor difference from their description of their method is that they seem to set $W = U$, but in a more general formulation this does not seem to be necessary.

More recently, Woodsend and Lapata (2012) proposed an ILP-based method that forms a summary by maximizing the objective function shown below. The objective function combines the importance $f_B(z)$ of the bigrams in the summary's sentences, the salience $f_S(z)$ of the parse tree nodes of the summary's sentences, and a unigram language model $f_{LR}(z)$, which penalizes sentences containing words that are unlikely to appear in summaries; we do not discuss $f_{LR}(z)$ further to save space.

$$max_z f_B(z) + f_S(z) + f_{LR}(z) \tag{7}$$

The argument z collectively denotes binary variables z_i, one z_i for each node of the parse tree of each sentence of the input documents. Each z_i shows whether or not the corresponding node has been retained or deleted. By deleting nodes, the method can compress sentences; hence, this is also an abstractive summarization method. The $f_B(z)$ component is the same as in Berg-Kirkpatrick et al.'s work ($f_B(z) = \sum_{i=1}^{|B|} w_i \cdot b_i$). Additional constraints ensure that a bigram can be selected only if at least a parse tree node that subsumes it has been selected, that the maximum summary length is not exceeded etc.

To compute $f_S(z)$, Woodsend and Lapata train a linear SVM, with separating hyperplane $W^T \cdot \Phi_i = 0$, to predict whether or not a sentence s_i of an input set of documents would be selected by a human creating a summary. The $f_S(z)$ score, defined below, is the sum of the trained SVM's predictions, for all the phrases that correspond to the retained parse tree nodes of the input sentences; Φ_i is a feature vector describing each retained phrase, with features indicating, for example, if the phrase was obtained from the first sentence of an input document, if it contains pronouns etc.; W are the feature weights learnt by the SVM.

$$f_S(z) = \sum_i (W^T \cdot \Phi_i) \cdot z_i \tag{8}$$

A second SVM is trained to exclude sentences that are too long, contain quotations etc. The predictions of the second SVM are used to add hard constraints to the ILP model, rather than including the predictions in the ILP objective function (7).

The method of Woodsend and Lapata optionally employs a quasi-synchronous tree grammar (QSTG), to generate candidate compressions and paraphrases of the source sentences. The QSTG grammar is learnt from aligned summary and source sentences. When the grammar is used, the rest of the method does not operate only on the sentences of the input documents, but also on rephrasings of these sentences, produced by the grammar. Hence, in its full form, the method of Woodsend and Lapata is abstractive not only because it can delete tree nodes of the parse trees, but also because it can rephrase sentences using the grammar. It can be turned into an extractive summarization method by disabling the QSTG grammar and disallowing tree node deletions. Woodsend and Lapata provide experimental results of their method without the QSTG grammar, but not without tree node deletions; hence, we could not compare directly to a purely extractive version of Woodsend and Lapata'a summarizer.

Lin and Bilmes (2011) construct summaries by maximizing a monotone submodular function. This is an NP-hard problem; however, there is a greedy algorithm that approximates the optimum by a constant factor. Lin and Bilmes show that several previous summarization approaches can be described in terms of submodular functions. They also propose their own submodular functions for summarization, which combine importance and diversity.

3 Our method

In this section, we first discuss our SVR model that assigns importance scores to the sentences of the input documents, and two greedy baseline summarizers that use the SVR without ILP. We then introduce our ILP method, which jointly maximizes the importance and diversity of the selected sentences, while respecting the maximum allowed summary length.

3.1 The SVR model of sentence importance

A Support Vector Regression (SVR) model aims to learn a function $f : \mathbb{R}^n \mapsto \mathbb{R}$, which will be used to predict the value of a variable $y \in \mathbb{R}$ given a feature vector $X \in \mathbb{R}^n$. In particular, given l training instances $(X_1, y_1), \ldots, (X_l, y_l)$, an SVR model is learnt by solving the following optimization problem (Vapnik, 1998); W is a vector of feature weights; ϕ is a function that maps feature vectors to a new vector space of higher dimensionality to allow non-linear functions to be learnt in the original space; $C > 0$ and $\epsilon > 0$ are given.

$$\min_{W,b,\xi,\xi^*} \frac{1}{2}\|W\|^2 + C\sum_{i=1}^{l}\xi_i + C\sum_{i=1}^{l}\xi_i^* \tag{9}$$

subject to (for $i = 1, \ldots, l$):

$$W^T \cdot \phi(X_i) + w_0 - y_i \leq \epsilon + \xi_i \tag{10}$$

$$y_i - W^T \cdot \phi(X_i) - w_0 \leq \epsilon + \xi_i^* \tag{11}$$

$$\xi_i \geq 0 \tag{12}$$

$$\xi_i^* \geq 0 \tag{13}$$

The goal is to learn a linear (in the new space) function, whose prediction (value) $W^T \cdot \phi(X_i) + w_0$ for each training instance X_i will not to be farther than ϵ from the target (correct) value y_i. Since this is not always feasible, two slack variables ξ_i and ξ_i^* are used to measure the prediction's error above or below the target y_i. The objective (9) jointly minimizes the total prediction error and $\|W\|$, to avoid overfitting.[2]

In our case, X_i is the feature vector of a sentence and y_i is the sentence's importance score. During training, the target score y_i of each sentence s, i.e., the score that the SVR should ideally return, is taken to be the average of the ROUGE-2 and ROUGE-SU4 scores (Lin, 2004) of s, comparing s against the corresponding gold (human-written) summaries; the latter are included in the training datasets that we used. We took the average of ROUGE-2 and ROUGE-SU4, because they are the two most commonly used measures to automatically evaluate machine-generated summaries against gold ones. Roughly speaking, both measures compute the bigram recall of a summary (or individual sentence) being evaluated against multiple gold summaries (provided by different human authors), but ROUGE-SU4 also considers skip bigrams with a maximum distance of 4 words between the words of each skip bigram. Both measures have been found to correlate well with human judgements in extractive summarization (Lin, 2004). Hence, training the SVR to predict the average ROUGE-2 and ROUGE-SU4 of each sentence can be particularly useful. Intuitively, a sentence with a high ROUGE score has a high overlap with the gold summaries; and since the gold summaries

[2] We use the SVR implementation of LIBSVM (`http://www.csie.ntu.edu.tw/~cjlin/libsvm/`) with an RBF (non-linear) kernel and LIBSVM's parameter tuning facilities.

contain the sentences that human authors considered most important, a sentence with a high ROUGE score is most likely also important. This is why we view our SVR, which attempts to predict the ROUGE score (average ROUGE-2 and ROUGE-SU4) of each sentence, as a component that assigns an importance score to each sentence.

The idea to use ROUGE during training is also present in the work of Berg-Kirkpatrick et al. (Section 2). The SVM that Berg-Kirkpatrick et al. use, however, in effect attempts to separate (prefer) the gold summaries from the other possible summaries; ROUGE (more precisely, a modified version of ROUGE-2) is included in the SVM as a loss function to force the SVM to place more emphasis on separating gold summaries from other possible summaries with high ROUGE scores. By contrast, the SVR that we use attempts to directly output the ROUGE score of each sentence. Furthermore, the RBF kernel that we use in the SVR allows the SVR to learn non-linear functions, whereas the linear SVM of Berg-Kirkpatrick et al. can learn only linear functions. We also note that the two SVMs used by Woodsend and Lapata (Section 2) perform binary classification (not regression), attempting to separate sentences that a human would include in a summary from sentences that would not be included. The (unsigned) distance from the learnt separating hyperplane of the first SVM is included in the objective function of the ILP model, in effect treating the distance as a confidence score. We believe that our use of a regression model (SVR) is a better choice, because the distance from an SVM's separating hyperplane is often a poor confidence estimate. We also note that the second SVM of Woodsend and Lapata contributes only hard constraints to the ILP model, without taking into account the SVM's confidence.

We include the following features in the feature vector X of each sentence s:

- Sentence position $SP(s)$:
$$SP(s) = \frac{pos(s, d(s))}{|d(s)|}$$
where $pos(s, d(s))$ is the position (sentence order) of sentence s in its document $d(s)$, and $|d(s)|$ is the number of sentences in $d(s)$.

- Named entities $NE(s)$:
$$NE(s) = \frac{n(s)}{len(s)}$$
$n(s)$ is the number of named entities in s, and $len(s)$ is the number of words in s.[3]

- Levenshtein distance $LD(s, q)$: The Levenshtein Distance (Levenshtein, 1966) between the user's query q and sentence s; insertions, deletions, and replacements affect entire words. In the datasets we experimented with, the documents to be summarized were relevant to a query q, which was always available.

- Word overlap $WO(s, q)$: The number of words shared by the query q and sentence s, after removing stop words and duplicate words from both q and s.

- Content word frequency $CF(s)$ and document frequency $DF(s)$: We use these measures as defined by Schilder and Ravikumar (2008). $CF(s)$ is defined as follows:
$$CF(s) = \frac{\sum_{i=1}^{c_s} p_c(w_i)}{c_s}$$

[3]We use Stanford University's named entity recognizer (consult `http://nlp.stanford.edu/`).

where c_s is the number of content words in sentence s, $p_c(w) = \frac{m}{M}$, m is the number of occurrences of content word w in the input documents, and M is the total number of content word occurences in the input documents. Similarly, $DF(s)$ is defined as:

$$DF(s) = \frac{\sum_{i=1}^{c_s} p_d(w_i)}{c_s}$$

where $p_d(w) = \frac{d}{D}$, d is the number of input documents the content word w occurs in, and D is the number of all input documents.

Experiments on the development set (see below) confirmed that all the features have a positive impact, i.e., the results are worse, if any of the features are removed.

3.2 The baseline summarizers

We compare against two greedy baselines that use the SVR model of sentence importance, but not ILP. The first one, called GREEDY, uses the trained SVR model of the previous section to assign importance scores to all the sentences of the documents to be summarized. It then ranks the sentences by decreasing importance score and constructs the summary by iteratively selecting (and removing from the ranked list of sentences) the sentence with the highest importance score that fits in the summary space left.

The second baseline, called GREEDY-RED, operates in the same way, but it also takes into account redundancy. When a new sentence (with the highest importance score among the remaining sentences in the ranked list) is about to be added to the summary, its cosine similarity (computed on words) to all the sentences that have already been included in the summary is computed. If the similarity between the new and any of the already selected sentences exceeds a threshold t, the new sentence is discarded and a new iteration starts, where the next sentence of the ranked list of remaining sentences is considered. In our experiments, t was determined by tuning GREEDY-RED on development data (see below).

3.3 Our ILP summarization model

Instead of directly using the importance score $f_{SVR}(s_i)$ of each sentence s_i, as returned by the SVR model of Section 3.1, we normalize it using the maximum and mimimum values that the SVR model returns for the $j = 1, \ldots, n$ sentences of the input documents:

$$a_i = \frac{f_{SVR}(s_i) - \min_j f_{SVR}(s_j)}{\max_j f_{SVR}(s_j) - \min_j f_{SVR}(s_j)} \tag{14}$$

The objective (15) of our summarization ILP model sums the normalized relevance scores a_i of the selected sentences to estimate the overall importance $imp(S)$ of the resulting summary S. It also estimates the diversity $div(S)$ of S by calculating how many word bigrams of the documents being summarized are present in the selected sentences; when more bigrams are present in the summary, the summary's sentences share fewer bigrams, i.e., they are less redundant. Notice that we do not assign importance scores to the bigrams, unlike the work of Berg-Kirkpatrick et al. and Woodsend and Lapata (Section 2). The binary variables x_i

and b_j indicate which sentences s_i and which word bigrams g_j, respectively, are present in the summary; see Figure 1 for an example of the relations between the x_i and b_j variables.

$$\max_{b,x} \lambda_1 \cdot imp(S) + \lambda_2 \cdot div(S) = \max_{b,x} \lambda_1 \cdot \sum_{i=1}^{n} \frac{a_i}{k_{max}} \cdot x_i + \lambda_2 \cdot \sum_{j=1}^{|B|} \frac{b_j}{n} \tag{15}$$

$$\sum_{i=1}^{n} l_i \cdot x_i \leq L_{max} \tag{16}$$

$$\sum_{g_j \in B_i} b_j \geq |B_i| \cdot x_i, \text{ for } i = 1, \ldots, n \tag{17}$$

$$\sum_{s_i \in S_j} x_i \geq b_j, \text{ for } j = 1, \ldots, |B| \tag{18}$$

Again, l_i is the length of sentence s_i, L_{max} is the maximum allowed summary length, and n is the number of input sentences. $imp(S)$ is normalized to $[0, 1]$ using the maximum number of sentences k_{max} that can be included in the summary. To estimate k_{max} we divide the maximum available space L_{max} by the length of the shortest input sentence. We also divide $div(S)$ by n, which causes $div(S)$ to range mostly in $[0, 1]$ in our experiments. The values of λ_1 and λ_2 are tuned on development data. We set $\lambda_1 + \lambda_2 = 1$. Constraint 16 guarantees that L_{max} is not exceeded. The other two constraints are explained below:

- Constraint 17: B_i is the set of bigrams that appear in sentence s_i, $|B_i|$ is the cardinality of B_i, g_j ranges over the bigrams in B_i, and b_j is the binary variable that shows if bigram g_j has been selected. If a sentence s_i is selected ($x_i = 1$), then all of its bigrams must also be selected, i.e., $\sum_{g_j \in B_i} b_j = |B_i|$ and Constraint 17 holds. If sentence s_i is not selected ($x_i = 0$), then some of its bigrams may still be selected, if they occur in another selected sentence; hence $\sum_{g_j \in B_i} b_j \geq 0$ and Constraint 17 holds again.
- Constraint 18: Again, b_j is the binary variable that shows if g_j has been selected. $|B|$ is the total number of (distinct) bigrams of the n input sentences; S_j is the set of sentences that bigram g_j appears in; and x_i is the binary variable that shows if sentence s_i has been selected. If a bigram g_j is selected ($b_j = 1$), then at least one sentence that contains that bigram must also be selected; hence, $\sum_{s_i \in S_j} x_i \geq 1$ and Constraint 18 holds. If bigram g_j is not selected ($b_j = 0$), then none of the sentences that contain it may be selected; hence, $\sum_{s_i \in S_j} x_i = 0$ and Constraint 18 holds again.

In preliminary experiments, we noticed that our ILP model above, called ILP1, tended to select many short sentences, which had a poor ROUGE match with the gold summaries. To address this issue, we developed an alternative ILP model, called ILP2, whose objective function (19) rewards longer sentences by multiplying their importance scores a_i with their lengths l_i (in words). The constraints of ILP2 remain as in ILP1 (Constraints 16–18).

$$\max_{b,x} \lambda_1 \cdot \sum_{i=1}^{n} a_i \cdot \frac{l_i}{L_{max}} \cdot x_i + \lambda_2 \cdot \sum_{j=1}^{|B|} \frac{b_j}{n} \tag{19}$$

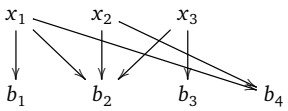

Figure 1: There are 3 sentences (corresponding to the binary variables x_1, x_2, x_3) containing 4 word bigrams (corresponding to variables b_1, b_2, b_3, b_4). For example, sentence s_1 contains the first, second, and fourth bigrams; and if sentences s_1 and s_2 are selected ($x_1 = 1$ and $x_2 = 1$), then the bigrams they contain must also be selected ($b_1 = 1$, $b_2 = 1$, $b_4 = 1$).

4 Experiments

We now present the experiments that we performed, starting from the datasets we used.

4.1 Datasets and experimental setup

We used the datasets of DUC 2005, DUC 2006, DUC 2007, and TAC 2008 (Dang, 2005, 2006; Dang and Owczarzak, 2008).[4] Each dataset contains document clusters. Each cluster contains documents relevant to a query (a question or topic description), which is also given. For each cluster, a summary not exceeding a maximum allowed length has to be produced, so that the summary will provide an answer to the corresponding query. Multiple reference (gold, human-authored) summaries are also provided per cluster. Table 1 provides more information on the datasets we used. For our experiments, we extracted all the sentences from the documents of each cluster, discarding sentences shorter than or equal to 7 words. We also applied a small set of cleanup rules to remove unnecessary formatting tags.

dataset	documents per cluster	clusters	reference summaries	word limit (in words)
DUC 2005	25–50	50	4–9	250
DUC 2006	25	50	4	250
DUC 2007	25	45	4	250
TAC 2008	10	48	4	100

Table 1: Datasets used in our experiments.

The SVR model of sentence importance (Section 3.1) was trained on the sentences of DUC 2006 (i.e., DUC 2006 was our training dataset) and it was used to assign importance scores to the sentences of the clusters of DUC 2005, DUC 2007, and TAC 2008. For each document cluster, we used the $n = 100$ sentences with the highest importance scores as input to the baseline and ILP summarizers of Sections 3.2 and 3.3.

We note that ILP problems are in the worst case (for the most difficult ILP problems) NP-hard. Our ILP1 and ILP2 models (Section 3.3) are generalizations of the 0-1 Knapsack problem, which is known to be NP-hard; hence, our models also constitute NP-hard problems. Nevertheless, very efficient ILP solvers are available.[5] In the worst case, the off-the-shelf solver that we use finds a solution (for ILP1 or ILP2, per summary) in 1.25 seconds and

[4] Consult also `http://duc.nist.gov/` and `http://www.nist.gov/tac/`.

[5] We use the implementation of the Branch and Cut algorithm of the GNU Linear Programming Kit (GLPK); consult `http://sourceforge.net/projects/winglpk/`.

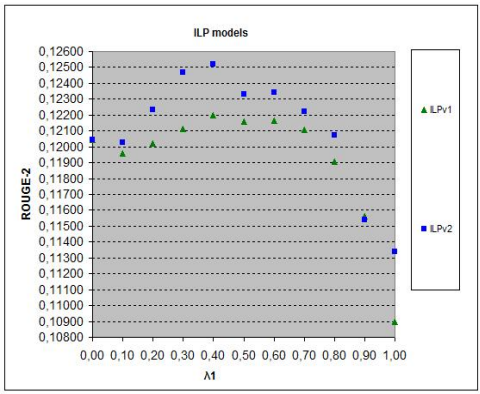

Figure 2: ROUGE-2 scores of the two versions of our ILP model on DUC 2007 data, used as development data, with the SVR model of sentence importance trained on DUC 2006 data.

0.9 seconds in the DUC 2007 and TAC 2008 datasets, respectively. The solver takes more time in DUC 2007 than in TAC 2008, because DUC 2007 summaries are longer (cf. Table 1) and, therefore, the search space is larger. This efficiency is mostly due to the fact that the x_i and b_j variables of ILP1 and ILP2 are in the order of hundreds and grow approximately linearly to the number and size (word bigrams) of the input sentences, as opposed to the quadratic (to the number of sentences) growth of the number of variables in McDonald's model (Section 2). Berg-Kirkpatrick et al. (2011) report very similar execution times; they report that the solver they use finds the solution of their extractive formulation in less than a second for most summaries of TAC 2008 and TAC 2009. Our method (ILP1 or ILP2) takes on average 10–11 seconds to form each summary, including the time to read and preprocess the input documents, formulate the ILP model etc. By contrast Woodsend and Lapata (2012) report that their method takes 55 seconds on average for each summary, though presumably this also includes parsing the input and applying the QSTG grammar.

4.2 Experiments on development data

To determine which of the two versions (ILP1 or ILP2) of our ILP model performs best and to tune their parameters, we experimented on the DUC 2007 dataset, i.e., we used the DUC 2007 dataset as our development data; recall that the DUC 2006 dataset was used as training data in all cases. We used 11 different values of λ_1 ($\lambda_2 = 1 - \lambda_1$) in both ILP1 and ILP2, and we evaluated the generated summaries using ROUGE-2. The results of these experiments are presented in Figure 2. ILP2 is better than ILP1 for all values of λ_1, and its best ROUGE-2 score is obtained for $\lambda_1 = 0.4$ ($\lambda_2 = 0.6$). The fact that the best results were obtained for non-zero λ_1 and λ_2 values also shows that both the sentence importance component (SVR) and the diversity component (bigram count) contribute to the results of our ILP models.

We also compared the average number of selected sentences per cluster of ILP1 and ILP2 on DUC 2007 data. As already noted and illustrated in Figure 3, ILP1 tends to select more and, therefore, shorter sentences than ILP2; these shorter sentences have worse ROUGE matches

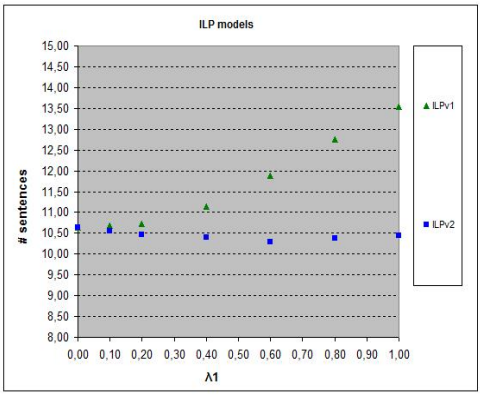

Figure 3: Average number of sentences selected by the two versions of our ILP model on DUC 2007 data, used as development data, with the SVR model trained on DUC 2006 data.

with the reference summaries, which is why ILP1 performs worse than ILP2. Figure 3 also shows that ILP2 selects approximately the same number of sentences for all λ_1 values; this is because ILP2 tends to always select relatively long sentences and, hence, the number of selected sentences that fit in the available space cannot vary as much as in ILP1.

In Table 2, we present the ROUGE scores of the two versions of our ILP model (for $\lambda_1 = 0.4$) on the DUC 2007 dataset, along with the corresponding scores of the GREEDY and GREEDY-RED baselines (Section 3.2), which use only the SVR without ILP. We also show the scores of several state of the art systems, both extractive and abstractive, as they were reported in the corresponding articles; more recently published results are shown first. Our ILP2 model has the best reported ROUGE-2 score on the DUC 2007 dataset, and the second best ROUGE-SU4 score, though one should keep in mind that the DUC 2007 dataset was our development set.

4.3 Experiments on test data

We then evaluated ILP2 with $\lambda_1 = 0.4$, which was our best system in the experiments on the development data (DUC 2007), against the systems with the highest published ROUGE scores on TAC 2008 and DUC 2005 data, our two test datasets.[6] The results of these experiments are listed in Tables 3 and 4, respectively. On the TAC 2008 dataset (Table 3), the most recent of the datasets we experimented with, our ILP2 method achieves the second best ROUGE-SU4 score and the second best ROUGE-2 score, following the method of Woodsend and Lapata with the QSTG grammar enabled, and the abstractive (full) method of Berg-Kirkpatrick et al., respectively (see Section 2). Our ILP2 method performs better than the method of Woodsend and Lapata *without* the QSTG grammar, even though the method of Woodsend and Lapata is still an abstractive one, even without the QSTG grammar (it can still delete parse tree nodes), whereas our method is purely extractive. If we exclude abstractive summarizers, our ILP2 method has the best ROUGE-2 and ROUGE-SU4 scores.

[6] We used Set A of TAC 2008.

system	ROUGE-2	ROUGE-SU4
ILP2	**0.12517**	0.17603
ILP1	0.12201	0.17283
GREEDY-RED	0.11591	0.16908
GREEDY	0.11408	0.16651
Lin and Bilmes 2011	0.12380	N/A
Celikyilmaz and Hakkani-Tur 2010	0.11400	0.17200
Haghighi and Vanderwende 2009	0.11800	0.16700

Pingali et al. 2007 (DUC 2007)	0.12448	**0.17711**
Toutanova et al. 2007 (DUC 2007)	0.12028	0.17074
Conroy et al. 2007 (DUC 2007)	0.11793	0.17593
Amini and Usunier 2007 (DUC 2007)	0.11887	0.16999

Table 2: Comparison of our ILP method against greedy baselines that use the same SVR model of sentence importance without ILP, and against other state of the art summarizers on DUC 2007 data (our development dataset). Our ILP method was trained on DUC 2006 data.

On the DUC 2005 dataset (Table 4), our ILP2 method has the best reported ROUGE-2 and ROUGE-SU4 scores. Berg-Kirkpatrick et al. and Woodsend and Lapata provide no results of their systems for this dataset. They also provide no results for the more recent TAC 2009 dataset, because they used it as their training set. We did not experiment with the TAC 2009 dataset, because our main competitors have not published results for that dataset.

We used paired t-tests ($p < 0.05$) to check if the differences between the scores of ILP2 and the other systems were statistically significant. In Tables 3–4, + and − denote the existence or absence of statistical significance, respectively. Unfortunately, the tests were possible only when comparing ILP2 against the few systems we had ROUGE scores for per topic.

5 Conclusions

We presented a new ILP method (in two versions) for multi-document summarization. Our method jointly maximizes the importance of the sentences it includes in a summary and their diversity, without exceeding a maximum allowed summary length. To obtain an importance score for each sentence, it uses an SVR model, trained on human-authored summaries to predict the ROUGE score of each sentence. Diversity is measured as the number of word bigrams of the input documents that occur in the resulting summary. Experimental results on widely used benchmarks for news summarization show that our ILP method achieves state of the art results among extractive summarizers. It also outperforms two greedy baselines that use the same SVR model of sentence importance without ILP, and it performs better than some abstractive summarizers. Our method is also very fast, and it does not require a parser or other resources that are not always available in less widely spoken languages.

We are already experimenting with an extended version of our method that also performs sentence compression. In future work, we hope to extend our ILP model to consider discourse coherence, sentence aggregation, and referring expression generation.

Abstract

Cross-lingual relevance modelling (CLRLM) is a state-of-the-art technique for cross-lingual information retrieval (CLIR) which integrates query term disambiguation and expansion in a unified framework, to directly estimate a model of relevant documents in the target language starting with a query in the source language. However, CLRLM involves integrating a translation model either on the document side if a parallel corpus is available, or on the query side if a bilingual dictionary is available. For low resourced language pairs, large parallel corpora do not exist and the vocabulary coverage of dictionaries is small, as a result of which RLM-based CLIR fails to obtain satisfactory results. Despite the lack of parallel resources for a majority of language pairs, the availability of *comparable* corpora for many languages has grown considerably in the recent years. Existing CLIR techniques such as cross-lingual relevance models, cannot effectively utilize these comparable corpora, since they do not use information from documents in the source language. We overcome this limitation by using information from retrieved documents in the source language to improve the retrieval quality of the target language documents. More precisely speaking, our model involves a two step approach of first retrieving documents both in the source language and the target language (using query translation), and then improving on the retrieval quality of target language documents by expanding the query with translations of words extracted from the top ranked documents retrieved in the source language which are thematically related (i.e. share the same concept) to the words in the top ranked target language documents. Our key hypothesis is that the query in the source language and its equivalent target language translation retrieve documents which share topics. The ovelapping topics of these top ranked documents in both languages are then used to improve the ranking of the target language documents. Since the model relies on the alignment of topics between language pairs, we call it the cross-lingual topical relevance model (CLTRLM). Experimental results show that the CLTRLM significantly outperforms the standard CLRLM by upto 37% on English-Bengali CLIR, achieving mean average precision (MAP) of up to 60.27% of the Bengali monolingual IR MAP.

COLING 2012, Mumbai, December 2012.

1 Introduction

Cross-language information retrieval (CLIR) involves retrieving documents in a language (target language), different from the language in which the users formulate their search (source language). A simple low resourced bi-lingual dictionary-based query translation followed by monolingual IR does not yield satisfactory results in CLIR mainly due to the poor vocabulary coverage of such a low resourced dictionary and the inherent ambiguities in query term senses (Hull and Grefenstette, 1996). More complex methods of query translation, e.g. statistical machine translation (SMT), perform better, but not entirely satisfactorily, due to the lack of availability of parallel resources such as sentence aligned corpora between resource-poor language pairs (Nie et al., 1999).

Regional languages of India are typical examples of languages with poor linguistic resources. The dominance of English, which has been used extensively as a medium of instruction and official work, can be exemplified by the fact that, while the English Wikipedia has almost 4M documents, the number of documents in the Hindi and Bengali Wikipedia are only around 100K and 23K respectively, although Hindi and Bengali ranks fourth and sixth respectively in terms of the number of native speakers[1]. The multi-linguality of Indian culture provides an ample motivation for the study of CLIR, e.g. a native Indian language speaker would often prefer to type his query in English due to his acquaintance with the English keyboard, although seeking to retrieve documents in his native language. Querying in English to a regional Indian language is thus a widespread real-life potential application for CLIR. The major hindrance to developing effective Indian language CLIR is the lack of *parallel corpora*, i.e. sentence aligned manually translated texts, to enable the development of effective standard translation tools. *Comparable corpora*, i.e. non sentence aligned texts which are not exact translations of each other but are roughly on the same topic, however are abundantly available owing to the growth of digital text in regional Indian languages. News articles published from the same source or from the same location in both English and a regional language over an identical time period are examples of such comparable corpora. Thus, despite the scarcity of parallel resources, significant comparable corpora are available for English and many Indian languages. This motivates us to research into new techniques effectively exploit these corpora for enhanced CLIR performance. This paper introduces and evaluates our proposed method to do this.

The main idea of our work can be outlined as follows. We assume that there exists a comparable corpus of documents in both the language of the query (source language) and the target language in which the documents need to be presented to the user. A query in the source language is translated into the target language by any available resource which is typically a small bi-lingual dictionary for low resourced language pairs. Documents are then retrieved using both queries from the corresponding collections. It is a common practise in IR to improve upon the initial retrieval quality by utilizing information from the top-ranked documents (which are assumed to be relevant), the method being called pseudo-relevance feedback (PRF). PRF often does not work well when precision at top ranked documents is low. For our case, retrieval quality of the source language documents is expected to be much better than those of the target language ones, since the translated query in the target language is likely to be ambiguous and imprecise due to the lack of sufficient context in the short queries and the poor vocabulary coverage particularly for low resourced language pairs. Since the top ranked documents on the source side are more likely to be relevant to the information need, it can be hypothesized that utilizing this information for PRF can potentially improve retrieval results of the target language documents. Our proposed method thus relies on extracting translations of terms from the source language documents to expand the query

[1] http://en.wikipedia.org/wiki/Most_spoken_languages

in the target language so as to improve the retrieval quality on the target side.

The novelty of this paper is in the proposal of a PRF method which utilizes information from the source language documents to enhance retrieval effectiveness in the target language. The remainder of this paper is organized as follows. Section 2 describes the related work on CLIR and topic modelling. Section 3 describes the proposed method in details. Section 4 details the experimental setup, followed by Section 5, which evaluates the proposed method. Finally, Section 6 outlines the conclusions and directions for future work.

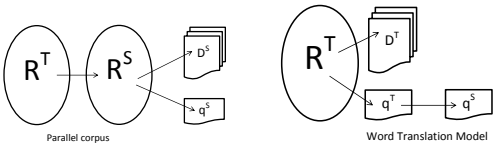
2 Related Work

This section starts with a brief review of the existing literature on general pseudo-relevance feedback (PRF). This is followed by a review on relevance models in IR, since our proposed method is a generalization of the cross-lingual relevance model (CLRLM). We then provide a brief survey on topic modelling applications in IR, as topic modelling is an integral part of our proposed method. Finally, we review existing work on combining PRF evidences in multiple languages, since our method involves a combination of pseudo-relevance information from the source and the target languages.

Pseudo-Relevance Feedback (PRF). PRF is a standard technique in IR which seeks to improve retrieval effectiveness in the absence of explicit user feedback (Robertson and Sparck Jones, 1988; Salton and Buckley, 1990). The key idea of PRF is that the top ranked initially retrieved documents are relevant. These documents are then used to identify terms which can be added to the original query followed by an additional retrieval run with the expanded query often involving re-weighting of the query terms (Robertson and Sparck Jones, 1988; Hiemstra, 2000), and re-ranking initially retrieved documents by recomputing similarity scores (Lavrenko and Croft, 2001).

Relevance modelling in (CL)IR. Relevance modelling (RLM) is a state-of-the-art PRF technique involving estimation of a model of relevance generating terms both from pseudo-relevant documents and the query terms (Lavrenko and Croft, 2001). Terms which co-occur frequently with query terms are assigned a high likelihood of being generated from the RLM. In addition to monolingual IR, RLM has also been applied successfully to cross-lingual IR (CLIR) (Lavrenko et al., 2002), under the name of cross-lingual relevance model (CLRLM). A limitation of CLRLM is that it depends either on a parallel corpus or on a bilingual dictionary. However for low resourced languages, parallel corpus seldom exist and dictionaries have poor vocabulary coverage. We address this limitation by exploiting the topical overlap of top ranked documents retrieved in the source and target languages to improve the relevance model estimation. Our method thus only requires a comparable corpus instead of the more stringent requirement of a parallel corpus.

Topic modelling applications in IR. A widely used technique for topic modelling is the latent Dirichlet allocation (LDA) which treats every document as a mixture of multinomial distributions with Dirichlet priors (Blei et al., 2003). Various inference techniques have been proposed to estimate the probabilities in LDA, including variational Bayes, expectation propagation, and Gibbs sampling (Blei et al., 2003; Griffiths and Steyvers, 2004). We use the Gibbs sampling method for LDA inference because it is computationally faster and has been shown to outperform the other two (Griffiths and Steyvers, 2004). LDA was applied for monolingual IR by (Wei and Croft, 2006). Their work involves estimating the LDA model for the whole collection by Gibbs sampling and then linearly combining the LM term weighting with LDA-based term weighting. An early attempt to utilize the topical structure in language pairs for CLIR can be found in (Littman et al., 1998), which involved automatic construction of a multi-lingual semantic space using a topic modelling technique



(a) Parallel corpus (b) Bilingual dictionary

Figure 1: Schematic diagrams of a CLRLM.

called latent semantic indexing (LSI). The major limitation of their method is that it relies on the existence of a parallel corpus for the training phase. In contrast, we leverage upon the existence of a comparable corpus to improve search results in the target language.

A recent work (Vulić et al., 2011) overcomes the parallel corpus restriction of CLRLMs by training a CLRLM on a comparable corpus using topic models inferred by bilingual LDA (Bi-LDA), which is a special case of polylingual LDA (Mimno et al., 2009). A major difference of their work with ours is that their method requires a separate training phase on comparable corpora to estimate the latent topic models in Bi-LDA. In fact, the authors used external resources such as Europarl and Wikipedia for the training purpose. In contrast, our method does not require a separate training phase or additional external resources. Moreover, our method applies topic modelling only on the set of pseudo-relevant documents. Furthermore, the idea of topic modelling in (Vulić et al., 2011) is only loosely coupled within the CLRLM framework, whereas we tightly integrate the topic modelling step in a graphical model with added nodes for the latent topics.

Feedback model combination. (Chen et al., 2010) exploited comparable corpora for CLIR by training *learning-to-rank* methods on out-of-domain source data to improve the retrieval effectiveness of the target domain. The Multi-PRF method improves monolingual retrieval by applying PRF in an assisting language, and mapping the feedback terms back in the language of the query with the help of a dictionary (Chinnakotla et al., 2010). The similarity of our method with Multi-PRF is that both involve an intermediate retrieval step in a language different from the language of the query. However, there are several differences which are highlighted as follows. Firstly, Multi-PRF improves monolingual retrieval by information from another language (typically English), whereas our proposed method improves CLIR performance. Secondly, Multi-PRF does not take into consideration the latent topics in the pseudo-relevant documents of the two languages, whereas topic modelling plays a crucial role in our approach.

3 Cross-lingual Topical Relevance Models

This section describes our proposed model in detail. We start the section with a brief motivation, where we discuss the limitations of CLRLM and how these can possibly be addressed. We then describe the schematics of our model which is then followed by the estimation details. Finally we present the algorithmic details for implementing the model.

3.1 Motivation

A limitation of CLRLM is that it depends either on a parallel corpus or on a bilingual dictionary to estimate the target language document models essential for estimating the relevance model for the query (source) language. The schematic diagrams of Figure 1a and 1b illustrate this. In the parallel corpus based approach, for every top ranked document retrieved in the source language

D_j^S, the corresponding document D_j^T in the target language is used to compute R^T, the estimated relevance model for the target language. This is shown in Figure 2a where the edge from $\mathbf{D}^T$ to $\mathbf{D}^S$ represents the event of transforming each document of the target language to its equivalent in the source language. The estimated probability of relevance is thus

$$P(w^T|\mathbf{q}^S) = \sum_{j=1}^{R} \underbrace{P(w^T|D_j^T)\, P(D_j^S|\mathbf{q}^S)}_{D_j^S \text{ parallel to } D_j^T} \tag{1}$$

where $P(D_j^S|\mathbf{q}^S)$ is the standard LM similarity of the given query $\mathbf{q}^S$ with a document D_j^S (Hiemstra, 2000). The parallel corpus based approach to CLRLM thus involves document side translation. A complementary approach is query side translation, as done in the bilingual dictionary-based CLRLM method shown in Figure 2b. The edge from $\mathbf{q}^T$ to $\mathbf{q}^S$ indicates generation of the query vector in the source language from a query vector in the target language via translation. The estimated probability of relevance in this case is given by

$$P(w^T|\mathbf{q}^S) = \sum_{j=1}^{R} P(w^T|D_j^T) P(D_j^T|\mathbf{q}^S) = \sum_{j=1}^{R} P(w^T|D_j^T) \prod_{i'=1}^{n^T} P(D_j^T|q_{i'}^T) \underbrace{\sum_{i=1}^{n^S} P(q_{i'}^T|q_i^S) P(q_i^S)}_{\text{word-based query translation}} \tag{2}$$

While it is possible to apply CLRLM in the presence of a bilingual dictionary, these dictionaries for low resourced languages cover only a very small part of the vocabulary, as a result of which it becomes impossible to compute the probabilities $P(s|t)$ for most (s, t) pairs (s and t refer to a word in the source language and the target language respectively). This in turn results in a poor performance of CLRLM for such low resourced languages.

The limitations of the current CLRLM method are that: a) it depends either on document translation with the help of a parallel corpus or on query translation with the help of a dictionary, without making provisions for a combination of the two; b) the document side translation depends on the availability of a parallel corpus which is rare for resource-poor languages; and c) it does not model the multiple aspects of relevance that are implicitly or explicitly expressed in a query. Assuming that there exists a comparable document collection in the two languages, the first two restrictions can be overcome with a two step retrieval process, one with the source language query and the other with a translated query in the target language to obtain separate working sets of documents in both the languages. The working set of the top ranked documents in the two languages, which

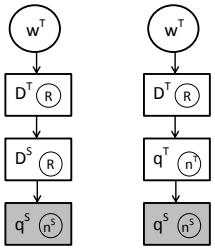


Figure 2: CLRLM dependence graphs for a) Parallel corpus (left) and b) Dictionary (right).

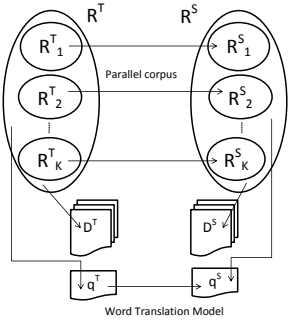

Figure 3: Schematic representation of a CLTRLM.

we refer to as pseudo-relevant document sets from now on, can thus potentially replace the parallel corpus requirement of the CLRLM. However, it is impractical to assume a one to one document level alignment between the pseudo-relevant documents in the two languages. Segmenting the pseudo-relevant documents into topics can result into a more accurate alignment at the level of topics rather than at the level of documents, with the underlying hypothesis that the documents retrieved in the two languages comprise of words related to overlapping concepts or topics. Topic modelling on the pseudo-relevant sets of documents also help in overcoming the third limitation where each topic addresses one particular sub information need associated with the query.

Our proposed methodology which we call cross-lingual topical relevance model (CLTRLM), involves estimation of two separate relevance models for both the source and target language pseudo-relevant documents. The target language relevance model is then updated by applying a word translation model to transform a word from each topic in the source language to a word in the target language. CLTRLM aims to achieve the benefits of a parallel corpus without actually having one. A topic level decomposition and mapping is helpful in adding contributions from the most likely topic, i.e. aspect of relevance, from the source language to a topic on target side. Note that the documents on which we apply topic modelling are the top ranked documents retrieved in response to the query in both the source language and its target language translation. Both document sets being focused on the query ensures that these documents share common topics. This is contrary to the approach of (Vulić et al., 2011), where the full comparable corpus is used for topic modelling. The working principle of a CLTRLM is illustrated schematically in Figure 3, which shows that the relevance models for both the source and the target languages have been split into topics. Each topic in a relevance model may refer to an individual aspect of the broad information need expressed in the query, and is thus associated with generating relevant documents related to that particular aspect. In contrast to the broad information need of a query, each particular aspect is more focused, and is thus easier to align from the target side to the source side. Although Figure 3 shows that the number of topics in the source and the target relevance models are identical, the number of topics may in fact be different on the source and the target sides. The next section presents the details of CLTRLM more formally.

3.2 Formal Description

Figure 4 shows the dependence network of CLTRLM in plate notation. Let w^T be a word in the target language. The top-most circle in Figure 4 represents a word in the target language for which

the objective is to calculate the probability $P(w^T|\mathbf{q}^S)$, i.e. to estimate the probability of generating this word from a hypothetical relevance model R^T. It is not possible to estimate this model directly because in ad-hoc retrieval, no prior information is provided about the relevant documents. The only observable entities are the query terms in the source language as shown in Figure 4. Let us denote this query by $\mathbf{q}^S$. The shaded rectangle at the bottom represents the vector q_i^S of observed variables having dimensionality n^S, each component representing the term frequency of a unique query term in the source language. The best way to estimate the probability $P(w^T|R^T)$ is thus to approximate it with $P(w^T|\mathbf{q}^S)$ i.e. $P(w^T|R^T) \approx P(w^T|\mathbf{q}^S)$. The rectangles $\mathbf{z}^T$ and $\mathbf{z}^S$ denote vectors of dimensionality K^T and K^S, the number of topics on the target and source sides respectively. While estimating the model, we assume that the topics for both the source and target langages have been obtained by latent Dirichlet allocation (LDA) (Blei et al., 2003), and thus we use the LDA estimated values viz. $\hat{\boldsymbol{\theta}}^T$, $\hat{\boldsymbol{\phi}}^T$, $\hat{\boldsymbol{\theta}}^S$ and $\hat{\boldsymbol{\phi}}^S$ in CLTRLM inference. The rectangles marked by $\mathbf{D}^T$ and $\mathbf{D}^S$ denote the set of top ranked R^T and R^S documents retrieved respectively for the target and source languages. $\mathbf{q}^T$ represents the translation of the observed query vector in the source language viz. $\mathbf{q}^S$, and is obtained by a bilngual dictionary or using a machine translation (MT) system. With these notations, we are now ready to work out the estimation details in the following subsection.

3.3 Estimation Details

With reference to Figure 4, the estimation of CLTRLM proceeds as follows.

$$\begin{aligned} P(w^T|\mathbf{q}^S) = & \underbrace{P(w^T|\mathbf{z}^T)P(\mathbf{z}^T|\mathbf{q}^S)}_{\text{target language generation event}} + \underbrace{P(w^T|\mathbf{w}^S)P(\mathbf{w}^S|\mathbf{q}^S)}_{\text{source language generation event}} \\ & = \sum_{k=1}^{K^T} P(w^T|z_k^T, \hat{\phi^T}_{k,w^T})P(z_k^T|\mathbf{q}^S) + \sum_{i=1}^{t(w^T)} P(w^T|w_i^S)P(w_i^S|\mathbf{q}^S) \end{aligned} \tag{3}$$

Equation (3) represents two chains of events via the two components shown: one associated with the target language retrieved documents obtained by query translation, and the other associated with $t(w^T)$ possible translations of word w^T in the source language (denoted by the set w^S), which in turn correspond to the words in the source language retrieved documents. Note that the two generation events pertain to the topic level alignment introduced informally in the previous section, where a word in the source language query can either be generated from a topic in the source language or from an *equivalent* topic in the target language. Inferencing along the left chain proceeds as follows.

$$\begin{aligned} & P(z_k^T|\mathbf{q}^S) = \sum_{j=1}^{R^T} P(z_k^T|D_j^T)P(D_j^T|\mathbf{q}^S) = \sum_{j=1}^{R^T} P(z_k^T|D_j^T) \sum_{i'=1}^{n^T} P(D_j^T|q_{i'}^T)P(q_{i'}^T|\mathbf{q}^S) = \\ & \sum_{j=1}^{R^T} P(z_k^T|D_j^T) \sum_{i'=1}^{n^T} P(D_j^T|q_{i'}^T) \sum_{j'=1}^{n^S} P(q_{i'}^T|q_{j'}^S)P(q_{j'}^S) = \sum_{j=1}^{R^T} P(z_k^T|D_j^T, \hat{\theta}_{j,k}^T) \underbrace{\sum_{i'=1}^{n^T} \frac{P(q_{i'}^T|D_j^T)}{R^T}}_{\text{LM similarity}} \underbrace{\sum_{j'=1}^{n^S} P(q_{i'}^T|q_{j'}^S)}_{\text{query translation}} \end{aligned} \tag{4}$$

In the last line of Eq. (4) we have ignored the prior probability of $P(q_{j'}^S)$, and used the LDA estimated $\hat{\boldsymbol{\theta}}^T$ values for computing $P(z_k^T|D_j^T)$ and the standard LM similarity score $P(q_{i'}^T|D_j^T)$ to compute the probability of generating a target language query term from a target language document model.

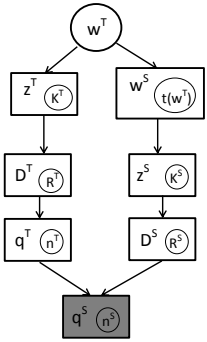

Figure 4: CLTRLM dependence graph in plate notation.

Similarily, the right side chain can be inferred as

$$P(w_i^S|\mathbf{q}^S) = \frac{1}{R^S}\underbrace{\sum_{k=1}^{K^S} P(w_i^S|z_k^S,\hat{\boldsymbol{\phi}}^S)\sum_{j=1}^{R^S} P(z_k^S|D_j^S,\hat{\boldsymbol{\theta}}^S)}_{\text{LDA document model of } D_j^S}\underbrace{P(D_j^S|\mathbf{q}^S)}_{\text{LM similarity}} = \sum_{j=1}^{R^S}\frac{P_{LDA}(w_i^S,D_j^S,\hat{\boldsymbol{\theta}}^S,\hat{\boldsymbol{\phi}}^S)P(D_j^S|\mathbf{q}^S)}{R^S} \tag{5}$$

where we have used the notation $P_{LDA}(.)$ to denote the LDA estimated probabilities marginalized over the latent topic variables. Substituting Eq. (4) and Eq. (5) into (3) gives the full expression of the probability of generating a target language word from the relevance model in case of CLTRLM.

$$P(w^T|\mathbf{q}^S) = \underbrace{\left(\sum_{k=1}^{K^T} P(w^T|z_k^T,\hat{\phi}_{k,w^T}^T)\sum_{j=1}^{R^T} P(z_k^T|D_j^T,\hat{\theta}_{j,k}^T)\sum_{i'=1}^{n^T}\frac{P(q_{i'}^T|D_j^T)}{R^T}\sum_{j'=1}^{n^S} P(q_{i'}^T|q_{j'}^S)\right)}_{\text{target language contribution estimated by query translation}} + \underbrace{\left(\sum_{i=1}^{t(w^T)} P(w^T|w_i^S)\times\sum_{j=1}^{R^S} P_{LDA}(w_i^S,D_j^S,\hat{\boldsymbol{\theta}}^S,\hat{\boldsymbol{\phi}}^S)\frac{P(\mathbf{q}^S|D_j^S)}{R^S}\right)}_{\text{source language contribution estimated by document word translation}} \tag{6}$$

In Equation 6, $\hat{\phi}_{k,w^T}^T$ denotes the probability of the word w^T belonging to the topic k, whereas $\hat{\theta}_{j,k}^T$ denotes the probability of the k^{th} topic in the j^{th} document. Both these quantities can be computed from the LDA estimation output matrices $\boldsymbol{\theta}^T$ and $\boldsymbol{\phi}^T$.

Also note that the CLTRLM as shown in Figure 4 involves two possible ways of generating the query in the source language, i.e. either directly using documents retrieved in the target language, or by using translations of words in documents retrieved in the source language. Thus, a natural question which arises is whether we need to introduce a new linear combination parameter to choose the two event paths with relative weights similar to (Chinnakotla et al., 2010). However, a closer look at Equation 3 reveals that the contribution from each path is inherently controlled by the two coefficients $P(w^T|\mathbf{z}^T)$ and $P(w^T|\mathbf{w}^S)$, thus eliminating the need for an extra parameter.

3.4 Estimation with Bi-LDA

In Section 3.3 we worked out the estimation details assuming that the source and the target language documents have different topic distributions denoted by the parameters $\hat{\boldsymbol{\theta}}^S$ and $\hat{\boldsymbol{\theta}}^T$ respectively. The CLTRLM estimation can also be performed with a stronger assumption that document pairs in the source and target languages share the same distribution of topics say $\hat{\boldsymbol{\theta}}$, with different topic-word distribution parameters say $\hat{\boldsymbol{\phi}}^S$ and $\hat{\boldsymbol{\phi}}^T$ respectively. This is a special case of polylingual LDA as proposed in (Mimno et al., 2009). For Bi-LDA estimation of CLTRLM, firstly we impose the restriction of $R^T = R^S$, i.e. to retrieve the same number of documents on the source and target sides, and secondly we set $\hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\theta}}^T = \hat{\boldsymbol{\theta}}^S$ in Equation 6. We refer to CLTRLM instances with Bi-LDA estimation as JCLTRLM (Joint CLTRLM). Note that a JCLTRLM has two parameters $R = R^T = R^S$ and $K = K^T = K^S$ as opposed to four of CLTRLM.

3.5 Algorithm

After presenting the estimation details, we now provide the implementation steps for CLTRLM.

1) Run initial retrieval on the source language query $\mathbf{q}^S$ using standard LM to obtain documents $\{D_j^S\}_{j=1}^R$ in the source language (Ponte, 1998) and let R^S be the number of top ranked documents assumed to be pseudo-relevant.
2) Use a source-target language dictionary to get the equivalent query $\mathbf{q}^T$ in the target language.
3) Retrieve documents $\{D_j^T\}_{j=1}^R$ using LM for the target language query $\mathbf{q}^T$, and assume that the top ranked among these are pseudo-relevant.
4) Perform LDA inference by N iterations of Gibbs sampling on the working sets $\{D_j^S\}_{j=1}^{R^S}$ and $\{D_j^T\}_{j=1}^{R^T}$ to estimate the parameters $\hat{\boldsymbol{\theta}}^S$, $\hat{\boldsymbol{\phi}}^S$, $\hat{\boldsymbol{\theta}}^T$ and $\hat{\boldsymbol{\phi}}^T$. For the case of JCLTRLM, use Bi-LDA to estimate parameters.
5) Let V^T be the vocabulary of $\{D_j^T\}_{j=1}^{R^T}$. For each word $w^T \in V^T$, use Eq. (6) to compute the probability of relevance $P(w|R^T) \approx P(w|\mathbf{q}^S)$.
6) Rerank every target language document $\{D_j^T\}_{j=1}^{R^T}$ by the KL divergence between its LM document model (as obtained by the initial retrieval) and the estimated $P(w^T|R^T)$ so as to get the final retrieval result.

The computational complexity of the above algorithm is $O((V^T + V^S)(R^T + R^S)(K^T + K^S)N)$ where V^T, V^S are the vocabulary sizes of $\{D_j^T\}_{j=1}^{R^T}$ and $\{D_j^S\}_{j=1}^{R^S}$ respectively, R^T and R^S is the number of pseudo-relevant documents, K is the number of topics, and N is the number of iterations used for Gibbs sampling. The computational complexity of CLRLM on the other hand is $O(V^T R^T)$. CLTRLM, as compared to CLRLM, has the added computational cost for the source language retrieved documents. However, it is expected that $V^S = O(V^T)$, $R^S = O(R^T)$, and that both K^T, K^S and N are small constant numbers independent of R^T and V^T. Thus, CLTRLM is only a constant times more computationally expensive than CLRLM.

4 Experimental Setup

In this section, we describe the details of our experimental setup for evaluating CLTRLM. Our experiments explore the following questions: a) Does integrating the event of generating a target language word from the source language lead to a better estimation of the generative model for relevance compared to CLRLM? b) Does the use of latent topics benefit the alignment between source and target language documents and thus leads to a better estimation of relevance? c) What is the effect of translation quality on the performance of CLTRLM estimation? and d) How does the performance of Bi-LDA estimation for JCLTRLM, and separate LDA estimation for CLTRLM compare against each other? To answer a), we compare CLTRLM against CLRLM on cross-lingual ad-hoc search. To explore question b), we instantiate CLTRLM with the number of topics on the

	Documents			Queries			
Language	Type	# Docs.	Vocab. size [words]	Field	# Queries	Avg. query len.	Avg. # rel. docs.
Bengali	News articles	123,048	641,308	title	50	3.6	13.6
English	News articles	125,586	318,922	title	50	4.9	10.2

Table 1: FIRE-2010 document and query characteristics.

source and target sides set to 1, i.e. we use $K^S = K^T = 1$ in Equation 6, and use this instantiation of CLTRLM as one of our baselines. To answer c), we obtain different translation qualities by applying a bilingual dictionary and Google translate[2], which is a free to use statistical machine translation service. The presence of OOV words across language pairs can impair the estimation quality of CLTRLM because for every target language word whose translation is not found in the dictionary, we fail to get the source language contribution in the generation probability (see Equation 3). To reduce the vocabulary gap we use transliteration of OOV words, since it has been reported that transliteration helps improve the retrieval quality of CLIR (Udupa et al., 2009). Finally to address question d), we evaluate the relative performance of CLTRLM and JCLTRLM.

Data set. We perform CLIR experiments from English to Bengali, i.e. the query is expressed in English (source language), and the objective is to retrieve documents in Bengali (target language). Experiments are conducted on the English and Bengali ad-hoc collections of FIRE-2010 dataset (Majumder et al., 2010), the documents of which comprise a comparable corpus of news articles published from the same news agency in Calcutta namely *Ananadabazar* and *The Telegraph* in Bengali and English respectively. Table 1 outlines the document collection and query characteristics. Note that we do not use any external parallel or comparable resources to train our model as was done in (Vulić et al., 2011; Littman et al., 1998; Chen et al., 2010).

Stopwords. The stopword list used for Bengali retrieval was the one provided by the track organizers[3] generated by following an approach of extracting the N most frequent words from the document collection (Fox, 1992; Savoy, 1999). This list comprises of 384 Bengali words. The stopword list used for English was the standard SMART stopword list which comprises of 573 words.

Stemming. We used a moderately aggressive rule-based stemmer[4] for Bengali retrieval (Leveling et al., 2010). The stemmer used for our experiments is able to increase mean average precision (MAP) by 21.82% (0.2250 to 0.2741) on the monolingual title-only Bengali queries of the FIRE-2010 test collection. Although there are more complex corpus-based approaches reported for Bengali stemming (Majumder et al., 2007; Paik et al., 2011), the focus of this paper is not on improving stemming, but rather to improve on cross-lingual retrieval performance from English to Bengali. We thus applied a simple rule based approach as a stemmer which does not require computationally intensive pre-processing over the vocabulary of the corpus. The stemmer used on the English side is the default stemmer of SMART, a variant of Lovin's stemmer (Lovins, 1968).

Translation. One of the major components of CL(T)RLM is the bilingual dictionary to translate a given query in the source language viz. $\mathbf{q}^S$ to the corresponding representation in the target language $\mathbf{q}^T$. In our experiments, we used the open source English-Bengali dictionary *Ankur*[5]. The dictionary

Table 2: English-Bengali query translation qualities.

at the time of writing this paper comprises of 9180 English words for each of which one or more Bengali word translations are provided. It can be seen that the vocabulary coverage of the *Ankur* English-Bengali dictionary is very small, in fact covering only 1.43% of the total vocabulary size of the English corpus (see Table 1), as a result of which a significant number of query words remain untranslated and hence play no role in estimating the CLTRLM. To increase the vocabulary coverage, and hence improve on the retrieval quality, we used Google translator, which is a statistical MT web-service, to translate the English queries to Bengali.

Transliteration. The out of vocabulary (OOV) words with respect to both the Google translator and the English-Bengali dictionary were left in the original English form. A manual inspection of these translated queries by one of the authors, who is a native Bengali speaker, revealed that most of these OOV words are English proper nouns. Proper nouns are important for retrieval (Xu and Croft, 2000), and thus need to be handled appropriately. An intuitive approach is to transliterate English names into Bengali which has proved to be beneficial for Indian language CLIR (Udupa et al., 2009). For transliteration, we applied *Google transliterate*[6] on the untranslated words of the Bengali queries as obtained by the dictionary-based and the Google translator approaches. Google transliterate returns five transliterations for each given word in decreasing order of likelihood. Out of these five Bengali transliterations for each English word, we use the top ranked one i.e. the most likely one. This simplistic approach of taking the most probable candidate from Google transliterate may not yield accurate transliterations. However, the focus of the paper is not to improve on the English-Bengali transliteration process itself, but rather to use transliteration as an intermediate tool to improve CLIR performance. Furthermore, an incorrect transliteration of a query term hardly has any effect on retrieval performance, since it is highly unlikely for an incorrectly transliterated word to match with the indexed vocabulary.

Table 2 shows the quality of the query translations obtained by the four methods. Translation quality of the English queries translated into Bengali is measured by the metric BLEU (Papineni et al., 2002), by using FIRE-2010 Bengali query titles as reference translations. We in fact report two versions, one which computes the BLEU score using the original word forms, and the other on the stemmed versions of the translated text and reference. The latter is a more appropriate measure for CLIR, because for the case of CLIR it is sufficient to match the stemmed forms rather than matching corresponding original word forms of a translated word with its reference. It can be seen that the BLEU scores are rather low compared to language pairs such as English-French (Dandapat et al., 2012), which is indicative of the fact that translation from English-Bengali is a difficult problem indeed. Application of transliteration however results in a significant improvement of BLEU score, indicating the importance of handling the OOV words.

CL(T)RLM Implementation. CLTRLM has been implemented as an extension to SMART[7] along with the CLRLM approach which is used as one of the baselines. The other baseline using Google translator involves estimating a monolingual relevance model (Lavrenko and Croft, 2001) which is also implemented in SMART. GibbsLDA++[8] was employed for Gibbs sampling for LDA inference. A modified version of GibbsLDA++ was used for Bi-LDA inference for JCLTRLM estimation.

5 Results

This section reports the results of the experiments and analyzes the observations. We start with a detailed description of the retrieval runs and parameter settings.

Retrieval run description. The CLRLM baselines shown in Table 3 start with the prefix "CLRLM". Results are shown for each method of translation (Google translator or the dictionary-based translation), with or without transliteration on the translation output, thus yielding 4 cases. The CLRLM approach does not use any information from the documents retrieved in the source language. To show that source language information is beneficial for retrieval, we report runs which use only the target language path in the generative model shown in Figure 4, i.e. for these runs we set $P(w^T|\mathbf{w}^S)$ (see Equation 3) to zero. These runs are shown the prefix "TgtCLTRLM" in Table 3. To show that topic decomposition is essential, we set the number of topics to 1 on both the source and the target sides, i.e. we set K^T and K^S to 1. These runs benefit from the information on the source side, but do not use the topical structures of documents to help achieve a fine grained alignment of the topics. These run names are prefixed with "UCLTRLM" in Table 3. Finally, we report (J)CLTRLM results prefixed with (J)CLTRLM.

Parameter settings. Each run reported in Table 3 has been optimized with the best parameter settings. The parameters were varied as follows. The Jelinek-Mercer language modelling smoothing parameter (Hiemstra, 2000) of initial retrieval for all the runs was empirically chosen as 0.4. The hyper-parameters α and β which control the Dirichlet distributions for CLTRLM, were set to $\frac{50}{K}$ (K being the number of topics) and 0.1 respectively as described in (Griffiths and Steyvers, 2004). The number of iterations for Gibbs sampling i.e. N, was set to 1000 for all CLTRLM experiments. We tuned the common parameters i.e. R^S and R^T, i.e. the number of top ranked documents used for pseudo-relevance in the source and target languages respectively, within the range of $[10, 50]$ in steps of 10 so as to obtain the best settings. An important parameter to CLTRLM is the number of topics on the source and target sides viz. K^S and K^T. These parameters were empirically optimized within the range of $[5, 50]$. The justification of using a much smaller value range for the number of topics, in comparison to the global LDA based approach (Wei and Croft, 2006) which used much higher values of K in the range of 100 to 1500, comes from the fact that LDA estimation in the CLTRLM is done on only a small number of documents rather than on the full corpus.

Observations. With reference to Table 3, it can be seen that the initial retrieval run NOFDBK-DICT performs very poorly achieving only 21.58% of the MAP as compared to the monolingual retrieval run NOFDBK-MONOLINGUAL. This shows that a low resourced dictionary-based query translation does not yield satisfactory retrieval performance. A cross-lingual relevance model based feedback approach is able to significantly[9] improve on the initial retrieval MAP by 42.40% as can be seen by comparing run CLRLM-DICT with NOFDBK. The CLRLM run only retrieves documents in the target language i.e. Bengali in this case. MAP is further improved by 10.91% by using documents retrieved in the source language i.e. English as seen from the run UCLTRLM-DICT

Table 3: Results for English-Bengali CLIR experiments.

in comparison to CLRLM-DICT. This run is a corner-case of a CLTRLM without using topical decompositions on the source and target sides i.e. by setting $K^T = K^S = 1$. Topical decomposition on the target side alone (see "TgtCLTRLM" prefixed runs) produces better results than the CLRLM runs, but are outperformed by the runs which use information from the source side as well, as shown by the (J)CLTRLM runs. It can be seen that both topical decomposition and using information from the source-side play a crucial role in correctly estimating the relevance model.

It turns out that Bi-LDA inference of CLTRLM, i.e. JCLTRLM performs better than separately inferencing the topic models on the source and target sides for all scenarios except the one which only uses the dictionary. The reason JCLTRLM performs poorly on dictionary-based approach is that the initial retrieval results on the target language is very poor (MAP: 0.0592). It is thus not a reasonable assumption that the document pairs on the source and target sides share the same topic distribution $\hat{\boldsymbol{\theta}}$. In such a scenario, it is helpful to use different number of documents on the source and target sides for the LDA estimation. However, when the initial retrieval quality improves on the target side with the help of transliteration or SMT or both, it is observed that Bi-LDA estimation proves more beneficial because of a better level of agreement between the pseudo-relevant document sets in the source and target languages. The improvements obtained by JCLTRLM over CLTRLM

are statistically indistinguishable with respect to MAP, except for the DICT-TLIT case.

To summarize, we observe that the CLTRLM runs (even with only one topic), using information from the source side, perform significantly better than CLRLM runs which in turn do not use any source information, thus indicating that *documents retrieved in the source language lead to a better relevance estimation*. This observation conforms to the Multi-PRF results where it was shown that using information from another language retrieval results helps improve the monolingual retrieval result in the language of the query (Chinnakotla et al., 2010). The CLTRLM approach achieves a similar benefit for CLIR. We also observe that the CLTRLM runs outperform the UCLTRLM prefixed runs, thus establishing that *the use of latent topics does benefit the alignment between source and target language documents*. The reason is that incorporating latent topic nodes in the estimation process helps, firstly in focusing co-occurrence computation on topics rather than on full documents, and secondly the alignment process of the fine grained topics is more reliable than aligning full documents in the source and target languages. The fact that CLTRLM improves retrieval effectiveness significantly over a range of query translation qualities, suggests that the method is robust to translation quality. Furthermore, JCLTRLM turns out to be slightly better than CLTRLM suggesting that Bi-LDA estimation is marginally better than separate LDA estimation.

Comparison to other reported results on Indian language CLIR. To the best of our knowledge, no results have been reported for fully automatic English-Bengali CLIR. (Leveling et al., 2010) report that manual English-Bengali query translation by native Bengali speakers achieves MAP up to 83.3% compared to monolingual Bengali retrieval, but on longer *TD* (title-description) queries. The fact that manual query translation by native Bengali speakers achieves 83.3% retrieval effectiveness in comparison to monolingual IR, demonstrates that English-Bengali CLIR is a considerably hard problem to solve. Our fully automatic approach achieves a satisfactory performance increasing MAP by 90.87% (see the rows CLTRLM-DICT and NOFDBK-DICT) compared to translation with a base dictionary, and achieves a MAP of 60.27% of the monolingual upper baseline.

6 Conclusions and Future work

This paper presented CLTRLM, a novel theoretical framework for exploiting the topical association of terms between pseudo-relevant documents of the source and target languages, to improve CLIR effectiveness. CLTRLM is a generalization of the standard cross-lingual relevance model, overcoming its limitations of: a) incompatibility with a comparable corpus; and b) co-occurrence computation at the level of whole documents, instead of likely relevant topics. CLTRLM uses a *comparable* corpus for IR on the retrieved set of top-ranked documents without the requirement of a separate training phase on the whole corpus. Empirical evidence of the effectivness of the method, specially on low resourced languages, is provided by achieving 41% (MAP: 0.1130) with a base dictionary of about 10K words, and 60.27% (MAP: 0.1652) with freely available SMT web-services of the monolingual MAP on English-Bengali CLIR (MAP: 0.2741).

The work presented in this paper treats an entire pseudo-relevant document as one document unit in the LDA estimation. A possible extension to this approach, which will be investigated as part of future work, would be to use smaller textual units, i.e. sentences or paragraphs as document units in the LDA estimation. This would naturally take into account the proximity evidence as well, in addition to the topical distribution of terms.

Structured Term Recognition in Medical Text

Michael Glass *Alfio Gliozzo*
IBM T.J. Watson Research, Yorktown Heights
mrglass@us.ibm.com, gliozzo@us.ibm.com

ABSTRACT
In this work we present a novel approach to bootstrap domain specific terminology, namely Structured Term Recognition, and we apply it to the medical domain. In contrast to previous approaches, based on observing distributional properties of terminology with respect to their contexts, our method analyzes the "internal structure" of multi-word terms by learning patterns of word clusters. Evaluation shows that our method can be used to boost the performances of term recognition systems based on dictionary lookup while extending the coverage of large ontologies like UMLS.

KEYWORDS: terminology recognition, bootstrapping, medical terminology, named entity recognition, joint inference.

Proceedings of COLING 2012: Technical Papers, pages 943–958,
COLING 2012, Mumbai, December 2012.

1 Introduction

Recognizing occurrences of domain specific terms and their types is important for many text processing applications. This problem is not easy, particularly in domains like medicine, where very rich terminology is generated by domain experts on a daily basis.

In spite of the large interest in statistical term recognition in Natural Language Processing (NLP), state of the art approaches for term recognition in the medical domain are still based on dictionary lookup with some heuristics for partial mapping (Aronson, 2001). In fact, very large terminological resources, such as the Unified Medical Language System (UMLS) (Bodenreider, 2004), have been developed in the medical domain. The reason is that medical terminology can not be identified by looking at superficial features only, such us capitalization of words, prefixes and suffixes. In fact, diseases names, symptoms and most medical terms are not proper names, so they are not capitalized. In addition, they are usually characterized by a rather complex internal structure and composed by many words. In addition, distributional similarity metrics, i.e. recognition approaches based on the analysis of the local context where the term is located, work well when applied to single words or very frequent words, which is not the case for most of the medical terms we are interested in.

In the context of the research on adapting a question answering system to the medical domain, we encountered the term recognition problem in many places. For example, recognizing names of diseases, symptoms and treatments is necessary to answer most of the Doctor's Dilemma^{TM}questions (American College of Physicians, 2012), an evaluation benchmark we used to measure the ability of our system to answer medical questions. To assess the validity of the answer "HFE hereditary hemochromatosis" with respect to the question "Metabolic condition that can set off airport metal detector", it is important to know that the answer is a type of metabolic condition. One way to address this problem is to use medical lexica where different terms are associated to semantic types, and then check whether the type of the candidate answer matches the type required by the question.

On the other hand, UMLS is far from complete. Many disease names (especially multi-words) are not recognized by dictionary lookup approaches. In many cases, specific terms are missing (e.g. "HFE hereditary hemochromatosis" in the question above). The problem is particularly evident when examining the answers to the Doctor's Dilemma questions. Analyzing 704 doctor's dilemma questions where the system located the correct answer as candidate, in 16.5% of the cases one of the correct answers was not in UMLS. About half of them were quantities (e.g. 20mg) while the remaining half were medical terms that are not in UMLS. On the latter subset of questions, the end to end accuracy of the full QA system dropped by almost 50% if compared to the performance on questions where the answer was an UMLS term. The explanation for this drop in performance is mostly due to type recognition problems: the system is not able to select the right answer on the basis of its type, for example confusing treatments with diseases.

This observation motivates the work presented in this paper. Our method is able to recognize the type of domain specific terms based on an innovative principle, called Structured Term Recognition (STR). We begin with a simple observation: in many technical domains - and in the medical domain in particular, terms have repetitive patterns. For example, terms describing cancer include "bladder cancer", "brain tumor", "skin cancer" and "uterine sarcoma". These terms are all composed of a word indicating a part of the human anatomy followed by a word similar to "cancer". If the sequence of words "pituitary tumor" appears in text, and "pituitary" is known to be an a word indicating a part of the anatomy, it is reasonable to identify this

as a cancer term even if it is not in the dictionary of cancer terms. A simple baseline where any noun phrase with the word "cancer" as it's head is identified as a cancer term will lead to such misidentifications as "some types of cancer" and "a different cancer". In fact, syntactic information alone is not enough to recognize technical terms, additional semantic information reflecting the type of the term constituents should be considered.

Structured Term Recognition (STR) is a way to address this problem. It works by examining the semantic structure of terms, acquiring semantic patterns describing it, and identifying new terms with similar structure. In this paper we focus on multi-word terms, in the case of single word terms our method becomes indistinguishable from prior work on extending a thesaurus by distributional similarity.

Similar to other existing bootstrapping methods, STR begins with an existing dictionary and uses patterns to extend its coverage. In contrast, it does not use contextual information or shallow features describing the term itself, instead it uses "internal deep semantic" features describing what a domain term should look like, i.e. its semantic pattern. Combinations of STR and techniques based on contextual information are obviously possible. However, in this paper we decided to focus on the contribution of the STR technique in isolation because we want to show that in the medical domain this information is a strong indicator of the entity type if well represented and handled. We present three different approaches to solve the problem, two based on recognizing terms on the basis of the sequences of the word clusters and a third one based on Probabilistic Context Free Grammars (PCFG) and we evaluate them on the task of predicting the semantic group of a held out subset of terms extracted from UMLS.

The paper is structured as follows. Section 2 describe STR into details, while section 3 is about evaluating our method. In section 4 a literature review is done, while section 5 concludes the paper and highlight directions for future work.

2 Structured Term Recognition

The inputs of STR are a set of terms $t \in T$ from a dictionary, each belonging to a set of types $\Gamma(t) = \{\gamma_1, \gamma_2, \ldots\}$, and a domain specific corpus U. Terms are composed of lists of words $t = w_1, w_2, \ldots, w_n$ as identified by a tokenizer. The union of all tokens for all of the terms is the word set W.

The output of STR is a set of pattern-to-type mappings $p \mapsto \gamma$ that can be used to recognize terms and their type in new texts. These terms are not necessarily present in U.

STR combines two key components:

1. Clustering words in W by their distributional and type similarity.
2. Constructing patterns describing terms in the dictionary.
   (a) Sequences of Clusters are patterns.
   (b) Patterns are the left hand side of PCFG rules.

2.1 Word Clustering

The goal of this component is to cluster the words in W into clusters $C_1, C_2, \ldots, C_n$. Clusters are partly determined by distributional similarity, meaning that words in the same cluster

have similar meanings because they are substitutable in context. This follows a large body of work in unsupervised clustering of words. Early work used distributional similarity to perform part-of-speech induction (Schütze, 1993). Later work has developed automatic methods of thesaurus construction using similar techniques (Lin, 1998).

Using a large, domain specific, unannotated corpus U, STR gathers vectors describing the context in which each word is found. Since parsing is generally lower quality in non-newswire domains, we do not use dependency based contexts. Instead the corpus is simply tokenized. Contexts are built from a small window of surrounding words: two words to the left and two words to the right. The information about the direction and distance from the word is retained. For example, in the sentence "Early detection of **cancer** increases the odds of successful treatment." the contexts for the word "cancer" are given in table 1.

cancer	
Direction	Context Word
Left-2	detection
Left-1	of
Right-1	increases
Right-2	the

Table 1: Contexts for "cancer"

For each word we build a vector of contexts. Note here that in order to build the context vector we do not restrict context words to words in W, instead we consider any possible token in the large corpus. Each dimension of the vector is an individual context f and its value is the number of times it occurred with the word. This vector of raw counts must be re-weighted, otherwise very high frequency but uninformative contexts, such as "of" and "the", will dominate. We use Pointwise Mutual Information (PMI) as a re-weighting method. PMI measures the strength of association between two events such as the occurrence of a word and the occurrence of a context.

$$\text{pmi}(w; f) = \log \frac{p(w, f)}{p(w)p(f)} \tag{1}$$

Equation 1 gives the formula for PMI, where $p(w)$ is the frequency of the word in the corpus divided by the number of words in the corpus and $p(f)$ is the frequency of the context divided by the total number of contexts.

Once the context vectors for each word are gathered and re-weighted they can be compared for similarity using the cosine similarity metric.

The domain specific dictionary may have many of the words in W mapped to types. However, in general a word need not be mapped to one type. It may have multiple senses, each with a distinct type. For each word we construct a type vector, where the dimensions are types and the value is either a one or zero depending on whether the word is given as that type in the dictionary. Since the dictionary groups words with similar meanings in the same type, words with overlapping type vectors will have some meanings that are similar.

2.2 Pattern Acquisition

The goal of this step is to learn a set of rules $R = \{p_1 \mapsto \gamma_1, p_2 \mapsto \gamma_2, \ldots, p_k \mapsto \gamma_k\}$ which are able to recognize most terms in T and at the same time can be used to identify new terms in the large corpus. This is done by generating a set of candidate rules and scoring them according to how they perform on the training set. We trained two different models for clusters and patterns.

In the sequence of clusters model, each word is assigned to a single cluster, patterns are sequences of clusters, and rules map a pattern to a type. Each possible sequence of clusters maps to at most one type.

In the probabilistic context free grammar (PCFG) model, words are assigned to multiple clusters, each assignment has some weight corresponding to a probability. The rules are a set of binary PCFG rules where two non-terminals are mapped to a single non-terminal. All non-terminals on the right hand side of such rules are types. Each possible sequence of clusters has a Viterbi (most likely) parse ending in a single type.

2.3 Sequence of Clusters

For the Sequence of Clusters model, the clustering is a mapping function $\Theta : W \rightarrow C$ assigning each word in W to its corresponding cluster. The patterns are the mappings of each term $t \in T$ into its corresponding pattern $P(t) = p = \Theta(w_1), \Theta(w_2), \ldots, \Theta(w_j)$, where t is the sequence of words $t = w_1, w_2, \ldots, w_j$. A term is typed if there is a rule $P(t) \mapsto \gamma \in R$. This typing is correct ($t \in Correct$) if t has γ as a type in the dictionary, $\gamma \in \Gamma(t)$, otherwise it is incorrect ($t \in Incorrect$).

An example sequence of clusters pattern and some of its recognized terms are given in Table 2. The clusters are named according to their most frequent members. So "{sensation, fear, feeling}" is the cluster that includes those words, as well as other distributionally similar words.

Pattern		
{spastic, flaccid, tonic}	{sensation, fear, feeling}	{tenderness, headache, tremor}
Recognized Terms		
horizontal	gaze	paresis
tonic	reflex	spasm
dural	puncture	headache
exertional	heat	exhaustion
charley	horse	cramps

Table 2: Example pattern and recognized terms

The training seeks to create rules and word-to-cluster mappings to maximize intra-cluster similarity and the performance of the rules on the training data. The intra-cluster similarity is measured by the cosine of each word to its cluster's centroid. The performance of the rules is given by $|Correct| - |Incorrect| + \theta_{REG} \cdot |R|$. The θ_{REG} is a regularization parameter to penalize the creation of too many rules.

2.3.1 Non-Joint Optimization

A straightforward way of doing this is to first optimize intra-cluster similarity, which can easily be converted to the objective function in spherical KMeans. We use GMeans (Dhillon et al.,

2001), a variant of KMeans that uses first variation to escape from some local maxima, to cluster. Then, given fixed word-to-cluster assignments, the optimal set of rules may be found in linear time. By mapping each term to its pattern and constructing a hash map from patterns to sets of terms we can determine for any possible θ_{REG} if mapping the pattern to the most frequent type γ_{ts} in its term set will improve rule performance. This method is fast, but it does not perform nearly as well as a joint optimization.

2.3.2 Joint Optimization

Our method of joint optimization is to cast the problem as a MAP (Maximum a posteriori) inference task in probabilistic logic and use a general purpose probabilistic inference engine to do the optimization. Different sets of word-to-cluster mappings and rules are different possible worlds. The probability of a world is given by the objective function and the inference attempts to find the most likely world.

The objective function is precisely described by the formulas in Figure 1, which closely matches the description given to the probabilistic inference engine. In this description, all variables are implicitly universally quantified. The quantity preceding the "#" in the formulas that have them is a weight, every true grounding of the formula on the right adds the quantity on the left to the weight of the possible world. Like Markov Logic (Richardson and Domingos, 2006), the semantics of the weight are that it is the log of an unnormalized probability. Note that unlike Markov Logic, we are not limited to first order logic.

$$\theta_{DC} \cdot \textbf{cosine}(v, cv) \;\#\; inCluster(w, c) \wedge distVect(w, v) \wedge distCentroid(c, cv)$$
$$cluster(c) \Rightarrow distCentroid(c, \textbf{sum}(\{v : inCluster(w, c) \wedge distVect(w, v)\}))$$
$$\theta_{TC} \cdot \textbf{cosine}(v, cv) \;\#\; inCluster(w, c) \wedge typeVect(w, v) \wedge typeCentroid(c, cv)$$
$$cluster(c) \Rightarrow typeCentroid(c, \textbf{sum}(\{tv : inCluster(w, c) \wedge typeVect(w, tv)\}))$$
$$wordAt(t, i, w) \wedge inCluster(w, c) \Rightarrow typeAt(t, i, c)$$
$$term(t) \Rightarrow patternOf(t, \textbf{makePattern}(\{(i, c) : typeAt(t, i, c)\}))$$
$$\theta_A \cdot \textbf{scoreType}(t, \gamma) \;\#\; isRule(p, \gamma) \wedge patternFor(p, t)$$
$$\theta_{REG} \;\#\; isRule(p, \gamma)$$

Figure 1: Logical description of the Sequence of Clusters model

There are three basic parts: the first four lines give the objective function for spherical KMeans, lines 1 and 2 using distributional similarity and lines 3 and 4 using type vector similarity. The next three lines evaluate the performance of the patterns on the training data. The final line is the regularization, penalizing the creation of too many patterns.

The predicates $distVect, typeVect, cluster, term, wordAt$ are given as evidence to the inference. Each word is related to its normalized distribution vector and type vector by $distVect$ and $typeVect$ respectively. A term, position and word at that position are related by $wordAt$. The function **makePattern** takes a set of index/cluster pairs and produces a sequence of clusters as a string so that for every term t, $patternOf(t, P(t))$. The distribution and type centroids are found by summing the corresponding vectors from the words in the clusters. Since cosine is our similarity metric, it is not necessary to renormalize these vectors. The function **scoreType**

implements the logic of returning a 1 for a correct type mapping, -1 for an incorrect type mapping and 0 for a $\emptyset$ type mapping.

The θ parameters control the balance of the different components of the optimization. We selected values of $\theta_{DC} = 1, \theta_{TC} = 1, \theta_A = 1, \theta_{REG} = -3$.

The predicates $inCluster, isRule$ are the proposal predicates. The basic inference algorithm is to make proposals which are then either accepted or rejected. We have three proposals: move a word to a different cluster, create a rule, and remove a rule. A proposal is accepted if and only if it improves the objective function. The proposals are described formally in Table 3. The variables in the proposal formula are bound to a random true grounding of the formula. Then the remove list is set false and the add list is set true.

Proposal Formula	Remove	Add
$inCluster(w, c_1) \wedge cluster(c_2) \wedge c_1 \neq c_2$	$inCluster(w, c_1)$	$inCluster(w, c_2)$
$patternFor(p, t) \wedge \gamma \in \Gamma(t) \wedge \neg isRule(p, \gamma)$	$\emptyset$	$isRule(p, \gamma)$
$isRule(p, \gamma)$	$isRule(p, \gamma)$	$\emptyset$

Table 3: Proposals for the Sequence of Clusters Model

A key optimization is to not recompute the centroid of each cluster on every proposal. Instead, it is recomputed with a probability that decreases as the size of the cluster increases. The intuition behind this idea is that the centroid does not change much if the size of the cluster is large.

A final step in sequence of clusters is to find the optimal pattern set given the word-to-cluster assignments, as in the non-joint approach. This step can also accommodate different precision-recall trade-offs by varying the θ_{REG} parameter.

In the sequence of clusters model we restrict our attention to terms of length two and three so that each sequence of clusters will have many terms that match it.

2.4 Probabilistic Context Free Grammar

In order to address longer terms, and to improve performance we developed a Probabilistic Context Free Grammar (PCFG) for terms. This grammar is binary with non-terminals consisting of types and clusters.

For all words in the dictionary as terms, we fix their cluster assignments to their types, initially with equal weight. Formally, for all single-word terms w and all types $\gamma \in \Gamma(w)$, $inCluster(w, \gamma, 1)$. We used the results of the previous model to assign clusters to the remaining words. This is a soft clustering.

An example PCFG parse is given in Figure 2. The non-terminal labeling a terminal (word) may be either a cluster or a type, but the non-terminal labeling a pair of non-terminals is always a type.

The objective function is to maximize the correctness of the Viterbi parses on the training data. The objective function is precisely described in Figure 3.

As before the predicates $wordAt, term$ are given as evidence. Now $term$ relates a term to its length. The function **maxType** takes a set of type/weight pairs and returns the type with the largest weight or $\emptyset$ if the set is empty. The key predicate is $chart$ which holds the chart parse as a set of ground predicates where $chart(t, i, j, \gamma, x)$ indicates that for term t the type γ spans

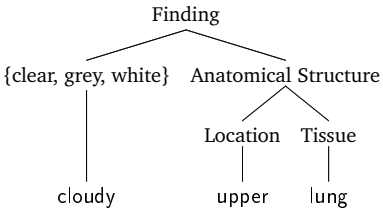

Figure 2: Example PCFG parse

$$wordAt(t,i,w) \wedge inCluster(w,\gamma,x) \Rightarrow chart(t,i,(i+1),\gamma,x)$$
$$isRule(\gamma_1,\gamma_2,\gamma_p,x_p) \wedge chart(t,i,j,\gamma_1,x_1) \wedge chart(t,j,k,\gamma_2,x_2) \Rightarrow$$
$$typeAt(t,i,k,\gamma_p,(x_1+x_2+x_p))$$
$$typeAt(t,i,j,\gamma,z) \Rightarrow chart(t,i,j,\gamma,\max(\{x : typeAt(t,i,j,\gamma,x)\}))$$
$$term(t,l) \Rightarrow vitParse(t,\textbf{maxType}(\{(\gamma,x) : chart(t,0,l,\gamma,x)\}))$$
$$\theta_A \cdot \textbf{scoreType}(t,\gamma) \ \#\ vitParse(t,\gamma)$$
$$\theta_{REG} \ \#\ isRule(\gamma_1,\gamma_2,\gamma_p,x_p)$$

Figure 3: Logical description of the PCFG model

i to j with log likelihood x. The proposal predicates are $isRule, inCluster$. The weights of rules and proposals are the log of their probability. The proposals are: change the weight of a parse rule or cluster assignment, add a parse rule, and remove a parse rule. Table 4 gives these proposals formally. The function $random(x,y)$ produces a random number between x and y.

Proposal Formula	Remove	Add
$inCluster(c,w,x)$	$inCluster(c,w,x)$	$inCluster(c,w,random(-2,2))$
$isRule(\gamma_1,\gamma_2,\gamma_p,x)$	$isRule(\gamma_1,\gamma_2,\gamma_p,x)$	$isRule(\gamma_1,\gamma_2,\gamma_p,random(-2,2))$
$\gamma_1 \in C \cup \Gamma \wedge \gamma_2 \in C \cup \Gamma \wedge \gamma_p \in \Gamma$	$\emptyset$	$isRule(\gamma_1,\gamma_2,\gamma_p,random(-2,2))$
$isRule(\gamma_1,\gamma_2,\gamma_p,x)$	$isRule(\gamma_1,\gamma_2,\gamma_p,x)$	$\emptyset$

Table 4: Proposals for the PCFG Model

Another key optimization is the use of declarative variable coordination inspired by the imperative variable coordination of Factorie (McCallum et al., 2009). The formulas with a "⇒" may be read as infinite weight implications, but unlike other approaches to combining hard and soft formulas we never consider states where the hard formulas are violated. Instead, for every true grounding of the left hand side, we immediately create a grounding of the right hand side. If all the left hand sides supporting a coordinated predicate become false, the corresponding coordinated predicate also becomes false. It may be more clear to consider the predicate on the right hand side as being defined by the disjunction of all its left hand sides.

Because the speed of the training is closely related to the length of the terms we only train on terms up to length four. However, we test the model on all terms.

3 Evaluation

The patterns found by the STR algorithm produce a term recognition function, able to decide the type of a term $t = w_1, w_w, \ldots, w_j$ by simply checking for a rule $P(t) \mapsto \gamma$ in the case of sequence of clusters, or by parsing the term with a chart parser in the PCFG model. We evaluate the quality of this recognition function by testing it on a held out set of terms in the dictionary. As with training, we consider a mapping correct if it maps the term to one of the types given in the dictionary.

3.1 Experimental Setup

For our input dictionary we use the Unified Medical Language System (UMLS). UMLS is an ontology of mostly medical terms called atoms. There is a type hierarchy with 133 semantic types these are collected into 15 semantic groups. The semantic groups are a flat and clear division of semantic types. Each UMLS atom may have multiple semantic types and possibly multiple semantic groups. In our test set 7.2% percent of the atoms had multiple semantic groups.

First we selected the multi-word UMLS atoms that occur in our corpus at least 20 times. Our corpus is 3.3 GB of text from Medline abstracts and medical textbooks. This first step is necessary because many UMLS atoms are not terms that occur in text and therefore there is no benefit to recognizing them. This set of UMLS atoms is then divided into a training and test set with 90 percent in training and the remaining 10 percent in test. We trained STR to recognize the semantic group of the terms in the training set, then evaluated the resulting rules on the test set. This produced a training size of around 72,000 terms.

3.2 Results

For the sequence of clusters model we obtain a precision recall curve by varying the pattern regularization parameter θ_{REG}. For the PCFG model we vary the parse score threshold to obtain a precision-recall trade-off.

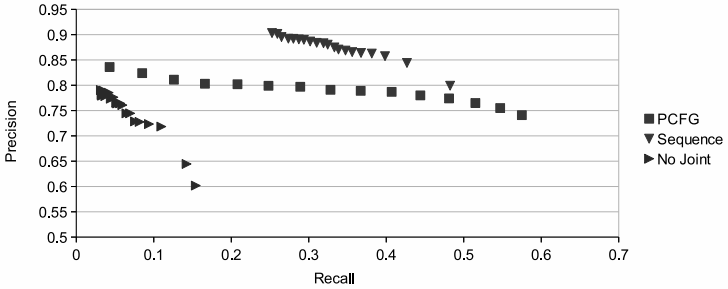

Figure 4: Precision Recall Curves

With a $\theta_{REG} = -20$ we obtain a precision of 90.3% and a recall of 25.3%. Setting the regularization parameter to zero maximizes recall at 48.2% with precision decreasing to 79.9%. With the parse score threshold of 3.5, we obtain a precision of 83.6%, but a very low recall,

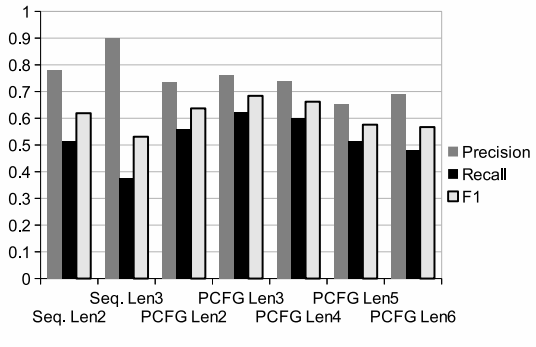

Figure 5: Performance per Term Length

4.3%. Dropping the threshold entirely gives a precision of 74.1% and a recall of 57.5%. Both of these models substantially outperform the non-joint method described in Section 2.3.1. A baseline model of selecting the most frequent semantic group would perform at precision = recall = F1 score = 23.8%. With a test set of approximately 8,000 all of these differences are highly significant.

Note that while the sequence of clusters model is evaluated only on length two and three terms, the PCFG model is evaluated on all terms. Figure 5 compares the performance of each model on different term lengths.

The performance of all models improves as the amount of optimization time increases. The learning curve for the sequence of clusters model is given in Figure 6. Note that the x-axis is the number of proposals, not the number of training instances. Performance grows from an F1 score of 49.4% with 500 thousand proposals to an F1 score of 60.2% after 27 million proposals.

The performance per group is given in Figure 7. The groups are listed in order of their frequency in the dictionary. There is a clear effect of term frequency on performance with all but one of the top performing half of groups in the top half of term frequency.

The performance of the PCFG model is broken down by group in Figure 8. The recall and F1 scores on “Genes and Molecular Sequences” and “Devices” show large gains relative to the sequence of clusters model. There is again a clear effect of term frequency.

Performance is generally lowest on the semantic groups that are not specifically biomedical: Objects, Devices, Phenomena, Activities & Behaviors, Organizations, Occupations and Geographic Areas. Other than a lower frequency in UMLS, this is likely due to a lower amount of regular structure in these less technical terms.

4 Related Work

The goal of our work is to extend UMLS with additional terms mapped to types. Other work has pursued similar goals. This section provides a state of the art about.

4.1 Automatic Term Recognition

There is a large body of work on Automatic Term Recognition ATR and term clustering. In STR we identify that a sequence of words is a term and that it has a particular type in a single process. ATR operates by first gathering strings that are terms and then clustering them, or extending existing clusters where each cluster of terms are terms of a common type.

After terms are identified, some measure of term similarity is applied to cluster the terms or extend existing clusters of terms. Some methods of term similarity are contextual, lexical and pattern-based. Contextual similarity uses information about what words appear before and after the term (Maynard and Ananiadou, 2000), or what words are nearby in a dependency parse (Grefenstette, 1994). The frequency of each of these contexts is a dimension in a vector describing the distribution of the term. These vectors can then be compared for similarity using some vector similarity function. Lexical similarity examines what words are in common between two terms. For example, two terms with the same head word are likely to have the same type. Pattern-based similarity (Nenadić et al., 2002) uses lexico-syntactic patterns like the such-as pattern "X such as Y and Z". These patterns can be used as evidence that the terms appearing as Y and Z have the same type.

ATR deals primarily with frequent words. The term must be frequent enough to be identified as a term and in the case of contextual similarity must be frequent enough to build a meaningful distribution vector. Only the lexical similarity metric examines the words inside the term and this metric only considers lexical matches between the words of the term, not the types of the words or the structure of the words in the term. The main advantage of this type of work is that it can proceed without an existing term dictionary.

4.2 Supervised Named Entity Recognition

Our methods are also similar to Named Entity Recognition (NER). NER is the task of identifying mentions of rigid designators, especially people, places and organizations (Coates-Stephens, 1992). Recently, biological types such as protein, DNA and cell line have gained attention (Settles, 2004). Unlike automatic term recognition, where the goal is to build a dictionary of terms, NER typically proceeds from a corpus annotated with mentions and their types and learns a model for detecting future mentions.

One common model is the linear chain Conditional Random Field (CRF) (McCallum and Li, 2003). This is the discriminatively trained variant of the Hidden Markov Model (HMM) (Bikel et al., 1997). In the simplest version of such models, each word belonging to a mention for some type is tagged with that type's identifier. One weakness of this simple version is that in the case where two mentions of a certain type are contiguous, it is not possible to tell where one begins and the other ends - or even that there are two mentions rather than one. To alleviate this problem, and enrich the model, more complex tag sets are used. A model might have a tag for the beginning, inside and end of each type of entity. This enables the model to learn words that are more likely to begin and end mentions, effectively learning a little of the structure of the entities.

NER systems have also addressed the lexical composition of mentions for each type. For example, organization names often include the name of a person or a place (Wolinski et al., 1995). Even common nouns such as "associates" can indicate that a mention is of type organization (Wolinski et al., 1995).

In the biomedical domain, supervised CRFs have shown success at identifying genes and proteins. Using an annotated corpus from Medline abstracts, state of the art systems reach F-Scores of 78.4% for protien names (Tsai et al., 2006). Unfortunately, over a broader set of medical term types, basic linear chain CRF models cannot generalize beyond the terms in the training data (Zhang et al., 2010), with only a handful of new, correct medical terms identified from thousands of candidate new terms.

Unlike most NER systems our focus is on terms composed primarily of common nouns. While NER systems are trained on a labeled corpus, STR instead uses a term dictionary and an unlabeled corpus.

4.3 Bootstrapping Named Entity Recognition

Other work has identified and typed named entities based on an existing list of entities for each type. Usually, NER bootstrapping focuses on building a gazetteer of relatively common entities given a very small initial set of entities for each type. One approach is to use a small set (4) of example entities and search the web for documents that contain all of the example entities (Nadeau et al., 2006). The resulting documents are likely to contain lists or tables of the entities for the relevant type. By using an HTML context classifier trained with the context of the search entities as positive examples, other entities in the same HTML contexts may be extracted (for example "<td> x </td>"). The extracted entities are added to the list of known entities enabling additional search queries to be generated.

Mutual bootstrapping (Riloff and Jones, 1999) simultaneously learns entities of the selected type and patterns for identifying the entities. From a small set of seed entities, lexico-syntactic patterns are learned that suggest an entity of the appropriate type. For example, the noun phrase following "headquarted in" is likely to be a location. Extraction patterns are scored by their frequency and (estimated) reliability and entities are scored by the weighted sum of patterns that identify them. This scoring helps to alleviate the core problem of bootstrapping: semantic drift and also allows for a precision/recall trade-off.

A related bootstrapping approach (Kozareva, 2006) trains an NER classifier based on the current gazetteer then runs the classifier over text and adds the new terms recognized by the classifier to the gazetteer. This method requires a recognition system that goes beyond dictionary matching and uses context to a significant degree. The features used by the classifier include capitalization, trigger words specific to locations, organizations and people, and whether words in the noun phrase belong to a gazetteer for the type of interest.

Unlike traditional NER bootstrapping, STR assumes an existing large dictionary with hundreds if not thousands of examples per type. STR can identify the long tail of entities that may never occur in an easily interpretable list, table or lexico-syntactic pattern.

4.4 Joint Clustering

Other work has pursued different goals using related methods. The segmentation and de-duplication of citations has received considerable attention as a joint inference task. The

decisions of linking author, title, venue and citation records are all interdependent, since linking two citations implies that the fields composing the citations should also be linked. The task of segmenting the citations and identifying their fields is also influenced by the record linking. An easily segmented citation linked to a difficult case may make the difficult case much easier.

Using Markov Logic a joint entity linking model showed improvement in citation, author and venue linking over an independent model based on the field similarities alone (Singla and Domingos, 2006). Imperatively-Defined Factor Graphs (IDFs) produced still higher performance by incorporating features that could not be tractably expressed in factor graph systems that fully ground the network before inference (Singh et al., 2009).

5 Conclusion and Future Work

In this paper we presented a novel approach to semi-supervised term recognition. Unlike previous approaches we induced structure of the known terms to predict new terms. This enables type recognition for terms that appear only once in the corpus. We compared three different methods. All of them substancially improved over a most frequent baseline. We proposed two methods based on recognizing sequences of clusters. The one based on joint optimization significantly increased both precision and recall over the same method based on static clustering, reaching 90% precision at almost 30% recall. PCFG grammars allow us to achieve better recall (60%) with reasonably high precision (75%). In addition, PCFG allows us to recognize terms of any length.

The results shown by this paper are only partial as they do not take into account the role of context in disambiguating the types of terms. This limitation is intentional because: (i) we are interested in recognizing the type of answers independently of their context in cases when they are generated from databases or other non-textual material (ii) we are interested in exploring to what extent the internal structure of terminology can be used to express the semantics of terms.

In the future we will integrate STR with existing approaches of contextual, lexical and pattern-based term recognition. In addition, we will apply our technique to more fine grained type systems and other domains.

The type of structure learned is currently very simple, either a sequence of word clusters or a binary grammar. Other types of regularities exist, such as reordering. The pair of terms “leg pain” and “pain in leg” as well as many other similar pairs suggest a general alternation rule. We are going to explore this direction in order to learn transformational rules that can lead to identification of synonyms, hypernyms and to a better understanding on the underlying linguistic phenomena characterizing the generation and recognition of domain specific terminology.

ABSTRACT
The standard training regime for transition-based dependency parsers makes use of an oracle, which predicts an optimal transition sequence for a sentence and its gold tree. We present an improved oracle for the arc-eager transition system, which provides a set of optimal transitions for every valid parser configuration, including configurations from which the gold tree is not reachable. In such cases, the oracle provides transitions that will lead to the best reachable tree from the given configuration. The oracle is efficient to implement and provably correct. We use the oracle to train a deterministic left-to-right dependency parser that is less sensitive to error propagation, using an online training procedure that also explores parser configurations resulting from non-optimal sequences of transitions. This new parser outperforms greedy parsers trained using conventional oracles on a range of data sets, with an average improvement of over 1.2 LAS points and up to almost 3 LAS points on some data sets.

KEYWORDS: dependency parsing, transition system, oracle.

1 Introduction

The basic idea in transition-based dependency parsing is to define a nondeterministic transition system for mapping sentences to dependency trees and to perform parsing as search for the optimal transition sequence for a given sentence (Nivre, 2008). A key component in training transition-based parsers is an *oracle*, which is used to derive optimal transition sequences from gold parse trees. These sequences can then be used as training data for a classifier that approximates the oracle at parsing time in deterministic classifier-based parsing (Yamada and Matsumoto, 2003; Nivre et al., 2004), or it can be used to determine when to perform updates in online training of a beam search parser (Zhang and Clark, 2008).

Currently, such oracles work by translating a given tree to a static sequence of parser transitions which, if run in sequence, will produce the gold tree. Most transition systems, including the arc-eager and arc-standard systems described in Nivre (2003, 2004), exhibit *spurious ambiguity* and map several sequences to the same gold tree. In such cases, the oracles implicitly define a canonical derivation order. We call such oracles *static*, because they produce a single static sequence of transitions that is supposed to be followed in its entirety. Static oracles are usually specified as rules over individual parser configurations – if the configuration has properties X and the gold tree is Y, then the correct transition is Z – giving the impression that they define a function from configurations to transitions. However, these rules are only correct for configurations that are part of the canonical transition sequence defined by the oracle. Thus, static parsing oracles are only correct as functions from gold-trees to transition sequences, and not as functions from configurations to transitions.

There are at least two limitations to training parsers using static oracles. First, because of spurious ambiguity, it is not clear that the canonical transition sequence proposed by the oracle is indeed the easiest to learn. It could well be the case that a different sequence which also leads to a gold tree is preferable. Second, it happens often in greedy deterministic parsing that the parser deviates from the gold sequence, reaching configurations from which the correct tree is not derivable. The static oracle does not provide any means of dealing with such deviations. The parser's classifier is then faced with configurations which were not observed in training, and this often leads to a sequence of errors. It would be preferable for the parser to explore non-gold configurations at training time, thus mitigating the effect of error-propagation.

In this paper, we introduce the concept of a *dynamic* parsing oracle. Rather than defining a single static canonical transition sequence for producing a given gold tree, the dynamic oracle answers queries of the form: Is transition Z valid in configuration X for producing the best possible tree Y? A key difference compared to a static oracle is that the dynamic oracle no longer forces a unique transition sequence in situations where multiple sequences derive the gold tree. In this case, the dynamic oracle permits all valid transition sequences by answering "yes" on more than one transition Z in a given configuration.[1] The second crucial difference to a static oracle is that the dynamic oracle defined in this work is well-defined and correct for *all* configurations, including configurations which are not a part of a gold derivation. For configurations which are not part of a gold derivation (and from which the gold tree is not reachable), the dynamic oracle permits all transitions that can lead to a tree with minimum loss compared to the gold tree. In this paper, we provide a provably correct dynamic oracle for the arc-eager transition system of Nivre (2003, 2008).

One important use for a dynamic oracle is in training a parser that (a) is not restricted to a

[1] This is similar to the parsing oracle used in the EasyFirst parser of Goldberg and Elhadad (2010).

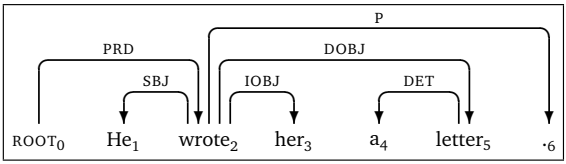

Figure 1: Projective dependency tree

particular canonical order of transitions and (b) can handle configurations that are not part of any gold sequence, thus mitigating the effect of error propagation. To this end, we provide an online training procedure based on the dynamic oracle that deals with spurious ambiguity by treating all sequences leading to a gold tree as correct, and with error-propagation by exploring transition sequences that are not optimal in the sense that they do not derive the gold tree, while training the parser to perform the optimal transitions on these non-optimal configurations. We show that both of these properties improve the accuracy of a deterministic left-to-right arc-eager parser by over 1.2 LAS points on average and up to almost 3 LAS points on some data sets, as compared to the conventional training procedure.

2 Background

2.1 Arc-Eager Transition-Based Dependency Parsing

Given a set L of dependency labels, we define a *dependency graph* for a sentence $x = w_1, \ldots, w_n$ as a labeled directed graph $G = (V_x, A)$, consisting of a set of nodes $V_x = \{0, 1, \ldots, n\}$, where each node i corresponds to the linear position of a word w_i in the sentence, plus an extra artificial root node 0, and a set of labeled arcs $A \subseteq V_x \times L \times V_x$, where each arc (i, l, j) represents a dependency with head w_i, dependent w_j, and label l. In order for a dependency graph to be well-formed, we usually require it to be a *dependency tree*, which is a directed spanning tree rooted at the node 0. In this paper, we further restrict our attention to dependency trees that are *projective*, that is, where the presence of an arc (i, l, j) entails that there is directed path from i to every node k such that $\min(i, j) < k < \max(i, j)$. Figure 1 shows a projective dependency tree for a simple English sentence.

In the arc-eager transition system of Nivre (2003), a *parser configuration* is a triple $c = (\Sigma, B, A)$ such that Σ (referred to as the *stack*) and B (the *buffer*) are disjoint sublists of the nodes V_x of some sentence x, and A is a set of dependency arcs over V_x (and some label set L); we take the initial configuration for a sentence $x = w_1, \ldots, w_n$ to be $c_s(x) = ([0], [1, \ldots, n], \{\})$; and we take a terminal configuration to be any configuration of the form $c = (\Sigma, [\,], A)$ (for any stack Σ and arc set A).[2] There are four types of *transitions*, defined formally in Figure 2, for going from one configuration to the next:

1. A LEFT-ARC$_l$ transition (for any dependency label l) adds the arc (b, l, s) to A, where s is the node on top of the stack and b is the first node in the buffer, and pops the stack. It has as a precondition that the token s is not the artificial root node 0 and does not already have a head.

[2] As is customary, we use the variables σ and β for arbitrary sublists of the stack and the buffer, respectively. For reasons of perspicuity, we will write Σ with its head (top) to the right and B with its head to the left. Thus, $c = (\sigma|s, b|\beta, A)$ is a configuration with the node s on top of the stack Σ and the node b as the first node in the buffer B.

Transition		Precondition
LEFT-ARC$_l$	$(\sigma\|i, j\|\beta, A) \Rightarrow (\sigma, j\|\beta, A \cup \{(j, l, i)\})$	$\neg[i = 0] \wedge \neg\exists k \exists l'[(k, l', i) \in A]$
RIGHT-ARC$_l$	$(\sigma\|i, j\|\beta, A) \Rightarrow (\sigma\|i\|j, \beta, A \cup \{(i, l, j)\})$	
REDUCE	$(\sigma\|i, \beta, A) \Rightarrow (\sigma, \beta, A)$	$\exists k \exists l[(k, l, i) \in A]$
SHIFT	$(\sigma, i\|\beta, A) \Rightarrow (\sigma\|i, \beta, A)$	

Figure 2: Transitions for the arc-eager transition system

2. A RIGHT-ARC$_l$ transition (for any dependency label l) adds the arc (s, l, b) to A, where s is the node on top of the stack and b is the first node in the buffer, and pushes the node b onto the stack.

3. The REDUCE transition pops the stack and is subject to the preconditions that the top token has a head.

4. The SHIFT transition removes the first node in the buffer and pushes it onto the stack.

A *transition sequence* for a sentence x is a sequence $C_{0,m} = (c_0, c_1, \ldots, c_m)$ of configurations, such that c_0 is the initial configuration $c_s(x)$, c_m is a terminal configuration, and there is a legal transition t such that $c_i = t(c_{i-1})$ for every i, $1 \leq i \leq m$. The dependency graph derived by $C_{0,m}$ is $G_{c_m} = (V_x, A_{c_m})$, where A_{c_m} is the set of arcs in c_m. The arc-eager system is sound and complete for the class of projective dependency forests, meaning that every legal transition sequence derives a projective dependency forest (soundness) and that every projective dependency forest is derived by at least one transition sequence (completeness) (Nivre, 2008). A projective dependency forest is a dependency graph where every connected component is a projective tree, with the special case of a projective dependency tree in case there is only one connected component. Hence, the arc-eager transition system is also complete (but not sound) for the class of projective dependency trees.

2.2 Static Oracles for Transition-Based Parsing

In the transition-based framework, parsing is implemented as search for an optimal transition sequence, that is, a transition sequence that derives the correct parse tree for a given sentence. The simplest version of this, and also the most efficient, is to train a classifier to predict the single best transition in each configuration and use a greedy deterministic procedure to derive a single dependency graph, which results in linear-time parsing provided that each transition can be predicted and executed in constant time (Nivre, 2003, 2008). The classifier is trained on a set of configuration-transition pairs, which can be derived from a dependency treebank by finding an optimal transition sequence for each sentence x with gold tree $G_{\text{gold}} = (V_x, A_{\text{gold}})$.

Algorithm 1 defines the standard oracle function used to find the next transition t for a configuration c and gold tree $G_{\text{gold}} = (V_x, A_{\text{gold}})$. This algorithm is provably correct in the sense that, for every sentence x and projective dependency tree $G_{\text{gold}} = (V_x, A_{\text{gold}})$, if we initialize c to $c_s(x)$ and repeatedly execute the oracle transition, then we derive exactly $G_{\text{gold}} = (V_x, A_{\text{gold}})$ (Nivre, 2006). Nevertheless, it has two important limitations.

Algorithm 1 Standard oracle for arc-eager dependency parsing

if $c = (\sigma|i, j|\beta, A)$ and $(j, l, i) \in A_{\text{gold}}$ **then**
  $t \leftarrow$ LEFT-ARC$_l$
else if $c = (\sigma|i, j|\beta, A)$ and $(i, l, j) \in A_{\text{gold}}$ **then**
  $t \leftarrow$ RIGHT-ARC$_l$
else if $c = (\sigma|i, j|\beta, A)$ and $\exists k[k < i \wedge \exists l[(k, l, j) \in A_{\text{gold}} \vee (j, l, k) \in A_{\text{gold}}]]$ **then**
  $t \leftarrow$ REDUCE
else
  $t \leftarrow$ SHIFT
return t

The first is that it ignores spurious ambiguity in the transition system, that is, cases where a given dependency tree can be derived in more than one way. The dependency tree in Figure 1 is derived by two distinct transition sequences:[3]

(1) SH, LA_{SBJ}, RA_{PRD}, RA_{IOBJ}, SH, LA_{DET}, RE, RA_{DOBJ}, RE RA_{P}
(2) SH, LA_{SBJ}, RA_{PRD}, RA_{IOBJ}, RE, SH, LA_{DET}, RA_{DOBJ}, RE RA_{P}

Algorithm 1 will predict (1) but not (2). More generally, whenever there is a SH-RE ambiguity, which is the only ambiguity that exists in the arc-eager system, the oracle prediction will always be SH. In this way, the oracle implicitly defines a canonical transition sequence for every tree.

The second limitation is that we have no guarantee for what happens if we apply the oracle to a configuration that does not belong to the canonical transition sequence. In fact, it is easy to show that the oracle prediction in such cases can be suboptimal. For example, suppose that we erroneously choose the SH transition instead of RA_{IOBJ} after the first three transitions in sequence (1). This results in the following parser configuration:

$$([0, 2, 3], [4, 5, 6], \{(0, \text{PRD}, 2), (2, \text{SBJ}, 1)\})$$

Starting from this configuration, the oracle defined by Algorithm 1 will predict SH, LA_{DET}, SH, SH, which derives the dependency graph in the left-hand side of Figure 3. Using labeled attachment score to measure loss, this graph has a loss of 3 compared to the correct tree in Figure 1, since it fails to include the arcs $(2, \text{IOBJ}, 3)$, $(2, \text{DOBJ}, 5)$, $(2, \text{P}, 6)$.[4] However, if we instead apply the transitions SH, LA_{DET}, LA_{DET}, RA_{DOBJ}, RE, RA_{P}, we end up with the tree in the right-hand side of Figure 3, which only has a loss of 1.

We say that Algorithm 1 defines a *static* oracle, because it produces a single static sequence of transitions that is supposed to be followed in its entirety. The main contribution of this paper is the notion of a *dynamic* oracle, which does not presuppose a single canonical transition sequence for each dependency tree and which can dynamically adapt to arbitrary configurations that arise during parsing and still make optimal predictions.

[3] To save space, we sometimes use the following abbreviations: LA_l = LEFT-ARC$_l$, RA_l = RIGHT-ARC$_l$, RE = REDUCE, SH = SHIFT.

[4] In most practical parser implementations, this graph is converted into a tree by adding arcs from the root node to all words that lack a head. However, the loss will be exactly the same.

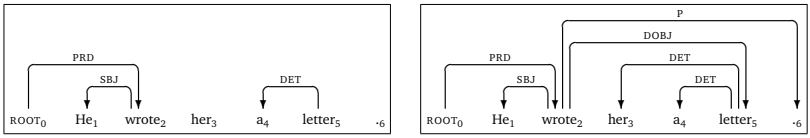

Figure 3: Dependency graphs with loss 3 (left) and loss 1 (right)

3 Dynamic Parsing Oracles

We want to define an oracle that (a) allows more than one transition sequence for a given tree and (b) makes optimal predictions in all configurations (not only configurations that are part of a globally optimal transition sequence). It follows from the first requirement that the oracle should define a *relation* from configurations to transitions, rather than a function, and we will represent it as a boolean function $o(t;c,G_{\text{gold}})$, which returns **true** just in case t is optimal in c relative to G_{gold}. But what does it mean for a transition to be optimal?

Intuitively, a transition t is optimal if it does not commit us to a parsing error, which we take to mean that the best dependency tree reachable from c is also reachable from $t(c)$. Consider the set of all dependency trees that are reachable from c. From this set, we pick the set of trees that minimize some loss function relative to G_{gold} and say that t is optimal if and only if at least one tree in this set is still reachable from $t(c)$. More precisely, we define the *cost* of t to be the difference in loss between the best tree reachable in c and the best tree reachable in $t(c)$ and say that t is optimal if it has zero cost. In the special case where the gold tree G_{gold} is reachable from c, the set of trees that minimize the loss function is the singleton set containing G_{gold}, which entails that t is optimal if and only if G_{gold} is still reachable from $t(c)$. Let us now try to make this precise.

3.1 Defining the Oracle

First, we define the *loss* $\mathscr{L}(G,G_{\text{gold}})$ of a dependency graph $G=(V_x,A)$ with respect to the gold tree $G_{\text{gold}}=(V_x,A_{\text{gold}})$ to be the number of arcs that are in G_{gold} but not in G:

$$\mathscr{L}(G,G_{\text{gold}}) = |A_{\text{gold}} \setminus A|$$

We then say that a dependency graph $G=(V_x,A)$ for a sentence x is *reachable* from a non-terminal configuration c for x, written $c \rightsquigarrow G$ if and only if there is a non-empty sequence of transitions $t_1,\ldots,t_m$ such that $[t_m \circ \cdots \circ t_1](c) = (\Sigma,[],A)$ and $G=(V_x,A)$.

Next, we define the *cost* $\mathscr{C}(t;c,G_{\text{gold}})$ of the transition t in the configuration c relative to the gold tree G_{gold} as the loss difference between the minimum loss tree reachable before and after the transition:

$$\mathscr{C}(t;c,G_{\text{gold}}) = \left[\min_{G:t(c)\rightsquigarrow G} \mathscr{L}(G,G_{\text{gold}})\right] - \left[\min_{G:c\rightsquigarrow G} \mathscr{L}(G,G_{\text{gold}})\right]$$

Note that, by definition, there must be at least one zero cost transition for every configuration c and gold tree G_{gold}. To see why, let G be some dependency graph with minimum loss reachable from c. Since G is reachable from c, there must be at least one transition t such that G is reachable from $t(c)$. And since $\mathscr{L}(G,G_{\text{gold}}) - \mathscr{L}(G,G_{\text{gold}}) = 0$, it follows that $\mathscr{C}(t;c,G_{\text{gold}}) = 0$.

Finally, we define the oracle $o(t; c, G_{\text{gold}})$ to return **true** just in case t has zero cost relative to c and G_{gold}:

$$o(t; c, G_{\text{gold}}) = \begin{cases} \textbf{true} & \text{if } \mathscr{C}(t; c, G_{\text{gold}}) = 0 \\ \textbf{false} & \text{otherwise} \end{cases}$$

3.2 A Dynamic Oracle for Arc-Eager Parsing

In order to implement the dynamic oracle in practice, we need an efficient method for computing the cost of each transition in a given configuration. A key property of the arc-eager system (stated here without proof) is that a dependency graph $G = (V_x, A)$ is reachable from a configuration c if G is a projective forest and if each individual arc in A is reachable in c. In the Arc-Eager system, an arc (i, l, j) is reachable in $c = (\Sigma, B, A')$ if either (i, l, j) is already in A' (since arcs can never be removed) or if $\min(i, j)$ is in Σ or B, $\max(i, j)$ is in B, and there is no arc in A that already assigns a head to j (since it is always possible to reach a later configuration where $\min(i, j)$ is at the top of the stack and $\max(i, j)$ is at the head of the buffer, in which case the arc can be added in a LEFT-ARC$_l$ or RIGHT-ARC$_l$ transition).

Given that our loss function (and hence our cost function) also decomposes into the loss of individual arcs, we can compute the cost of each transition by simply counting the gold arcs that are no longer reachable after that transition. We do this on a case by case basis. In all the cases, we assume a configuration c of the form $c = (\sigma|s, b|\beta, A)$.[5]

- $\mathscr{C}$(LEFT-ARC$_l$; c, G_{gold}): Adding the arc (b, l, s) and popping s from the stack means that s will not be able to acquire any head or dependents in β. The cost is therefore the number of arcs in A_{gold} of the form (k, l', s) or (s, l', k) such that $k \in \beta$. Note that the cost is 0 for the trivial case where $(b, l, s) \in A_{\text{gold}}$, but also for the case where b is not the gold head of s but the real head is not in β (due to an erroneous previous transition) and there are no gold dependents of s in β.[6]

- $\mathscr{C}$(RIGHT-ARC$_l$; c, G_{gold}): Adding the arc (s, l, b) and pushing b onto the stack means that b will not be able to acquire any head in σ or β, nor any dependents in σ. The cost is therefore the number of arcs in A_{gold} of the form (k, l', b), such that $k \in \sigma$ or $k \in \beta$, or of the form (b, l', k) such that $k \in \sigma$. Note again that the cost is 0 for the trivial case where $(s, l, b) \in A_{\text{gold}}$, but also for the case where s is not the gold head of b but the real head is not in σ or β (due to an erroneous previous transition) and there are no gold dependents of b in σ.

- $\mathscr{C}$(REDUCE; c, G_{gold}): Popping s from the stack means that s will not be able to acquire any dependents in $b|\beta$. The cost is therefore the number of arcs in A_{gold} of the form (s, l', k) such that $k \in b|\beta$. While it may seem that a gold arc of the form (k, l, s) should be accounted for as well, note that a gold arc of that form, if it exists, is already accounted for by a previous (erroneous) RIGHT-ARC$_l$ transition when s acquired its head.

- $\mathscr{C}$(SHIFT; c, G_{gold}): Pushing b onto the stack means that b will not be able to acquire any head or dependents in $s|\sigma$. The cost is therefore the number of arcs in A_{gold} of the form (k, l', b) or (b, l', k) such that $k \in s|\sigma$.

[5] This is a slight abuse of notation, since for the SHIFT transition s may not exist, and for the REDUCE transition b may not exist.

[6] One may want to associate a lower cost with cases in which the arc endpoints are correct and only the label is wrong. This extension is trivial.

$$
\begin{aligned}
\mathscr{C}(\text{LA}_l;\ c=(\sigma|s,b|\beta,A),G_g) &= \left|\{(k,l',s)\in A_g \mid k\in\beta\}\cup\{(s,l',k)\in A_g \mid k\in\beta\}\right| \\
\mathscr{C}(\text{RA}_l;\ c=(\sigma|s,b|\beta,A),G_g) &= \left|\{(k,l',b)\in A_g \mid k\in\sigma\vee k\in\beta\}\cup\{(b,l',k)\in A_g \mid k\in\sigma\}\right| \\
\mathscr{C}(\text{RE};\ c=(\sigma|s,\beta,A),G_g) &= \left|\{(s,l',k)\in A_g \mid k\in\beta\}\right| \\
\mathscr{C}(\text{SH};\ c=(\sigma,b|\beta,A),G_g) &= \left|\{(k,l',b)\in A_g \mid k\in\sigma\}\cup\{(b,l',k)\in A_g \mid k\in\sigma\}\right|
\end{aligned}
$$

Figure 4: Transition costs for the arc-eager transition system with gold tree $G_g = (V_x, A_g)$.

The computation of transition costs is summarized in Figure 4. We can now return to the example in Section 2.2 and analyze the behavior of the static oracle in the presence of erroneous transitions. In the example there, the last two SHIFT transitions predicted by the static oracle each has a cost of 1, because they each lose an arc going into the first word of the buffer. By contrast, the transition LEFT-ARC$_{\text{DET}}$ in place of the first SHIFT has a cost of 0, despite the fact that the arc $(5, \text{DET}, 3)$ is not in the gold tree, because it does not eliminate any gold arc that is still reachable – the cost of the incorrect attachment is already accounted for in the cost of the erroneous SHIFT action.

After defining the concept of a *dynamic oracle* which is correct over the entire configuration space of a transition system and providing a concrete instantiation of it for the arc-eager transition system, we now go on to present one useful application of such an oracle.

4 Training Parsers with the Dynamic Oracle

Greedy transition-based parsers trained with static oracles are known to suffer from error propagation (McDonald and Nivre, 2007). We may hope to mitigate the error propagation problem by letting the parser explore larger portions of the configuration space during training and learn how to behave optimally also after committing previous errors. While this is not possible with the usual static oracles, the dynamic oracle defined above allows us to do just that, as it returns a set of optimal transitions for each possible configuration.

Algorithm 2 is a standard online training algorithm for transition-based dependency parsers using a static oracle. Given a training sentence x with gold tree G_{gold}, it starts in the initial configuration $c_s(x)$ and repeatedly predicts a transition t_p given its current feature weights $\mathbf{w}$ and compares this to the transition t_o predicted by the static oracle. If the model prediction is different from the oracle prediction, the feature weights are updated, but the new configuration is always derived using the oracle transition (line 10), which means that only configurations in the canonical oracle-induced transition sequence are explored.[7]

Algorithm 3 is a modification of the standard algorithm which makes use of the dynamic oracle to explore a larger part of the configuration space. The first difference is in line 7, where the new algorithm, instead of getting the single prediction of the static oracle, gets the set of

[7]Some readers may be more familiar with a two-stage process in which first the oracle is used to create oracle transition sequences from the entire training set, which are then transformed to individual training examples and passed on to an external classifier. This process is equivalent to the one in Algorithm 2 in case the external classifier is a multiclass perceptron (or any other online classifier), with the only difference being that the training examples are generated on-the-fly whenever they are needed. The online formulation is used to facilitate a smooth transition to Algorithm 3.

Algorithm 2 Online training with a static oracle

```
 1: w ← 0
 2: for I = 1 → ITERATIONS do
 3:     for sentence x with gold tree G_gold in corpus do
 4:         c ← c_s(x)
 5:         while c is not terminal do
 6:             t_p ← arg max_t w · φ(c, t)
 7:             t_o ← o(c, G_gold)
 8:             if t_p ≠ t_o then
 9:                 w ← w + φ(c, t_o) − φ(c, t_p)
10:             c ← t_o(c)
11: return w
```

transitions that have zero cost according to the dynamic oracle. The weight update is then performed only if the model prediction does not have zero cost (lines 9–10), which means that updates no longer need to reflect a single canonical transition sequence. Finally, the transition used to update the parser configuration is no longer the single transition predicted by the static oracle, but a transition that is chosen by the function CHOOSE_NEXT, which may be a transition that does not have zero-cost (lines 11-12). In our current implementation, CHOOSE_NEXT is conditioned on the predicted transition t_p, the set of zero cost transitions, and the iteration number. However, more elaborate conditioning schemes are also possible.

We propose two versions of the CHOOSE_NEXT function. In the first version, $\text{CHOOSE\_NEXT}_{\text{AMB}}$, the training algorithm only follows optimal (zero cost) transitions but permits spurious ambiguity by following the model prediction t_p if this has zero cost and a random zero cost transition otherwise. In the second version, $\text{CHOOSE\_NEXT}_{\text{EXP}}$, the training algorithm also explores non-optimal transitions. More precisely, after the first k training iterations, it follows the model prediction t_p regardless of its cost in 100(1-p)% of the cases and falls back on $\text{CHOOSE\_NEXT}_{\text{AMB}}$ in the remaining cases. It is worth noting that Algorithm 3 subsumes Algorithm 2 as a special case if we define ZERO_COST to contain only the prediction t_o of the static oracle, and define CHOOSE_NEXT to always return t_o.

The novel training algorithm presented here is based on perceptron learning.[8] Since the dynamic oracle provides a cost for every transition-configuration pair, it could be used also for cost-sensitive learning. Our preliminary attempts with cost-sensitive learning through the max-loss and prediction-based passive-aggressive algorithms of Crammer et al. (2006) show that the cost-sensitive variants of the algorithms indeed improve upon the non-cost-sensitive variants. However, the best passive-aggressive results were still significantly lower than those obtained using the averaged perceptron. We do not elaborate on cost-sensitive training in this work, and leave this direction for future investigation.

5 Experiments

We present experiments comparing greedy arc-eager transition-based parsers trained (a) using the static oracle (Algorithm 2), (b) using the dynamic oracle with spurious ambiguity (Algorithm 3 with $\text{CHOOSE\_NEXT}_{\text{AMB}}$), and (c) using the dynamic oracle with spurious ambiguity

[8] In practice, we use an averaged perceptron, although this is not reflected in the algorithm descriptions above.

Algorithm 3 Online training with a dynamic oracle

```
1: w ← 0
2: for I = 1 → ITERATIONS do
3:     for sentence x with gold tree G_gold in corpus do
4:         c ← c_s(x)
5:         while c is not terminal do
6:             t_p ← arg max_t w · φ(c, t)
7:             ZERO_COST ← {t | o(t; c, G_gold) = true}
8:             t_o ← arg max_{t∈ZERO_COST} w · φ(c, t)
9:             if t_p ∉ ZERO_COST then
10:                w ← w + φ(c, t_o) − φ(c, t_p)
11:            t_n ← CHOOSE_NEXT(I, t_p, ZERO_COST)
12:            c ← t_n(c)
13: return w
```

```

```

and non-optimal transitions (Algorithm 3 with CHOOSE_NEXT$_{\text{EXP}}$). We evaluate the models on a wide range of English data sets, as well as the data sets from the CoNLL 2007 shared task on multilingual dependency parsing (Nivre et al., 2007).

The parser is a greedy transition-based parser using the arc-eager transition system of Nivre (2003, 2008) with the feature representations defined by Zhang and Nivre (2011). As our primary goal is to compare the training methods, and not to achieve the highest possible score for each data set, we use the exact same feature representations and training parameters across all experiments. Specifically, we train an averaged perceptron model for 15 iterations. When using CHOOSE_NEXT$_{\text{EXP}}$, we set $k = 2$ and $p = 0.1$, meaning that the algorithm allows non-optimal transitions in 90% of the cases, starting from the third training iteration. Note that many of these transitions will nevertheless be correct, as the first training iterations already put the model in a good region of the parameter space.

The English model is trained on Sections 2–21 of the Penn-WSJ Treebank (Marcus et al., 1993), converted to Stanford basic dependencies (de Marneffe et al., 2006), with part-of-speech tags assigned by a structured-perceptron tagger trained on the same corpus with 4-fold jack-knifing. We use Section 22 to tune parameters, and we evaluate on the following data sets, which are also converted to the same dependency scheme, and pos-tagged using the same

structured-perceptron tagger, trained on the entire training set.

- WSJ22: Section 22 of the Penn-WSJ Treebank (development set).
- WSJ23: Section 23 of the Penn-WSJ Treebank (test set).
- BNC: 1,000 manually annotated sentences from the British National Corpus (Foster and van Genabith, 2008).
- BRN: The entire Brown Corpus (Kucera and Francis, 1967).
- FTBL: The entire Football Corpus (Foster et al., 2011).
- QB: The entire QuestionBank (Judge et al., 2006).
- ANS, EML, GRPS, REVS, BLGS: the question-answers, emails, newsgroups, reviews and weblogs portions of the English Web Treebank (Bies et al., 2012; Petrov and McDonald, 2012).

The CoNLL models are trained on the dedicated training set for each of the ten languages and evaluated on the corresponding test set, with gold standard part-of-speech tags in both cases. Since the arc-eager parser can only handle projective dependency trees, all trees in the training set are projectivized before training, using the baseline pseudo-projective transformation in Nivre and Nilsson (2005). However, non-projective trees are kept intact in the test sets for evaluation. We include all ten languages from the CoNLL 2007 shared task:

- ARA: Arabic (Hajič et al., 2004)
- BAS: Basque (Aduriz et al., 2003)
- CAT: Catalan (Martí et al., 2007)
- CHI: Chinese (Chen et al., 2003)
- CZE: Czech (Hajič et al., 2001; Böhmová et al., 2003)
- ENG: English (Marcus et al., 1993)
- GRE: Greek (Prokopidis et al., 2005)
- HUN: Hungarian (Czendes et al., 2005)

Table 2: Results on the CoNLL 2007 data sets

- ITA: Italian (Montemagni et al., 2003)
- TUR: Turkish (Oflazer et al., 2003)

Table 1 gives the results for the English model, while Table 2 presents the multilingual evaluation. In both cases, we present unlabeled and labeled attachment scores excluding punctuation.

For the English data sets, we see that adding spurious ambiguity (Dynamic-ambiguity) generally improves both labeled and unlabeled attachment scores by up to 0.5 percent absolute. The only exception is GRPS, where there is a small decrease in unlabeled attachment score. When the training procedure in addition explores non-optimal transitions (Dynamic-explore), the improvement is even greater, in some cases up to about 1.5 percentage points, which is quite substantial given that our baseline parser already performs at the state-of-the-art level for greedy deterministic transition-based parsers on English Stanford-dependencies.[9]

For the CoNLL data sets, results for the Dynamic-ambiguity condition are mixed causing a drop in accuracy for some data sets, but the Dynamic-explore condition makes up for it and brings substantial improvement in accuracy for all except two languages. We see very substantial improvements in both UAS and LAS for Arabic, Basque, Czech, English and Greek, as well as improvements for Catalan, Chinese and Italian. The average LAS improvement across all the CoNLL datasets is 1.5 LAS points. The only two exceptions are Hungarian and Turkish, where unlabeled attachment scores drop slightly as a result of not using the static oracle, and labeled attachment scores are practically unaffected. More analysis is needed to find out what is going on for these languages, but it is likely that results could be improved with language-specific tuning.[10]

Overall, the experimental results show a considerable improvement in the accuracy of deterministic linear-time classifier-based dependency parsing through training procedures that explore a larger part of the search space than traditional methods based on static oracles.

[9] Note that the web data sets (ANS, EML, GRPS, REVS, BLGS) are annotated according to the Ontonotes corpus guidelines, which are somewhat different than the original Penn Treebank guidelines used in the training corpora. In particular, base-NPs in the web data sets are more nested. Our scores on these data sets are thus artificially lower than they could be. We could get better scores for these data sets for all training conditions by training on the Ontonotes corpora instead, but as our main concern is not in achieving the best scores, we opted for the simpler experimental setup.

[10] Language-specific tuning is likely to improve results for the other languages as well – we did not perform any language-specific tuning, and it is well established that individual languages parsing accuracies can greatly benefit from tuning of the feature set, the transition system being used and the learning parameters (Hall et al., 2007).

6 Related Work

Deterministic classifier-based dependency parsing is an instance of independent sequential classification-based structured prediction. In sequential classification models, such as Maximum-Entropy Markov Models (McCallum et al., 2000), a structured output is produced by repeated application of a locally trained classifier, where each classification decision is conditioned on the structure created by previous decisions. Several methods have been developed to cope with error propagation in sequential classification, including stacked sequential learning (Cohen and Carvalho, 2005), LaSO (Daumé III and Marcu, 2005), Searn (Daumé III et al., 2009) and its followers SMILe (Ross and Bagnell, 2010) and DAgger (Ross et al., 2011).

While stacked learning is well suited for sequence prediction tasks such as tagging and chunking, it is not clear how to apply it to parsing.[11] Searn and the closely related DAgger algorithm are more promising for dealing with the complexity of dependency parsing, but it appears that previous attempts to apply Searn-based learning to dependency parsing have been unsuccessful. A key component in the specification of a Searn learning algorithm is an *optimal policy* mapping states in the search space (such as parser configurations) to optimal outcomes (such as transitions). Attempts to approximate the optimal policy for parsing using static oracles are unlikely to work very well, since a static oracle is only correct for a small subset of the search space. The dynamic oracle introduced in this paper, which is correct for arbitrary parser configurations, can be used to define an optimal policy for Searn-based learning. Both Searn and DAgger require several complete training rounds over the entire data set and take a relatively long time to train. We instead use a simpler online algorithm which can be viewed as a stochastic approximation of the DAgger algorithm, which is itself heavily inspired by the Searn algorithm.

Recent work on beam search and structured prediction for transition-based dependency parsing has shown that parsing accuracy can be improved considerably if models are trained to perform beam search instead of greedy one-best search, and if training is done using a global structured learning objective instead of local learning of individual decisions (Zhang and Clark, 2008; Zhang and Nivre, 2011; Bohnet and Kuhn, 2012; Huang et al., 2012). Like our method, beam search with global structured learning mitigates the effects of error propagation by exploring non-canonical configurations at training time, but the use of a beam reduces parsing speed by a factor that is roughly proportional to the size of the beam, making parsing less efficient. Our method in contrast still trains classifiers to perform local decisions, and thus incurs no efficiency penalty at parsing time, but each local decision is trained to take into account the consequences of previous, possibly erroneous, decisions. Although we may not be able to reach the accuracy level of a beam-search parser, we show that a substantial improvement in accuracy is possible also for a purely deterministic classifier-based parser, making our method suitable for training accurate parsers in situations where maximum efficiency is needed, e.g., when there is a need to process very large corpora. Integrating our dynamic oracle in the training procedure for a transition-based parser with beam search is an interesting question for future work.

The work that probably comes closest to ours is Choi and Palmer (2011), who improve the accuracy of a greedy transition-based dependency parser through an iterative training procedure that they call bootstrapping. They start by training a classifier using a standard static oracle for a hybrid transition system combining elements of the arc-eager system and the algorithm of

[11] Stacked learning has been explored to some extent in the context of parsing for integrating approximate higher order features as well as for combining the predictions of different parsers (Nivre and McDonald, 2008; Martins et al., 2008).

Covington (2001). In a second step, they then use this classifier to parse the training corpus, creating one new training instance for every configuration visited during parsing, using an adapted version of the static oracle to predict the optimal transition for each configuration. They iterate this procedure as long as parsing accuracy improves on a held-out development set and report improvements in parsing accuracy of about 0.5 percent absolute for English and almost 2 percent absolute for Czech. The main difference compared to our approach, except for the fact that they use a different transition system, is that their method for finding the optimal transition after the first training round is heuristic and does not guarantee that the best parse is still reachable.

Finally, Cohen et al. (2012) tackle the problem of spurious ambiguity for static oracles by eliminating ambiguity from the underlying transition system instead of modifying the oracle. They show how this can be achieved for the arc-standard system of Nivre (2004) as well as the non-projective extension by Attardi (2006). It is still an open question whether their technique can also be applied to the arc-eager system targeted in this paper.

7 Conclusion

We have highlighted the shortcoming of traditional static oracles used to train transition-based dependency parsers, and instead proposed the notion of a *dynamic oracle*, which allows more than one correct transition sequence in the case of spurious ambiguity, and which can predict an optimal transition also for non-optimal configurations. We have defined a concrete dynamic oracle for the arc-eager transition system and showed how it can be used in online training of greedy deterministic parsers.

Greedy deterministic transition-based dependency parsers are among the most efficient systems available for syntactic parsing of natural language. In terms of parsing accuracy, they perform near the state-of-the-art level for many languages but tend to suffer from prediction errors and subsequent error propagation. This problem can be mitigated by using our proposed training method. Experimental results for English show consistent improvements in parsing accuracy of up to almost 1.5 percent absolute on a wide range of data sets. Experimental results on the ten languages from the CoNLL 2007 shared task on dependency parsing show significant improvements of up to almost 3 LAS points for some languages, but there are also few cases where we see little or no improvement in parsing accuracy, a phenomenon that requires further investigation. Other topics for future research is the effective use of cost-sensitive learning instead of the perceptron loss used in this paper, the derivation of dynamic oracles for other transition systems, and utilizing the dynamic oracles in non-greedy settings, such as beam-search parsers.

ABSTRACT
Many of the state-of-the-art methods for constructing a polarity lexicon rely on the propagation of polarity on the lexical network. In one of those methods, where the Ising spin model is employed as a probabilistic model, it is reported that the system exhibits the phase transition in the vicinity of the optimal temperature parameter. We provide an analysis of this phenomenon from the viewpoint of statistical mechanics and clarify the underlying mechanism. On the basis of this analysis, we propose a scheme for improving the extraction performance, i.e., by removing the largest eigenvalue component from the weight matrix. Experimental results show that the scheme significantly improves the accuracy of the extraction of the semantic orientations at negligible additional computational cost, outperforming the state-of-the-art algorithms. We also explore the origin of the high classification performance by analyzing eigenvalues of the weight matrix and a linearized model.

KEYWORDS: sentiment analysis, polarity lexicon, spin model, label propagation.

1 Introduction

A huge amount of semantic information is constantly being produced and accumulated on the Internet by the activities of individuals through, for example, their blog, Twitter, and Facebook postings. The information tends to focus on personal interests but can include generally useful information such as opinions about fashion and comments about new products. This means that extracting and structuralizing such information can be beneficial for both producers and consumers, which led us to focus on the development of methods for handling semantic information.

In general, each word constituting sentences possesses its specific orientation. For example, we usually receive positive impressions for words such as "good", "excellent" and "enjoyable", while "bad", "poor" and "boring" sound negative. Such word-specific orientation of impression is termed *polarity* (or *semantic orientation*). A polarity lexicon is a list of words and phrases that are labeled by their polarity, and is an important resource in extracting semantic information from natural language data. Accordingly, the construction of such lists under various conditions has been a major focus in sentiment analysis research (Hatzivassiloglou and McKeown, 1997; Choi and Cardie, 2009). Many construction methods have been developed so far (Hatzivassiloglou and McKeown, 1997; Takamura et al., 2005; Turney and Littman, 2003; Velikovich et al., 2010; Kamps et al., 2004; Rao and Ravichandran, 2009).

Among those methods for polarity lexicon construction, the method proposed by Takamura et al. (2005) is distinctive in terms of emphasizing the utility of probabilities. In their method, the construction of a polarity lexicon is mapped to the Ising spin model of magnetism at a finite temperature. This mapping, in conjunction with the formalism of equilibrium statistical mechanics, yields a probabilistic model for assigning a polarity to each word. The optimal assignment of the polarities is determined by approximately evaluating the averages of the spin variables. Its experimental application to a lexical network of 88,015 words demonstrated its utility. Besides this, we would like to draw attention to the following observations:

- The classification performance is optimized at a finite temperature. This is somewhat counterintuitive, since the cost (energy) function is not minimized unless the temperature vanishes. At a finite temperature, the probability mass is split and given to all states, instead of a single one that minimizes the cost function. As a result, most of the spin averages are hardly biased. This suggests that performance can be optimized by using relatively small signals which are offered by the hardly biased spin averages.
- The experimental data indicates that the spin system exhibits a ferromagnetic phase transition in the vicinity of the optimal temperature.

The purpose of this paper is to propose a simple but effective scheme to improve the performance of the original spin-model-based method by clarifying the mechanism underlying the above observations. We show that the rate of correct word classification is significantly increased simply by removing the largest eigenvalue component from the weight matrix of the lexical network, which is directly related to avoidance of the ferromagnetic phase transition. The computational cost for the removal grows only linearly with network size, which means that the improved method is highly practical and useful. We also show that this scheme of removing the largest eigenvalue component also improves the linearized model, which is almost equivalent to the label propagation (Zhu and Ghahramani, 2002).

Although we focus on a specific problem of constructing the polarity lexicon in this paper, the developed methodology can be employed for general purposes of assessing influences of a few representative nodes in a network via local communications. In fact, network-based semi-supervised models are used in a number of tasks in natural language processing, such as word sense disambiguation (Yu et al., 2011), machine translation (Alexandrescu and Kirchhoff, 2009), query classification (Hu et al., 2009; Li et al., 2008).

2 Related Work

There has been much related work on building polarity lexicons.

One of the earliest studies was done by Hatzivassiloglou and McKeown (1997), who focused on conjoined adjectives in the Wall Street Journal corpus (Marcus et al., 1993). They deduced the polarity of adjectives by using pairs of adjectives appearing with a conjunction in the corpus. For example, pairs of adjectives joined with an "and" tend to have the same semantic orientation (e.g., "simple and well-received") while those joined with a "but" tend to have the opposite semantic orientation (e.g., "simplistic but well-received"). Because of the limited applicability of this method, only adjectives can be entried in a polarity lexicon.

Taking a corpus-based approach, Turney and Littman (2003) built a polarity lexicon by using two algorithms. They used a query such as "word NEAR good" and "word NEAR bad," where "good" and "bad" are seed words (their polarities are known), and obtained the number of hits returned by a search engine. The association strength of the target word with positive (negative) seed words was calculated. In their work, 3596 words from the General Inquirer lexicon (Stone et al., 1966) were used for empirical evaluation. General Inquirer is a list of words with polarity labels such as "Positiv" and "Negativ", which we also used for our evaluation.

Kamps et al. (2004) proposed a thesaurus-based method for adjectives that uses a network constructed by connecting each pair of synonymous words provided by WordNet (Fellbaum, 1998) in which the shortest paths to two seed words, "good" and "bad," are used to obtain the polarity of a word. This method is attractive in terms of computational cost, but the shortest paths are sensitive to local disturbances in the network topology.

Similarly, Velikovich et al. (2010) developed a method that aggregates a huge amount of unlabeled corpus data from the Web and constructs a lexical network. They used a graph propagation algorithm, in which the weighted shortest paths from seed words are used.

Kaji and Kitsuregawa (2007) proposed a method for constructing a Japanese polarity lexicon from Web data. They collected positive (negative) sentences from the Web using structural clues such as HTML tags and then extracted polar phrases from them.

The method proposed by Rao and Ravichandran (2009) increases robustness against network disturbances. It treats polarity detection as a semi-supervised label propagation problem in a graph in which higher order correlations of network topology other than the shortest paths are involved. They showed that the *label propagation* algorithm (Zhu and Ghahramani, 2002) leads to a significant improvement in the accuracy of polarity detection for WordNet-based networks compared to various known heuristics. The label propagation is used for word polarity extraction also in the recent literature (Speriosu et al., 2011; Brody and Diakopoulos, 2011).

The linearized model in Section 5.3 can also be interpreted as a graph kernel, which is used in natural language processing (e.g., Komachi et al. (2008)).

3 Ising spin model

3.1 Overview of Ising spin model

For later analysis, we briefly summarize the basic notation and techniques of Ising spin systems. In general, the Ising spin model is composed of N binary variables termed (*Ising*) *spins*: $\boldsymbol{S} = \left(S_1, S_2, \ldots, S_N\right)$, where $S_i \in \{+1, -1\}$ $(i = 1, 2, \ldots, N)$, for which energy function

$$E(\boldsymbol{S}, \beta) = -\beta \sum_{i>j} J_{ij} S_i S_j - \sum_{i=1}^{N} h_i S_i \tag{1}$$

is defined. Here, J_{ij} represents the efficacy of interactions between two spins, S_i and S_j, and h_i stands for the external field added to S_i, and β is called the inverse temperature. The most fundamental assumption of equilibrium statistical mechanics is that, when a system is characterized by energy function $E(\boldsymbol{S})$, the probability that microscopic state $\boldsymbol{S}$ is generated in equilibrium at temperature T $(= \beta^{-1} > 0)$ is provided by the Boltzmann-Gibbs distribution:

$$P(\boldsymbol{S}) = \frac{e^{-E(\boldsymbol{S}, \beta)}}{Z}, \tag{2}$$

where Z is the normalization factor. This equation assigns a larger probability to microscopic state $\boldsymbol{S}$ if it has a lower value of energy (Equation (1)). This tendency is more/less significant when β is set to a higher/lower value. Given this assumption, the main task of statistical mechanics is to evaluate the averages of various quantities using Equation (2), which is unfortunately computationally difficult.

A family of mean field approximations offers a practical solution for resolving this difficulty (Opper and Saad, 2001). The approximations are calculated on the basis of the Kullback-Leibler divergence between Equation (2) and test distribution $Q(\boldsymbol{S})$: $D(Q||P) = \sum_{\boldsymbol{S}} Q(\boldsymbol{S}) \log(Q(\boldsymbol{S})/P(\boldsymbol{S})) = \log(Z) + F[Q, \beta]$, where

$$F[Q, \beta] = \sum_{\boldsymbol{S}} Q(\boldsymbol{S}) E(\boldsymbol{S}, \beta) + \sum_{\boldsymbol{S}} Q(\boldsymbol{S}) \log Q(\boldsymbol{S}) \tag{3}$$

is termed the variational free energy. $D(Q||P)$ is generally non-negative and vanishes if and only if $Q(\cdot) = P(\cdot)$, which means that minimizing $F[Q, \beta]$ with respect to test distribution $Q(\cdot)$ leads to the correct evaluation of the true distribution, $P(\cdot)$.

A naïve approximation is derived by limiting the test distribution to one in factorizable form:

$$Q(\boldsymbol{S}) = \prod_i \frac{1 + m_i S_i}{2}. \tag{4}$$

Here, m_i denotes the mean of spin S_i with respect to the test distribution, which parameterizes the marginal distribution as $Q_i(S_i) = \sum_{\boldsymbol{S} \backslash S_i} Q(\boldsymbol{S}) = (1 + m_i S_i)/2$. Here, $A \backslash x$ generally denotes exclusion of x from set A. Plugging Equation (4) into Equation (3) and minimizing $F[Q, \beta]$ with respect to m_i $(i = 1, 2, \ldots, N)$ yield the *mean field equation*:

$$m_i = \tanh\left(\beta \sum_j J_{ij} m_j + h_i\right). \tag{5}$$

In many cases, Equation (5) can be solved by iterative substitution. Its computational cost is at most $O(N^2)$ per update, which is much lower than that required for the exact evaluation of the spin average, $O(2^N)$.

3.2 Analytical analysis

Although obtaining the exact solution is technically difficult, one can still handle Equation (5) analytically to a certain extent if $h_i = 0$ $(i = 1, 2, \ldots, N)$ is satisfied. For this, we set $h_i = 0$ $(i = 1, 2, \ldots, N)$ and use a Taylor series, $\tanh(x) = x - x^3/3 + \ldots$, on the right hand side of Equation (5), which yields

$$m_i = \sum_j \beta J_{ij} m_j - \frac{1}{3}\left(\sum_j \beta J_{ij} m_j\right)^3 + \ldots. \tag{6}$$

This guarantees that Equation (5) possesses the trivial solution[1] $m_i = 0$ $(i = 1, 2, \ldots, N)$. When T (β) is sufficiently high (low), this solution minimizes Equation (3) under the constraint of Equation (4) since the second term (the negative entropy part) of Equation (3) is dominant and provides an appropriate approximation. Let us decompose (symmetric) matrix $\boldsymbol{J} = (J_{ij})$ as $\boldsymbol{J} = \sum_{\mu=1}^{N} \lambda_\mu \boldsymbol{x}_\mu (\boldsymbol{x}_\mu)^{\mathrm{tr}}$, where $\lambda_1 \geq \lambda_2 \ldots \geq \lambda_N$, and $\boldsymbol{x}_\mu$ $(\mu = 1, 2, \ldots, N)$ are eigenvalues of $\boldsymbol{J}$ and the corresponding unit eigenvectors, respectively, and tr denotes the matrix transpose. As explained in Appendix A, since the eigenvalues of the Hessian of the mean field free energy (Equation (16)) are given as $\beta^{-1} - \lambda_\mu$ $(\mu = 1, 2, \cdots, N)$, the trivial solution becomes unstable in the direction of $\boldsymbol{x}_1$ when

$$1 - \beta\lambda_1 = 0, \tag{7}$$

breaking the stability condition that all eigenvalues of the Hessian are positive. When no solutions other than the trivial one coexist, which is experimentally confirmed in our system shown later, this signals the onset of a phase transition to a non-trivial solution. In particular, when $J_{ij} \geq 0$ holds for all spin pairs, which is the case for models of ferromagnetism, every element of the critical eigenvector $\boldsymbol{x}_1$ has an identical sign. As a consequence, the non-trivial solution is characterized by a non-vanishing value of *magnetization*:

$$m = \frac{1}{N}\sum_i m_i, \tag{8}$$

whose absolute value is kept non-negligible as N becomes large if and only if m_i $(i = 1, 2, \ldots, N)$ mostly have an identical sign being dominated by the components of $\boldsymbol{x}_1$. This is considered to correspond to the emergence of spontaneous magnetization in ferromagnetic materials, which is particularly referred to as the *ferromagnetic phase transition*.

More precisely, the analysis presented above means that, when the trivial solution is perturbed by weak fields $\boldsymbol{h} = (h_i)$ for $\beta < \lambda_1^{-1}$, the spin averages depend linearly on $\boldsymbol{h}$ (to the first order):

$$\boldsymbol{m} \simeq (\boldsymbol{I} - \beta\boldsymbol{J})^{-1}\boldsymbol{h}, \tag{9}$$

where $\boldsymbol{I}$ is the identity matrix. This can be derived from Equation (6) by ignoring the $O(\beta^3)$ terms, adding $\boldsymbol{h}$, and solving $\boldsymbol{m} \simeq \beta\boldsymbol{J}\boldsymbol{m} + \boldsymbol{h}$. An expression of eigenvalue decomposition, $(\boldsymbol{I} - \beta\boldsymbol{J})^{-1} = \sum_{\mu=1}^{N} (1 - \beta\lambda_\mu)^{-1} \boldsymbol{x}_\mu (\boldsymbol{x}_\mu)^{\mathrm{tr}}$, suggests that the phase transition signaled by Equation (7) is brought about by divergence of the sensitivity of the spin averages with respect to the addition of infinitesimal external fields that are proportional to $\boldsymbol{x}_1$.[2]

[1] Trivial solution is called *paramagnetic solution* in statistical mechanics.

[2] $\boldsymbol{x}_\mu (\boldsymbol{x}_\mu)^{\mathrm{tr}}$ works as an operator that projects a vector $\boldsymbol{h}$ to the direction of $\boldsymbol{x}_\mu$ when multiplied as $\boldsymbol{x}_\mu (\boldsymbol{x}_\mu)^{\mathrm{tr}} \boldsymbol{h}$.

4 Original Method

The original method (Takamura et al., 2005) is based on a lexical network constructed from three types of resources: a dictionary, a corpus, and a thesaurus. Although it is not easy to directly infer word polarities from those resources, it is relatively easy to obtain the tendency that two words have the same polarity as described in the next paragraph. One of the simplest probabilistic models that connect such tendency and the polarity assignment is the Ising spin model.

First, two words taken from the dictionary are linked if one of them appears in the gloss of the other. Each link is classified as either *same orientation SL* or *different orientation DL*. Next, synonyms, antonyms, and hypernyms taken from the thesaurus are connected by the link. Only antonym links are categorized as *DL*. Two adjectives are connected if they appear in a conjunctive form in the corpus (Hatzivassiloglou and McKeown, 1997).

After the links are provided, the weight of each link is set:

$$J_{ij} = \begin{cases} \frac{1}{\sqrt{d(i)d(j)}} & (l_{ij} \in SL) \\ -\frac{1}{\sqrt{d(i)d(j)}} & (l_{ij} \in DL), \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

in order to introduce interactions into the spin model. Here, l_{ij} denotes the link between words i and j, and $d(i)$ denotes the degree of word i, i.e., the number of words linked directly to word i.

We assume that a small set of seed words, for which the correct polarities are known, is available. This assumption can be implemented into the spin model by imposing sufficiently large external fields on the spins of the initial word set:

$$E(\boldsymbol{S}, \beta) = -\beta \sum_{i>j} J_{ij} S_i S_j - \alpha \sum_{i \in L} a_i S_i, \tag{11}$$

where L denotes the initial word set (set of seed words), a_i denotes polarity (± 1) of a seed word i, and α denotes the strength of the external field of the seed words.

Substituting Equation (11) into Equation (2) yields the joint probability that all words simultaneously have semantic orientations labeled by $\boldsymbol{S} = (S_i)$ and $P(\boldsymbol{S})$. $P(\boldsymbol{S})$ can be used to evaluate marginal distribution $P(S_i) = \sum_{S \setminus S_i} P(\boldsymbol{S})$, which stands for the probability that word i has a polarity of S_i.

Given the marginal probabilities, the Bayesian framework guarantees that assigning a polarity $\sigma_i = \mathrm{argmax}_{S_i}\{P(S_i)\}$ to word i maximizes the rate of correct classification (Iba, 1999). In practice, this can be approximated as $\sigma_i = \mathrm{sign}(m_i) = m_i/|m_i|$ by solving the mean field equation (Equation (5)).

The performance of the method was evaluated for a lexical network constructed from WordNet (Fellbaum, 1998), the Wall Street Journal and Brown corpora of the Penn Treebank (Marcus et al., 1993), partially using TreeTagger (Schmid, 1994). The network was composed of 88,015 nodes (words) that were sparsely connected as they were characterized by a power-law-type degree distribution with an average of 18.94 (Figure 1). Only 5.63% of the weights were negative, which suggests that the spin system had a tendency to exhibit the

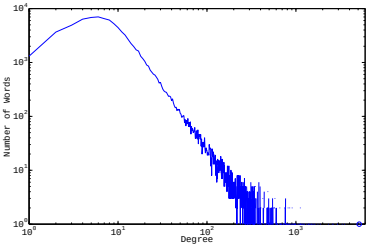

Figure 1: Degree distribution of constructed lexical network (log-log plot). Average degree was 18.94; maximum was 5144 (circle on the horizontal axis).

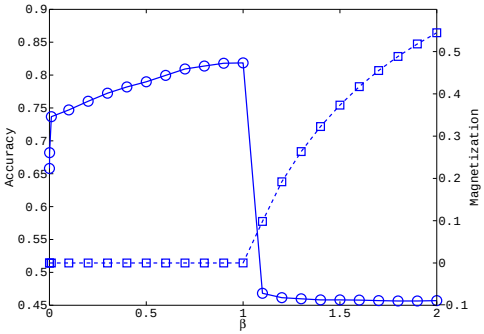

Figure 2: Temperature dependence of classification accuracy (circles) and magnetization (squares) for original method for 14 seed words.

ferromagnetic phase transition described above. The performance was assessed by using the General Inquirer labeled word list (Stone et al., 1966) as the gold standard. Of the 88,015 words in the network, 3596 were included in this list. Of these words, 1616 were positive, and 1980 were negative.

Testing was performed by varying β from 0.1 to 2.0 by 0.1 and setting α to 1000. The number of fixed seed words ranged from 2 to 14: {good, bad}, {good, superior, bad, inferior}, and {good, nice, excellent, positive, fortunate, correct, superior, bad, nasty, poor, negative, unfortunate, wrong, inferior}.

Figure 2 shows how the classification accuracy (rate of classifying words correctly) and magnetization depended on temperature for the case of 14 seed words. Classification accuracy was maximized at $\beta \simeq 1.0$, where non-zero magnetization appeared, signaling the ferromagnetic phase transition, but deteriorated drastically as soon as β was raised to $\beta > 1.0$. Similar behavior was observed for four and two seed words.

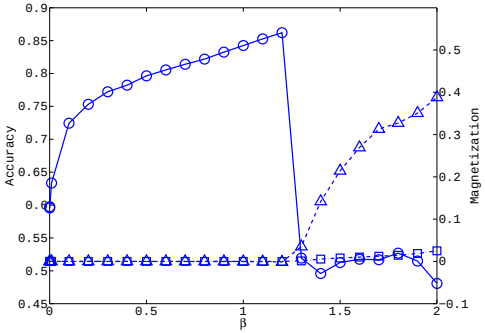

Figure 3: Classification accuracy and magnetization with improved method for 14 seed words. Circles ∘ denote classification accuracy. Squares □ and triangles △ denote magnetization evaluated using all words and only the 3596 labeled words, respectively.

5 Improved Method

5.1 Attention to Largest Eigenvalue

The setting and results described above naturally led to the following considerations.

1. Because external fields are added to only a small number of seed words, a spin system operating at high temperature (small β) can be handled as a perturbed state from the trivial solution.

2. When the temperature is lowered from a sufficiently high value, classification accuracy monotonically improves until non-vanishing magnetization appears. This suggests that the ferromagnetic phase transition is the main cause of the drastic performance deterioration.

The second consideration suggests that the classification accuracy can be improved by preventing the ferromagnetic phase transition. Equations (7) and (9), in conjunction with the first consideration, imply that the phase transition is caused by divergence of the sensitivity matrix, $(\boldsymbol{I}-\beta\boldsymbol{J})^{-1}=\sum_{\mu=1}^{N}(1-\beta\lambda_\mu)^{-1}\boldsymbol{x}_\mu(\boldsymbol{x}_\mu)^{\mathrm{tr}}$, in the direction of $\boldsymbol{x}_1$. This means that a possible way to prevent this transition is to simply expurgate the λ_1 component from weight matrix $\boldsymbol{J}=(J_{ij})$:

$$\boldsymbol{J}'=\boldsymbol{J}-\lambda_1\boldsymbol{x}_1(\boldsymbol{x}_1)^{\mathrm{tr}}. \tag{12}$$

Figure 3 shows the profiles of the classification accuracy and magnetization versus β for the modified weight (Equation (12)) for 14 seed words. Similar profiles were obtained for the other two cases. Note that solving the mean field equation for $\boldsymbol{J}'$ does not increase the computational cost significantly; $\boldsymbol{x}_1$ can be obtained using the power method, for which the computational cost is similar to that of solving the original mean field equation. The $\lambda_1\boldsymbol{x}_1(\boldsymbol{x}_1)^{\mathrm{tr}}$ term requires only $O(N)$ computations per update in the iterative substitution scheme.

Seeds	SP	LP	Original	Improved	Improved (II)
2	70.0	74.8(0.6)	75.2(0.8)	84.5(1.2)	84.4(1.2)
4	70.0	74.2(0.7)	74.4(0.6)	83.5(1.2)	83.7(1.1)
14	74.2	81.6(0.9)	81.9(1.0)	86.2(1.2)	86.2(1.2)

Table 1: Optimal classification accuracy (%) for 2, 4, 14 seed words, and the cross-validation setting. "SP" corresponds to the method based on shortest path. "LP" corresponds to label propagation. "Original" and "Improved" correspond to original method (Takamura et al., 2005) and one based on Equation (12). "Improved (II)" is same as "Improved" except that second largest eigenvalue component, λ_2, is also removed from Equation (12). Values in parentheses are β value at which accuracy was optimized.

As we speculated, the ferromagnetic phase transition was prevented, as shown by the magnetization for "all words" (squares) in Figure 3. As a consequence, classification accuracy was improved beyond $\beta \simeq 1.0$. Classification performance was evaluated on General Inquirer as in the previous work (e.g., (Turney and Littman, 2003)). Table 1 shows the optimal classification accuracy achieved for the original method (Original) and two improved methods, together with two existing state-of-the-art algorithms (SP and LP). SP is the method based on the shortest-path from seed words on the network (Velikovich et al., 2010). LP is the label propagation (Rao and Ravichandran, 2009). Note that, since we are interested in the impact made by the choice of algorithms, both of SP and LP were test on the lexical network that we used for our method, except that the edges with negative weights are removed because SP and LP cannot work properly with negative weights.[3] Also, although the label propagation by Rao and Ravichandran (2009) did not have the parameter β, we introduced it to LP for the purpose of fair comparison. Its value is optimized on the test set.

The performance of Original was improved in all cases by using the proposed scheme (Improved). All the differences were statistically significant in the sign test with significance level of 1%. The result also shows that the improved methods are significantly better than the shortest-path based method and the label propagation.[4] Note that the increase in accuracy compared with the values previously reported in some other papers (e.g., 82.8% (Turney and Littman, 2003) and 82.2% (Esuli and Sebastiani, 2005)) is substantial.

The results with a few seed words (e.g., 2, 4, and 14) are more important since semi-supervised methods should be applied to resource-scarce languages or new domains where creating a large amount of seed words is not very practical. However, in order to examine the behavior of our method when we have many seed words, we employed 10-fold cross validation (i.e., approximately 3,200 seed words). The accuracy of 91.5% (Original) was slightly improved to 91.8 (Improved) and 91.9 (Improved (II)).

5.2 Removal of more eigenvalue components

Figure 3 also shows that the performance still deteriorated at a higher β value (1.3). To clarify the reason for this, we also plotted "selected magnetization" (triangles), which was evaluated

[3] The label propagation is not guaranteed to converge in the presence of negative weights.

[4] Yu et al. (2011) used the shortest-path based method on an extended lexical network, and compared it with the label propagation on a non-extended lexical network, resulting in a better performance of the former method. The combination of their extended network with our algorithm would be a promising piece of future work.

using only the 3596 labeled words for checking a possibility that a certain phase transition relevant to only the labeled words brings about the deterioration. The plot indicates that the selected magnetization bifurcates to a finite value for $\beta \simeq 1.3$. This indicates that another phase transition occurred due to the second largest eigenvalue component, λ_2.

However, this indication is only partially correct. Figure 4 plots the profiles of the first and second eigenvectors. While the components of the first eigenvector (top) are evenly spread across almost all sites, those of the second one (bottom) are significantly localized at several sites. This "localization" feature is actually quite common for the eigenvectors of many other relatively large eigenvalues. Figure 5 plots the 30 largest eigenvalues and the inverse participation ratio (IPR), which is defined as

$$\mathrm{IPR} = \frac{\sum_i v_i^4}{(\sum_i v_i^2)^2}, \tag{13}$$

for a real vector, $\boldsymbol{v} = (v_i)$, of their eigenvectors (Biroli and Monasson, 1999). This quantity IPR takes a value between 0 and 1. In particular, as the dimensionality tends to infinity, it remains positive for localized vectors but vanishes for spread ones, so this quantity is widely used as a standard measure for characterizing the localization property of high dimensional vectors.

The plots in Figure 5 show that, although λ_1 is isolated, many other eigenvalues are distributed in a rather degenerated manner and are accompanied by localized eigenvectors. The localized eigenvectors have non-negligible values only for a few elements. Therefore, removal of one of such components does not provide significant effects for most spins. This suggests that the bifurcation of the selected magnetization is caused by not only the λ_2 component but also by many other components that are simultaneously excited at $\beta \simeq 1.3$. Accordingly, little improvement in the classification accuracy can be gained by removing the components of the second largest eigenvalue component from the weight matrix, as shown in the rightmost column of Table 1. The performance was not improved significantly by further removing the third and the fourth eigenvalue components.

Note that most of the edges in the current network have positive weights, i.e., very biased to the same sign. This is the reason why the first eigenvector is not localized and the first eigenvalue is much larger than the others. Also, the localization of eigenvectors with large eigenvalues, which is observed except for the first eigenvalue in the current network, often happens in *complex network*. The theoretical background can be found in the paper by Kabashima and Takahashi (2012). Therefore, the characteristics of the network is not completely accidental.

5.3 What is Essential?

The analysis presented so far indicates that high classification performance is achieved for a relatively small β, at which no magnetization appears unless external fields are imposed. Figure 6 plots the average of spins obtained using the improved method for $\beta = 1.2$ and 1.3 for 14 seed words. Most of the absolute values of the spin averages were rather small when a high classification accuracy was gained ($\beta = 1.2$, top) and became much larger after the performance deteriorated due to a phase transition ($\beta = 1.3$, bottom). When the spin averages have small absolute values, one can handle the system as a state produced by slightly perturbing the trivial solution by external fields imposed on only the seed word spins. This suggests a possibility that the linear response for the external fields plays a key role for the

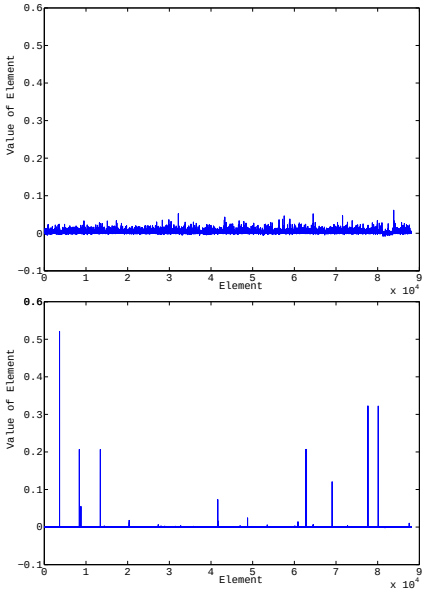

Figure 4: Eigenvectors of λ_1 (top) and λ_2 (bottom) of weight matrix $\boldsymbol{J}$.

Seeds	14	4	2
Accuracy	81.6(0.9)	74.2(0.7)	74.8(0.7)

Table 2: Optimal classification accuracy (%) of linearized model. Values in parentheses are β at which accuracy was optimized.

high classification accuracy. For checking this possibility, we examined the performance of a simplified model defined by the linear approximation of Equation (9):

$$\boldsymbol{m} = (\boldsymbol{I} - \beta \boldsymbol{J}')^{-1} \boldsymbol{h}^0, \tag{14}$$

where $\boldsymbol{h}^0 = (h_i^0)$ is provided as $h_i^0 = \alpha a_i$ if i is included in the set of seed words and vanishes otherwise. A power series expression, $(\boldsymbol{I} - \beta \boldsymbol{J}')^{-1} = \sum_{n=0}^{\infty} (\beta \boldsymbol{J}')^n$, indicates that this can be practically assessed by iterating the recursive equations:

$$\boldsymbol{m}^{t+1} = \boldsymbol{m}^t + \boldsymbol{u}^t \quad \text{and} \quad \boldsymbol{u}^{t+1} = (\beta \boldsymbol{J}') \boldsymbol{u}^t, \tag{15}$$

a sufficient number of times by setting the initial conditions as $\boldsymbol{m}^0 = \boldsymbol{0}$ and $\boldsymbol{u}^0 = \boldsymbol{h}^0$. This can be carried out with a computational cost similar to that of the naive mean field method.

Table 2 shows the optimal classification accuracy obtained with the linearized model. These results, in conjunction with those in Table 1, indicate that the performance of the linearized model was worse than that of the improved method, but similar to those of the original

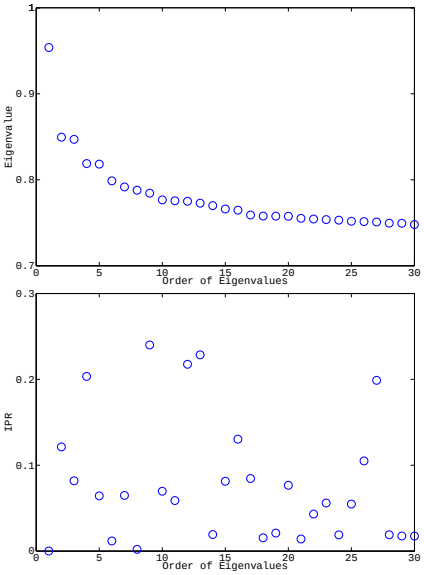

Figure 5: 30 largest eigenvalues of $\boldsymbol{J}$ (top) and inverse participation ratio (IPR) for corresponding eigenvectors (bottom). Larger IPR suggests that the corresponding eigenvector is more localized.

one (Takamura et al., 2005). This suggests that much of the information needed to correctly classify words is included in the linear response of the spin averages to the polarities of the seed words at high temperature.

As shown in Figure 5, the eigenvectors of large eigenvalues, which are emphasized at low temperature, are mostly localized and could contain relevant classification information only for a few words that corresponds to non-negligible values of elements. Therefore, they are individually insufficient for correctly classifying most other words corresponding to negligible elements. This means that, assigning polarities at high temperature so that information for all spin alignments is summed up with moderate probabilities is essential in the current spin-model-based method. This is achieved by assessing the linear response of the trivial solution to external fields representing the polarities of the seed words in the simplified scheme of Equation (14), and employment of the mean field equation (Equation (5)) offers a further gain under favor of the nonlinearity effect of tanh(·). This is in contrast to other approaches in which a single state that (approximately) optimizes a certain cost function is used for determining polarities (Blum and Chawla, 2001; Blum et al., 2004; Choi and Cardie, 2009).

A question that arises would be whether or not the removal of the largest eigenvalue component improves the linearized model. To answer this question, we conducted more experiments with the linearized model with the largest eigenvalue component being removed. The result

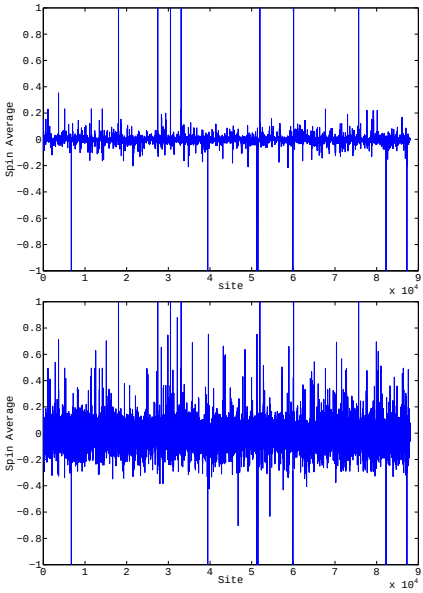

Figure 6: Spin averages m_i for $\beta = 1.2$ and 1.3 for 14 seed words. The mean of the absolute value of $|m_i|$ increased more than ten times, from 0.0028 ($\beta = 1.2$, top) to 0.0310 ($\beta = 1.3$, bottom).

is shown in Table 3. The comparison with the result in Table 2 suggests that the removal of the largest eigenvector also improves the linearized model. We note that the linearized model is almost equivalent to the label propagation (see the Taylor series in (Equation (6)); the difference is simply the presence of the normalization step. In fact, the result of the linearized model (Table 2) is almost the same as that of the label propagation (Table 1). The experimental result in Table 3 suggests that an idea similar to the removal of eigen components might also improve the label propagation, although we need to overcome the difficulty that the label propagation is not guaranteed to work properly if some edge weights are negative.

Conclusion

We have provided an analytical analysis of the behavior of a previously proposed spin-model-based method for constructing a polarity lexicon from the viewpoint of statistical mechanics.

Seeds	14	4	2
Accuracy	85.3(1.1)	83.8(1.1)	83.8(1.1)

Table 3: Optimal classification accuracy (%) of linearized model with the largest eigenvector being removed. Values in parentheses are β at which accuracy was optimized.

On the basis of this analysis, we proposed a scheme for improving the performance of polarity lexicon extraction, i.e., removing the largest eigenvalue component from the weight matrix of the lexical network, the result is quite significant. For example, classification accuracy was increased from 75.2 to 84.5% for the case of two seed words without significantly increasing computational cost. This scheme also improves the linearized model.

We also examined the possibility of improving the performance further by removing more eigenvalue components. However, the resulting degeneracy of the eigenvalues in the weight matrix, which is accompanied by eigenvector localization, minimizes the gain improvement. In addition, we investigated a linearized model to characterize the classification performance and found that the linear response to the polarities of the seed words at high temperature contains essential information. While many methods have been proposed for binary classification, apparently most of them are based on optimization of a certain cost function or on achievement of the low-temperature state of the Boltzmann-Gibbs distribution. In general, high-temperature states are technically easier to handle than low-temperature ones because a greater variety of perturbative techniques can be used. The utility of the (linear) response in the high-temperature state shown here offers a novel promising approach to generic classification when labels are provided for a small fraction of representative instances.

The developed methodology can be employed for general purposes of assessing influences of a few representative nodes in a network via local communications. The Ising spin model or similar models including its linearized model are used in a number of tasks in natural language processing.

Future work includes more use of language data and development of applications using this polarity lexicon construction method as well as use of other approximation schemes such as advanced Markov chain Monte Carlo methods in which equilibration is significantly accelerated by using extended ensembles (Iba, 1999).

Acklowdedgments

This work was partially supported by JSPS KAKENHI No. 22300003 and Mitsubishi Foundation (YK).

A Stability of Trivial Solution

Inserting Equation (4) into Equation (3) and setting h_i to zero ($i = 1, 2, \ldots, N$) yields an expression of the *mean field free energy*:

$$F_{\mathrm{MF}}(\boldsymbol{m}) \quad = \quad -\beta \sum_{i>j} J_{ij} m_i m_j + \sum_{i=1}^{N} \sum_{S_i=\pm 1} \frac{(1+m_i S_i)}{2} \log \frac{(1+m_i S_i)}{2}. \tag{16}$$

To examine the local stability of the paramagnetic solution, $m_i = 0$ ($i = 1, 2, \ldots, N$), we evaluated the Hessian of $F_{\mathrm{MF}}(\boldsymbol{m})$:

$$\boldsymbol{H} = \left(\left. \frac{\partial^2 F_{\mathrm{MF}}(\boldsymbol{m})}{\partial m_i \partial m_j} \right|_{\boldsymbol{m}=\boldsymbol{0}} \right) = -\beta \boldsymbol{J} + \boldsymbol{I}. \tag{17}$$

The solution is locally stable if and only if $\boldsymbol{H}$ has no negative eigenvalues. Equation (17) indicates that the eigenvalues of $\boldsymbol{H}$ are given as $\beta^{-1} - \lambda_\mu$ ($\mu = 1, 2, \ldots, N$) using the eigenvalues of $\boldsymbol{J}$, $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_N$. Thus, as β increases from a very low value, the stability condition that all eigenvalues are positive is broken when $\beta^{-1} - \lambda_1 = 0$ holds, i.e., Equation (7).

Finding Thoughtful Comments from Social Media

Swapna Gottipati, *Jing Jiang*
School of Information Systems, Singapore Management University, Singapore
swapnag.2010@smu.edu.sg, jingjiang@smu.edu.sg

ABSTRACT
Online user comments contain valuable user opinions. Comments vary greatly in quality and detecting high quality comments is a subtask of opinion mining and summarization research. Finding attentive comments that provide some reasoning is highly valuable in understanding the user's opinion particularly in sociopolitical opinion mining and aids policy makers, social organizations or government sectors in decision making. In this paper we study the problem of detecting thoughtful comments. We empirically study various textual features, discourse relations and relevance features to predict thoughtful comments. We use logistic regression model and test on the datasets related to sociopolitical content. We found that the most useful features include the discourse relations and relevance features along with basic textual features to predict the comment quality in terms of thoughtfulness. In our experiments on two different datasets, we could achieve a prediction score of 79.37% and 73.47% in terms of F-measure on the two data sets, respectively.

KEYWORDS: Opinion mining, Information Extraction, Text Classification.

Proceedings of COLING 2012: Technical Papers, pages 995–1010,
COLING 2012, Mumbai, December 2012.

1 Introduction

In recent years sentiment analysis and opinion mining has been extensively studied in natural language processing (Pang and Lee, 2008), largely because of the availability of a huge amount of opinionated text in online product reviews, blogs, social networking sites, forums, etc. Most work on opinion mining is about mining reviews of products and services, and the focus of these studies has been on a few important subtasks such as sentiment classification (Pang et al., 2002; Cui et al., 2006; Jiang et al., 2011) and opinion extraction (Popescu and Etzioni, 2005; Choi et al., 2006; Wu et al., 2009).

When we go beyond product review mining and consider the general problem of opinion mining from social media, many other subtasks and challenges arise. One of them is how to assess the quality of online comments and select high quality ones for further analysis and summarization. Consider the problem of mining the comments found in online social media towards a political speech such as Obama's State of the Union address. By restricting the search space to politically active blogs and forums and by using queries such as "*State of the Union*," likely we are able to retrieve highly relevant comments to the speech. However, not every comment contains valuable insight into the public's opinions regarding the sociopolitical issues addressed in the speech. Comments such as "*innovate and innovation appeared 10 times*" and "*To him..investment = more deficit spending*" are subjective but lack thoughtful explanations to support their claims. In comparison, comments like "*You want to really drive innovation, job growth and entrepreneurs? Make education, health care and retirement less of a burden on the average family, adopt more socialist policies like Norway (paid for by higher taxes, especially on the rich), and watch our standard of living rise at last!*" provide much more insightful reasoning that government policy makers may find highly valuable in understanding the general public's sentiment. Hence, we define thoughtfulness as insightful reasoning with relevance to the issues discussed in the article. So, detection of the comments with reasoning or justification is the focus of our task. Thoughtfulness is accessed only for relevant comments. This problem of finding *thoughtful* comments from social media is what we study in this paper. Formally, a *thoughtful comment* is relevant to the target document and has a justification or an argument to the issue(s) in the target document. It is particularly important for sociopolitical opinion mining because of the complexity of sociopolitical issues.

Intuitively, finding thoughtful comments is related to measuring text quality. There has been a large body of previous work on text quality prediction, but the methods are usually applied to student essays (Attali and Burstein, 2006) and news articles (Tang et al., 2003), (TREC novelty track 2003 and 2004). In social media mining, there have also been a number of studies on finding high quality reviews (e.g. (Kim et al., 2006; Agichtein et al., 2008)), but the focus in not on finding thoughtful comments, which requires us to look for reasoning in text. Presumably, a thoughtful comment should be logically well organized and coherent. We therefore hypothesize that discourse relations such as comparison, expansion and contingency will play an important role in finding thoughtful comments. A well organized comment is not always thoughtful. Comments such as, "*He is a great speaker as he writes the speech by himself and also delivers it very confidently*" are justified but are not relevant to the issues discussed in the article. Hence we hypothesize that relevance factors play an important role in detecting thoughtful comments.

We adopt a supervised learning approach and consider a diverse set of factors ranging from lexical usage to discourse relations, all derived from the textual content of comments. Many

of the factors we consider are based on the study by (Pitler and Nenkova, 2008). In addition, we also consider a relevance feature because of the nature of our problem. We construct two data sets to evaluate the various factors, one based on Singapore Prime Minister's National Day Rally speech[1] and the other on US President's State of the Union address[2].

Empirical evaluation reveals that discourse relations and relevance scores together with the standard textual features aid in better prediction of thoughtful comments. We could achieve a prediction score of 79.37% and 73.47% in terms of F-measure on the two data sets, respectively. We further tested our model across data collections. Our test result shows that the model with combined textual, discourse and relevance features still performs better than textual features alone.

The rest of the paper is organized as follows. We present the related work in Section 2. In Section 3, we formally define our problem and give an overview of our solution. We present the various features we consider in Section 4. The data set details are presented in Section 6. Evaluation and results are presented in Section 7. Finally we conclude and discuss some future work.

2 Related work

Our work is related to a large body of literature on measuring text quality in NLP, but our problem has some essential differences. The main difference is that in traditional sense, high-quality text should be grammatical, coherent and readable. For online comments, we focus more on the insightfulness or thoughtfulness of comments.

Many recent studies examined the challenges on the quality of comments. (Kim et al., 2006) studied how to predict the helpfulness of product reviews. They found that a helpful review should describe the features of the products and the pros/cons of the features. A more elaborative review that provides the complete details of the product is more likely to be considered high quality. Our problem is more general and the comments are not necessarily about products. Moreover, comments on sociopolitical articles need not elaborate on all the issues in the article. Therefore products and their features are not relevant to our problem. Another study by (Ghose and Ipeirotis, 2011) on review helpfulness looked into factors related to the reviewer, such as reviewer characteristics and reviewer history. In our work, we focus on features observed from the text only. Other social factors such as a commenter's profile or past behavior are complementary to our method.

Our work is also related to opinion retrieval (Zhang and Ye, 2008; Huang and Croft, 2009; Macdonald et al., 2009), which aims at automatically finding attitudes or opinions about specific targets, such as named entities, consumer products or public events. In most existing work on opinion retrieval, only relevance and subjectivity are considered, whereas we propose that quality in terms of thoughtfulness is also an important factor.

Work on measuring quality of social media content considers not only the quality of the content itself but also its authority in the social network through the author's authority, its popularity, etc. (Hsu et al., 2009). Several researchers explored the social network together with the content of the reviews to predict the review quality. (Bian et al., 2009) proposed a mutual reinforcement learning framework to simultaneously predict content quality and user reputation, whereas (Lu et al., 2010) proposed a linear regression model with various social contexts

[1] http://www.pmo.gov.sg/
[2] http://www.whitehouse.gov/

for review quality prediction. They combined textual and social context information to evaluate the quality of individual reviewers and to assess the quality of the reviews. We do not consider these factors as we want to focus on textual cues first. These additional features can be factored in as an independent step. Similar line of work can be seen by (Chen et al., 2011; Liu et al., 2007; Bian et al., 2009).

Our work is similar to (Amgoud et al., 2011) where they introduced argument analysis together with opinion. In their task, properties of a person or product (honesty, rigor, friendliness, etc.) are treated as arguments. The task is oriented towards aggregating features related to the product and supporting arguments to detect polarity. The task we address in this paper is quite different from their work in two main aspects. Firstly, for sociopolitical issues, the policy makers look for insightful reasoning text to understand the public sentiment in which case, properties are insufficient. Secondly, we study the attentiveness of the comments but not the polarity. Polarity orientation is a separate task which can be studied individually.

3 Problem Definition and Overview of Solution

We assume the following general definition of the task of finding thoughtful comments: Given a comment c made with respect to a *target* document d, we would like to determine whether c is a thoughtful comment. We will explain in Section 6 how we instruct the human annotators to label thoughtful comments. Generally speaking, a thoughtful comment is relevant to the target document and has a justification or an argument to the issue(s) in the target document.

While the task defined above is certainly not trivial, and theoretically speaking one would need a deep understanding of both the target document and the comment as well as relevant world knowledge to be able to judge whether a comment is thoughtful. Here we take an empirical approach and test whether features defined at lexical, syntactic, discourse levels and relevance factors have correlations with the thoughtfulness of comments and whether they can be used to achieve decent prediction accuracy. A large portion of the linguistic features we consider are inspired by existing work on measuring text quality. Indeed, at first glance our problem may appear to be the same as measuring text quality. News articles and student essays are formal and usually lengthier, whereas online comments are usually much shorter and less formal. In traditional sense, high-quality text should be grammatical, coherent and readable. Our problem seems to be text quality assessment which is defined as above, but we are not looking for grammar and readability. Instead we look for insightful reasoning with relevance to the article, as mostly user comments are not formal in social media.

We adopt a supervised learning approach to our problem. Specifically, we assume that we have a set of N training examples $\{(d_i, c_i, y_i)\}_{i=1}^{N}$, where d_i is a target document, c_i is a comment on d_i, and y_i is a binary label indicating whether c_i is a thoughtful comment with respect to d_i. With a set of feature functions, we can represent (d_i, c_i) by a feature vector $\mathbf{x}(d_i, c_i)$ (which we refer to as $\mathbf{x}_i$). We can then use standard classification algorithms to learn a classifier from $\{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$. This classifier can be used to predict y for any unseen pair of d and c. In the following sections, we will explain in detail the features we consider and the classification algorithm we use.

4 Features

There have been many studies on measuring text quality and many features have been proposed to capture text quality. As mentioned previously our methodology is based on existing work on this topic. In particular, we follow the work by (Pitler and Nenkova, 2008). They

conducted a systematic study on text quality using various linguistic features and Wall Street Journal articles. Based on the major findings of their study, we take the following features as our starting point.

4.1 Structural Feature

Structural features are generated from the comment structure. (Pitler and Nenkova, 2008) tested various structural features including the average number of characters per word, the average number of words per sentence, the maximum number of words per sentence, and article length. According to their findings, article length was the only significant factor with good correlation with text quality. Hence, we define our first feature F_1 as the number of words in the comment.

4.2 Lexical Feature

Lexical features aim to capture the lexical usage of a piece of text compared to some reference corpus. (Pitler and Nenkova, 2008) used a lexical feature based on unigram language models, which provide a principled way to statistically model text. Specifically, it is assumed that there is a reference corpus that represents high quality text, e.g. a corpus of Wall Street Journal articles. A unigram language model, denoted as θ_r, can be estimated from this reference corpus. The lexical feature is defined as the log likelihood of the comment based on θ_r, calculated as:

$$\sum_w n(w,c) \log P(w|\theta_r), \tag{1}$$

where $P(w|\theta_r)$ is the probability of word type w according to θ_r, and $n(w,c)$ is the number of times word type w appears in comment c. We call this feature F_2.

4.3 Syntactic Feature

(Pitler and Nenkova, 2008) examined various syntactic features including the average parse tree height, the average number of noun phrases per sentence, the average number of verb phrases per sentence and the average number of subordinate clauses per sentence. They found that the average number of verb phrases per sentence was a useful feature with high correlation with text quality. So, the third feature F_3 we use for our study is the average number of verbs per comment.

We also experimented with other syntactic features like average number of noun phrases and noun to verb ratio calculated from the user's comments. We found that the average number of verbs per comment had the highest correlation with comment quality, and therefore we do not consider these other syntactic features in our experiments.

4.4 Discourse Features

Previous study by (Pitler and Nenkova, 2008) found that discourse relations were also correlated with text quality. Discourse relations aim to capture textual structures such as comparison, elaboration, cause-effect explanations and examples. They are considered key for the ability to properly interpret or produce discourse. For the problem of finding thoughtful comments, we hypothesize that discourse relations may play an even larger role because a logical argument will likely rely on coherently connecting textual units through discourse relations.

Discourse relations are divided into four major semantic classes (Prasad et al., 2008):

Expansion covers those relations where the second argument expands the discourse of the first argument or move its narrative forward.

Comparison relations highlight prominent differences between the two arguments of a relation.

Contingency is marked when one of the situations described in an argument causally influences the other argument.

Temporal relations are marked when the situations described in the arguments are related temporally, either synchronously or sequentially.

It has been found that a large portion of discourse relations can be detected through connectives, i.e. cue words and phrases (Pitler et al., 2008). We use a list of such connectives compiled by (Prasad et al., 2008) and study the statistics of our corpus to discover the discourse relations. Table 1 shows that the statistics of discourse relations in our dataset.

DR Class	Singapore	US
COMPARISON	44.50%	45.87%
EXPANSION	16.75%	15.47%
CONTINGENCY	38.75%	38.66%
TEMPORAL	5.70%	5.72%

Table 1: Discourse relations statistics in our corpus

Table 1 shows that the frequency of temporal relations is low in our corpus. It is not surprising because for many online comments the arguments are not temporal. Hence, we ignore the temporal class for the rest of our paper, and restrict our attention to only the other three major classes, namely, expansion, comparison and contingency. At the same time, many relations are explicit and can be discovered using the connectives/words as used in other applications (Saito et al., 2006).

The full list of the phrases for each class are shown in Table 2. This list is collated from (Prasad et al., 2008). We observed that some words are ambiguous: 'if', 'and', 'but', 'as' etc. In our study, such words are counted only once while combining the classes for the feature generation.

In the earlier work by (Pitler and Nenkova, 2008), the Penn Discourse Treebank was used for computing the discourse features. For us, we take a simpler approach and count the number of discourse relations in a comment. This becomes the F_4 in our experiments.

4.5 Relevance Feature

One of the important differences between our problem and standard text quality assessment is that the quality of a comment also relies on its relevance to the target of the comment. In our problem definition, the target is also a piece of text. For example, consider comments made to Obama's State of the Union speech. A comment such as "We are very lucky to live in the USA. I always have and always will support our president" is not directly related to any issue addressed by Obama in his speech, and therefore is not considered to be a thoughtful comment. Hence, for thoughtful comment prediction, we also consider a relevance feature

Class	Phrases
COMPARISON	although, as though, but, by comparison, even if, even though, however, nevertheless, on the other hand, still, then, though, while, yet, and, meanwhile, in turn, next, ultimately, meantime, also, as if, even as, even still, even then, regardless, when, by contrast, conversely, if, in contrast, instead, nor, or, rather, whereas, while, yet, even after, by contrast, nevertheless, besides, much as, as much as, whereas, neither, nonetheless, even when, on the one hand indeed, finally, in fact, separately, in the end, on the contrary, while
EXPANSION	accordingly, additionally, after, also, although, and, as, as it, as if besides, but, by comparison, finally, first, for example, for one thing, however, in addition, in fact, in other words, in particular, in response, in sum, in the end, in turn, incidentally, indeed, instead, likewise, meanwhile, nevertheless, on the one hand, on the whole, overall, plus, separately, much as, whereas, ultimately, as though, rather, at the same time, or, then, if, in turn, furthermore, in short, turns out, while, yet, that is, so, what's more as a matter of fact, further, in return, moreover, similarly, specifically,
CONTINGENCY	and, when, typically, as long as, especially if, even if, even when, if, so, when if only, lest,once, only if, only when, particularly if, at least partly because, especially as, especially because, especially since, in large part because, just because, largely because, merely because, not because, not only because, particularly as, particularly because, particularly since, partly because, because, simply because, since, then, after, one day after, reportedly after, consequently, mainly because, for, thus, apparently, in the end, in turn, primarily because, largely as a result, as, because, therefore, only because, particularly, when, so that, thereby, presumably, hence, as a result, if and when, unless, until, in part because, now that, perhaps because, only after, accordingly,

Table 2: Discourse relations

in addition to text quality features. There are many ways to measure relevance, and here we choose KL-divergence score, a principled measure for relevance commonly used in information retrieval tasks.

The KL-divergence score between a comment c and a target document d is defined as the KL-divergence between the unigram language models θ_c and θ_d estimated from c and d, respectively:

$$Div(\theta_c||\theta_d) = \sum_{w \in \mathcal{V}} p(w|\theta_c) \log \frac{p(w|\theta_c)}{p(w|\theta_d)}, \tag{2}$$

where $\mathcal{V}$ is the vocabulary.

KL-divergence using only nouns: We hypothesize that the topical relevance between a comment and its target relies more on the overlap of nouns in the two pieces of text. Hence, we consider another KL-divergence measure using only nouns in c and d. Specifically, we use the unigram language models that are defined over nouns only. Let θ_c^N and θ_d^N denote the two language models. We have

$$Div(\theta_c^N||\theta_d^N) = \sum_{w \in \mathcal{V}} p(w|\theta_c^N) \log \frac{p(w|\theta_c^N)}{p(w|\theta_d^N)}. \tag{3}$$

We define the fifth feature that uses only nouns, F_5=-$Div(\theta_c^N||\theta_d^N)$ and the sixth feature which is based on all words, F_6=-$Div(\theta_c||\theta_d)$.

KL-Divergence between comment and average comment: (Lu et al., 2010) proposed conformity features in which the comment c is compared with other comments by looking at the KL-divergence between the unigram model of the comment c, and unigram model of an "average" comment that contains the text of all comments for an article. We did a preliminary analysis to study the impact of conformity on the quality. We found that this KL-divergence score has low correlation with comment quality on our data sets, and therefore we do not consider it in the rest of this paper.

5 Logistic Regression

So far we have introduced six features, which are summarized in Table 3.

Feature Set	Description
F_1	Comment length
F_2	Comment likelihood
F_3	Average number of verbs
F_4	Number of discourse relations
F_5	Relevance score using nouns only
F_6	Relevance score using all words

Table 3: Full feature set for comment representation

Once features are defined, we can use a classification algorithm to learn a model from the training data and apply the model to unseen data for thoughtful comment prediction. In this paper we use logistic regression as our classification algorithm.

As we have pointed out earlier, a comment c together with its target document d can be represented by a feature vector $\mathbf{x}$. A logistic regression classifier models the probability of observing a discrete label y for a given $\mathbf{x}$ as follows:

$$p(y|\mathbf{x};\mathbf{w}) = \frac{1}{Z(\mathbf{x},\mathbf{w})}\exp(\mathbf{w}_y^T\mathbf{x}), \tag{4}$$

where

$$Z(\mathbf{x},\mathbf{w}) = \sum_{y\in\mathscr{Y}}\exp(\mathbf{w}_y^T\mathbf{x}).$$

Here $\mathbf{w}$ is a weight matrix and $\mathbf{w}_y$ is the weight vector corresponding to class y, and $\mathscr{Y}$ is the set of class labels.

Given training data $\{\mathbf{x}_i, y_i\}_{i=1}^N$, we learn a weight matrix by minimizing the following objective function:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}}\left[\lambda\|\mathbf{w}\|^2 - \frac{1}{N}\sum_{i=1}^{N}\log p(y_i|\mathbf{x}_i;\mathbf{w})\right], \tag{5}$$

where $\|\mathbf{w}\|^2 = \sum_{y\in\mathscr{Y}}\|\mathbf{w}_y\|^2$ and λ is a regularization parameter that is empirically set.

6 Data Set

6.1 Data Collection

Our objective is to study how the thoughtfulness of a comment is reflected in the various linguistic factors including discourse relations and relevance factors to the article. As we have mentioned earlier, measuring the thoughtfulness of a comment is especially important for sociopolitical opinion mining. We therefore collected two data sets in this domain for our evaluation. We first acquired the following two political speeches: (1) Singapore Prime Minister's National Day Rally Speech in 2010. (2) US President's State of the Union address in 2011. We further broke down each speech into several segments based on topical boundaries. The topics of each speech are listed in Table 4.

Speech	**Topics**
Singapore	Economy & Productivity, Immigration, Congestion, Housing, Education, National Service (NS), Singapore Spirit, Founding Fathers, Youth Olympics
US	Economy, Innovation & Research, Education, Rebuild, Spending & Taxes, Debts, Military

Table 4: Topics in the two speeches.

To collect an unbiased sample of comments for each speech, we use two search queries ("national day rally speech 2010" and "president state union address 2011") and Google API to obtain a list of top 50 URLs. We further manually selected URLs from online forums and blogs. We cleaned the data and removed short comments with no more than two words.

For F_2, the lexical feature, we need a suitable reference corpus. For the Singapore data set, we collected 1200 news articles from AisaOne.com to form our reference corpus. For the US data set, we used a set of 1358 New York Times articles to form the reference corpus.

6.2 Annotation

We engaged two human annotators to judge the comments we had collected. The annotators were asked to judge (1) whether a comment was relevant to each segment of its corresponding speech, and if so, (2) whether the comment was a thoughtful one. In other words, we treat each segment of a speech as a target document. For each pair of a comment c and a target document (i.e., a speech segment) d, we obtained two binary labels: a label z that indicates whether c is relevant to d, and a label y that indicates whether c is a thoughtful comment with respect to d.

To judge whether a comment was thoughtful, the annotators were asked to use the following criteria:

1. Is the comment a mere repetition or a rephrase of the speech text? For example, "PM says that we should stay open for the foreigners" is a repetition of the text from the article in passive voice. Such comments are relevant to the article, but not insightful.

2. Does the comment contain opinions of the commenter? For example, "Eliminating the deficit-Im sure this makes Mitch happy" is about the topic "Spending and Taxes" but without any insightful opinion. Such comments are relevant but not insightful.

3. Does the commenter provide argument to support her opinion? For example, "All this deficit crap reminds me of when Reagan ran for president ; how the deficit was terrible etc, etc, and after he got elected he ran up the biggest deficit ever. This was mostly due to spending on the military and tax cuts for the rich. This was even after he slashed domestic spending. If the US would wake up to the fact that we can't afford the wars, we might be able to move forward."

In total, the human judges annotated 1350 pairs of issue-comments for PM speech and 1150 pairs of issue-comments for Obama Speech. Since the annotation is still subjective, we calculated the inter-annotator agreement level using Cohen's Kappa coefficient. Cohen's kappa on quality is 0.8965 for all comments. On relevance the kappa is 0.7355 for all comments. We use the judgment from the judge who is stricter as our ground truth. The statistics of the labeled data are shown in Table 5.

Comment type	**Singapore**	**US**
Thoughtless	63.35%	68.25%
Thoughtful	36.65%	31.75%

Table 5: Comment statistics for both articles

7 Experiments

To check whether the features we have defined correlate with the thoughtfulness of comments based on human judgement, we first compute the Pearson correlation coefficients for all the features summarized in Table 3. The results are shown in Table 6. We observe that all features are positively correlated with the thoughtfulness of comments.

Feature	**Singapore**	**US**
F_1	0.3744	0.3594
F_2	0.3782	0.3755
F_3	0.3639	0.3911
F_4	0.3913	0.3554
F_5	0.1606	0.2437
F_6	0.1191	0.2146

Table 6: Pearson correlation coefficients between the features and the thoughtfulness of comments.

In the remaining of this section, we show our experimental results that answer the following questions:

RQ1: Does the KL-divergence relevance score based on nouns work better than the KL-divergence score based on all words?

RQ2: Which discourse relations have bigger impact on the performance?

RQ3: Which combination of various features gives the best prediction of thoughtfulness?

For all the experiments below, we use the standard precision, recall and F-score as our performance measures.

7.1 Relevance Model

To answer our RQ1, we first tested the performance on finding relevant comments on the Singapore dataset for both KL methods discussed in Section 4.5 . For this evaluation, we used only the labels z from the human judgment, i.e. the relevance judgment. We tested both relevance models: KL-divergence using all words and KL-divergence using only nouns. The results are shown in Table 7. We used the F-measure to evaluate the results. If score is greater than $\tau >$ -2.2 (set empirically), the comment is relevant to the topic. We can see that using nouns to compute the KL-divergence score works better. So, for the succeeding experiments we use F_5 which is the feature based on KL-divergence score between a comment and a target speech segment using nouns only.

Feature	Model	F-1
F_5	KL-Divergence using nouns only	**0.634**
F_6	KL-Divergence using all words	0.611

Table 7: Comparison between the two KL-divergence scores on the Singapore dataset.

7.2 Discourse Relations

To answer our RQ2, we studied the influence of various discourse relations on the F-measure of the comment thoughtfulness using the logistic regression model. For this evaluation, we used the labels y from the human judgment, i.e. the thoughtful comment. Table 8 shows the comparison of all three classes of discourse relations (Comparison, Expansion and Contingency) on comment quality. We can see that for both data sets, when *comparison* relations are used, the accuracy is the highest for both data sets. For the subsequent experiments, we use only the *comparison* relations to form our discourse feature, i.e. F_4 is set to be the number of *comparison* relations in a comment.

DR-Level	Singapore	US
All	0.6186	0.6464
Comparison	**0.6313**	**0.6538**
Expansion	0.5824	0.6111
Contingency	0.6213	0.6309

Table 8: Comparison of different classes of discourse relations using F-measure.

7.3 Thoughtful Comment Study

To answer RQ3, we conducted a detailed analysis on all the feature combinations we summarized in Table 3. We tested the thoughtfulness of the comments for a given article using the logistic regression model. The results of our experiments are shown in Table 9 for Singapore and in Table 10 for US. For all our experiments we performed 5-fold cross validation and with all the combinations of the features. For better analysis, we show only the most important combinations in the results.

For the Singapore data set, using linguistic features alone (F_1+F_2+F_3) leads to a F-score of 73.33%. Our hypothesis is that discourse relations play important role in detecting thoughtful comments. The results confirm that using discourse relations together with linguistic features

Feature Set	Recall	Precision	F-1
F_1+F_2+F_3	0.7097	0.7586	0.7333
F_1+F_2+F_4	0.8065	0.7143	0.7576
F_1+F_3+F_4	0.8387	0.6667	0.7429
F_2+F_3+F_4	0.8065	0.6944	0.7463
F_1+F_2+F_3+F_4	0.7742	0.7273	0.7500
F_1+F_2+F_3+F_5	0.7419	0.7667	0.7541
F_1+F_2+F_4+F_5	0.8065	0.7813	**0.7937**
F_1+F_3+F_4+F_4	0.7419	0.7931	0.7667
F_2+F_3+F_4+F_5	0.7742	0.7500	0.7619
F_1+F_2+F_3+F_4+F_5	0.7742	0.8000	0.7869

Table 9: Prediction results of thoughtful comments for Singapore using various feature combinations.

yields (F_1+F_2+F_3+F_4) a 75% F-score. But the model performs slightly better without syntactic features (F_1+F_2+F_4)) with 75.76%, which is a 0.76% increase over combined features and 2.43% higher than the linguistic features. Our second hypothesis is that relevance factors play an important role in detecting thoughtful comments. The results confirm that using relevance scores together with linguistic features and discourse relations (F_1+F_2+F_3+F_4+F_5) leads to 78.69% F-score, which is a 3.69% increase compared to linguistic together with discourse relations. Here again, we notice that the model has better performance without syntactic features (F_1+F_2+F_4+F_5) with F-score of 79.37, which is a 4.37% increase compared to linguistic together with discourse relations and 6.04% higher than linguistic features alone.

Feature Set	Recall	Precision	F-1
F_1+F_2+F_3	0.6522	0.6818	0.6667
F_1+F_2+F_4	0.7826	0.6429	0.7059
F_1+F_3+F_4	0.7391	0.6296	0.6800
F_2+F_3+F_4	0.7391	0.5862	0.6538
F_1+F_2+F_3+F_4	0.7826	0.6207	0.6923
F_1+F_2+F_3+F_5	0.7391	0.6296	0.6800
F_1+F_2+F_4+F_5	0.7826	0.6923	**0.7347**
F_1+F_3+F_4+F_4	0.7826	0.6429	0.7059
F_2+F_3+F_4+F_5	0.7391	0.6538	0.6939
F_1+F_2+F_3+F_4+F_5	0.7826	0.6667	0.7200

Table 10: Prediction results of thoughtful comments for US using various feature combinations.

For experiments on US data set, using linguistic features (F_1+F_2+F_3) alone leads to the F-measure of 66.67%. Discourse relations together with linguistic features (F_1+F_2+F_3+F_4) yields 69.23% F-measure which is a 2.56% increase over features without discourse relations. Here, we also notice that the model performs slightly better without syntactic features (F_1+F_2+F_4) with F-score of 70.59% which is 1.36% increase over combined features. Using relevance scores together with linguistic features and discourse relations (F_1+F_2+F_3+F_4+F_5) leads to 72% F-measure which is 2.77% increase compared to linguistic together with discourse relations. We also notice that the model has better performance with out syntactic

features (F_1+F_2+F_4+F_5) with F-score of 73.47, which is 4.24% increase compared to linguistic together with discourse relations.

During our analysis, we observed that the US data is less verbose compare to Singapore data. Another thing we also noticed is that the US data users focus more on the speech delivery rather than the actual speech issues. At the same time, they tend to discuss mostly one issue in each comment where as, Singapore users tend to combine many issues in their comments. So, even if one issue is justified in the comment, the comment is treated as thoughtful comment. This explains the performance differences in the two data sets. It will be interesting to study more fine grained opinion analysis at the comment level and we leave it for our future work.

7.4 Cross Collection Experiments

We further perform cross data collection experiments to test the performance of our model. We tested Singapore using USs' 5-feature model and viceversa. To compare the cross data collection results with original results, we depict Table 11 which shows the F-measure prediction on thoughtful comments. Singapore performed with a quality prediction F-measure lowered by 4.49%, whereas the US performance decreased by 5.11% compared to actual model.

		train	
		Singapore	**US**
test	**Singapore**	0.7937	0.7488
	US	0.6836	0.7347

Table 11: Cross data collection comparison. F-Measure for thoughtful comments.

We show some sample comments in Table 12 for both datasets. Due to space constraints we show 2 sample thoughtful and thoughtless comments for two issues in each articles.

Topic	**Quality**	**User Comment**
Innovation	Thoughtless	I love these plans on energy, but alas, the energy secretary appears to be asleep.
	Thoughtful	You want to really drive innovation, job growth and entrepreneurs? Make education, health care and retirement less of a burden on the average family, adopt more socialist policies like Norway
Spending & Taxes	Thoughtless	..Oh, so Obama "compromised" on the tax cuts for the wealthy
	Thoughtful	Low taxes aren't helping the vast middle and working class and aren't creating more jobs, it's a policy that only benefits the rich.
Housing	Thoughtless	By the way did anybody count the no of flags on a HDB flat. believe me 95% of the time u will take less than 10 sec to do it
	Thoughtful	I am glad that to hear more HDB houses to be built. But do I got a taste of this pie? What about those who are genuine to upgrade their existing 3 room flat but not 1st timer?..
National Service	Thoughtless	i'm still waiting before the budget and erection. otherwise i'll vote oppo. 9k is ?
	Thoughtful	Just 9000 for NSman. Those foreign scholar in NUS NTU got tution non-subsidize fee alone is 20000 one year. That even exclude lodging and return ticket fully paid by PAP.

Table 12: Sample comments: First two topics are from US and last two are from Singapore

7.5 Parameter Sensitivity

The regularization parameter λ in Equation 5 is set empirically. We study the optimal value and tuned it by regular cross validation. Figure 1 shows our experiments for both Singapore and US datasets. We get optimum results when we set λ to 0.1 or 1. We choose 0.1 for both datasets as it generates higher prediction performance in general.

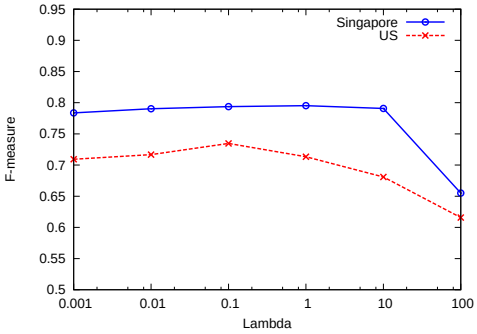

Figure 1: Regularization parameter sensitivity study

Conclusion and perspectives

Detecting thoughtful opinions is an important subtask of opinion mining and summarization. We perform an empirical study using syntactic, vocabulary, discourse and relevance features for prediction and combination of all is substantally better than the baseline surface features. Moreover, through our cross data collection experiments, we show that prediction using our approach achieves competitive performance.

Currently, we use KL divergence to compute the similarity but users tend to use abbreviations for some words and this impacts the performance of KL-divergence scores. We want to try other similarity techniques based on topic modeling and enhance the relevance performance. Extending the problem to identify the sentiment orientation is another useful subtask of opinion mining which we want to try next. In the future, we would like to extend our work to application base, and investigate the usage of thoughtful opinions in opinion summarization.

Abstract

Sanskrit, the classical language of India, presents specific challenges for computational linguistics: exact phonetic transcription in writing that obscures word boundaries, rich morphology and an enormous corpus, among others. Recent international cooperation has developed innovative solutions to these problems and significant resources for linguistic research. Solutions include efficient segmenting and tagging algorithms and dependency parsers based on constraint programming. The integration of lexical resources, text archives and linguistic software is achieved by distributed interoperable Web services. Resources include a morphological tagger and tagged corpus.

Keywords: Indian language technology, Resources and annotation, Morphology and POS tagging, Parsing.

COLING 2012, Mumbai, December 2012.

1 Introduction

Formal and computational linguistics was dominated by English at its inception and developed in subsequent decades primarily in the environment of European languages. More recently there has been a concerted effort to undertake formal linguistic analysis of a wide variety of languages, with particular interest in those with dramatically different features, and to enrich linguistic theory to account for linguistic variety. In spite of this effort, analytic structures and procedures utilized in formal linguistics remain dominated by those invented for, and most suitable for, English and other European languages. Linguistic theory remains unduly weighted in favor of European languages even as their extension to the variety of the world's languages involves undue complication thereby revealing their inadequacy in representing language universally. The inadequacy of contemporary computational methods is vividly apparent in the analysis of Sanskrit. Recent worldwide collaboration to overcome the challenges to conducting computational linguistic research on Sanskrit offers insights into methods and procedures that may be useful generally for languages that differ markedly from western European languages.

1.1 Sanskrit

Sanskrit is the primary culture-bearing language of India, with a continuous production of literature in all fields of human endeavor over the course of four millennia. Preceded by a strong oral tradition of knowledge transmission, records of written Sanskrit remain in the form of inscriptions dating back to the first century B.C.E. Extant manuscripts in Sanskrit number over 30 million - one hundred times those in Greek and Latin combined - constituting the largest cultural heritage that any civilization has produced prior to the invention of the printing press. Sanskrit works include extensive epics, subtle and intricate philosophical, mathematical, and scientific treatises, and imaginative and rich literary, poetic, and dramatic texts. The primary language of the Vedic civilization, Sanskrit developed constrained by a strong grammatical tradition stemming from the fairly complete grammar composed by Pāṇini by the fourth century B.C.E. In addition to serving as an object of study in academic institutions, the Sanskrit language persists in the recitation of hymns in daily worship and ceremonies, as the medium of instruction in centers of traditional learning, as the medium of communication in selected academic and literary journals, academic fora, and broadcasts, and as the primary language of a revivalist community near Bangalore. The language is one of the twenty-two official languages of India in which nearly fifty thousand speakers claimed fluency in the 1991 Indian census.

India developed an extraordinarily rich linguistic tradition over more than three millennia that remains under-appreciated and under-investigated. A cursory glance at the long tradition of discussion and argumentation within and between Indian sciences of phonetics (śikṣā), grammar (vyākaraṇa), logic (nyāya), ritual exegesis (karmamīmāṃsā), and literary theory (alaṃkāraśāstra) reveals that Indian linguistic traditions have much to offer contemporary linguistic theory in the areas of phonetics, morphology, syntax, and semantics.

1.2 Computational linguistic processing challenges

Since computational linguistics developed primarily in the environment of western European languages, its methods were structured and remain suited to those languages. Prior to undertaking any kind of computational analysis of Sanskrit text, one must deal with several challenges presented by features of the language that differ markedly from those of modern western European languages. In addition to the complexity introduced by lexical complements, which is relevant in these languages

as well, Sanskrit has orthographic, prosodical, and inflectional complexities not encountered in western European languages. The rich inflectional and derivational morphology of the language permits relationships that are shown positionally in western European languages to be made known by the morphology instead. As a result, the word order is much less constrained by governance structure and is free to intimate discourse structure and performative aspects of language. For the analysis of Sanskrit syntax, therefore, positional grammars, and constituency parsers which are based on them, are not very relevant, and dependency parsers are more suitable.

1.2.1 Prosody and orthography

In English, where the heritage is received in writing, and standardized spelling and printing were introduced several hundred years ago, a given morpheme is represented with a single orthography despite the fact that it has different surface phonetic representations in different contexts. For example, the past tense suffix -⟨ed⟩ is so written despite three distinct phonetic realizations in three clearly defined contexts:

/t/ e.g. dip /dɪp/, dipped /dɪpt/
/d/ e.g. boom /bu:m/, boomed /bu:md/
/id/ e.g. loot /lu:t/, looted /lu:tid/

In contrast, in Sanskrit, where oral tradition dominated the sphere of learning and an advanced discipline of phonetics explicitly described prosodic changes, these prosodic changes, well known by the term *sandhi*, are represented in writing. Hence the past passive participle suffix *-ta* variously realized as *ta* or *dha* depending solely upon the phonetic context, is written as follows:

/ta/ e.g. from *su* 'press', *suta* 'pressed'
/d^ha/ e.g. from *budh* 'awake', *buddha* 'awakened'

Moreover, the prosodic changes obscure word boundaries in speech, and these word boundaries are correspondingly eliminated in writing as well. For example, *vasati* 'dwells' followed by *atra* 'here' becomes वसत्यत्र (*vasatyatra*) in continuous speech. The semisyllabic Indic scripts such as Devanāgarī forestall word separation here obliterating the word boundary. Some prosodic changes, like this one, can be separated in alphabetic Roman transcription despite the sound alteration, viz. *vasaty atra*. Other prosodic changes, however, preclude word separation even in alphabetic transcription because the final sound of the preceding word and the initial sound of the following word merge in a single sound. Thus *vidyā* 'knowledge' *āpyate* 'is attained' becomes *vidyāpyate*; the single sound *ā* belongs to both words. The most difficult task in parsing a Sanskrit sentence is determining the word boundaries. Solutions to the problem have valuable ramifications for speech analysis where a similar problem is encountered in virtually all languages.

1.2.2 Inflectional morphology

In English, inflectional morphology is minimal. A present active verbal paradigm contains six slots: three for first, second and third person times two for singular and plural number. Yet the forms that fill these slots number just two, for example, *go* and *goes* for the verb 'to go'. Description of the abstract grammatical structure requires mentioning five items while description of the forms directly requires mentioning only two. Grammatical description is therefore more prolix than listing. It is nearly as efficient to describe English morphology with reference to individual forms as it is to describe it in abstract grammatical structures. (Karp et al., 1992) create a hash table of just 317,477 forms from 90,196 lexical entries, a ratio of 3.5:1. The reverse is true for Sanskrit. In Sanskrit full

verb paradigms number hundreds of unique forms in as many as sixteen hundred slots. The modest full-form lexicon created by (Scharf and Hyman, 2009a) from a lexicon of 170,000 entries numbers more than eleven million forms, a ratio of 64.7:1. It is by far more economical to describe such forms in abstract grammatical categories than it is to list them. The implication of the brevity of grammatical description of Sanskrit in comparison to listing forms is that it is misguided to attempt to describe Sanskrit grammar with reference to individual word forms. This fact was explicitly recognized by Patañjali in his massive commentary *Mahābhāśya* on Pāṇini's concise grammatical description of Sanskrit in the *Aṣṭādhyāyī*.

1.2.3 Lexical complements

In statistical analysis of a corpus of sentences, slots for lexical complements are combined. In computational linguistic processing of English it is recognized that the forms *is* and *are* belong to the same lexical unit as the forms *was* and *were*. Likewise in Sanskrit grammar, forms derived from the root *bhū* are recognized as complements of forms derived from the root *as*.[1] Because it is concerned only with individual word forms, computational linguistic processing of English treats *is* and *are* as lexical complements of each other and *was* and *were* as lexical complements of each other in the same manner as it considers the first pair as lexical complements of the second pair. Such processing treats *a* and *an* as lexical complements in the same manner. Historical linguists differ from computational linguists in their treatment of these forms. They view *is* and *are* as inflectional varieties derived from one common root, and *was* and *were* as inflectional varieties derived from another root. They consider the two roots to be lexical complements. They recognize that *a* is a phonetic variant of *an*, both derived from the word *one*. Sanskrit grammarians agree with historical linguistics here. Only semantically related roots are treated as lexical complements. Variants such as *a/an* are treated as phonetic variants, and variants such as *is/are* are treated as inflectional variants.

1.2.4 Syntax

In languages such as English where word order is strongly associated with roles, it may be reasonable to define positions in relation to roles as is done in positional grammars. Hence in an active sentence, the first position is called the subject position, the second the verb position and the third the object position. In free-word order languages such as Sanskrit, however, position does not determine role. Although certain patterns are common — such as subject, object, verb — even unmarked word order leaves some roles in indeterminate position. Alteration of the word order does not change the roles, and the position is highly influenced by discourse structure and emphasis. Phrase-structure grammars are unsuitable to describe governance structure which is more accurately described by dependency grammars.

2 Birth of a discipline

A number of projects began accumulating digitized texts in the late 1980s. The largest collection was made by the TITUS[2], which accumulated more than eighty digital Sanskrit texts within a decade. The next decades witnessed the growth of other large collections including GRETIL, which serves as a central registry of digitized Indic texts.

In the meantime a couple of projects developed digital dictionaries of Sanskrit. The Cologne Digital Sanskrit Lexicon project began by digitizing Monier Williams' A Sanskrit-English Dictionary (MW)

[1] *Aṣṭādhyāyī* 2.4.52 *aster bhū*

[2] `http://titus.uni-frankfurt.de/`

between 1994 and 1996, and followed by digitizing several other major bilingual Sanskrit dictionaries. The Digital Dictionaries of South Asia project at the University of Chicago included Apte's and MacDonell's Sanskrit-English dictionaries among its digitized Indian language dictionaries.

There were a few early isolated attempts to process Sanskrit text mechanically, such as Pushpak Bhattacharya's Sanskrit parser included as part of his M.Tech. thesis at IIT Kanpur in 1987 and Pr. Lakshmitatachar's verbal cognition generator for Bhandarkar's Sanskrit primer developed at the Academy of Sanskrit Research in Melkote in the early 1990s (Rāmapriya and Saumyanārāyaṇa, 2001).

The Indian Ministry of Communications and Information Technology provided a strong impetus for computational processing of Indian languages beginning at the turn of the century with its Technology Development for Indian Languages program (TDIL). Several periodic conferences were launched to foster research in computational linguistics, such as the International Conference on Natural Language Processing (ICON), and the Language Engineering Conference (LEC). The Akshar Bharati group developed "Anusāraka", a language accessor, for accessing texts in other languages that employed techniques inspired by Pāṇini's *Aṣṭādhyāyī* (Bharati et al., 1995). K. V. Ramakrishnacaryulu introduced natural language processing programs specifically for Sanskrit at the Rashtriya Sanskrit Vidyapeetha, Tirupati, such as "Śābdabodha Systems and Language Technology" in 2005.

In 2002, under the guidance of Amba Kulkarni, the toy morphological analyser developed at Melkote was enriched with the MW lexicon and the Dhātu-ratnākara database resulting in a wide coverage morphological analyser. Amba Kulkarni developed prototypes of several other analytic tools for Sanksrit when she began teaching specialized courses in the subject at Tirupati. Her appointment as the head of the newly formed Department of Sanskrit Studies at the University of Hyderabad, and Girish Nath Jha's appointment to the Special Center for Sanskrit Studies, J.N.U., Delhi beginning in 2002 allowed the systematic training of students in Sanskrit computational linguistics.

In 1998-1999, Peter Scharf and Ralph Bunker developed a Web-based Sanskrit reader program at Brown University called *Kramapāṭha* equiped in 2001 by Hyman with an index program and audio feature. The index program allowed Peter Scharf's *Rāmopākhyāna* to be searched by lexical and inflectional categories as well as by verbal roots, nominal stems, inflected forms, text ranges, or combinations thereof. In 2003-2004, Hyman and Peter Scharf collaborated to produce a digital edition of Whitney's roots (Whitney, 1997), that served as the source of verbal stems for their inflectional generation software. Between 2006 and 2009 Peter Scharf led the International Digital Sanskrit Library Integration project in the Classics Department at Brown University. The project created a digital Sanskrit library by integrating the texts provided by the TITUS with the digital MW dictionary of the Cologne Digital Sanskrit Lexicon project at Universität zu Köln (CDSL). The dictionary was upgraded with the assistance of Jim Funderburk and R. Chandrashekar by converting character code markers to explicit XML tags and systematically classifying and tagging additional information.

Separating linguistic processing from issues of input and display simplifies linguistic processing and also permits precise processing and display of accented dialects. Peter Scharf and Hyman designed the Sanskrit Library Phonetic encodings (SLP), described in (Scharf and Hyman, 2009b), after a thorough investigation of ancient Indian linguistic treatises, that allows all sounds represented in Vedic texts to be represented digitally. After an investigation of Sanskrit paleography, Peter Scharf initiated worldwide collaboration to extend the Unicode Standard to include 68 additional

characters required for the proper display of the ancient Vedic heritage texts of India[3]. The Unicode Standard version 5.2 incorporated the characters in two code blocks, Devanagari Extended and Vedic Extensions under South Asian Scripts on the Unicode Character Code Charts page[4]. SLP serves as the basis of a suite of transcoders that convert between standard Sanskrit Romanization of Sanskrit in Unicode, several popular Roman meta-encodings, and the Unicode pages of the major Indic scripts. Users are permitted to select their preferences for input and display at the Sanskrit Library site.

Around 2000, Gérard Huet started to develop a Sanskrit Heritage platform (SH), centered around an electronic version of the Sanskrit-French Sanskrit Heritage dictionary[5]. The dictionary was structured from the start to serve both as a computerized lexical database for morphology generation, and as a human-readable hypertext encyclopedia on Classical India (Huet, 2001, 2004). It is internally consistent in that each lexical entry is provided with hypertext links to its generating components, and it prepares the ground for syntax analysis by systematically formalizing information about complements (ākāṅkṣā).

Various tools for morpho-phonemic computation, as well as efficient structures for lexicon representation, were adapted to Sanskrit from a general computational linguistics toolkit called the Zen library, implementing general finite state transducers in functional programming style, as instances of a new relational computing paradigm called effective Eilenberg machines (Huet, 2002; Huet and Razet, 2006, 2008; Razet, 2009). The global architecture of this platform is that of interconnected Web services allowing interaction with digital libraries and other external resources. The main tool is a Sanskrit Reader, allowing segmentation (sandhi analysis), tagging, and parsing (Huet, 2003, 2005, 2006, 2007, 2009; Goyal and Huet, 2013).

In 2008 the Indian Government funded a major consortium project to develop various tools for analysis of Sanskrit text and a Sanskrit-Hindi Machine Translation System. Sanskrit scholars and computational linguists collaborated to develop the prototype of an interactive reader consisting of the 100-verse Saṅkṣepa Rāmāyaṇa. They also developed elaborate guidelines for annotating sandhi, compounds (*samāsa*) and syntactico-semantic roles (*kāraka*), and an annotated 800K corpus. Compound analysis is essential to Sanskrit parsing because 15-20% of the words in a random text are compounds and compounding is productive. A modular compound processor (Kumar, 2012) was developed that segments a given linear string into morphologically valid components (Kumar et al., 2010), determines the underlying constituency structure (Kulkarni and Kumar, 2011), and identifies the compound type (Kulkarni and Kumar, 2013). A paraphrase of the compound is then produced from the labeled constituency tree (Kumar et al., 2009). The morphological analyser previously developed by Amba Kulkarni was enhanced further by employing the head words of MW, and supplying additional derived forms before generating a full-form lexicon of 140 million words. (Kulkarni and Shukl, 2009). The constraint-based parser developed by her employing this analyser is described in section 6 below. All these tools for analysis of Sanskrit texts were used in a Sanskrit-Hindi language accessor (*anusāraka*) and a machine translation system. Comparative study of the divergences between Sanskrit and Hindi were taken up to improve the translation quality (Shukla et al., 2010) of the translator. The morphological analyser, generator, sandhi joiner and splitter, full-fledged parser, and Sanskrit-Hindi Machine Translation system were assembled in what is called *Saṁsādhanī*[6].

[4] http://www.unicode.org/charts
[5] http://sanskrit.inria.fr
[6] http://tdil-dc.in/san

These various efforts started coordinating themselves around 2006, with the creation of a joint team in Sanskrit computational linguistics between INRIA and Department of Sanskrit Studies, University of Hyderabad. In October 2007 the First International Sanskrit Computational Linguistics Symposium (Huet et al., 2009), organized by Gérard Huet at INRIA, allowed the presentation of the various teams and tools, and the development of cooperative software and resources. It was soon followed by the Second Symposium, organized at Brown University by Peter Scharf in May 2008, the Third one organized at University of Hyderabad by Amba Kulkarni in January 2009 (Kulkarni and Huet, 2009), the Fourth one organized at J.N.U. Delhi by Girish Nath Jha in December 2010. The Fifth one is scheduled for January 2013, organized at I.I.T. Bombay by Malhar Kulkarni.

In 2010–2011 the Sanskrit Library linked its texts to the Sanskrit Heritage reader. Each sentence in which sandhi has not been analysed is dynamically linked to the SH parser. The parser analyses the sentence using various syntactic criteria and a full-form lexicon of 700,000 forms derived from the SH lexicon of about 25,000 words. Unpenalized solutions are selected and displayed. The site allows one to examine penalized solutions and to reedit the sentence and resubmit it for further analysis. The Sanskrit Heritage site additionally allows one to submit analysed sentences for syntactic analysis by Amba Kulkarni's dependency tree parser.

The year 2012 saw a significant progress in the integration of the various tools. Pawan Goyal integrated an HTML version of the Monier-Williams dictionary as an alternative plug-in component to the Sanskrit Reader. The simultaneous invitation of Peter Scharf and Ralph Bunker to Paris eased the synchronization of tagging schemes and development of more robust protocols for interoperable Web services. In close collaboration with the other authors, Ralph Bunker developed a software-assisted human interface for morphological tagging currently being used by human annotators to prepare a tagged corpus.

3 Basic Architecture

The basic architecture of the collaborative platform is based on interactions between various Web-services. The main idea is not to have a monolithic system but various platforms, where selected components can inter-operate. These components can be software or linguistic resources. The glue between various platforms is interoperable Web-services via user interfaces and remote procedure calls.

This way of doing distributed computing has several advantages from a software engineering point of view. Firstly, Web technology gives a universal standard user interface with XHTML. Conformant HTML pages permit a uniform viewing by the various browsers offered by the various operating systems of personal computers and workstations. The technology offers automatic adaptation to the display medium, thus accommodating tablets, personal assistants, and smartphones. Furthermore, Unicode allows display in all the scripts of all the human languages. For Sanskrit, this means it is easy to display in Devanāgari script, as well as in the standard Indological romanised script with diacritics, as well as in the various transliteration schemes in use. Actually our joint distributed platform recognizes four such transliteration schemes, permitting equally easy access to scholars trained in using one scheme or another.

Secondly, developing separate components at the various sites does not commit us to any specific programming environment. The various teams at the various sites use different programming languages. There is no need for linking the executables of these various services. Finally, versioning is distributed, there is no need of synchronisation of new versions of the various services, once clear interfaces for data interchange are agreed upon (that is, we only have to agree on the XML abstract

structures defining the marshalling of interchanged data at the interfaces).

We have not felt the need to have a sophisticated orchestration of these various services. The main ingredient is remote procedure call (so-called CGI in the Web jargon). We remedy the poverty of the memory-less protocol (HTTP) by transmitting parameters summarizing the interaction history in the current session.

One common feature of our various developments is the use of UNIX platforms (Linux or MacOS) for development and server deployment. Users of the software, for instance annotators, may of course use any client operating system.

The configuration of the various platforms allows a choice between using a service as a remote process using network communication with the proper server, or alternatively to the same service run locally on the client station. This is easily achieved in Unix clients, where Web servers such as Apache or Tomcat are easy to install. Sometimes, one service is available locally as a plug-in to the server site. Thus, the Sanskrit Heritage segmenter is available as a plug-in to the University of Hyderabad Sanskrit computational platform, in order to undo sandhi in sandhied corpus. Conversely, the University of Hyderabad Sanskrit parser, using sophisticated constraint technology, may be used in the Sanskrit Heritage platform as a filter to its segmenter-tagger, superior in precision to its original crude dependency analyser.

4 Lexicon

Independent projects had previously used different lexicons as the basis for generating inflected forms used in linguistic software. The task of coordinating those lexicons with each other and with other available lexical resources presents a challenge. A current project jointly funded by the NEH and the Deutsche Forschungsgemeinschaft extends the Sanskrit Library's multidictionary interface by integrating supplements to the major bilingual dictionaries already included, and by adding specialized dictionaries, indigenous Indian monolingual dictionaries, traditional thesauri, and traditional linguistic analyses. Even after data-entry of the various lexical sources, the task of integrating them is complicated by the different conventions used by their original compilers. Compilers differ in the scripts they use, conventions of sandhi, selection of stem versus an inflected form, determination of the base form, etc. The project examines the conventions used in each lexical source, and determines ways of mapping the differences to each other.

The Sanskrit Heritage platform uses a Sanskrit-French dictionary. The desire arose to express the output of the various tools of the platform multilingually. The first step was to project the headwords of the SH dictionary onto those of the digitalised Monier-Williams dictionary. To this end, Pawan Goyal engaged in using data-mining techniques and automated translation tools to develop a protocol for the non-trivial task of mutually linking lexical resources, as described in the remainder of this section.

Let us consider the stem, *aṅga* in Sanskrit. This stem appears in two SH entries:

aṅga$_1$: membre; partie du corps; le corps en entier; la personne, la forme
En: member, part of the body the whole body, the person, the form

aṅga$_2$: affirme, confirme, ou exprime le désir ou l'impatience bien, d'accord; certes, vraiment; s'il vous plaît; vite
En: affirms, confirms, or express a desire or impatience, okay, sure, really, please, quickly

MW also has this stem listed in two different entries as:

aṅga$_1$: a particle implying attention, assent or desire, and sometimes impatience, it may be rendered, by well

aṅga$_2$: a limb of the body

So, in this example, *aṅga*$_1$ in SH should link to *aṅga*$_2$ in MW. Clearly, the matching can not be done simply based upon the name of the stem, but the concepts involved in the corresponding entry also need to be used. Thus, the headword linking problem is not trivial because of 1). **Homophony indexes:** SH and MW have their own systems of giving homophony indexes to the entries. Thus *aṅga*$_1$ in SH may correspond to either *aṅga*$_1$ or *aṅga*$_2$ in MW, and 2). **Cross-lingual resources:** While SH is a dictionary from Sanskrit to French, MW is a dictionary from Sanskrit to English. Thus, it is difficult to match the direct meanings as obtained after extracting the meaning text from both the lexicons.

4.1 Labeling MW with the lexical information

Pawan Goyal converted the XML file of the MW dictionary described in section 2 to strict XHTML by XSLT (Extensible Stylesheet Language Transformations). Each entry in the XHTML dataset was labeled with its lexical category information. This avoids the homophony problem across the lexical categories. For an example, the Sanskrit word *bhū* can be used as a noun, meaning 'earth' as well as a root meaning 'to become' and is given the homophony *bhū*$_2$ and *bhū*$_1$ in the MW XML dataset for the lexical categories corresponding to noun and root respectively. In the XHTML file, the nouns were labeled with a suffix '-*pr*[7]' and the roots were labeled with a suffix '-*dh*[8].C_n', where C_n denotes the corresponding class number of the verb (*gaṇa*) and varies from 1 to 10. In the case where a root entry has more than one *gaṇa*, multi-labels were given to that entry. Nominal verbs and verbs with preverb sequences were labeled with the suffix '-*dh*.Nom[9]' and '-*cpvb.*(ps,dh). *cpvb.*(ps,dh) denotes the verb with a preverb sequence 'ps' and the root 'dh'. Thus a verb '*ānī*', consisting of preverb '*ā*' and root '*nī*' was labeled as *ānī*-*cpvb.*(*ā*,*nī*).

4.2 Matching Dictionary Headwords

Once the MW was labeled with the lexical information, the headwords from the SH dictionary were matched with the MW headwords based on their lexical categories, which is explicit in the SH dictionary. As a rough estimate, there are approximately 16000 nouns, 600 roots, 110 nominal verbs and 1200 verbs with preverb sequences in the SH dictionary.

From the MW XHTML pages, the labels corresponding to each entry were extracted (called MW_{ent} henceforth), which, as discussed above, were marked with the lexical information. For each lexical category, the entry in the SH dictionary was looked up in the MW_{ent} and the search results were categorized in one of the following categories for further treatment: 'one to one' mapping of headword, 'many to one' mapping, 'one to many' mapping, 'many to many' mapping and 'not found'. For instance, 'one to many' mapping implies that a single headword in SH maps to many different headwords in MW and requires further disambiguation to select the desired match among the many possible matches.

While one to one mapping indicates that an entry in SH matches with one and only one entry in MW and the match results were used as it is, the cases of many to one mappings were very rare and were

[7] '*pr*' stands for *prātipadika*, the substantival base.
[8] '*dh*' stands for *dhātu*, the verbal base
[9] *dh*.Nom stands for the nominal verbs

dealt with in the same way as that of one to one mapping. The reasoning behind this design decision was the fact that MW has a wider coverage of lexicon entries. The next two cases, 'one to many' and 'many to one' mappings were problematic because these require further disambiguation to select exactly which of the many headwords in MW corresponds to the SH headword. To solve this problem, an approach based on matching the word concepts in the two dictionaries was employed.

4.3 Matching dictionary headwords using concept matching

A dictionary headword can be considered to be a concept-node in the particular ontology expressed by the dictionary and thus, the problem of matching dictionary headwords can be seen as the problem of ontology mapping. In the particular approach adopted by the authors, the problem of headword matching was translated to the problem of matching the concepts expressed by the particular concept-nodes, these headwords represent in different ontologies.

Matching the headword concepts was not so trivial because of the fact that while the SH dictionary stores the word concepts in French, the MW dictionary contains word concepts in English. To overcome this problem, the concepts from the SH dictionary were extracted and translated into English using Google Translate[10]. This ensured that we had the concepts for each entry in SH in the same language as that in MW. For a given word in SH, the concepts from the corresponding MW headwords were extracted. The concepts were preprocessed to remove stopwords such as {on, for, to, and, by} etc. These concepts were then considered similar to the Wordnet notion of 'synset'. Representing these concepts as a 'bag-of-words', the matching between the concept vectors X and Y was performed using the following function:

$$match(X, Y) = \sum_i \sum_j sim(X_i, Y_j)$$

where $sim(X_i, Y_j)$ denotes the similarity function between the strings X_i and Y_j, belonging to the concept vectors X and Y respectively. The similarity function accounted for the fact that even if the two strings have different suffixes, they represent the same concept. For example, 'rained' and 'raining' represent the same concept. The similarity function was directly proportional to the intersecting letters between X_i and Y_j and was inversely proportional to the maximum number of letters in X_i or Y_j. A threshold value was also given such that the similarity function only contributes to the matching score if its value is greater than the threshold.

Once an SH word was matched to all the possible MW headwords, the matching values were sorted and the headword with the highest match was marked as the suitable match. However, if the top two headwords have the same matching score (this also includes the case, where all the headwords obtained a score of 0.0), the SH headword along with all the MW headwords and their meanings were dumped in a text file interface, where the exact match was decided manually.

Note that the problem of solving 'one to many' mapping in the case of verbs with preverb sequences can be expressed in terms of matching the structure (ps,dh) between SH and MW and assuming that the roots have been mapped from SH to MW by following the procedure outlined above, this would not require the matching of headword meanings again. For example, consider the verb *saṃmā*$_1$ in SH, which is analysed as consisting of preverb *sam* and the verb *mā*$_1$. Once this *mā*$_1$ has been mapped to *mā*$_3$ in SH, this information can be utilized to match *saṃmā*$_1$ in SH with *saṃmā-cpvb*(*sam*,*mā*$_3$) in MW.

[10] http://translate.google.com/

5 Segmentation and Tagging

The first computational problem attacked in the framework of the Sanskrit Heritage platform was segmentation, i.e. *sandhi-viccheda*. Sandhi occurs in Sanskrit in several places. In generative morphology, it occurs internally for stem formation and affixes glueing, for instance for declension and conjugation. This so-called internal sandhi is complex, since it gives rise to long-distance retroflexion, not easily invertible by finite-state methods. On the other hand, junction of words within the sentence, as well as compound formation, uses a simpler notion of external sandhi, that may be modeled as a rational relation over words, invertible by finite-state techniques. It was thus decided to divide the task into generation of non-compound word forms in pre-processed databanks, and analysis of sentences in terms of these elementary forms.

A general toolkit for computational linguistics in functional programming style, called Zen (Huet, 2002), was first implemented. It uses in a systematic manner a notion of *decorated tries*, usable both as efficient data structures for lexicon representation, and applicative representation of automata and transducers. A new general framework for relational programming, called effective Eilenberg machines (Huet and Razet, 2006, 2008; Razet, 2009), was designed as a restriction to partial recursive relations of a mathematical model of automata theory due to Samuel Eilenberg (Eilenberg, 1974). This framework, allowing reactive programming over streams of data, proved adequate to the efficient solution of the segmentation problem in Sanskrit (Huet, 2005).

Since segmentation is directed by the inflected forms databases, presented as lemmatized segments, each segmentation solution gives rise to a canonical tagging, where each segment is tagged with the set of combinations of lexemes and morphological parameters used to generate it. The main problem to be faced was the enormous number of potential solutions of even moderately long sentences. In order to control this complexity, several devices were introduced. Firstly, the notion of binary compound was generalized into a notion of multi-segment pre-compounds, replacing a potentially exponential number of binary trees into a single linear pre-compound. Secondly, a dependency graph analysis was performed, on a restricted subset of semantic roles (mostly agent and patient). Each analysis gives rise to some penalties issued from graph-matching. Restricting the segmentation solutions to the minimal penalty ones yields a shallow parser with more manageable output. These developments have been well documented in publications (Huet, 2003, 2005, 2006, 2007, 2009), and thus will not be detailed further here.

The first effective collaboration effort between INRIA and Department of Sanskrit Studies, University of Hyderabad consisted in making the Saṁsādhanī dependency parser available as a further filtering on the Heritage engine segmenter, making it more precise, and allowing the visualization of the dependency graph, labeled with semantic roles. Conversely, the Heritage segmenter was made available in the Saṁsādhanī system as a plug-in, allowing the processing of sandhied corpus.

One important concern is that of the correctness of the computational processes used in the morpho-phonetics routines of the Heritage engine with respect to the Pāṇinian grammatical tradition, seen as a gold standard. To this effect, Pawan Goyal and Gérard Huet strived to give correspondences between the computation routines, and sequences of rewrite rules (*sūtra*s) from Pāṇini's grammar. The current state of this correspondence will appear as (Goyal and Huet, 2013).

The next concern was to start the development of a Sanskrit dependency treebank, a necessary development to benefit from statistical methods and obtain more precise analysers. To this effect, a cooperation between the Sanskrit Library effort and the Sanskrit Heritage platform was started, in view of using the platform for semi-automatic annotation of corpus by Sanskrit specialists. This more recent development is giving rise to a new interface to the segmenting tool, allowing the

synthetic visualisation of all segmentation solutions. The annotator may select any segment, and an automatic tool trims away from the forest of all solutions the ones that are inconsistent with the choice. This allows an exponential saving, and fast focusing on the intended interpretation.

6 Dependency Parsing

The parse of positional languages such as English are well expressed by constituency structure while languages like Sanskrit which are morphologically rich and to a large extent free word order are better represented by a dependency tree where the nodes represent the prātipadikas or dhātus and the edges between the nodes represent the relations between them expressed through the suffixes. Unlike other languages such as English where special efforts were put in as described in PARC (King et al., 2003), Stanford dependency manual (M. Marneffe and Manning, 2006) etc. for defining the set of relations, we are fortunate to have a well defined set of relations for Sanskrit described in traditional grammar books. All these relations have been compiled and classified under the two broad headings viz. inter sentential and intra sentential relations (Ramakrishnamacharyulu, 2009). This work provided a starting point for developing guidelines for annotation of Sanskrit texts at kāraka level and also for the development of an automatic parser for Sanskrit. These tags were further examined from the granularity point of view and a subset of 31 tags was chosen for annotation as well as for developing the parser (Kulkarni and Ramakrishnamacharyulu, 2013). The criterion used for deciding the granularity is simple. If one can tell one relation from the other purely on the basis of syntax or morphology, then the two relations were treated as distinct.

A generative grammar of any language provides rules of generation. For analysis, we require a mechanism by which we can reverse these rules. The reversal in general may not always be deterministic. This problem of non-determinism was well recognised by the mīmāṁsakas (exegesists) who proposed three conditions viz. ākāṅkṣā (expectancy), yogyatā (mutual compatibility), and sannidhi (proximity) as necessary for proper verbal cognition. The ākāṅkṣā is the syntactic expectancy a word has in order to co-relate to the other. This expectancy may be either mutual or one-way. Yogyatā helps in ruling out solutions which satisfy syntactic expectancy but which are not meaning-compatible. Sannidhi is defined as an utterance of words without any gap. The words with mutual expectancy should not be separated by other words. The condition of not allowing separation is only a necessary condition in the process of śābdabodha 'verbal cognition'. We have implemented a parser that uses two constraints viz. ākāṅkṣā and sannidhi. Implementing yogyatā requires a semantically rich lexicon. A study was undertaken to understand the structure of a Sanskrit thesaurus "Amarakośa" and comparison of its synonyms with those of Sanskrit Wordnet (Nair and Kulkarni, 2010; Nair, 2011). The implementation of yogyatā is postponed till a reasonable size of semantically rich lexicon is available.

The problem of parsing is modelled as finding a directed Tree from a Graph where the nodes correspond to the words in a sentence and the edges correspond to the relations between them. Ākāṅkṣā postulates the possible relations. Together with sannidhi it also imposes certain constraints. These constraints are solved using a generic constraint solver Minion [11]. The parses are ranked associating costs to various relations. Detailed description of the parser is available in the earlier publication (Kulkarni et al., 2010). After getting a parse, the sharing of arguments, clausal relations and the anaphora resolution indices are marked.

Let us now describe the communication between Saṁsādhanī and Heritage engine. Both platforms provide a segmenter as well as a parser. The segmenter of Saṁsādhanī (Kumar et al., 2010) works

[11] `http://minion.sourceforge.net`

in two stages. In the first stage it generates all possible segments following the sandhi rules, and in the second stage it validates the splits by a morphological analyser, throwing out almost 90% of the splits it has generated in the first stage. This results in slowing down the process. Heritage splitter on the other hand splits only if the split is morphologically valid, and thus is an efficient implementation. The parser of Saṁsādhanī is a full fledged one which handles various kinds of relations among words, sharing of arguments, and also anaphora resolution to some extent. The shallow parser of Heritage (Huet, 2007) uses mostly minimum information of transitivity of a verb as a sub-categorisation frame and models it as a graph-matching algorithm. In order to benefit from each other's work, we worked towards plugging-in these modules in each other's engine. Though the two systems were developed using different programming environments, their communication through UNIX pipes made their composition transparent. We just had to agree on the input and output specifications for the modules. Here we faced the linguistic challenges. These linguistic challenges owe to different systems being followed for the morphological analysis. Saṁsādhanī follows the Pāṇinian system while Heritage precompiles certain derivations into paradigm tables in the Western manner. This leads to differences in stems of the words in certain cases. For example, Heritage takes *aham* as the stem for the first person pronoun, while for Saṁsādhanī the stem is *asmad*. Similarly, in case of adjectives, Saṁsādhanī treats the feminine, neuter and masculine stems as different, whereas Heritage derives all the forms from the same stem. Another problem was mapping the verbal roots, since there are several classifications of verbs (*dhātupāṭha*s), and there are various views concerning verbal forms in *-yati* (roots of class 10 vs denominative verbs vs causative conjugations). The sole dhātupāṭha available in an exploitable electronic form is the *Mādhavīya dhātuvṛtti*[12]. An effort is on to link various *dhātuvṛttis* through the canonical index of verbal roots and canonical meanings (Shailaja and Kulkarni, 2013). Meanwhile, the number of primary verbal roots being a closed set, these roots were mapped manually based on their meanings. Then there is a problem of homonymy index. Saṁsādhanī uses Apte's Practical Sanskrit-Hindi dictionary. So there is a need to match the head entries of the Heritage Sanskrit-French dictionary with those of Apte's Sanskrit Hindi dictionary. In the current parser, since it does not attempt to disambiguate the words, the homonymy index is just ignored. The effort described in section 4 above may be repeated with Apte's dictionary to map the homonymy indices.

7 Annotation Tools

Syntactic research on Sanskrit is hindered by the fact that there does not exist a morphologically and syntactically tagged corpus of Sanskrit texts. Despite the large number of digitized texts now available at various websites, and the significant number that have been partially or fully sandhi-analysed, only relatively small portions of a small number of texts have been morphologically tagged. In June, Ralph Bunker, Gérard Huet, and Peter Scharf collaborated to create an interface that allows machine-assisted human-validated tagging. Sentences in digital texts in the Sanskrit Library (SL) are fed to the SH parser. The results of possible solutions are summarized in a user-friendly single-page interface that allows a Sanskrit scholar to select among presented words, stems, and morphological tags. As elements are validated, competing solutions are deprecated in the solutions summary and unique tags are automatically copied to the candidate solution. The interface also allows the scholar to edit and resubmit the sentence for re-analysis by the SH-parser, to edit, add, or delete words, stems, and tags, or to tag the sentence manually. Inflectional morphology tagsets designed independently by Peter Scharf and by Gérard Huet in categories familiar to Europeans and by Amba Kulkarni in Pāṇinian terms were mutually mapped and rendered convertible. A convenient dialogue box for tag construction ensures ease and validity of tagging. Results are saved in XML

[12] `http://sanskrit1.ccv.brown.edu/Sanskrit/Vyakarana/Dhatupatha/index2.html`

files that can be reviewed with the same interface. The project contracted IIT Bombay to engage two post-doctoral Sanskrit researchers to utilize the interface to tag digital texts.

We built the webpage for each sentence by parsing the HTML output of the SH parser and converting it to the SL format. This procedure permitted immediate integration of the SH and SL resources while work began to develop the next version of the SH parser with summarization.

The summary mode greatly improves the robustness of the SL/SH interface, specially for long complicated sentences, where the large number of potential solutions could possibly choke the server. Both the SH and SL servers are installed locally on machines running Ubuntu Linux or Mac OSX. The SH parser uses a locally installed Apache server. The SL webpages are served using a Tomcat server installed on the assistant's machine. The SL sentence webpage performs most of its work in Javascript in order to enhance responsiveness of the page. Installing the servers locally allows the assistants to tag the sentences independent of Internet access.

In the meantime, Amba Kulkarni has designed XML output of her parser for integration with the next version of the SL tagging interface, and Pawan Goyal and Gérard Huet have designed a new interactive HTML interface that summarizes the union of all solutions returned by the SH parser. This new interface presents a summary of possible sentence segmentations with each possible word positioned at the point where it begins beneath the sentence. As users validate particular words, inconsistent segmentations are discarded. When the number of parsing solutions is sufficiently low, the user can switch to explicit listing of solutions, allowing the semi-automatic selection of ambiguous morphological features.

8 Conclusions and Future Work

Decades of independent digitization of Sanskrit texts and lexical resources and development of Sanskrit linguistic resources have culminated in the collaborative efforts to develop the automated processing of Sanskrit text described in this paper. The emphasis of this collaboration over the past several months has been to build an annotation toolkit to help linguists create a morphologically tagged corpus. Due to the paucity of resources for the Sanskrit language, creating a large-scale annotated corpus is a prerequisite to the use of statistical methods for developing high-performance and robust Sanskrit text analysers. Since it is expensive to produce annotated corpora by hand, our efforts are directed towards reducing the annotation labor by building tools to permit semi-automated annotation. As discussed, the platform produced by the collaboration includes a state-of-the-art user interface with interactions between digital libraries and various text analysers.

The annotated corpus will help us explore the use of statistical methods to enhance our existing models for text analysis. Oliver Hellwig (Hellwig, 2009b,a) has already demonstrated promising results by using various statistics from inflected form n-grams to build a POS tagger. The morphologically tagged corpus under construction will allow the extended use of statistics on more abstract linguistic features. Since the corpus used as the source for annotation consists of complete texts that preserve the context of sentences within their discourse structures, the tagged corpus will be potentially helpful to pursue research towards discourse-level dependency parsing, including anaphora resolution and ellipsis determination.

ABSTRACT
We present a framework for the analysis of Machine Translation performance. We use multivariate linear models to determine the impact of a wide range of features on translation performance. Our assumption is that variables that most contribute to predict translation performance are the key to understand the differences between good and bad translations. During training, we learn the regression parameters that better predict translation quality using a wide range of input features based on the translation model and the first-best translation hypotheses. We use a linear regression with regularization. Our results indicate that with regularized linear regression, we can achieve higher levels of correlation between our predicted values and the actual values of the quality metrics. Our analysis shows that the performance for in-domain data is largely dependent on the characteristics of the translation model. On the other hand, out-of domain data can benefit from better reordering strategies.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE

Modelos Lineales para el Análisis del Desempeño de la Traducción Automática

En este documento presentamos una metodología para el análisis del desempeño de los sistemas de traducción automática. Utilizamos modelos lineales multivariados para determinar el impacto que diversas variables tienen en la calidad de las traducciones. En este estudio se asume que las variables que más contribuyen a predecir la calidad de las traducciones, son determinantes para entender las diferencias entre buenas y malas traducciones. Nuestros resultados demuestran que usando regresión lineal penalizada, se pueden obtener altos índices de predicción de calidad de traducción. Un análisis detallado revela que el desempeño de los sistemas de traducción frente a datos *in-domain* dependen en gran medida de las características de nuestros modelos de traducción. En contraste, la traducción de documentos *out-of-domain* está fuertemente ligada a las estrategias de reodenamiento que se utilicen.

1 Introduction

In their strive to improve machine translation, researchers constantly introduce new models and features; new training and decoding algorithms, or experiment with variations and combination of existing approaches. This is often done based on experience and intuition. The success or failure of an algorithm is based on trial and error, guided by the end-to-end automatic translation quality metrics as a measure of performance. However, little attention is paid to an equally important task: understanding how the different components in the complex SMT systems affect performance. Such knowledge could allow researchers and engineers to address specific weaknesses of their systems. For example, knowing that coverage is an issue, a team might decide to increase the amount of in-domain training data to match their specific needs. In this paper, we develop a methodology to perform this type of analysis. We propose a framework that uses linear models to identify the variables that most contribute to predict the performance of a translation system when dealing with a specific translation task. Our assumption is that variables that most contribute to predicting translation performance are the key to improving performance. Detecting them will provide leverage to design better translation systems.

In our paper, we employ linear models to predict translation quality. Linear regression is a widely known and applied technique. It models the response variable y as a weighted linear combination of a feature vector X. For instance:

$$y = \theta^T X + \varepsilon \tag{1}$$

where θ represents the parameter vector for the regression model and ε is the model error. On a multivariate regression model, Equation 1 represents an hyperplane that minimizes the error ε.

In this paper, we analyze the output of several translation systems that use the same decoder, but differ in the alignment models that they use to build their respective translation model. We use different characteristics of their corresponding translation hypotheses and translation models as input features X to predict their translation performance y in terms of three popular automatic translation quality metrics: BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) and TER (Snover et al., 2006). We use a regularized regression model to estimate the parameters of our prediction model. We use Spearman's rank correlation, Pearson's correlation and RMSE to evaluate the fitness of the regression models estimated for two different domains (News, Proceedings) and a mixed-domain, general model.
Our results indicate that using a regularized linear regression, we can achieve high levels of correlation between our predicted values and the actual values of the quality metrics. We take a closer look at the most important features according to the regression coefficients and discuss the results. We find that many features are shared as the most important predictors across the different objective functions (BLEU, Meteor, TER). Our analysis shows that the performance for in-domain data is largely dependent on the characteristics of the translation model. On the other hand, performance in out-of-domain tasks relies on characteristics such as reordering and alignment distortion. Note, however that the results are dependent on the specific datasets analyzed as well as the features included in the model. Our goal is not to provide a one-hat-fits-all set of recommendations that would address every possible scenario, but rather to provide an analytical framework that researchers can apply to their own systems.

2 Related work

The work presented in this paper is related to previous analysis done in the past few years. For instance, the correlation between characteristics of the translation model and the automatic quality metrics has previously been addressed. Lopez and Resnik (2006) make a study of different phrase-based translation model (TM) features and their impact translation quality. They also analyze variations in the translation search space of the decoder by having alignments of gradually degraded quality. On the other hand, Birch et al. (2008) study different language-pair characteristics and use them as predictors of BLEU translation quality using linear regression. Furthermore, Pado et al. (2009) use linear models to build a higher-level translation quality metric that uses features from other established metrics (e.g. BLEU, METEOR, TER) as well as Textual Entailment features (Dagan et al., 2006) and that achieves higher correlation with human judgements. However, multivariate regression, has not been used as a tool to predict translation quality based on the characteristics of the translation model.

Others have focused on identifying characteristics of the word alignments upon which these models have been built. Fraser and Marcu (2007) study how alignment quality (AER) is related to its translation quality relative BLEU. As a result, they proposed a modified version of AER to increase the correlation between alignment quality and translation performance. Lambert et al. (2009, 2010) analyze how alignment characteristics correlate with translation quality. They analyze the effect of the number of links of different types of alignments including its repercussions on the size of phrase tables and the ambiguity of the translation model. They also propose new structural metrics for alignments such as link length, distortion and crossings. In this study, we also include alignment features to characterize our translation models.

A closely related topic to this study is the task of Quality Estimation for Machine translation (Specia et al., 2009; Specia, 2011), where sentence-level prediction models are used to estimate quality of Machine Translation output. In that task, researchers have many sources of information available (typically: model scores, automatic metric scores, post-editing effort scores, etc.) and the goal is to provide a model that reliably is able to distinguish good from bad translations. The proposed work differs from Quality Estimation in two aspects: First, here we are interested in contrasting the output from several translation models, to be able to learn their shared features that help predict better quality scores. Second, we are not interested in performing a local estimation (at a sentence level) but at a document level.

Finally, recent work by Devlin and Matsoukas (2012), focuses in using variation in traits, or hypothesis characteristics to generate alternative hypotheses that are later used for system combination. In their work, they use null words, reordering, ngram-frequency, hypothesis length, among other features. In our view, the current study is complementary to that work, given that our framework allows to detect important features of "traits" which could serve as input a trait-based hypothesis selection system.

Summarizing, in this paper we propose a framework for the analysis of Machine Translation performance in terms of characteristics of the translation models and translation hypotheses. The main difference to previous research relies on the use of multivariate linear models to determine the impact of a wide range of features in translation performance. While we present results only for a phrase-based approach, this type of analysis can be applied to different approaches and language pairs. The systematic identification of important features, as proposed in this study, can help to focus development efforts in in critical areas which will help to improve translation performance.

3 Problem formulation

Our task is to find the parameter vector θ that minimizes the squared error of the fitted function $\theta^T X$. For instance, if we define the error as function of the parameter vector:

$$\varepsilon(\theta) = y - \theta^T X \tag{2}$$

then our learning task is to find $\hat{\theta}$ that minimizes the squared error:

$$\hat{\theta} = \arg\min_{\theta_i} \frac{1}{m} \varepsilon(\theta_i)^T \varepsilon(\theta_i) \tag{3}$$

where m represents the number of training examples in our training set. In other words, we want to find the weights for each of the input features X such that their weighted sum minimizes the error across the training set. This serves as a predictor function for our dependent variable (y).

In our scenario, the dependent variable is automatic metric based translation quality, in terms of BLEU, METEOR or TER. The independent variables are features extracted from the translation hypotheses and their corresponding translation models. Below, we describe each of the components of this learning problem. First, we describe the dependent and independent variables. Then, we introduce the algorithms employed for estimating the parameters.

3.1 Features and objective functions

In linear regression, we are interested in building a function $f(\theta, X) \rightarrow y$ to predict y. In our specific application, we are interested in predicting translation quality. Thus y represents a translation quality score. Since most evaluation metrics operate at a document level (i.e. they aggregate statistics of several translations) we need to adapt our formulation to be able to handle this data.

Let (s_i, t_i^M, r_i) be a source document (s_i), its MT translation (t_i^M) given a model M and its human reference translations (r_i).

We define $y_i = g(t_i^M, r_i) \rightarrow \mathbb{R}$, where $g(\cdot,\cdot)$ represents an automatic translation quality metric that takes as input a translated document t_i^M and its corresponding reference translation r_i .

Similarly, we need to use aggregated features over the full document set. As such, our features take into account (s_i, t_i^M, M). We divide these into two types of features: the translation hypothesis features (i.e. they take into account only t_i) and the translation model features (that take into account s_i and M to compute their value. Below, we introduce each group briefly.

3.1.1 Translation model features

In this study, we are interested in the characteristics of the part translation model M that is visible to the decoder when translating. Therefore, for each input document s_i we extract features from a submodel M_i s.t. $M_i \subset M$. In other words, we only keep entries of M that had a match in the corresponding sub-document s_i. In practice, this is achieved by filtering the phrase-table to the specific document s_i. The features measured are the following:

Model entropy For each of the translation features (inverse and direct, phrasal and lexical translation probabilities) in the baseline phrase-based models, we used a variation of

the conditional entropy, assuming a uniform distribution over x (i.e. $p(x) = 1/|X|$), For instance, the entropy for the inverse phrasal probability $p(f|e)$ is:

$$H_p(F_i|E_i) = 1/|E_i| \sum_{e \in E_i} \sum_{f \in F_i} p(f|e) \log p(f|e) \quad (4)$$

Translation model size For each phrase-table, we measure the number of entries (log), as well as the number of source and target singletons.

Alignment density variables We use the per-phrase pair number of links (Ayan and Dorr, 2006), source and target gaps (Guzman et al., 2009), averaged over the phrase-table.

Alignment distortion variables We use the per-phrase pair number of link-crossings (Lambert et al., 2009), relative link distortion, and a new distortion feature we call diagonality, which is the absolute value of Pearson's correlation (from 0 to 1) of the positions in the source and target words of an alignment.

3.1.2 Translation hypothesis features

These types of features include the translation cost for each of the features used in the Moses phrase-based decoder (Koehn et al., 2007). These include:

Translation feature costs The per-phrase cost for each of the translation probability features in the translation model averaged over the translation set t_i. We used the baseline translation features in the phrase-based model (Koehn et al., 2003): inverse and direct phrasal translation probabilities and inverse and direct lexical probabilities.

Lexicalized reordering costs The per phrase cost for the distance-based reordering feature and each of the three different orientations (mono, swap, discontinuous) in a bidirectional setting averaged over the translation set t_i.

Language model cost The per-word language model cost for each translation hypothesis averaged over the translation set t_i.

Additionally, we include word-alignment based features:

Word aligment variables Similarly to the translation model features, we used aligment density and alignment distortion variables, averaged over the number of phrases used.

3.2 Learning algorithm

There are several algorithms to estimate the multivariate regression parameters (regression coefficients). Here, we use a numerical optimization method with $L2$ regularization, which allow for the inclusion of many types of variables, regardless of collinearity. For the linear regression problem, the regularized cost function is defined as follows:

$$J(\theta) = \frac{1}{m} \varepsilon(\theta)^T \varepsilon(\theta) - \lambda \theta^T \theta \quad (5)$$

There are several minimization methods available for solving this problem. In our experiments, we used a Polack-Ribiere based conjugate gradient minimization routine by Carl Rasmussen[1]. We optimized the λ regularization constant to minimize cost on a cross-validation set.

3.3 Framework architecture

In order to implement this analysis framework, these are the steps that need to be followed.

1. **Translation model generation**
   The first step consists in training the MT system (or systems) of interest, using a standard training pipeline (e.g. Moses). Additionally, use a standard tuning metric (e.g. MERT) to assign optimal parameter weights for each system.

2. **Dataset selection**
   The next step consists in partitioning a dataset (or multiple datasets) for analysis into equally sized subdocuments (source and target parts). For a more diverse sample, we recommend using subdocuments extracted from different datasets.

3. **Hypothesis generation**
   Translate each of the translated subdocuments using the MT systems of interest. Additionally, generate the first-best feature-cost information (e.g. with the `-n-best-list` parameter in Moses).

4. **Feature extraction**
   Extract the relevant features corresponding to each subdocument. For the translation model features, filter each of phrase-tables of interest to each of the input subdocuments and extract the phrase-table level features. For the hypothesis features, use the extracted feature costs from the n-best list. For the translation quality, use the generated hypotheses and evaluate them against the given references.

5. **Regression**
   Use the generated data to fit the translation quality regularized regression model with an off-the-shelf ML package. Using zero-mean normalization of features is highly recommended, because it facilitates the interpretation of the results. Cross-validation is recommended to set the optimal regularization penalty.

6. **Analysis**
   Finally, obtain the regression weights and analyze them. To facilitate this task, we recommend using only the top-k largest (in magnitude) coefficients.

4 Experimental setup

For our experiments, we used a phrase-based system (Moses). For training, we used the Spanish-English portion of Europarl v5, the United Nations, and the news-commentary datasets as provided for the WMT2010 competition. The statistics of this data are shown in table 1.

UN	6.2M	190.6M	1.4M	4.9M	129.8M	330.1K
total	8.0M	236.2M	1.6M	6.4M	167.2M	387.9K

Table 1: Statistics for Raw and preprocessed data for Europarl (EU), News Commentary (NC) and UN training data. We present the total number of training examples (lines), number of tokens (tok) and the vocabulary size (voc).

4.1 Translation model training

The data was lowercased and tokenized with the standard preprocessing toolkit available in Moses. To introduce variation in our translation models, we used different types of alignments. The aligners used for these systems were a discriminative aligner (DWA) (Niehues and Vogel, 2008) with different density thresholds (0.4, 0.5, 0.6, 0.7) to have a variety of dense and sparse alignments. The DWA aligner was trained using hand aligned data from the EPPS (Lambert et al., 2006) dataset. Additionally, we used the symmetrized GIZA++ alignments using the heuristics grow-diag, grow-diag-final and grow-diag-final-and. While these variations in alignments might seem minor, in reality, as previously observed by (Guzman et al., 2009; Niehues et al., 2010) they can have a large impact on the characteristics of the translation model. In total we experimented with 7 different translation models.

Each of the systems was tuned using MERT on the WMT news2008 set.

4.2 Feature generation

For our regression training, we translated and analyzed the quality of different documents. We used a variety of different test-sets publicly available for the Spanish-English translation task for the WMT competitions[2]. The description of the different datasets is presented in Table 2.

4.2.1 Sub-document sampling

To better appreciate the effect of a translation model into translation quality, we split each dataset into used several sub-documents long enough to provide accurate translation statistics (e.g. ngram counts for BLEU), but short enough to allow us to appreciate the differences between different translation models. Sub-document splitting is a known technique that has been used previously for confidence interval estimation (Koehn, 2004).
In our study, we chose a slightly more conservative sub-document size of 100 translation sentences to get smoother results. For our experiments we used only 4 subdocuments (one hundred sentences each) from each of the 9 datasets presented in Table 2. We restricted to 4 samples to ensure that each dataset was equally represented (some datasets are shorter than others). We obtained translations for each of the 7 different translation systems. This resulted in a total set of (9x7x4) 252 different training instances for our regression models (for the cross domain set).

Table 2: Description of the different datasets used in this study. We present the number of the original sentences as well as the percentage of coverage w.r.t. to our training corpus described in Table 1

We also performed a domain-specific (news, proceedings) training, and validation of our linear models to discover which variables were most important in describing performance for each of those genres.

4.3 Regression training

We divided our experiments into three different tasks: learn predictive models for each of the objective functions (BLEU, METEOR and TER). Additionally, to showcase how this technique can be applied to a variety of different scenarios, and to get a better insight of which variables affect different translation tasks, we computed three types of domain-dependent models for each objective function. The first type is a cross-domain or general model, which predicts translation performance regardless of the translation task. For this prediction task, we used all available data from the cross-domain training samples. The second type of prediction model is for out-of-domain news-based data. For training this type of model, we only used the portion of documents that are news related (NW09, NW10). Finally we also present the results for in-domain proceedings data. For these models we used the parliamentary proceedings (WMT06, WMT07, WMT08).

4.4 Measuring regression performance

One caveat of regression, is that given enough features, it can find the appropriate weights to fit the training set. Regularization helps in part to alleviate over-fitting. However, we performed several tests to ensure that over-fitting was not a problem. Each evaluates a different aspect of our predictions. First, we obtain the root mean square error (RMSE), which gives us an idea of the distance between our predictions and the real value of the translation quality metrics we are approximating. RMSE is given by:

$$RMSE = \sqrt{\sum_{j}^{m}(y_j - \theta^T X_j)^2} \tag{6}$$

The other two metrics we used for comparison are Spearman's rho, also known as rank correlation and Pearsons's correlation. These metrics allows us to measure to which degree the

	PROC			NEWS			GENERAL		
	BLEU	MET	TER	BLEU	MET	TER	BLEU	MET	TER
Spearman	0.71	0.72	0.70	0.80	0.80	0.78	0.84	0.82	0.77
Pearson	0.70	0.74	0.65	0.79	0.89	0.84	0.84	0.83	0.78
RMSE	1.38	0.71	1.91	1.05	0.69	1.51	3.04	2.06	3.90

Table 3: Leave-one-out crossvalidation results for the regression algorithm. We present three different performance metrics: Sperman's rank correlation, Pearson correlation and RMSE. We trained different regression models to fit BLEU, Meteor and TER across three different domains (general, news and proceedings.)

values and rank (order) of our predicted variables are correlated to the values and ranks of the actual values. In other words, how monotonic is the relationship between the predicted and real values. The formula for the correlation is:

$$\rho = \frac{\sum_j^m (x_j - \bar{x})(y_j - \bar{y})}{\sqrt{\sum_j^m (y_j - \bar{y})^2 \sum_j^m (x_j - \bar{x})^2}} \tag{7}$$

where each x_j and y_j are values (for Pearson's) or ranks (for Spearman's).

4.4.1 Cross-validation

Given the reduced amount of data we had (252 training instances), we opted to use leave-one-out cross validation instead of having separate training and test sets. Thus, we trained our models in all-but-one instances, and used the remaining one for testing purposes. We repeated this process for each of our training instances. For our parameter analysis, used the average parameter values of all iterations of our cross-validation.

In Table 3 we observe the results for each of the document sets (general, news, proceedings) and for the each of the three translation quality metrics used.

First, note that correlation (both rank and real-valued) we observe large correlation values (> 0.65). This indicates that our regression algorithm is doing a good job in predicting translation quality using the available information. However, notice that we have a larger correlation values for the general set. This hints that our algorithm can benefit from having additional training data for making more accurate estimations. This is despite the fact that the general set has the highest variance, which naturally results in a higher RMSE.

5 Analysis

By using linear regression, we find the parameter vector θ that minimizes the error between our prediction and the actual values of the metrics. By looking at the values of each specific θ_i we can deduce the relative importance of the relationship between a certain feature X_i and the quality metric y.

To simplify the analysis, we only look at the five most important features in the feature vector (according to their absolute magnitude). Given that the features were originally normalized (to

Keys	Description	BLEU	MET	TER
General				
Const	Constant term	28.57	33.81	54.15

FSG	Source Gaps in the alignment of first-best		-0.73	1.16

Table 4: Most important features for the regression models for BLEU, Meteor and TER. For simplicity, only those features shared across two or more objective functions are shown. Features that are important to all metrics are marked with a $(*)$. Notice that for TER (lower is better) the weights have opposite sign than for BLEU and Meteor (higher is better)

have an average of 0 and variance of 1), the magnitude of the scores allows us to compare the strength of the relationship across features.

In Table 4 we present the top five variables for our models, for each of the different scenarios: general, proceedings and news. To further highlight the agreement of the most important features across BLEU, Meteor and TER, we only present those features which are most important to at least two of these quality metrics. We do so to facilitate the analysis.

Looking at the table, we find the most important features and their coefficients. For completeness, we also include the constant term. Simplifying, this term could be interpreted as a base or default translation quality value for any of our systems. Then, each of the feature coefficients indicates how changes in a specific feature value (assuming everything else remains unchanged) could affect performance. A positive coefficient indicates that the larger the feature value, the more gain in performance is obtained. Conversely, with a negative coefficient, the results indicate that the larger the feature value is, the larger the loss in performance. Note that BLEU and Meteor are positively defined, while TER is not. In BLEU, a higher value is considered better, while for TER, the lower the better. This is reflected by opposing signs in the corresponding feature coefficients.

5.1 General set

For the general models, one of the most important features is the direct lexical entropy of the translation model (PT4). This feature has a negative weight for translation quality which indicates that the more lexical entropy we have in our model, the worse translations we will have. In other words, given a specific source phrase f, there should be little ambiguity of which is the best translation for it.

The next important feature is the length of the source phrases used to construct our translation (FPSL). This feature indicates that the fewer phrases we need to translate a sentence, the more reliable our translations will be.

Another feature of importance is size of the translation model (PNE). This variable indicates that the more translation options we have in our translation model, the better results we will be able to obtain across metrics. This can be interpreted as the importance of coverage. Not only to reduce the number of unseen words, but also to have a good inventory of phrases.

Finally, another feature that is present is the average length of the source phrases in the translation model (PSL). In this case, the feature has a negative weight, which indicates that the longer the phrases in the translation model, the worse our translations are. This result is opposite to that of FPSL and could be interpreted in two ways: First, that this is a shortcoming of performing linear regression with two correlated features, (overshooting the weight for one variable can be compensating by setting the complementary with a negative weight). The other interpretation, which we favor, is that usually longer phrases also allows for more noise within boundaries (e.g. more source gaps in the alignment), which are an indication of a poorer model estimation.

In summary, when dealing with an unknown test set, we should aim for larger models (coverage), that are of the best quality possible (low entropy, good estimation).

5.2 News set

One interesting result comes from the news set, where the coverage is considerably lower. These results, however, need to be taken with a grain of salt, as due to the fewer number of training instances regression results (even if regularized) can be unstable.
For the news set, the direct lexical cost (FT2) is an indicator of better translations. This result is rather counter-intuitive, given that we would expect that better translations are formed using phrases with higher probability. One possible interpretation for this is that in the news set better translations require words, which are less frequently seen and which therefore are penalized with low lexical scores.

Additionally we have three juxtaposing features that regard distortion and reordering. On one hand, the number of alignment crossings at the phrase-table level (PCR) and at hypothesis level (FCR) indicate that the use of phrases that carry local reordering (more alignment crossings) has a negative effect on translation quality. On the other hand, we have a preference for hypotheses that have discontinuous reordering.
Altogether, these findings may suggest that for the news set, the phrase boundaries are not sufficient to capture the correct reordering necessary to generate good translations. We require more reordering monotonicity inside the phrases, yet to be able to move phrases as a unit for longer distances. In summary, we need to allow for more rare words to be chosen and to allow longer distance reorderings.

5.3 Proceedings set

For this type of documents, where coverage is not an issue, translations benefit from having longer distance reorderings (FD0). Also, the negative weight of variable (FTG) indicate that phrases which lack alignment support (have more target gaps in the alignment), trend to degrade the quality of the translation. Ill-defined, high entropy direct translation model lexical features will hurt performance (PT4). These results are more in line with the expected behavior of a translation system. Furthermore, as we will present later, they will allow us to perform quick fixes that will result in a gain in translation quality.

5.4 Discussion

Notice that a constant in our models is the lack of a language model component as an important predictor for translation quality. This is a result of our translations being generated using a single language model but different phrase-tables. This does not mean, however, that language models do not matter in translation, but it is merely a result of our experimental design.

As we observed, some of the results rather counter-intuitive and the interpretation is difficult, especially the case for the news test. More data needs to be analyzed in order to make more reliable estimations. However, we should note that there is a consistent agreement between features that are important for BLEU, Meteor and TER.

It is well known that the behavior of translation systems depend on many factors, not only on the techniques used for generating translation models or the choices of a specific aligner or symmetrization heuristic. While the results in our study might not be applicable to every possible scenario or language pair, our purpose is not to attain the highest level of generalization, but to encourage the use of analytic methodologies for the design of targeted systems.

6 Practical considerations

While the focus of this paper is the analysis of the most important features for translation quality, which in itself is an important goal, the application of the acquired knowledge is essential for the improvement of translation systems. Therefore, below we provide a set of pointers on how to address specific issues. Furthermore, we provide one case scenario where using this information gives positive results for the in-domain translation task.

6.1 Addressing target gaps: a practical case study

From our models for in-domain data, we observed that translation hypotheses with more target gaps have lower translation quality. Inspired by that fact, and to give the decoder more control over the gaps in the translation hypotheses we introduce a new decoding feature that takes into account the alignment gaps information and uses it dynamically at decoding time. This might be regarded as a low hanging fruit, but it showcases the potential of our methodology. As we will observe later, using such a feature enables the decoder to turn an originally liability (more gaps meant less translation quality) into an asset. The target gap decoding feature (h_{ftg}) is defined as follows:

$$h_{ftg}(e_1^I, f_1^J) = J - \sum_{j \in J} \prod_{i \in I} (1 - l(i, j)) \tag{8}$$

In our experiments, we use the weights for the new features tuned by the Minimum Error Rate optimization on the newstest2008 dataset. For comparison, we used a set of different translation

models, which were generated from the alignments we had analyzed previously (DWA-4 to DWA-7, grow-diag, grow-diag-final, grow-diag-final-and). The considered documents were both in-domain Europal test-sets (WMT06, WMT07, WMT08), the also limited domain Acquis corpus (AC) and the News test sets (NW09, NW10, SC09). The translation results are shown in Figure 1. In the image, we see the gains for each of the systems (circles) with respect to their baseline.

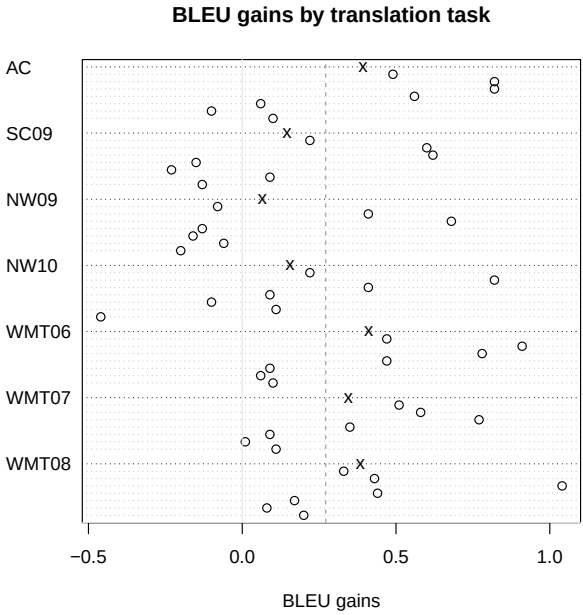

Figure 1: BLEU gains of systems using the target gap feature segmented by test-document. On the left axis we present the different document groups. On the horizontal axis, the gains of BLEU $\Delta BLEU = BLEU_{ftg} - BLEU_{bl}$. For each document set, the overall average gain is marked with an x. The general average is represented by the vertical dashed line.

Notice how for each in-domain document set, the results are consistent with what was expected, and we get significant improvements by using the feature. For instance, for the WMT06 document set, we get an improvement of 1.04 blue-points (BP) for the best-case, while the worst case increases 0.08 BP, with an average of 0.38 BP gain. For the out-of domain sets the results are mixed. For instance, for NW10, the best-case system gets an improvement of 0.8 BP, while the worse, presents a loss of 0.46 BP, with an average gain of 0.15 BP which is barely significant. On the positive side, the general average gain is 0.27 BP.

Notice also, how there is a marked difference between clusters of points. For WMT06, we observe three points with almost no gain, while other points have stronger gains. Upon analysis, we discovered that the no-gain group consists on translation models based on heuristics (grow-diag, etc.), which allow for less gaps in the target phrases than the discriminative type of alignments.

6.2 Addressing other issues

Lexical entropy has arisen as an important factor in several of our models. More entropy can lead to modeling errors. One possible alternative to address this problem is to use phrase-table filtering. Filtering techniques have already been proven effective to shrink the footprint of translation models. The challenge however is to preserve the balance between high coverage and low entropy.

Another problem is how to favor longer, yet well defined, phrases. One possibility would be to include the source entropy information for each phrase pair, as a translation feature. In this way, the decoder would be able do counterbalance length vs. entropy for the phrases.

There are many other fixes that could be suggested. Unfortunately, addressing each of them would be lengthy, and out of the scope of this paper.

7 Conclusions and future work

In this paper, we presented a framework to analyze the differences in translation quality between several translation systems based on characteristics of their translation models and hypotheses. We use multivariate linear regression to predict different translation quality metrics using a wide range of features. We measured its performance in different scenarios and with different objective functions. We analyzed the results of our regression models emphasizing on the most important features that contribute to explain quality in terms of BLEU, Meteor and TER.
Some of the conclusions from these models are straightforward and match the empirically developed intuition. However, the insight gained from this type of analysis can be valuable for designing new systems for new translation tasks. To this end, we gave hints on how this information can be used and provided a practical example on how the information from the regression models can be transformed into features to improve translation.
As a follow up, we plan to carry on with ablation studies that showcase the full potential of this analytic framework. As a future research direction, we anticipate to build a handbook in which important features in our models can be transferred to actions to improve our MT systems.

Abstract

Geolocation prediction is vital to geospatial applications like localised search and local event detection. Predominately, social media geolocation models are based on full text data, including common words with no geospatial dimension (e.g. *today*) and noisy strings (*tmrw*), potentially hampering prediction and leading to slower/more memory-intensive models. In this paper, we focus on finding location indicative words (LIWs) via feature selection, and establishing whether the reduced feature set boosts geolocation accuracy. Our results show that an information gain ratio-based approach surpasses other methods at LIW selection, outperforming state-of-the-art geolocation prediction methods by 10.6% in accuracy and reducing the mean and median of prediction error distance by 45km and 209km, respectively, on a public dataset. We further formulate notions of prediction confidence, and demonstrate that performance is even higher in cases where our model is more confident, striking a trade-off between accuracy and coverage. Finally, the identified LIWs reveal regional language differences, which could be potentially useful for lexicographers.

Keywords: Social Media, Geolocation, Feature Selection.

1 Introduction

With the ever-growing popularity of social media, massive volumes of user-generated data are produced everyday, e.g. in the form of Twitter messages (tweets) and Facebook updates.[1] This data provides many new opportunities and challenges for natural language processing. One such challenge is geolocation prediction: predicting the geolocation of a message or user based on their social media posts. In this paper, we focus on user-level geolocation based on the aggregated body of tweets from a user, and estimate the user's location at the city level.

As is well established in previous work (Cheng et al., 2010; Wing and Baldridge, 2011; Kinsella et al., 2011), it is reasonable to assume that user posts in social media reflect their geospatial locum, because lexical priors differ from region to region. For example, a user in London is much more likely to talk about *Piccadilly* and *British* than a user in New York or Beijing. That is not to say that those terms are uniquely associated with London, of course: *British* could be used by a user outside of the UK to discuss something relating to the UK. However, the use of a range of such terms with high relative frequency is strongly indicative of the fact that a user is located in London.

Our objective in this work is to automatically identify "location indicative words" (LIWs), that is words that implicitly or explicitly encode an association with a particular location. To this end, we refine the geolocation task in Section 3, and explore the impact of LIWs on user geolocation.

Our contributions are as follows: (1) we apply feature selection methods for automatically learning LIWs, and show that both accuracy and efficiency in geolocation are vastly improved using the resultant feature set, achieving state-of-the-art performance over an existing dataset; (2) we develop a city-based world division and a new global geolocation dataset, and demonstrate the effectiveness of the proposed method over this dataset;[2] (3) we conduct a pilot study on the correlation between prediction confidence, as measured by a series of heuristic variables, and classifier accuracy (see Section 5.4); and (4) we find that LIWs selected by our methods are both intuitive and have potential utility in lexicographic research on regional language differences.

The remainder of the paper is organised as follows: Section 2 introduces related work and describes the key questions investigated in this paper. Section 3 outlines the task setting, datasets and evaluation metrics used in this research. Section 4 describes different feature selection methods for extracting LIWs. Section 5 compares the results of the different feature selection methods and discusses their impact on geolocation prediction, and proposes several methods for associating beliefs with predictions. Finally, we conclude the paper and outline possible future work.

2 Related Work and Key Questions

While acknowledging potential privacy concerns (Mao et al., 2011; Pontes et al., 2012), accurate user geolocation is a key driver for location-specific services such as localised search, and has been the target of research across different disciplines. The most reliable and straightforward approach to geolocation prediction is IP-based methods (Buyukokkten et al., 1999), but in many contexts, it is not possible to access the IP of the device used to post content, or the IP is relatively uninformative (as is the case with, e.g. mobile devices). As a result, research has focused on the harder task of geolocation prediction via the textual content of a document (or document set). In the information retrieval community, e.g. web pages (Ding et al., 2000; Amitay et al., 2004; Zong et al., 2005; Silva et al., 2006), search query logs (Wang et al., 2005; Backstrom et al., 2008), Wikipedia edit logs

[1] www.twitter.com; www.facebook.com

[2] The dataset is available from http://www.csse.unimelb.edu.au/~tim/etc/coling2012-geo.tgz.

(Lieberman and Lin, 2009) and Flickr image tags (Crandall et al., 2009; Serdyukov et al., 2009; Hauff and Houben, 2012) have been used as the basis for geolocation prediction. These methods are primarily designed for longer or more homogeneous document sets. In contrast, social media data consists of terse noisy texts, presenting a challenge for these approaches. For instance, any reliance on named entity recognition is thwarted by the unedited nature of social media data, where spelling and capitalisation are much more ad hoc than in edited document collections.

The spatial data mining community has tended to approach the task via identifying geographical references in documents (also known as *geoparsing*: Leidner and Lieberman (2011)). Methods range from naive gazetteer matching and rule-based approaches (Bilhaut et al., 2003), to machine learning-based methods (mainly based on named entity recognition: Qin et al. (2010); Gelernter and Mushegian (2011)). The principal drawback of these methods is that they rely on explicit mentions of addresses or formal placenames in the text, rather than words which are more informally associated with a place. In social media data, we can't rely on a given user mentioning an address or formal placename, severely limiting the coverage of such methods.[3]

There has been a limited amount of work on geolocation prediction based on social network analysis (Backstrom et al., 2010), but social networks are dynamic and the data is often hard to obtain. In terms of text-based geolocation prediction, Cheng et al. (2010) estimate the city-level user geolocation for the continental US with a simple probabilistic model, which they complement with strictly local words and smoothing. Compared with their approach, our LIW selection requires no explicit training data and is more flexible. Wing and Baldridge (2011) use KL-divergence (Kullback and Leibler, 1951) to measure the similarity between different geo-grids specified by geospatial coordinates. Recently, Roller et al. (2012) extend this idea using a KD-tree-based adaptive grid and grid centroids, achieving state-of-the-art geolocation prediction results. Li et al. (2011) investigated the prediction of Places of Interest (POIs) based on linear rank combination of content and temporal factors. Kinsella et al. (2011) compare a variety of geolocation prediction classification models at different location granularities. Adams and Janowicz (2012) utilise external geo-reference data to infer locations. Mahmud et al. (2012) combine timezone information and content-based classifiers in a hierarchical model for geolocation. They only consider nouns, hashtags and place names as features. Recently, Li et al. (2012) integrate both friendship and content information in a probabilistic model. In addition, topic modelling has been applied to the study of geospatially-related tasks including user dialect (Eisenstein et al., 2010), topic discovery (Yin et al., 2011), object matching (Dalvi et al., 2012), factorisation of different geospatial features (Hong et al., 2012), and spatial-temporal analysis (Bauer et al., 2012).

Most work uses the full token set from the training document collection, or a relatively rudimentary approach to feature selection. In this paper, we propose a targeted approach to identify LIWs using various feature selection methods (Yang and Pedersen, 1997), focusing on two key questions:

1. What empirical properties do we observe in LIWs, and what feature selection methods best capture those properties?
2. Can we boost the accuracy of geolocation prediction through targeted identification of LIWs?

3 Geolocation Task Scope and Formulation

We approach geolocation as a text classification task. Tweets from each city are employed to represent a class. All tweets from a given user are aggregated and assigned to the city where that user is based. There are four key components to a geolocation prediction system, which we discuss

[3] An exception is automatically-generated posts from services such as FourSquare which explicitly mention an address.

in turn below: (1) the representation of different geolocations, (2) the model, (3) the data, and (4) the feature set. We then discuss evaluation metrics for geolocation prediction.

3.1 Representation: Earth Grid vs. City

Geolocations can be captured as points, or clustered based on grids (Wing and Baldridge, 2011; Roller et al., 2012) or population centres (Cheng et al., 2010; Kinsella et al., 2011). A point-based representation presents computational challenges, and is too fine-grained for our task. We opt for a city-based representation rather than a grid-based representation because there is considerable variability in the shape and size of geographical regions: a coarse-grained grid cell is perhaps appropriate in central Siberia, but for densely-populated and linguistically/culturally diverse regions such as Luxembourg, doesn't lead to a natural representation of the administrative, population-based or language boundaries in the region. A city-based representation is able to capture these boundaries more intuitively. The only downside to a city-based representation is that it is inappropriate for classifying users in rural areas. As we will see, however, the bulk of users on services such as Twitter are, unsurprisingly, based in cities.

We use the publicly-available Geoname dataset as the basis for our city categorisation.[4] Geoname contains city-level metadata, including the full city name, population, latitude and longitude. The city name is associated with hierarchical regional information, like the state and country it is based in, so that London in Britain, e.g. is distinguished from London in Canada. We hence use a city-region-country format to represent each city (e.g. Toronto, Canada is represented as toronto-08-ca, where 08 signifies the province of Ontario and ca signifies Canada). Because region coding schemes vary across different countries, we only employ the first and second level region fields in Geoname as the region. Furthermore, if the second level field is too specific (i.e. longer than 4 letters), we then only incorporate the first level region field (e.g. instead of using melbourne-07-24600-au, we use melbourne-07-au). Moreover, because cities are sometimes complex in structure (e.g. Boston in Massachusetts colloquially refers to the metropolitan area rather than the city, which is made up of cities including the cities of Boston, Revere and Chelsea), we collapse together cities which are adjacent to one another within a single administrative region, as follows:

1. Identify all cities which share the same region code (i.e. are located in the same state, province, county, etc.) in the Geoname dataset.
2. For each region, find the city c with the highest population.
3. Collapse all cities within 50km of c into c.
4. Select the next-largest city c, and repeat.
5. Remove all cities with a population less than 100K. The remaining cities form our city-based representation of geolocations.

As a result of these procedures, Boston ends up as a single city (incorporating Revere and Chelsea), but neighbouring Manchester is a discrete city (incorporating Bedford) because it is in New Hampshire. This algorithm identifies a total of 3,709 cities throughout the world.

3.2 Generative vs. Discriminative models

Generative models (e.g. naive Bayes) are based on estimation of the class priors (i.e. $P(c_i)$) and the probability of observing a given term vector given a class (i.e. $P(w_1, w_2, \ldots, w_n|c_i)$). In contrast, discriminative models are based on estimation of a given class given a term vector (i.e.

[4] http://www.geonames.org.

Name	Cities	Users	Tweets	Types	Tokens	Region
NA	378	500K	38M	4.92M	436M	North America
WORLD	3135	1.39M	12M	0.85M	103M	the world

Table 1: Details of the two datasets used in this research.

$P(c|w_1, w_2, \ldots, w_n)$). The objective of both models is to find a city $c_{max} \in C$ such that the relevant probability is maximised. We experiment with both types of models in our experiments in Section 5.3. In this paper, we choose a generative multinomial naive Bayes (NB) model as our benchmark, for two reasons: (1) it incorporates a class prior, allowing it to classify an instance in the absence of any features shared with the training data; and (2) generative models outperform discriminative models when training data is relatively scarce (Ng and Jordan, 2002).[5]

3.3 Data

In this paper, we employ two geo-tagged datasets: (1) the regional North America geolocation dataset of Roller et al. (2012) (NA hereafter), for benchmarking purposes; and (2) a novel dataset that covers the entire globe (WORLD), collected for the purposes of this research via the Twitter public Streaming API[6] from September 21 2011 to February 29 2012.

In building WORLD, we first filter non-English tweets using `langid.py`, an open-source language identification tool (Lui and Baldwin, 2012), and then apply a Twitter tokeniser (adapted from O'Connor et al. (2010)). We restrict WORLD to English tweets in order to create a dataset similar to NA (in which English is the predominant language), but covering the entire world. A further reason for only using English tweets is to control for the influence of language priors on geolocation performance. For example, we expect that a language such as Japanese would tend to be more skewed towards particular cities than English, making the task of text-based geolocation easier.[7] We further eliminate Foursquare check-ins, as they mention the location of the user and are geo-tagged, and duplicate tweets. We also remove tweets from users with less than 10 geo-tagged tweets to reduce feature sparsity. Finally, we eliminate all tweets which aren't close to a city by dividing the earth into $0.5' \times 0.5'$ grids, and discarding any tweet for which no city is found in any of the 8 neighbouring grid cells. We then assign each user to the single city in which the majority of their tweets occur. Note that the processing described in this paragraph applies only to WORLD; NA was left as-is to ensure comparability with previous work.

Analysis of a sample of 26 million tweets (not filtered as above) reveals that 92.1% of tweets are "close" to (in a neighbouring $0.5' \times 0.5'$ grid cell) of one of our 3,709 cities, and that the top 40% of cities contain 90% of the tweets, as shown in Figure 1.

A statistical profile of NA and WORLD is presented in Table 1.[8] We also analyse the spread of WORLD in Figure 2, in terms of: (1) the number of users with a given number of tweets; and (2) the number of users with differing levels of geographical spread in their tweets, measured as the average distance between each of a user's tweets and the centre of the city to which that user is allocated.[9] This analysis shows that most users have a relatively small number of geo-tagged tweets, and most

[5] There is certainly an abundance of Twitter data to train models over, but the number of Twitter users with sufficient amounts of geo-tagged tweets to be able to perform geolocation prediction is small, relative to the number of parameters in the model (the product of the number of features and classes).

[6] `https://dev.twitter.com/docs/streaming-apis`

[7] All of the methods we consider could nevertheless be easily applied to a mixed-language setting in the future.

[8] WORLD has only 3,135 (as opposed to 3,709) cities because some cities have no tweets.

[9] The geographical spread is calculated over a random sub-sample of 10 tweets for a given user, for efficiency reasons.

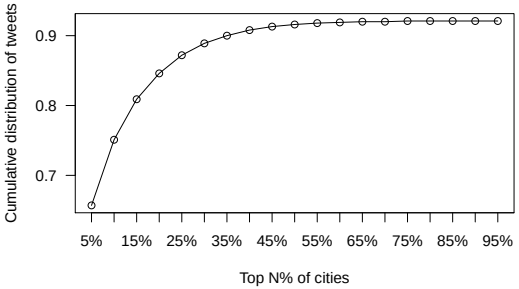

Figure 1: Cumulative coverage of tweets for increasing numbers of cities based on 26 million geo-tagged tweets.

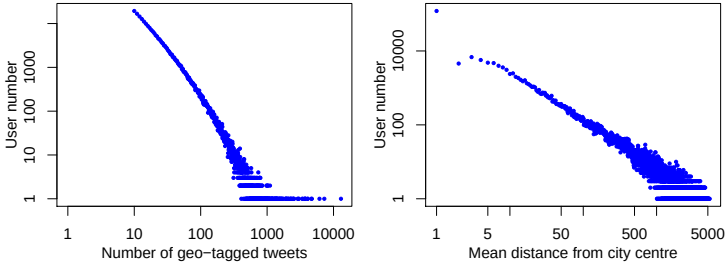

Figure 2: The number of users with different numbers of tweets, and different mean distances from the city center, for WORLD.

users stay near a single city.

3.4 Features: All unigrams vs. Location Indicative Words

Feature selection is a key contribution of this paper, based on the notion of "location indicativeness", as described in Section 4. Our hypothesis is that using only location indicative words (LIWs) as features will be more efficient and effective than using all terms. Rather than engineering new features or attempting to capture named entities or higher-order n-grams, we focus on feature selection over simple term unigrams. This is partly a pragmatic consideration (preliminary results with both named entities and higher order n-grams were disappointing). Partly, however, it is for comparability with past work, in determining whether a strategically selected subset of terms can lead to significant gains in geolocation accuracy.

3.5 Evaluation Metrics

Having reformulated the geolocation prediction task into a discrete class space through the use of our city class set, it is possible to use simple classification accuracy to evaluate our models. However, given that all of our class labels have a location (in the form of latitude–longitude coordinates),

we can also sensitise our evaluation to the distance-based error in predictions. For instance, if the correct location for a user is Seattle, USA, a prediction of Vancouver, Canada is arguably better than a prediction of Los Angeles, USA, on the basis of geospatial proximity. In line with past work (Cheng et al., 2010; Wing and Baldridge, 2011; Roller et al., 2012), we use a number of evaluation metrics which capture spatial proximity, in addition to classification accuracy:

1. **Acc** : the classification accuracy of the highest-probability prediction of the model;
2. **Acc@161** : the classification accuracy of the highest-probability prediction of the model, within a circle of radius of 100 miles (161 kilometres) from the true city centre of the user;
3. **Mean and Median Error**: mean and median prediction error, measured in kilometres between the predicted city centres and the true geolocations.

4 Finding Location Indicative Words

In this section, we experiment with different methods for ranking location indicative words. As a first step, to determine the statistical "signature" of LIWs, we manually pre-identified seed sets of: (1) local words (denoted as 1-local) that are used primarily in a single city, namely *yinz* (used in Pittsburgh to designate locals), *dippy* (used in Pittsburgh to refer to a style of fried egg, or something that can be dipped in coffee, etc.) and *hoagie* (used primarily in Philadelphia, to refer to a kind of sandwich);[10] (2) semi-local words (*n*-local) that refer to some feature of a relatively limited subset of cities, namely *ferry* (found, e.g. in Seattle, New York and Sydney), *Chinatown* (common in many of the largest cities in the USA, Canada and Australia, but much less common in European and Asian cities), and *tram* (found, e.g, in Vienna, Melbourne and Prague); and (3) common words (common) which aren't expected to have substantial regional frequency variation, namely *twitter*, *iphone* and *today*. We use this small set of 9 words to empirically motivate our feature selection approach.

4.1 Decoupling City Frequency and Word Frequency

High-utility LIWs should have both of the following properties:

1. High Term Frequency (TF): there should be a reasonable expectation of observing it for a given user;
2. High Inverse City Frequency (ICF): the term should occur in tweets associated with a relatively small number of cities.

We calculate the ICF of a term i simply as $icf_i = \frac{N}{cf_i}$, where N is the number of cities and cf_i is the number of cities with users who use that term in the training data. Combining the two together, we are seeking words with high "TF-ICF", analogous to seeking terms with high TF-IDF values in information retrieval. As with TF-IDF, however, the exact formulation for calculating the individual values and combining them into a single term weight is not necessarily obvious. A simple TF×ICF product is dominated by the TF component: for example, *twitter* scores as highly as *Jakarta*, because *twitter* has a very high TF. We resolve this issue by decoupling the two factors and applying a radix sort ranking: we first rank features by ICF then by TF, in decreasing order. This procedure has the desired effect of promoting local words and demoting common words. We present evidence for this hypothesis over the pre-identified 1-local, *n*-local and common words in Figure 3.

We can observe that 1-local words have high ICF and relatively low TF, *n*-local words have mid-range ICF and TF values, and common words have low ICF and high TF values, anecdotally justifying our feature ranking method. In order to filter out low-utility words and noise, we only keep words with

[10]These terms are identified with the aid of datasets of regional terms such as DARE `http://dare.wisc.edu/`.

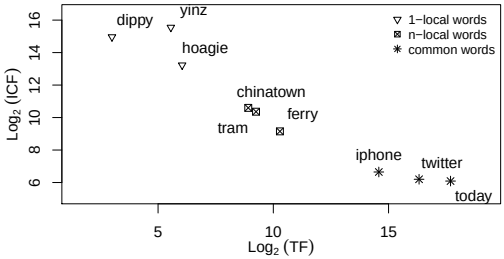

Figure 3: Inverse city frequency vs. term frequency on WORLD

1-local terms	IGR	*n*-local terms	IGR	common terms	IGR
yinz	0.287	ferry	0.125	iphone	0.012
dippy	0.169	tram	0.188	twitter	0.005
hoagie	0.183	chinatown	0.107	today	0.027

Table 2: Information gain ratio numbers for our sample terms based on WORLD

minimum character length of 3 and $TF \geq 10$ hereafter. As this approach is largely based on the inverse city frequency, we denote it as *ICF* below.

4.2 Information Gain Ratio

In addition to ICF, we also employ Information Gain (IG), an information-theoretic measure of the decrease in entropy a word brings about, where higher values indicate greater predictability on the basis of that feature. Given a set of words $\mathbf{w}$, the IG of a word $w_i \in \mathbf{w}$ across all cities (C) is calculated as follows:

$$IG(w_i) = H(C) - H(C|w_i) \quad (1)$$

$$\propto P(w_i)\sum_{j=1}^{m} P(c_j|w_i) log P(c_j|w_i) + P(\bar{w}_i)\sum_{j=1}^{m} P(c_j|\bar{w}_i) log P(c_j|\bar{w}_i) \quad (2)$$

where $H(C|w_i)$ is the conditional entropy given w_i, which is proportional to $IG(w_i)$.

Words carry varying amounts of "intrinsic entropy", which is defined as $IV(w_i) = -P(w_i) log P(w_i) - P(\bar{w}_i) log P(\bar{w}_i)$. Local/regional words occurring in a small number of cities often have a low intrinsic entropy, where non-local common words have a high intrinsic entropy. For words with comparable IGs, the words with smaller entropies are preferred. Therefore, following Quinlan (1993) we further normalise $IG(w_i)$ using the intrinsic entropy of word $IV(w_i)$, culminating in information gain ratio (IGR): $IGR(w_i) = IG(w_i)/IV(w_i)$. Returning to our earlier sample words, we present IGR scores for WORLD in Table 2.

4.3 Maximum Entropy-based Feature Weights

The previous two feature selection methods optimise across all classes simultaneously. Given that some LIWs may be strongly associated with certain locations, but are less tied to other locations, we also conduct per-class feature selection based on maximum entropy (ME) modelling.[11]

[11] https://github.com/lzhang10/maxent

1-local	Weight	City	*n*-local	Weight	City	common	Weight	City
yinz	6.8e-3	Pittsburgh, US	ferry	1.4e-2	San Francisco, US	iphone	3.2e-2	London, UK
dippy	4.6e-4	Gosport, UK	tram	2.7e-2	Melbourne, AU	twitter	3.7e-2	Bowie, US
hoagie	4.2e-3	Philadelphia, US	chinatown	9.5e-3	Singapore	today	9.3e-2	London, UK

Table 3: ME-based feature weights, and associated cities, for our sample terms based on WORLD.

Given a collection of cities C, the ME model calculates the probability of a user (e.g. represented by word sequence: $w_1, w_2, \ldots, w_n$) assigned to a city c by linearly combining eligible ME feature weights:

$$p(c|w_1, w_2, \ldots, w_n) = \frac{1}{Z} \sum_{k=1}^{m} \lambda_k f_k \tag{3}$$

Here, Z is the normalisation factor, m is the total number of features, and f_k and λ_k are the features and feature weights, respectively. As with other discriminative models, it is possible to incorporate arbitrary features into ME, however, a feature (function) in our task is canonically defined as a word w_i and a city C_j. When w_i occurs in C_j, a feature $f_k(w_i, C_j)$ is denoted as $[class = C_j \wedge w_i \in C_j]$. Each f_k maps to a feature weight denoted as $\lambda_k \in \mathscr{R}$.

Our goal is to estimate feature weights using a ME model. The key idea is that ME features connect a word and a class, with larger λ_k weights indicating stronger word–class associations. Therefore, we should be able to use the learned weights as a means of both ranking features and grouping features by cities. With all features, we generate a weight per term–class pair and rank all weights in decreasing order. Only the first rank position is kept for a given term, and this then forms the final aggregated class-independent feature rank. We don't incorporate a regularizer in our ME model (which can help to avoid over-fitting) because we already removed infrequent words (see Section 4.1), which serves as a basic count-based heuristic regularizer. The comparable results on the development and test sets presented in Sections 5.2 and 5.3 indicate that the feature selection is indeed not overfitting.

We show the ME-based weights, and associated cities, for our sample terms for the WORLD dataset in Table 3. Note that in the case of the 1-local terms *yinz* and *hoagie*, the expected city associations have been learned. Such associations could further be of use to lexicographers in identifying regional usages from social media.

5 Experiments and Analysis

5.1 Comparison of Feature Selection Methods

First we compare the effectiveness of the different feature selection methods in experiments on both NA and WORLD. In total, 214K and 96K features are extracted from the training sections of NA and WORLD, respectively. For each feature selection method, we select the $top\ N\%$ of these features, and then use the selected features in multinomial naive Bayes classification; we compare performance using Acc@161. In this section we consider results only on the development portion (10K held-out users) of each dataset; we use these results to optimise feature selection parameters which we then use in subsequent experiments in the following subsections. Results for NA are shown in Figure 4; results for WORLD are similar and thus omitted from the paper.

For ICF and IGR, Acc@161 rises as the percentage of features selected is increased, and drops dramatically at a very high percentage of selected features. The features which are selected last

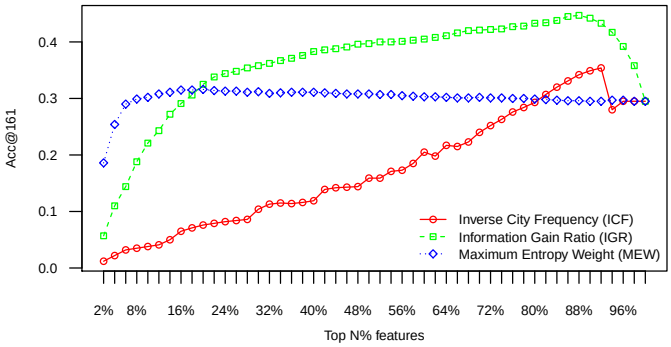

Figure 4: Acc@161 for varying percentages of features selected using the feature selection methods on the NA dataset. The Optima for ICF, IGR, and MEW are 92%, 88%, and 20%, respectively.

appear to be high-frequency function words (e.g. *the*) and common terms (e.g. *facebook*), which give little indication as to geolocation and lead to prediction errors. By identifying and removing these features, performance can be improved. On the other hand, when insufficient features are used, naive Bayes appears to be under-fitting the training data, and tends to assign classes according to the prior. For instance, when using just the top 2% of features, the most likely class in each case is monterrey-19-mx, because Spanish words are highly location indicative of the small number of Mexican Cities in the NA dataset. For maximum entropy weighting (MEW) we see a very different pattern: we attain the highest Acc@161 using the top 20% features, with performance gradually decreasing as more features are added. The overall poor performance of MEW seems to be due at least in part to the first-occurrence heuristic (see Section 4.3), which causes some non–location indicative words to be ranked higher than local words. Overall, IGR achieves the highest accuracy.

We observe that, as expected, the highly-ranked LIWs for IGR include local dialectal terms (e.g. *yinz*) and place names (e.g. *portland*). We further note the importance of word frequency on location indicativeness. For example, in WORLD the *n*-local term *tram* is roughly an order of magnitude more frequent than the 1-local term *hoagie*, but has higher IGR (see Table 2). Although 1-local words might be useful in geolocation, the impact of infrequent terms on overall accuracy is limited. In particular, frequent words with some geographical association might be more informative for geolocation than words with highly-local distribution but lower frequency. Furthermore, from this analysis it seems that a binary distinction cannot be made between local and non-local words (as in Cheng et al., 2010), but rather that many words carry some geographical indications. As for LIW selection by class (city) with MEW, city names are unsurprisingly strong indicators for locations. For example, *philadelphia* and *philly* are amongst the top-three words associated with philadelphia-pa101-us in NA. Furthermore, upper level administrative regions are also useful for geolocation with, e.g. *georgia* being a strong indicator of atlanta-ga121-us in NA.

5.2 Improved Accuracy with Location Indicative Words

In this subsection we compare the accuracy of classifiers trained using just the optimised LIWs obtained in the previous subsection to that of the full model. The performance is measured on the

Dataset	Features	Mean	Median	Acc@161	Acc
NA	Full	1010	571	0.308	0.171
	ICF	1026	533	0.359	0.209
	IGR	**814**	**260**	**0.450**	**0.260**
	MEW	890	520	0.326	0.183
WORLD	Full	2215	917	0.203	0.081
	ICF	2299	878	0.239	0.107
	IGR	3002	926	**0.259**	**0.124**
	MEW	**1953**	**646**	0.241	0.103

Table 4: Geolocation performance of the full feature set compared to that of each feature selection methodology on both NA and WORLD. The best results for each dataset and accuracy metric are shown in boldface.

test data (10K held-out users for both NA and WORLD).

Results on NA show that using LIWs offers an improvement over the full feature set for all evaluation metrics and all feature selection approaches (except for ICF with mean distance). On WORLD the findings are similar in terms of Acc and Acc@161, however, mean distance in particular is substantially higher for IGR. We hypothesize that this is because incorrect world-level predictions can potentially be off by thousands of kilometres, driving up the mean distance more than the other metrics. Overall, these numbers clearly demonstrate that identification of LIWs can improve text-based geolocation. IGR performs best in terms of Acc@161 on both datasets, achieving a 14.2% and 5.6% absolute improvement over the full feature set on NA and WORLD, respectively. Finally, it is worth noting that the raw accuracy on NA is higher than that on WORLD. This is unsurprising because the smaller average number of tweets and larger number of classes for WORLD make it a more challenging dataset.

5.3 Comparison with Benchmarks

We further compare the best-performing method from Section 5.2 to benchmarks and baselines. Here we only consider NA, for which results have been previously reported. We experiment with two partitionings of the Earth's surface: (1) the new city-based division used in the previous experiments, and (2) the KD-tree based partitioning of Roller et al. (2012) which creates grid cells containing roughly even amounts of data, but differing geographical sizes, such that higher-population areas are represented with finer-grained grids. We consider the following methods:

Baseline Because the geographical distribution of tweets is skewed towards higher-population areas (as indicated in Figure 1), we consider a most-frequent class baseline. We assign all users the coordinates of the most-common city centre or KD-tree grid centroid in the training data.

Placemaker Following Kinsella et al. (2011), we obtain results from Yahoo! Placemaker,[12] a publicly-available geolocation service. The first 50K bytes (the maximum query length allowed by Placemaker) from the tweets for each user are passed to Placemaker as queries. The returned city centre predictions are mapped to our collapsed city representations. For queries without results, or with a predicted location outside NA, we back off to the baseline.

KL divergence The previous best published results over NA were achieved using KL divergence and the KD-tree grid. Specifically, KL divergence is measured between the distribution of terms in a user's aggregated tweets and that in each grid cell, with the predicted location being the centroid of the most-similar grid cell. We use the same settings as Roller et al..

Multinomial naive Bayes This is the model used in Section 5.2.

[12] `http://developer.yahoo.com/geo/placemaker/`, accessed in August 2012.

Partition	Method	Mean	Median	Acc@161	Acc
KD-tree	Baseline	1528	1189	0.118	0.003
	KL	859	469	0.344	0.117
	KL+IGR	766	**273**	**0.437**	**0.161**
	NB	835	404	0.367	0.122
	NB+IGR	**763**	280	0.432	0.153
City	Baseline	2707	3089	0.062	0.003
	Placemaker	2188	1857	0.150	0.049
	NB	1010	571	0.308	0.171
	NB+IGR	**814**	**260**	**0.450**	**0.260**
	ME	1336	878	0.232	0.129
	ME+IGR	891	369	0.406	0.229

Table 5: Geolocation performance for baselines, KL divergence (KL), multinomial naive Bayes (NB), and Maximum Entropy (ME). Results using the optimised feature set (+IGR) are also shown. The best-performing method for each evaluation metric and partitioning is shown in boldface.

Maximum entropy The features from Section 5.2 with a maximum entropy learner.[13]

The results are shown in Table 5. We begin by considering the baseline results. The most-frequent class for the KD-tree grid is New York (the state), while for the city-based partition, it is los angeles-ca037-us. Both baselines perform below the other models, suggesting that geolocation cannot be trivially solved. Looking at the results for Placemaker (which we only consider for the city-based partition) we see very high mean and median scores. This appears to be due to the scope and domain of this service, which predicts locations at the world level, whereas the other methods are restricted to North America.

The KL-divergence method of Roller et al. (KL) and multinomial naive Bayes method (NB) both clearly outperform the baseline. Moreover, approaches incorporating the best features selected in Section 5.2 — KL+IGR and NB+IGR — both outperform KL and NB, demonstrating that for a variety of approaches, identification of LIWs can improve text-based geolocation.[14] From the results on the KD-tree grid it is not decisively clear which of KL or NB is better for our task: in terms of Acc@161, e.g., NB outperforms KL, but KL+IGR outperforms NB+IGR.

Turning to the results for the city-based grid, our best-performing method from Section 5.2 (City, NB+IGR) performs best overall in terms of Acc, Acc@161, and median distance, confirming the effectiveness of LIWs. Compared to the best published results at the time of writing (KD-tree, KL), our method offers a 10.6% absolute improvement in terms of Acc@161, and reduces the mean and median prediction error by 45Km and 209Km, respectively.[15] Finally, although maximum entropy (ME) performs poorly compared to NB, ME+IGR is still a substantial improvement over ME. We plan to further explore the reasons for ME's poor performance in future work.

In addition to improving the accuracy of geolocation, LIW-based feature selection leads to more compact models, which are more efficient in terms of computational processing and memory.

[13] Although there are many other classifiers we could consider, when sufficient training data for each class is available, the performance of different methods is comparable (Yang and Liu, 1999). Moreover, many state-of-the-art classifiers (Wu et al., 2007) are not primarily designed for massively multi-class problems (e.g. support vector machines (Vapnik, 1995)), or are not efficient when applied to such problems (e.g. *k*-nearest neighbour (Steinbach et al., 2006)).

[14] Note that after LIWs are selected, a small proportion of users end up with no features. These users are not geolocatable in the case of KL, a discriminative model. We turn off feature selection for such users, and backoff to the full feature set, so that the number of test cases is consistent in different settings.

[15] Acc is not comparable for the different partitionings, i.e. KD-tree vs. city, because of the differing numbers of grid cells. High accuracy could trivially be achieved with a very coarse-grained grid.

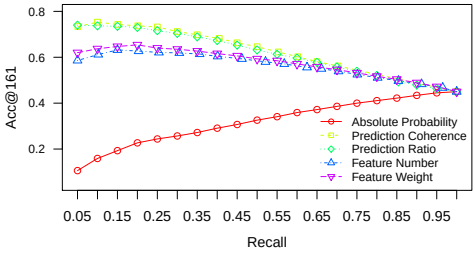

Figure 5: Acc@161 for classification of the top-n% most-confident predictions for each measure of prediction confidence.

Comparing the model based on LIWs selected using IGR with the full model, we find that the prediction time is faster by a factor of roughly five.

5.4 The Confidence of Geolocation Prediction

In the task setup to date, we have forced our models to geolocate all users. In practice, however, many users don't mention any explicitly geolocating terms in their posts, making the task nigh on impossible even for a human oracle. An alternative approach would be to predict a user geolocation only when the model is confident of its prediction. Here, we take our best-performing method (city-based grid, multinomial naive Bayes classifier with LIWs selected using IGR) and consider different methods for selecting users where the model is sufficiently confident of its prediction:

Absolute probability (AP) Only consider predictions with probability above a specified threshold.

Probability ratio (PR) If the model is confident in its prediction, the first prediction will tend to be much more probable than other predictions. We formulate this intuition as PR, the ratio of the probability of the first and second predictions.

Prediction coherence (PC) We hypothesize that for reliable predictions, the top-ranked locations will tend to be geographically close. In this preliminary exploration of coherence, we formulate PC as the sum of the reciprocal ranks of the predictions corresponding to the second-level administrative region in our class representation (i.e. state or province) of the top-ranking prediction, calculated over the top-10 predictions. For example, suppose the top-10 second-level predictions were in the following states: TX, FL, TX, TX, CA, TX, TX, FL, CA, NY. The top-ranking state-level prediction is therefore TX, which also occurs at ranks 3, 4, 6 and 7. In this case, PC would be $\frac{1}{1} + \frac{1}{3} + \frac{1}{4} + \frac{1}{6} + \frac{1}{7}$.

Feature number (FN) We take the number of features found in a user's posts as the prediction accuracy. The intuition here is that a geolocation prediction based on more features is more reliable than a prediction based on less features.

Feature weight (FW) Similar to FN, but in this case we use the sum of IGR of all features, rather than just the number of features.

For this analysis we use the NA dataset. We sort the predictions by confidence (independently for each measure of prediction confidence) and measure Acc@161 amongst the top-n% of predictions for the following values of n: $\{0.0, 0.05, ..., 1.0\}$, akin to a precision–recall curve. Results are shown in Figure 5. The naive AP method is least reliable with, surprisingly, accuracy increasing

as AP decreases. It appears that the raw probabilities are not an accurate reflection of prediction confidence. In comparison, PR — which focuses on relative, as opposed to raw, probabilities — performs much better, with higher PR generally corresponding to higher accuracy. Nevertheless, the best-performing method is PC, which only uses the probabilities to rank the class predictions, and roughly captures the geographical proximity of the top predictions, confirming our hypothesis that accuracy will tend to be higher when the top-ranked predictions are relatively near each other. For PC, Acc@161 is about 75% when only the 10% most-confident predictions are considered, which is well above the 45% Acc@161 for the full dataset. FN and FW show similar trends to PC and PR, but don't perform as well. These experiments suggest that there is indeed a trade-off between coverage and accuracy, which could be exploited to obtain higher-accuracy predictions by applications that do not require all the data to be classified.

Discussion and Conclusion

We have investigated various methods for applying feature selection to identify LIWs (location indicative words) for the task of text-based geolocation. Our results on two different datasets demonstrate that using LIWs leads to an improvement over using a full feature set for a variety of evaluation metrics. Furthermore, our best method using LIWs outperforms the previous state-of-the-art on a standardised dataset, and is much faster. These results demonstrate the potential for improving text-based geolocation through feature selection. The LIWs identified by our method, and their associations with particular locations, may also be useful for lexicographers in describing regional usage and variation. We further considered prediction confidence, and showed that it is possible to strike a trade-off between coverage and accuracy; given the very large amount of Twitter data available, a system which gives more-accurate predictions, but only for a subset of the data, may be useful in some applications. Finally, the proposed LIW selection methods, although developed and evaluated on English datasets, could be easily applied in a multilingual setting.

This paper (as well as previous work on this topic) only considered tweets with gold-standard geo-tags, but in an applied setting we envision these models being applied to non-geotagged tweets to infer their locations. However, it might not be the case that geo-tagged tweets (typically sent from a GPS-enabled device such as a smart phone) have the same properties as those which are not geo-tagged (and are sent from a variety of devices, including desktop computers). In future work, we intend to investigate the relationship between these two sources of data. Although the aim of this paper was to examine the relationship between text and location, there are nevertheless further sources of information available on Twitter, such as user profile and social network information, that could be leveraged in a method for geolocation. In future work we intend to consider the incorporation of such information into our methods. Finally, this paper proposed a new city-based representation of locations. We plan to continue in this direction in future work to explore alternative regional partitionings, as well as hierarchical classification methods.

ABSTRACT
We investigate the problem of reading level assessment for German texts on a newly compiled corpus of freely available *easy* and *difficult* articles, targeted at adult and child readers respectively. We adapt a wide range of syntactic, lexical and language model features from previous research on English and combined them with new features that make use of the rich morphology of German. We show that readability classification for German based on these features is highly successful, reaching 89.7% accuracy, with the new morphological features making an important contribution.

TITLE AND ABSTRACT IN GERMAN

Lesbarkeitsklassifizierung für das Deutsche mit lexikalischen, syntaktischen und morphologischen Merkmalen

Wir untersuchen das Problem der Lesbarkeitsklassifizierung für deutsche Texte anhand eines neuen Korpus frei zugänglicher Artikel, die einerseits Erwachsene und andererseits Kinder als Zielgruppe haben. Wir adaptieren eine Vielzahl syntaktischer, lexikalischer und *language model* Merkmale aus der englischen Lesbarkeitsforschung und kombinierten sie mit neuen Merkmalen, die sich die ausgeprägte Morphologie des Deutschen zu Nutze machen. Wir zeigen, dass diese Merkmale sehr erfolgreich dazu eingesetzt werden können, deutsche Texte nach ihrer Lesbarkeit zu klassifizieren. In unseren Experimenten erreicht die Klassifikation eine Genauigkeit von 89,7%, wozu die neuen morphologischen Merkmale einen wichtigen Beitrag leisten.

KEYWORDS: Readability, Complexity, Simplification, Second Language Acquisition, Proficiency.

KEYWORDS IN GERMAN: Lesbarkeit, Komplexität, Textvereinfachung, Zweitspracherwerb, Sprachniveau.

COLING 2012, Mumbai, December 2012.

1 Introduction

The last decade has seen an increasing interest in building automatic readability assessment systems. Such systems can help users in finding texts that they can understand, for example by identifying appropriate texts from the huge number of documents available on the web (Bennöhr, 2005; Miltsakaki, 2009; Ott and Meurers, 2010; Collins-Thompson, 2011). This is particularly relevant for first or second language learners as well as for people with intellectual disabilities. Readability classification systems can also be used as a starting point in identifying targets for text simplification, with the goal of ensuring that information can be accessed and understood by a broader audience. The need for such applications is likely to increase given the increasing relevance of information from the web for everyday life.

While early research on readability assessment derived readability formulae from superficial language properties, most current research takes advantage of natural language processing tools to analyze the texts. The resulting features are combined for classification using machine learning. While syntactic, lexical, language model and discourse features have been examined extensively in readability classification, the influence of morphological indicators has received only little attention. This may also be due to the fact that most of the readability research has focused on English. However, there is some recent interest in automatic readability assessment for other languages such as French, German, Italian and Portuguese.

In this paper, we present and evaluate a readability classification approach for German, as a first step towards our overall goal of identifying targets for text simplification. Since there are no existing German corpora that met our needs, we created a two-level readability corpus collected from publicly accessible websites. On this basis, we explore a wide range of syntactic, lexical and language model features derived from previous research on English. In addition, as German has a rich morphology, morphological features may also provide valuable information on the reading level. Hence, we devised a new set of features based on the inflectional and derivational morphology of German. We then conducted classification experiments to examine how well the different feature groups work as indicators of the reading level. We also compared the performance of these feature groups in isolation as well as in combination with each other. To summarize, in this paper, we show that the features used in English readability research can be successfully applied to German, and that the addition of German language-specific morphological features will improve the classification accuracy.

The paper is organized as follows: Section 2 summarizes related work in the field of readability assessment. Section 3 provides information about the origin and nature of our dataset. Section 4 introduces our approach to readability classification including the features we used. Section 5 describes our experimental setup and the results. We conclude this paper with a discussion of the results and directions of future work.

2 Related Work

Research on English readability assessment has a long history spanning several decades (DuBay, 2006). Many traditional readability formulae, such as the Flesch-Kincaid score (Kincaid et al., 1975), relied on easy to calculate approximations of syntactic or lexical complexity, such as number of characters per word or average sentence length. Other early approaches, like the Dale-Chall formula (Chall and Dale, 1995), approximated semantic complexity by using word frequency lists. More recent approaches benefit from advances in natural language processing and machine learning. Si and Callan (2001) and Collins-Thompson and Callan (2004)

used a unigram model for readability classification. Heilman et al. (2007, 2008) combined unigram models with grammatical features and trained machine learning models for readability assessment. Their aim in the context of the *REAP* project (`http://reap.cs.cmu.edu`) was to retrieve reading material for language learners.

Schwarm and Ostendorf (2005) and Petersen and Ostendorf (2009) combined traditional features with syntactic parse tree features and n-gram language models. Their work is based on the *Weekly Reader*, an educational newspaper consisting of articles at four reading levels. Feng (2010) also used the *Weekly Reader* dataset to build classification models with several discourse features alongside parse features, language model features, and traditional features. The discourse features are motivated by the cognitive processes involved in text understanding and underline their focus on finding appropriate texts for people with mild intellectual disabilities. Crossley and McNamara (2011) and the overall *CohMetrix* project (`http://cohmetrix.memphis.edu`) also explored a wide range of cognitively grounded features related to text cohesion and coherence. Vajjala and Meurers (2012) showed that reading level assessment can benefit from Second Language Acquisition (SLA) research. They enriched the lexical and syntactic features from previous approaches by using features derived from measures of the language proficiency of learners.

Readability research on English has ignored morphological features to a large extent. However, with recent interest in readability assessment for languages other than English, the use of features which are relevant for other languages is gaining some prominence. Research on Italian and French readability is taking advantage of the rich verbal morphology of these languages. Dell'Orletta et al. (2011) worked with a corpus of Italian newspaper text at two different reading levels. They used a mixture of traditional, morpho-syntactic, lexical and syntactic features for building a two class readability model for Italian. Among others, their feature set included verbal mood based features, which relied on the rich verbal morphology of Italian. François and Fairon (2012) built their French readability classification model using a text book corpus designed for adult learners of French. They also considered verb tense and mood based text difficulty features along with several other features. Readability assessment was also studied for Portuguese using various lexical, syntactic, discourse and language modeling features derived from English research (dos Santos Marujo, 2009; Aluisio et al., 2010). Lau (2006) utilized the nature of the Chinese script to form several sub-character and character level features in addition to the common word and sentence level features for Chinese readability classification.

The only published research on German readability assessment that we know of is the *DeLite* readability checker (Vor der Brück and Hartrumpf, 2007; Vor der Brück et al., 2008a,b). *DeLite* was built using a human annotated corpus of 500 texts from the municipal domain, such as city ordinances. It was classified into ten levels of difficulty. The corpus includes mostly legal texts and is generally at a higher level of reading difficulty compared to ordinary texts. *DeLite* makes use of a comprehensive set of features that aim to capture readability at lexical, syntactic, semantic and discourse levels. They also considered some morphological indicators, such as the number of nouns that are derived from adjectives or verbs, the complexity of compounds, and the number of acronyms.

Due to the lack of multi-level graded corpora for languages other than English, researchers often built readability models from freely available collections of two or three classes collected from the web. Dell'Orletta et al. (2011), Aluisio et al. (2010), and Klerke and Søgaard (2012)

report on creating and experimenting with such corpora in Italian, Portuguese and Danish respectively. Napoles and Dredze (2010) performed a similar experiment for English with a corpus built from Wikipedia and Simple Wikipedia. Incidentally, all of these groups worked on readability assessment in the context of text simplification.

3 Data: The *GEO-GEOlino* Corpus

Research on the readability classification of English texts has often used the *Weekly Reader* as a gold standard. An established resource that could be compared to this dataset does not exist for German. The only existing German readability corpus is the one collected for the readability checker *DeLite*, but as discussed in the previous section, it is a domain specific collection, consisting mostly of legal texts from the municipal domain. Hence, we created our own two class corpus (*easy* vs. *difficult*) with articles collected from the web, based on the assumption that texts written for children are easier to read than those for adults.

We crawled articles from the websites of two related German magazines, *GEO* (`http://www.geo.de`) and *GEOlino* (`http://www.geolino.de`), published by Gruner & Jahr. *GEO* is a monthly magazine containing articles in the domains of nature, culture and science. *GEOlino* is a magazine on similar topics by the same publisher, but it is targeted at children from age 8–14. *GEOlino* it is not a simplified version of *GEO*; the content is specifically created for child readers.

Table 1 shows the distribution of the articles we crawled across all topics. The overall corpus we collected consists of 4603 articles from both websites.[1]

	GEOlino			GEO		
Topics:	**Num. tokens**	**Num. sentences**	**Num. articles**	**Num. tokens**	**Num. sentences**	**Num. articles**
Nature	189 004	13 976	321	877 920	54 300	1 459
Human	412 769	33 497	901	443 221	29 482	662
Technology	57 819	4 356	83	204 891	12 674	392
Culture	–	–	–	442 888	30 748	463
Creative	169 800	12 354	322	–	–	–
Total	829 392	65 183	1 627	1 968 920	127 204	2 976

Table 1: Composition of the *GEO-GEOlino* corpus

For the experiments discussed in this paper, we randomly selected an equal number of documents from each of the topics that existed in both *GEO* and *GEOlino*: 321 articles from Nature, 662 from Human and 83 from Technology. We cleaned the data obtained from the web by removing all html markup, meta data, and non-text content. We also eliminated duplicate articles. We then tagged the corpus using a Java interface[2] to the RFTagger (Schmid and Laws, 2008), a statistical tagger that provides a fine grained morphological analysis. The tagged articles, mapped to the Stuttgart-Tübingen Tagset (STTS) for German, were then parsed with the Stanford Parser for German (Rafferty and Manning, 2008), which comes with a German model trained on NEGRA.[3]

4 Features

We modeled readability using five groups of features: features from traditional readability formulas, lexical features, syntactic features, language model features, and morphological features. For the first three groups, we essentially adapted the English features described by

[1] Contact us by email if you are interested in using this corpus for non-commercial research purposes.
[2] `http://www.sfs.uni-tuebingen.de/~nott/rftj-public/`
[3] `http://www.coli.uni-saarland.de/projects/sfb378/negra-corpus/negra-corpus.html`

Vajjala and Meurers (2012) to German. Given the effectiveness of language models in previous work on English (e.g., Petersen and Ostendorf, 2009; Feng, 2010), we included language model features as our fourth group. In the fifth group, we explored new features that encode aspects of the inflectional and derivational morphology and compounding of German.

4.1 Traditional Features (TRAD)

The traditional features group we used includes the average sentence length in words, the average number of characters, and syllables per word. These properties have often been used in traditional readability formulae (e.g., Kincaid et al., 1975). Although they do not analyze readability at a deeper level, they have been popular in the English readability literature for a long time. They also constitute a useful baseline against which to interpret the effect of broader and deeper analysis in current readability classification.

4.2 Lexical Features (LEX)

Vajjala and Meurers (2012) employed the lexical richness measures that were originally developed for judging the proficiency of second language learners (Lu, 2011) for English readability classification. We adapted these features for German and added some further features we considered worth exploring. We added the noun token ratio, the verb token ratio and the verb-noun token ratio as additional lexical features, with the hypothesis that easy documents will include fewer nominalizations compared to difficult documents. Additionally, we added the ratio of *sein* to verbs and *haben* to verbs. The list of all implemented lexical features is shown in Table 2. As the class of lexical words (Lex) mentioned in several of the formulas, we used nouns, adjectives, adverbs, and full verbs – i.e., in terms of the STTS tagset: AD.*, N.*, VV.*.

Lexical Richness Features from SLA	**Other Lexical Features**
Type-Token Ratio	*sein* to Verb Token Ratio
Root Type-Token Ratio	*haben* to Verb Token Ratio
Corrected Type-Token Ratio	Avg. Num. Characters per word
Bilogarithmic Type-Token Ratio	Avg. Num. Syllables per word
Uber Index $= \log(Typ^2)/\log(Tok/Typ)$	Verb Token Ratio $= Tok_{Verb}/Tok$
Measure of Textual Lexical Diversity (McCarthy, 2005)	Noun Token Ratio
Lexical Density $= Tok_{Lex}/Tok$	Verb-Noun Token Ratio
Lexical Word Variation $= Typ_{Lex}/Tok_{Lex}$	
Noun Variation $= Typ_{Noun}/Tok_{Lex}$	
Adjective Variation, Adverb Variation	
Modifier Variation $= (Typ_{Adj} + Typ_{Adv})/Tok_{Lex}$	
Verb Variation 1 $= Typ_{Verb}/Tok_{Verb}$	
Verb Variation 2 $= Typ_{Verb}/Tok_{Lex}$	
Squared Verb Variation 1 $= Typ^2_{Verb}/Tok_{Verb}$	
Corrected Verb Variation 1 $= Typ_{Verb}/\sqrt{2Tok_{Verb}}$	

Table 2: The lexical features we implemented

4.3 Syntactic Features (SYN)

For the syntactic features, we adapted a range of parse tree based features from English readability assessment research to German. The features include the average parse tree height

and the average length and number of NPs, VPs and PPs per sentence (Petersen and Ostendorf, 2009; Feng, 2010). Following Vajjala and Meurers (2012), we also adapted proficiency measures from SLA (Lu, 2010), including various ratios that try to capture level of embedding and coordination, length of production unit, and relationships between specific structures. Table 3 lists all the syntactic features we implemented.

Syntactic Features from SLA	**Other Syntactic Features**
Avg. length of a clause	Num. NPs per sentence
Avg. length of a sentence	Num. VPs per sentence
Avg. length of a T-unit	Num. PPs per sentence
Num. of Clauses per Sentence	Num. VZs per sentence
Num. of T-Units per sentence	Avg. length of a NP
Num. of Clauses per T-unit	Avg. length of a VP
Num. of Complex-T-Units per T-unit	Avg. length of a PP
Dependent Clause to Clause Ratio	Num. Dependent Clauses per sentence
Dependent Clause to T-unit Ratio	Num. Complex-T units per sentence
Co-ordinate Phrases per Clause	Co-ordinate Phrases per sentence
Co-ordinate Phrases per T-unit	Avg. parse tree height
Complex Nominals per Clause	
Complex Nominals per T-unit	
Verb phrases per T-unit	

Table 3: The syntactic features we implemented

Three basic production units, *sentences*, *clauses*, and *T-Units* are relevant for computing these measures. We adapted their definitions from those used in the SLA literature (Lu, 2010). A *sentence* is a group of words delimited with a punctuation mark (period, question mark, exclamation mark, or quotation mark). We implemented sentence splitting using the Stanford Document Processor with the default tokenizer factory.

Clauses for English are characterized as structures that contain a subject and a finite verb (Hunt, 1965). Different from English, German allows subjectless sentences, so we consider all maximal projections headed by a finite verb, as well as elliptical constructions where the finite verb is omitted. One word exclamations such as *Stop!* are excluded. In the parsed data, this notion of a *clause* corresponds to the category S of the NEGRA annotation scheme (Skut et al., 1997).

T-Units are defined as "one main clause plus any subordinate clause or non clausal structure that is attached to or embedded in it" (Hunt 1970, p. 4; cf. Lu, 2010). Only independent clauses (including their dependents) count as a T-unit. Consider, for example, the sentence in (1).

(1) Tom fragt Maria, ob sie die Wahrheit sagt, aber sie antwortet nicht.
Tom asks Maria whether she the truth says but she answers not
'Tom asks Maria, whether she says the truth, but she does not answer.'

Figure 1 shows the parse tree of this example sentence. It includes three clauses (shown by the category S) but only two T-Units (indicated by rectangles). One of the clauses is a dependent clause (underlined) and the T-Unit containing it is therefore a complex T-Unit.

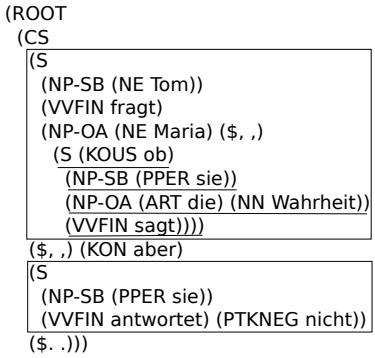

Figure 1: Parse tree of example sentence (1)

At the phrasal level, *coordinated phrases* are defined as coordinated adjective, adverb, noun, and verb phrases. *Verb phrases* include non-finite as well as finite verb phrases. Finally, *complex nominals* are nouns with an adjective, possessive, possessive, prepositional phrase, relative clause, participle, or appositive; nominal clauses, gerunds and infinitives in subject position are also included.

In addition to adapting the patterns and categories for German, we also added VZs ('zu'-marked infinitives) per phrase as a feature. In the so-called incoherent constructions in German (Bech, 1955; Meurers, 2000), the verb always appears in the 'zu'-infinitival form and the phrase it heads is similar in function to a subordinate clause. This naturally is only a coarse approximation of clause-like infinitival constructions given that many verbs selecting 'zu'-infinitivals can alternatively appear in non-clausal, coherent constructions.

On the practical side, TregEx (Levy and Andrew, 2006) was used to extract the patterns that identify the relevant syntactic structures. Lu (2010) created such patterns for English. We modified those patterns to suit the German parse tree structures and categories. As an example, (2a) shows the TregEx pattern for coordinated phrases, for which (2b) is an example structure from our corpus (translating to *parents and children*). (3a) shows the regular expression for complex nominals and (3b) a corpus instance matching that pattern (*a spoiled child*).

(2) a. CAC|CAVP|CNP|CVP
b. (CNP (NN Eltern) (KON und) (NN Kindern))

(3) a. @NP|NN|NE < S | < @AP | < @PP | < @PP | < ADJA|ORD
b. (NP (ART ein) (ADJA verwöhntes) (NN Kind))

4.4 Language Model Features

Following Petersen and Ostendorf (2009), we chose a separate data set for training the language models. For building the *easy* language model, we collected 2000 articles from *News4Kids* (`http://www.news4kids.de`), a German website which adapts news found on the web for children. The *difficult* language model was created using 2000 articles from the website of the

German news channel *NTV* (`http://www.n-tv.de`). For these web texts, we followed the same preprocessing routine as explained in Section 3.

Schwarm and Ostendorf (2005) and Feng (2010) suggested that mixed models combining words and parts of speech are more effective for readability assessment than simple word based models. But Petersen and Ostendorf (2009) reached the opposite conclusion. We experimented with both types of models. For preparing the mixed models, we followed the procedure suggested in Petersen and Ostendorf (2009). We trained a bag-of-words classifier with our language modeling dataset (*News4Kids* and *NTV*) and employed Information Gain (Yang and Pedersen, 1997) for feature selection. All words below an empirically determined threshold were replaced by their part of speech.

We used the SRI Language Modeling toolkit (Stolcke, 2002) for training unigram, bigram and trigram models on the *words-only* and *mixed word/part of speech* corpora for each of our two reading levels. This resulted in twelve language models. For all models, we selected Kneyser-Ney smoothing (Chen and Goodman, 1999) as smoothing technique. The perplexity scores from all twelve language models were used as features for building the classifier. These features are listed in Table 4.

Level of Difficulty	Word Based Model	Mixed Model
Easy	Unigram perplexity	Unigram perplexity
	Bigram perplexity	Bigram perplexity
	Trigram perplexity	Trigram perplexity
Difficult	Unigram perplexity	Unigram perplexity
	Bigram perplexity	Bigram perplexity
	Trigram perplexity	Trigram perplexity

Table 4: The twelve perplexity scores used as language model features

4.5 Morphological Features (MORPH)

German has a rich inflectional and derivational morphology. Although not to the same extent as Romance languages, German uses inflectional morphemes to convey a range of grammatical meanings. For example, person and number of a verb are indicated by inflectional endings (e.g., *ich kaufe* [*I buy*], *du kaufst* [*you buy*]). On the nominal side, German has four cases and nouns fall into several different declension paradigms. Case information is sometimes carried by the articles and sometimes by the noun.

German derivational morphology uses various prefixes and suffixes. Nominalizations with a suffix (*regieren* [*govern*] – *Regierung* [*government*]) or without (*laufen* [*to run*] – *der Lauf* [*the run*]) are very common. Compounding is another productive morphological process in German.

Since these three morphological processes may reflect distinctions of relevance for identifying the reading level of a text, we included them in our experiments.

4.5.1 Inflectional Morphology of the Verb (INFLV) and the Noun (INFLN)

We wanted to investigate if the verbal tense and mood encodes relevant information about a text's difficulty. Hence, we examined a broad range of features related to the inflectional properties of the verb including person, tense, mood and type of verb (finite, non-finite, auxiliary). Additionally, we included the case properties of nouns as features. The case of a

nominal argument, for example, reflects the nature and complexity of the subcategorization frame of the head that selects it. The list of all our features related to inflectional morphology is shown in Table 5.

Verb (INFLV)	**Noun** (INFLN)
Num. infinitive Vs / Num. Vs	Num. accusative Ns / Num. Ns
Num. participle Vs / Num. Vs	Num. dative. Ns / Num. Ns
Num. imperative Vs / Num. Vs	Num. genitive Ns / Num. Ns
Num. present tense Vs / Num finite Vs	Num. nominative Ns / Num. Ns
Num. past tense Vs / Num. finite Vs	
Num. 1st person Vs / Num. finite Vs	
Num. 2nd person Vs / Num. finite Vs	
Num. 3rd person Vs / Num. finite Vs	
Num. subjunctive Vs / Num. finite Vs	
Num. finite Vs / Num. Vs	
Num. modal Vs / Num. Vs	
Num. auxiliary Vs / Num. Vs	
Num. Vs / Num. S	

Table 5: The features based on inflectional morphology

4.5.2 Derivational Morphology of the Noun (DERIV)

Two features based on derivational morphology were previously used for German. Vor der Brück et al. (2008b) measured the number of words that are derived from a verb or an adjective. Derived nouns are linguistically more complex than simple nouns. Additionally, derivational suffixes often differ for words which are native German words and lexical items that have come into German from other languages, e.g., *linguist* can be translated into German as either *Lingu**ist*** or as *Sprachwissenschaft**ler***.

We included relatively fine grained derivational properties by taking into account the distribution of a number of individual suffixes. We manually compiled a set of suffixes from a comprehensive overview of native and foreign suffixes (Fleischer and Barz, 1995). For each suffix, we listed all of the different gender and number forms. The counts are accumulated per type of suffix. For example, if there are two instances of *-ismus* and one instance of *-ismen* (the plural form), then a sum of three instances is recorded for *-ismus*. To avoid counting instances of homomorphic nouns as suffixes (e.g., *Ei* [*egg*] vs. suffix *-ei*), we only considered polysyllabic words for the suffix analysis. A list of all the suffixes we used is shown in Table 6.

All occurrences of each suffix (and its forms) were counted per document. Three different ratios can then be generated for each suffix. Let S be the count of a given suffix from Table 6 for a given document, and let T, N and DN be the number of tokens, nouns, and derived nouns in that document. We defined derived noun as a noun which ends in one of the suffixes listed in Table 6. The suffix token ratio (STR), suffix noun ratio (SNR) and suffix derived noun ratio (SDNR) can then be calculated as follows:

- **Suffix Token Ratio (STR)** $= \frac{1}{T}S$
- **Suffix Noun Ratio (SNR)** $= \frac{1}{N}S$
- **Suffix Derived Noun Ratio (SDNR)** $= \frac{1}{DN}S$

suffix	further suffix forms
ant	anten, antin, antinnen
arium	arien
ast	asten, astin, astinnen
at	ate
ator	atoren, atorin, atorinnen
atur	aturen
ei	eien
er	erin, erinnen
ent	ents
enz	enzen
eur	eure, eurin, eurinnen
heit	heiten

suffix	further suffix forms
ist	isten, istin, istinnen
ion	ionen
ismus	ismen
ität	itäten
keit	keiten
ling	lingen
nis	nisse
schaft	schaften
tum	tümer
ung	ungen
ur	
werk	werke
wesen	

Table 6: List of German derivational suffixes used

For example, consider the sentence in (4) and assume that this is a one sentence document.

(4) Die Regier**ung** muss die Nutz**ung** der landwirtschaftlichen Flächen mit großer
the government has to the use of agricultural areas with great
Präzis**ion** planen.
precision plan
'The government has to plan the use of the agricultural areas with great precision.'

In this example, there are two instances of the suffix *-ung* and one instance of the suffix *-ion* (shown in bold). *Regierung* and *Nutzung* are both nominalizations of native words with native origin, and *Präzision* is of foreign origin. This one sentence document includes twelve tokens, four nouns and three derived nouns, so one obtains $\text{STR(ung)} = 2/12$, $\text{SNR(ung)} = 2/4$ and $\text{SDNR(ung)} = 2/3$. For the suffix *-ion* we get $1/12$, $1/4$ and $1/3$, respectively. The values for all other suffixes are zero. In addition to the specific suffix ratios, we also computed the overall ratio of derived nouns to nouns.

4.5.3 Nominal Compounds (COMP)

Compounds are frequent in German and compounding is a productive mechanism of word formation in German Fleischer and Barz (1995, p. 85). Vor der Brück et al. (2008b) included two compounding features into the classifier for the readability checker *DeLite*: the number of words that form a compound and the number of semantic concepts that are incorporated into a compound. In our approach, we considered the ratio of compound nouns to all nouns and the average number of words in a compound as our compounding based features. For identifying compounds and splitting them into their parts we used JWordSplitter 3.4[4].

5 Experiments and Results

We performed our classification experiments using the *Geo-GeoLino* dataset described in Section 3. We employed the *WEKA* (Hall et al., 2009) implementation of the Sequential Minimal

[4]http://www.danielnaber.de/jwordsplitter

Optimization (SMO) algorithm to create our classification models. For all our classification experiments, we report the overall accuracy after 10-fold cross validation.

We first report the results with language modeling (LM) and the morphological feature groups separately. We then report the performance of each of the other feature groups introduced in Section 4 separately, before turning to combinations.

5.1 Language Modeling

In previous research on the use of language model features for readability assessment, it remained unclear if word based models or mixed word/part of speech models are more effective. While Schwarm and Ostendorf (2005) reported that the mixed models performed better, this was not confirmed by Petersen and Ostendorf (2009). Schwarm and Ostendorf (2005) trained the language models on the same dataset they used for training their classifier, whereas Petersen and Ostendorf (2009) used different datasets for training the language models and the classifier. Feng (2010), who also trained the language models on the same data as the readability classifier, reports that the mixed models outperformed the purely word based models.

As we discussed in section 4.4, we followed Petersen and Ostendorf (2009) in training the language model on a separate data set, to test whether the information picked up about easy vs. difficult texts generalizes across corpora. We trained one classifier on the purely word based models and another one on the mixed model. We combined all perplexity scores from both word based and mixed models. In our experiments, the mixed model (71%) performed only slightly better than the word based model (70.8%). However, an experiment using all twelve perplexity scores as features showed that a combination of mixed and word based models improved classification accuracy (77.6%). So we kept all twelve scores in the feature group for further experiments.

5.2 Morphological Features

We investigated the morphological features in detail given that most of them had not been employed before. In the case of derivational morphology, as described in Section 4.5.2, we calculated three ratios: suffix token ratio, suffix noun ratio and suffix derived noun ratio for each of the 25 derivational suffixes and also calculated the overall ratio of derived nouns to nouns, leading to a total of 76 features. We first performed classification experiments with all three suffix ratio feature subsets separately. The suffix token ratio features performed best (76.6%), followed by suffix noun ratio features (74.4%) and suffix derived noun ratio features (74.0%). However, a combination of all the derivational suffix based features achieved a higher accuracy (78.5%) than the individual subsets. The verbal inflection (INFLV) and nominal inflection (INFLN) features (Table 5) alone achieved accuracies of 74.3% and 67.2%, respectively. Combining all the inflectional features resulted in a classifier that performed much better, at 79.0%.

Table 7 shows the results for each of our morphological feature groups. The derivational features (DERIV) achieved the highest accuracy followed by the features that use verbal inflection (INFLV) and nominal inflection (INFLN). The nominal compound features (COMP) were the least effective predictors among the morphological groups.

The combined feature set (MORPH) consisting of all four morphological subsets performed with an accuracy 85.4%, which is better than any of the individual subsets. Removing the compounding features from MORPH had no impact on the accuracy.

Feature set	Num. Features	Accuracy
DERIV	76	78.5%
INFLN	4	67.2%
INFLV	13	74.3%
INFLN & INFLV	17	79.0%
COMP	2	56.96%
MORPH	95	85.4%

Table 7: Results for the different types of morphological features

5.3 Most Predictive Features

Apart from the various feature subsets, we also determined the most predictive features using Information Gain. The ten most predictive features (TOP 10) are shown in Table 8. Training a classifier with the TOP10 features resulted in an accuracy of 84.3%.

Feature	Group
Avg. Word Length	Lex/Trad
Num. 2nd person Vs / Num. finite Vs	Morph
Num. Syllables Per Word	Lex/Trad
Num. 3rd person Vs / Num. finite Vs	Morph
Avg. length of a T-unit	Syn
Avg. length of a Sentence	Syn/Trad
Complex Nominals per Clause	Syn
Complex Nominals per T-unit	Syn
Num. PPs per sentence	Syn
Avg. length of a clause	Syn

Table 8: The ten most predictive features according to Information Gain

Most of the features in the TOP 10 belong to the syntactic feature group, but morphology features and some traditional measures are included as well. The dominance of syntactic features, especially of those from SLA research, confirms the conclusions of Vajjala and Meurers (2012) for English that these measures are particularly effective for readability classification. The list also indicates that investigating the usefulness of morphological features for readability classification was well-worth the effort, even at this relatively shallow level of morphological modeling. Note also that the three traditional readability features (TRAD) that we view as a baseline are among the TOP10 features. While these superficial features have little conceptual value, they seem to be good predictors of reading level.

5.4 Results for Feature Groups and Combinations

We trained classifiers with various individual feature groups and some of their combinations. Table 9 summarizes the results for the different classification models. For the feature group combinations, only the most successful combinations are shown.

Feature set	Num. Features	Accuracy
TRAD	3	82.2%
LEX	23	82.1%
SYN	26	76.8%
MORPH	95	85.4%
LM	12	77.6%
SYN & MORPH	120	86.7%
LEX & LM & MORPH	130	89.4%
ALL	155	89.7%
TOP 10	10	84.3%

Table 9: A comparison of all five feature groups

Among the models trained on a single feature group, the morphological classifier (MORPH) performed best with an accuracy of 85.4%. The lexical classifier (LEX) (82.1%) and the baseline classifier (TRAD) (82.2 %) performed almost equally well, but slightly worse than the morphological classifier (MORPH). The classifiers trained on language model features (LM) and syntactic features (SYN) proved to be less effective predictors when taken on their own. However, they proved to be valuable when combined with other feature groups. Our experiments combining different feature groups showed that the syntactic (SYN) and morphological (MORPH) feature groups together were the most predictive two group combination with 86.7 % accuracy. When using three feature groups a combination of lexical (LEX), language model (LM) and morphological (MORPH) features performed best (89.4%).

Overall, the best result was achieved by combining all feature groups (ALL), which resulted in 89.7% accuracy. Compared to the traditional readability measures (TRAD) as baseline (82.2%), our best model improved classification performance by 7.5%. The classifier built with the ten best features (TOP 10) at 84.3% accuracy performed at about the level of the best single feature group (MORPH).

Conclusion and Outlook

As empirical basis of our work, we created the *GEO-GEOlino* corpus, a German corpus with two different reading levels that we collected from magazine articles that were available online. The *easy* reading level consists of the *GEOlino* articles targeted at children, while the *GEO* articles targeted at adults were labeled as *difficult*.

We trained classifiers with syntactic, lexical, and language model features derived from research on English, to see how well they can predict the reading level of German texts. We then introduced language-specific morphological complexity indicators as an additional group of features. We inspected a broad set of inflectional properties for German and for the first time made use of the derivational and inflectional morphology of nouns as features for readability classification of German. The novel morphological features proved to be especially good indicators for reading level, outperforming all other feature groups, when considered in isolation.

While all the individual feature groups except morphological features performed below the baseline, combinations of various feature sets resulted in higher accuracies. The best performance was obtained by combining all features. This achieved an accuracy of 89.7%, which is 7.5% above a baseline classifier using only traditional readability measures.

In terms of outlook, we are investigating how well the trained models generalize to other data sets, for which obtaining more graded reading material for German is an important next step. Going beyond readability classification of entire documents, we want to explore which features are effective not only at the document level but already at paragraph or sentence levels. Being able to identify simple and difficult paragraphs or sentences is relevant for identifying targets for simplification – the next step for our overall goal of building text simplification systems.

Finally, some of the features used in this paper were originally developed as measures of language proficiency in Second Language Acquisition research. Given how well SLA measures of language proficiency (based on texts produced by the learners) work as features for readability classification of native texts, it would be natural to take the features developed for our readability research back to the SLA domain and explore their applicability to classifying the language proficiency of language learners. In addition to quantitatively testing their impact for proficiency classification, strengthening that link could also help with qualitatively interpreting and further refining the different features on the background of SLA insights into stages of language development.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback on the paper, and Niels Ott and Ramon Ziai for the RFTagger Java interface. The research leading to the reported results has received funding through the European Commission's 7th Framework Program under grant agreement number 238405 (CLARA, `http://clara.uib.no`).

ABSTRACT
We propose a new measure of semantic similarity between words in context, which exploits the syntactic/semantic structure of the context surrounding each target word. For a given pair of target words and their sentential contexts, labeled directed graphs are made from the output of a semantic parser on these sentences. Nodes in these graphs represent words in the sentences, and labeled edges represent syntactic/semantic relations between them. The similarity between the target words is then computed as the sum of the similarity of walks starting from the target words (nodes) in the two graphs. The proposed measure is tested on word sense disambiguation and paraphrase ranking tasks, and the results are promising: The proposed measure outperforms existing methods which completely ignore or do not fully exploit syntactic/semantic structural co-occurrences between a target word and its neighbors.

KEYWORDS: contextual word similarity, word sense disambiguation, paraphrase, kernel method.

Proceedings of COLING 2012: Technical Papers, pages 1081–1096,
COLING 2012, Mumbai, December 2012.

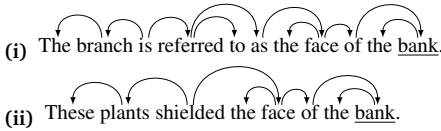
1 Introduction

Word ambiguity poses a great difficulty in natural language processing (Deerwester et al., 1990; Berger and Lafferty, 1999; Navigli, 2009). In document classification, for example, polysemous words may provide spurious evidence for misclassifying documents of different categories into a single category. Synonyms may also cause problems; without the knowledge of two words being synonyms, classifiers might be unable to detect similarity of documents in which they appear.

These problems can be alleviated with the help of contextual similarity (Jurafsky and Martin, 2008, Section 20.7). Polysemous words have identical surface forms, but the contexts in which they appear are often distinct; and even though synonyms have different surface forms, they are expected to appear in similar context.

There has been a volume of work investigating semantic similarity of words in context. However, syntactic or semantic *structure* in the context has not been fully explored. The methods representing context as a *bag of words* or a *bag of n-grams* (Schütze, 1998; Reisinger and Mooney, 2010; Erk and Padó, 2010; Dinu and Lapata, 2010; Giuliano et al., 2009) ignore the underlying syntactic/semantic structure. Recent studies on compositional semantics of words (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2010) take advantage of structure in context, but they only use information of words that directly stand in a predicate-argument relation with the target word.

Consider the following sentences (i) and (ii), shown with the word dependency relations.



In sentence (i), the noun (homonym) *bank* means *"a financial institution"* whereas the one in sentence (ii) means *"the slope of land adjoining a river."*

If these sentences are treated as bags of words, we see that the words unique to (i) and (ii) are respectively {*branch*, *is*, *refer*} and {*plant*, *shield*}, excluding functional words. However, these sets of words are not likely to be sufficient to discriminate the sense of the two *bank*s. The bag-of-*n*-grams representation (Giuliano et al., 2009) collects *n*-grams containing a target word from the context. This representation is still short on distinguishing the senses of the two *bank*s above, as the *n*-grams around them are completely identical up to $n = 5$; i.e., the 5-grams surrounding *bank* are *"the face of the bank"* in both sentences. Recent methods (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2010) exploit direct syntactic/semantic relations with target words, but these methods would still fail in the above examples, because the direct structural neighbors of *bank*s are the same in the two contexts.

On the other hand, syntactic/semantic structural co-occurrences of multiple words, obtained from the dependency relations, seem effective for this example. Consider structural collocations *referred* → *as* → *face* → *of* → *bank* and *shielded* → *face* → *of* → *bank*, which can be obtained if we follow multiple dependency arrows in the dependency structure. The problem is how to compute such co-occurrences efficiently from given syntactic/semantic structures.

Contributions. In this paper, to fully exploit syntactic/semantic co-occurrences of words in contexts, we represent a target word in a context as a *bag of walks* on the *parse graph* (Section 3). In this graph, nodes represent words, and edges represent syntactic/semantic relations between nodes. Such a graph can be readily obtained from the output of state-of-the-art semantic parsers.

We further define the *bag-of-walks* kernel between graph nodes (Section 4). With this kernel, word similarity is calculated as the sum of the similarity of walks starting from target words in their respective parse graphs. Here, the similarity of two walks is the product of the similarity of individual nodes and edges visited during the walks. Since nodes represent words and edges represent syntactic/semantic relations between them, this similarity computation takes into account syntactic/semantic structural co-occurrence of multiple words in context.

We verify effectiveness of the proposed method in two experiments: one on word sense disambiguation and the other on paraphrase ranking (Section 5).

2 Related work

The simplest representation of a context is to regard it as a *bag of words*, or a vector holding the frequency of words co-occurring with the target word in the given context. We call this vector *local context vector* in this paper. Depending on the task, context can be a fixed number of words around the target word, or the sentence or paragraph in which it appears.

We can regard a local context vector as representing a particular meaning the target word conveys in the given context. However, these vectors may be too sparse to provide enough information, especially when the available context is short. Hence, recent studies have focused on the way to make a richer representation of context utilizing information extracted from external resources, such as corpora.

The majority of research along this line utilizes a context-free representation of a word, called *type vector* (Erk and Padó, 2010). The type vector of a word, in its simplest form, is built by aggregating local context vectors made for individual occurrences of the word in the corpus. Thus, it does not represent a specific context of a word, but is a general representation of a word viewed as a type. Still, type vectors can be used as building blocks of *contextualized* feature vectors (Thater et al., 2010) representing the context around the target word.

Schütze (1998) proposed the *word vectors* as one such contextualized feature vector. The word vector of a target word is the sum of the type vectors of the words appearing in its surrounding context. Because it is an aggregate of dense type vectors of different words, we can expect a word vector to hold information richer than a naive, bag-of-words local context vector. More elaborate contextualization has been proposed recently, which combines (e.g., via component-wise vector multiplication) the type vector of the target word with those of the words occurring in the context (Mitchell and Lapata, 2008) in a compositional way. Erk and Padó (2008) and Thater et al. (2010) took a similar compositional approach, but they made type vectors by taking the semantic structure into account, i.e., by counting frequency of words in the corpus that participate in syntactic or semantic relations with the target word.

Erk and Padó (2010) proposed a corpus-based method that does not rely on type vectors. They first make a bag-of-words local context vector $\mathbf{v}$ for a given target word, in a usual manner. They then collect k instances of the target word in a corpus whose contexts are most similar to the one for the target instance (with respect to a predefined similarity measure of contexts). The

local context vectors for these k instances are then added to the original local context vector $\mathbf{v}$ to make it denser. The idea behind this method is that because these k instances appeared in a context similar to that of the target instance, they are likely to have the same sense.

As we have seen above, even the most recent methods do not use syntactic/semantic structure of context at all, or make only limited use of it; namely, only the words that directly participate in a relation (e.g., predicate-argument) with a target word are taken into account.

3 Bag-of-walks representation of word in context

In this section, we introduce the *bag-of-walks* representation of words in context. This representation encodes syntactic/semantic co-occurrences of words around a target word as a collection of walks in a *parse graph*, a graph that can be obtained from the structure output by syntactic/semantic parsers.

We first describe how to make a parse graph from a parser output, and then define a natural random walk model on this graph. The parse graph and the random walk model will be used to define the "bag-of-walks kernels" in Section 4, which allow us to evaluate the similarity of two contexts represented as bags of walks.

For brevity, we assume below that the context is a sentence containing a target word. Smaller fragments (e.g., phrases) can also be used in place of sentences, as long as the relations between words in a fragment can be obtained. For instance, we could use a subtree (corresponding to a phrase) extracted from the dependency tree of an entire sentence.

3.1 Parse graphs

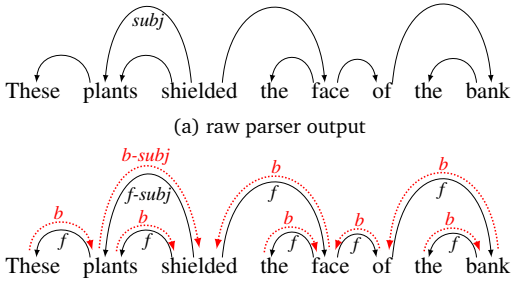
The *parse graph* can be obtained from the output of (semantic) dependency parsers.

Basic dependency parsers output a tree in which nodes are the words in the input sentence and (directed) edges between them represent syntactic head-dependent (dependency) relations. A dependency may be expressed as a directed edge either from the head to the dependent, or from the dependent to the head. The choice is arbitrary, but both head-to-dependent relations and dependent-to-head relations potentially provide useful features for semantic similarity of words. The same should be true for other types of syntactic/semantic relations output by more advanced parsers, such as the *"semantic subject"* of a verb in passive voice. Hence, we represent each individual relation output by the parser as two distinct edges having the same pair of end nodes (words), but with direction opposite to each other. The two edges have the same label representing the type of the relation, but one of them is prefixed *"forward"* (or *"f"* for short) and the other is prefixed *"backward"* (or *"b"*), so that the two edges can be distinguished by the label. Thus for example, if the parser outputs a relation called *"semantic subject"* between two nodes, one edge will be labeled *"forward semantic subject"*, and the other, opposite direction edge will have the label *"backward semantic subject."*

We call a labeled directed graph created in this way a *parse graph*. See Figure 1 for illustration.

3.2 Walks in a graph

We now consider walks in the parse graph starting from the target word. Given a graph G, a walk is a series of nodes and edges, formally defined as follows. Let $\mathrm{Out}(w)$ denote the set of outgoing edges from node w, and $\mathrm{sink}(r)$ denote the sink node of directed edge r. A *walk* $z = (w_0, r_1, w_1, r_2, \ldots, r_t, w_t)$ in graph G is an alternating series of nodes $(w_0, \ldots, w_t)$ and edges



(a) raw parser output

(b) after conversion

Figure 1: Illustration of parse graph construction. (a) The raw dependency structure extracted from the output of the Enju parser. Notice multiple edges from "shielded" to "plants"; the parser outputs a semantic relation named "*subj*" in addition to syntactic dependencies (shown without edge labels). (b) Each relation in the parser output is converted to two edges, to allow "forward" and "backward" (shown as a dotted red arrow) traversal of each relation. In the figure, "*b*" and "*f*" are the shorthands for "backward" and "forward," respectively.

$(r_1, \ldots, r_t)$ in G such that w_{i-1} and w_i are the source and sink of edge r_i; i.e., $r_i \in \mathrm{Out}(w_{i-1})$ and $w_i = \mathrm{sink}(r_i)$ for every $i = 1, \ldots, t$. We call t the *length* of z and denote it by $|z|$. A walk may contain duplicate nodes and edges. Thus it is possible that $w_i = w_j$ or $r_i = r_j$ for some i and j, $j \neq i$.

A walk starting from a target word (node) on a parse graph represents the structural co-occurrence of multiple words around the target word. For example, an entire predicate-argument structure consisting of a predicate p and arguments $\{a_1, a_2, \ldots, a_n\}$ may be represented by a walk $p \to a_1 \to p \to a_2 \to p \to \cdots \to p \to a_n$, traveling between the predicate and each of its arguments alternately; as mentioned above, a walk may visit the same nodes multiple times.

In this way, we represent the context surrounding a target word as a bag of all walks (of bounded length) starting from the target word on a parse graph; we call this a *bag-of-walks* representation of context.

We now introduce a random walk model on a parse graph, as a way to systematically associate a probability (or weight) to each walk in the "bag." In this model, a walk starts from a node corresponding to the target word, and the following process is repeated: (1) Flip a biased coin (with head probability γ). If it comes out heads, terminate the walk. If it comes out tails, proceed to step 2. (2) Choose an edge outgoing from the current node uniformly at random. (3) Follow the edge to the next node. After this process is repeated L times, the walk is terminated, but as step 1 shows, it may also be terminated prematurely at each step with a constant probability γ.

This random walk model assigns probability to each walk of length at most L, starting from the target word in the parse graph. Let w be a node in G, and let $z = (w_0, r_1, w_1, r_2, \ldots, r_{|z|}, w_{|z|})$, be a walk. By the way the random walk model is defined, it is easy to verify that the probability

of taking walk z from node w, written $p(z \mid w)$, is given by

$$p(z \mid w) = \begin{cases} 0, & \text{if } w \neq w_0 \text{ or } |z| > L; \\ \gamma^{I[|z| \neq L]}(1-\gamma)^{|z|} \prod_{i=1}^{|z|} \frac{1}{|\mathrm{Out}(w_{i-1})|}, & \text{otherwise;} \end{cases} \quad (1)$$

where $I[X]$ is an indicator function taking 1 if proposition X holds, or 0 otherwise. Recall that γ is the predefined stopping probability.

As we can see from Eq. (1), walk probability can be tuned by the model parameters L and γ; e.g., the larger the stopping probability γ, the smaller the probability of taking longer walks. These parameters control how much weight should be placed on long-distance dependencies between words, and how far we should look for such dependencies. Section 4 defines the bag-of-walks kernels using the walk probability $p(\cdot)$ as the weight of individual walks.

4 Contextual word similarity via bag-of-walks kernels

This section presents a new method of computing similarity between words occurring in different contexts, which takes syntactic/semantic structural co-occurrences around target words into account. As noted in the previous section, we first build parse graphs for sentences containing target words, using a syntactic or semantic parser. In a parse graph, nodes represent words in the sentence, and edges represent (binary) relations between the words. We then compute the similarity between a pair of target words, represented as nodes in two different parse graphs, using a kernel that defines an inner product between nodes in graphs.

A popular approach to measuring the similarity of structured data is to count shared substructures with the so-called *convolution kernels* (Haussler, 1999; Gärtner, 2003). Our method also takes this approach; to measure the similarity between words in parse graphs, we use a variation of the kernel proposed by Desrosiers and Karypis (2009). This kernel is designed to evaluate the similarity of target nodes in a graph (or possibly in two different graphs) in which nodes and edges are labeled. The basic idea is to compute the number (weight) of identical walks starting from the nodes in respective graphs. Here, two walks are deemed identical if they have the same length and the series of labels along the nodes and edges in the two walks exactly match. We can also relax the requirement of exact matching, and instead allow for varying degree of similarity between different node/edge labels. The resulting kernel computes the node similarity through the degree of similarity of every pairs of (possibly non-identical) walks.

Below, we first give a definition of kernel (or similarity) between two individual walks in the parse graphs (Section 4.1), and then explain how to compute the kernel between two contexts viewed as bags of walks (*bag-of-walks kernel*) in Section 4.2. Under the random walk model presented in Section 3.2, this formulation allows efficient recursive computation without explicitly enumerating all single walks in the graphs.

Let G be a directed graph consisting of a union of two disjoint subgraphs, each of which corresponds to the parse graph for sentences S and S', respectively.

4.1 Walk similarity

We assume two kernel (similarity) functions $K_{\mathrm{word}}(w, w')$ and $K_{\mathrm{rel}}(r, r')$ are at our disposal, which are defined respectively over pairs of nodes (w, w') and pairs of edges (r, r') in G. In parse graphs, nodes represent words, so a natural example for $K_{\mathrm{word}}(w, w')$ is the cosine of

$\mathbf{v}_w$ and $\mathbf{v}_{w'}$, where $\mathbf{v}_w$ is the feature vector (e.g., type vector of Section 2) of word w; for edges, we can simply define $K_{\text{rel}}(r, r') = 1$ if the directed edges r and r' have the same relation label, or 0 otherwise. Using these basic kernels, we define kernel $K_{\text{walk}}(z, z')$ between two walks $z = (w_0, r_1, w_1, r_2, \ldots, r_t, w_t)$ and $z' = (w'_0, r'_1, w'_1, r'_2, \ldots, r'_{t'}, w'_{t'})$. First, if z and z' have different length $t \neq t'$, let $K_{\text{walk}}(z, z') = 0$. For two walks with the same length $t = t'$, we define

$$\begin{aligned} K_{\text{walk}}(z, z') &= K_{\text{word}}(w_0, w'_0) \cdot K_{\text{rel}}(r_1, r'_1) \cdot K_{\text{word}}(w_1, w'_1) \cdot \ \ldots \ \cdot K_{\text{rel}}(r_t, r'_t) \cdot K_{\text{word}}(w_t, w'_t) \\ &= \prod_{i=0}^{t} K_{\text{word}}(w_i, w'_i) \prod_{i=1}^{t} K_{\text{rel}}(r_i, r'_i). \end{aligned} \tag{2}$$

Thus, $K_{\text{walk}}(z, z')$ is the product of the similarity of the pairs of nodes and edges visited along the two walks z and z'.

4.2 Bag-of-walks kernels

Let w and w' be nodes in a graph[1] G. The *bag-of-walks kernels* between w and w', denoted by $K(w, w')$, is defined as a weighted sum of similarity given by K_{walk} between all pairs of walks of length at most L, with each walk starting from w and w', respectively. Here, L is the parameter of the kernel. Formally speaking,

$$K(w, w') = \sum_{\substack{z \in Z(w;L) \\ z' \in Z(w',L)}} p(z \mid w) p(z' \mid w') K_{\text{walk}}(z, z') \tag{3}$$

where $Z(w; L)$ denote the set of all walks of length at most L, starting from w in G. $p(z \mid w)$ is a function that assigns a non-negative weight to walk z. In the rest of the paper, we define $p(z \mid w)$ to be the one given by Eq. (1), i.e., the probability of taking walk z from w according to the random walk model defined in Section 3.2.

4.3 Efficient computation

Naively enumerating all walk pairs (z, z') in Eq. (3) is intractable when L is large, because the number of possible walks grows exponentially with length bound L. However, for the specific weight function $p(z \mid w)$ given by Eq. (1), we can efficiently compute $K(w, w')$ in a recursive manner, as follows.

For $t = 0, 1, \ldots, L$, and any node pair w and w' in G, let $K^{(t)}(w, w')$ be the quantity defined as

$$K^{(t)}(w, w') = \sum_{\substack{z \in Z(w;t) \\ z' \in Z(w';t)}} p(z \mid w) p(z' \mid w') K_{\text{walk}}(z, z'). \tag{4}$$

Eq. (4) has the same form as Eq. (3), except that it is parametrized by the maximum length t of allowed walks. Especially, $K(w, w') = K^{(L)}(w, w')$.

We now show how to compute $K^{(t)}$ recursively over $t = 0, \ldots, L$. For $t = 0$, there exists only one walk pair of length 0, namely, $z^{(0)} = (w)$, $z'^{(0)} = (w')$. Thus we have

$$K^{(0)}(w, w') = K_{\text{walk}}(z^{(0)}, z'^{(0)}) = K_{\text{word}}(w, w'), \tag{5}$$

[1] Note that even if two nodes w and w' appear in different graphs, they can be regarded as nodes in a single graph, namely, the graph union of the two graphs. Hence two nodes can be assumed to belong to a graph G without loss of generality.

where the second equality follows from Eq. (2).

For $t \geq 1$, observe that every walk starting from w will either (i) be terminated immediately with probability γ, or (ii) with probability $(1-\gamma)/|\mathrm{Out}(w)|$, follows an edge $r \in \mathrm{Out}(w)$ and connects to a walk of length at most $(t-1)$ starting from $\mathrm{sink}(r)$, yielding a walk of length at most t as a whole. Recall that $|\mathrm{Out}(w)|$ is the out-degree of nodes w. It follows that

$$K^{(t)}(w,w') = \gamma^2 K_{\mathrm{word}}(w,w') + \frac{(1-\gamma)^2}{|\mathrm{Out}(w)||\mathrm{Out}(w')|} \cdot K_{\mathrm{word}}(w,w') \sum_{\substack{r \in \mathrm{Out}(w) \\ r' \in \mathrm{Out}(w')}} K_{\mathrm{rel}}(r,r') \cdot K^{(t-1)}(\mathrm{sink}(r), \mathrm{sink}(r')). \quad (6)$$

By iteratively computing $K^{(t)}(v,v')$ for all pairs of nodes (v,v') in graph G over $t = 0, 1, \ldots, L$, we eventually obtain the desired quantity $K(w,w') = K^{(L)}(w,w')$, namely, the local structural similarity of nodes w and w' in graph G. The time complexity of this calculation is $O(|G|^2 L)$, where $|G|$ is the number of nodes in graph G. If G comprises two disjoint subgraphs corresponding to the parse graphs for sentence S and S', we can show that the computation time can be reduced to $O(|S||S'|L)$, where $|S|$ and $|S'|$ are the number of words in sentences S and S', respectively; or equivalently, these are the number of nodes in their respective parse graphs. It follows that in practice computation of this bag-of-walks kernel is feasible, because sentences S and S' usually contain only a moderate number of words.

Depending on the structure of the parse graphs and the value of L, we can further save computation. To obtain the value of $K(w_{\mathrm{target}}, w'_{\mathrm{target}}) = K^{(L)}(w_{\mathrm{target}}, w'_{\mathrm{target}})$, we need to compute Eqs. (5) and (6) not for all pairs of words in the sentences, but only for pairs (w,w') such that w and w' are within L steps from the target words w_{target} and w'_{target} in the parse graph.

4.4 Relation to other kernels for structured data

4.4.1 Desrosiers-Karypis kernels

The bag-of-walks kernels are similar to but not identical to the kernels proposed by Desrosiers and Karypis (2009), which also measures the similarity of nodes in the labeled graph using their surrounding structure.

The Desrosiers-Karypis kernels can also be viewed as a special case of Eq (3), but the underlying random walk model $p(\cdot)$ is different. Desrosiers and Karypis use a random walk model that do not cast a bound on the length of walks. In contrast, our model poses a strict upper bound L on the walk length; this model was chosen because co-occurrences comprising hundreds of words are unlikely to be effective for contextual word discrimination. Also, this upper bound reduces computational complexity.

Different random walk models lead to different recursive computations. Observe that the formula for Desrosiers-Karypis kernels (see the unnumbered equation for $\sigma_{u,u'}$ in (Desrosiers and Karypis, 2009, Section 3.3, page 266)) is given as a sum of the probability of generating parallel walks, and every term in the sum is multiplied by a square of stopping probability γ. This is not the case with the bag-of-walks kernels; notice that stopping probability γ is absent from Eq. (5), the base formula for recursive computation.

Another minor difference is that Desrosiers-Karypis kernels do not count the similarity of walks

with zero length. Our kernels take this into consideration, as reflected in Eq. (5) and the first term of Eq. (6).

Both the bag-of-walks kernels and the Desrosiers-Karypis kernels borrow idea from Kashima et al. (2003) who defined a kernel (*marginalized graph kernel*) between two graphs (not graph nodes) on the basis of the marginal probability of parallel random walks taking place in the two graphs. Elegant product graph formulations of various graph kernels can be found in Vishwanathan et al. (2010).

4.4.2 Tree kernels

Tree kernels (Collins and Duffy, 2001; Kashima and Koyanagi, 2002; Moschitti et al., 2008; Croce et al., 2011) efficiently count all common subtrees in two tree-structured data. Although it is tempting to apply these kernels to measure the similarity between the dependency (sub)trees surrounding the target words, it should be noted that our goal is to measure the similarity of particular word pairs in two sentences, and not of the sentences or their entire dependency trees. In particular, tree kernels do not give any special treatment of the target words, and thus they even count subtrees that do not involve a target word at all. Tree kernels are hence not suitable for measuring word similarity. In contrast, the bag-of-walks kernels distinguish target words from the other words in the sentence, as they only count walks starting from the target words. Moreover, tree kernels cannot deal with parser outputs containing semantic relations, as these outputs are in general graphs and not trees.

5 Experiments

In this section, we evaluate the bag-of-walks kernels in two tasks: word sense disambiguation (WSD) and paraphrase ranking. For the WSD task, we use the kernels to construct SVM classifiers. For the paraphrase ranking task in which no training data is provided, we use the kernel value simply as the similarity score used to rank candidate words.

We need to define two basic kernels, K_{word} between words (nodes) and K_{rel} between relations (edges) as the building blocks of the bag-of-walks kernels K (Eq. (3)). Throughout the experiments, we let K_{word} be the cosine between context-independent type vectors for words (see below). For K_{rel}, we use the identity function of edge labels; i.e., $K_{\text{rel}}(r, r')$ is 1 if the labels of edges r and r' are identical, or else it is 0.

Before proceeding to the experimental procedures and results, we describe how we built the type vectors for words. These type vectors are used for both the WSD and paraphrase ranking experiments.

Construction of context-independent type vectors for words. We first parse the written text part of British National Corpus (BNC) with syntactic-semantic parser Enju[2]. The outputs of Enju are then converted to parse graphs. The edges of the resulting parse graph have one of the following labels: "forward dependency", "backward dependency", "semantic subject (forward semantic subject)", and "semantic predicate (backward semantic subject)." We next collect pairs of (stemmed and lemmatized) words such that (i) each word occurs at least 10 times in BNC, and (ii) the pair is linked by a syntactic/semantic relation at least once in the parse graph collection we converted from BNC, but excluding the pairs for which the *pointwise mutual information* (pmi) (Church and Hanks, 1990) between the words are less than 1. Finally, for

[2] `http://www-tsujii.is.s.u-tokyo.ac.jp/enju/index.html`

every word w occurring in this collection, we make a type vector in which each component corresponds to a pair (w', r) of another word w' and the relation type r between w and w', and holds the pmi score of word w and the pair (w', r),

In preliminary experiments, we also tested type vectors made from the words in a fixed contextual window size (i.e., without using parser outputs), but the results were inferior.

5.1 Experiment 1: word sense disambiguation

For the WSD experiment, we apply the bag-of-walks kernels to the Senseval-3 English lexical sample (ELS) task (Mihalcea et al., 2004).

5.1.1 Task and dataset

The Senseval-3 ELS dataset is a collection of instances of polysemous target words and the contextual paragraphs in which they appear, consisting mostly of several sentences. Each target instance is annotated with one or more gold standard senses selected from a sense inventory (also distributed with the dataset). The dataset comes with predefined training/test splits, and the task goal is to predict a sense for each of the 3944 test instances of 57 polysemous words: 1807 instances for 20 nouns, 1978 for 32 verbs, and 159 for 5 adjectives.

A standard approach for this task is to represent contextual paragraphs as bag-of-words local context vectors. It then predicts the sense of the target word according to rules constructed from training data, usually with a machine learning technique. Recently, to further improve the WSD performance, Giuliano et al. (2009) built a kernel that measures similarity of n-gram collocations containing target words, and combined it with the cosine of local context vectors[3] In this WSD experiment, following Giuliano et al. (2009), we also combine the bag-of-walks kernels with the cosine of local context vectors, and evaluate the performance.

5.1.2 Experimental procedure

WSD with the bag-of-walks kernels consists of four steps: (1) computing the cosine of local context vectors computed from the contextual paragraphs, (2) computing bag-of-walks kernels on parse graphs output by a parser, (3) combining kernels computed in Steps 1 and 2, and (4) sense prediction by support vector machines (SVMs) using the combined kernels. We detail each step below.

Step 1. Compute the cosine of local context vectors. We construct a local context vector, for each target instance according to a standard procedure for WSD (Mihalcea, 2004; Navigli, 2009). Specifically, we treat a contextual paragraph simply as a bag-of-words. After removing stop words[4], we make a local context vector in which components are the weighted frequencies (tf-idf) of words in the "bag." Then we construct a matrix holding cosine between every pairs of local context vectors. Because cosine matrices are positive semi-definite, this matrix can be regarded as a kernel matrix.

Step 2. Compute bag-of-walks kernels. We compute a bag-of-walks kernel between instances of a target word as follows. For each target instance, we pick up a sentence containing the target word from the paragraph given as a context, and then construct a parse graph by

[3] The cosine of local context vectors is called *bag-of-words kernel* in Giuliano et al. (2009).

[4] We use a list of English stop words available from the on-line appendix to (Lewis et al., 2004).

parsing the sentence with the Enju parser. Then we compute the bag-of-walks kernel K using the recursive formula (6) in Section 4.3, for all pairs of target instances. As described in the beginning of this section, K_{word} in Eq. (2) is the cosine similarity between context-independent type vectors, and $K_{\text{rel}}(r, r')$ is the identify kernel of edge labels. Finally, we normalize the obtained bag-of-walks kernel matrix K, so that the (i, j) component of the resulting kernel matrix becomes $K(i, j)/\sqrt{K(i, i)K(j, j)}$.

Step 3. Combine two kernels. In a way similar to Giuliano et al. (2009), we compute a composite kernel by simply adding together the two kernel matrices obtained in Steps 1 and 2.

Step 4. Train SVMs and predict senses of the test data We train multi-class SVMs[5] with the Senseval-3 ELS training data, using the composite kernels obtained in Step 3. After tuning the parameters for each of the polysemous target words by five-fold cross validation on the training set, we train multi-class SVMs with entire training set. The tuned parameters are the walk length bound L and the stopping probability γ of the bag-of-walks kernels, and SVM's soft-margin parameter C. Finally, the trained SVMs are used to predict the sense of the test instances.

5.1.3 Compared methods

We use the most frequent sense prediction as the first baseline. It totally ignores the context, and always predicts the most frequent sense in the training data. This baseline is helpful to evaluate the difficulty of the WSD tasks.

As the second baseline, we use the cosine of local context vectors. Note again that we are interested in how much the performance improves when the bag-of-walks kernels are combined with this simple similarity measure.

We also compare our method with the one proposed by Giuliano et al. (2009), which is also kernel-based. Like bag-of-walks kernels, their kernel takes multi-word co-occurrences with a target word into account, but these co-occurrences are taken in terms of (gap weighted) n-gram collocations; i.e., their kernel counts the overlap of n-gram sequences surrounding the two target words. In contrast, bag-of-walks kernels compute multi-word co-occurrence in the syntactic/semantic structure present in parse graphs. Hence, the comparison of bag-of-walks kernels and Giuliano et al.'s kernel allows us to assess the effectiveness of using syntactic/semantic structure to measure word co-occurrence, rather than using n-grams.[6]

5.1.4 Evaluation

We evaluate predicted senses for test data by F1 score, computed with the scoring script distributed with the Senseval-3 ELS dataset.

5.1.5 Results

Table 1 shows the performance (F1 scores) of the compared methods. The F1 score of Giuliano et al. (2009) is taken from their paper. In total ("ALL"), the proposed method outperforms the

[5] We use the $SVM^{multiclass}$ package: `http://svmlight.joachims.org/svm_multiclass.html`

[6] Giuliano et al. (2009) combined cosine of local context vectors with not only the n-gram collocation kernels, but also "domain kernels." The domain kernels exploit external lexical knowledge sources and singular value decomposition to infer the domain of words. Since our focus is on the effective way of using word co-occurrence in local context, we compare our proposed method only with n-gram collocation kernels (combined with baseline bag-of-words kernels).

Method	ALL	Noun	Verb	Adjective
most frequent sense	55.2	54.2	56.5	49.7
cosine of local context vectors	63.6	64.1	60.3	46.5
proposed method	**71.0**	**72.1**	**71.7**	**50.3**
Giuliano et al. (2009)	69.7	-	-	-

Table 1: F1 scores on the WSD experiment.

baselines and Giuliano et al. (2009)'s method.

These results indicate the effectiveness of using syntactic/semantic structural co-occurrences of multiple words for the WSD tasks.

Table 1 also shows the F1 scores when the test data was broken down by part-of-speech (noun, verb, and adjective). In all parts-of-speech, the proposed method outperformed the baseline. Giuliano et al. (2009) do not report break-down results of their method on individual parts-of-speech, so the corresponding columns are left blank.

The stopping probability γ, and walk length bound L of the bag-of-walks kernels, obtained by cross-validation on the training data, were $\gamma = 0.08$ and $L = 3.0$ on averaged over all the 57 target words. The average value of L for each part-of-speech was $L = 3.6$ for noun, $L = 2.5$ for verb, and $L = 4.2$ for adjective. Thus in all cases, we have $L > 1$, so we conclude that it is worth considering structural co-occurrence of multiple words, not just single words that are directly connected to target words (which corresponds to $L = 1$).

5.2 Experiment 2: ranking paraphrases

In the second experiment, we evaluate bag-of-walks kernels on the task of ranking paraphrases.

5.2.1 Task and dataset

In the paraphrase ranking task, the system is given a target word and the list of its paraphrase candidates. Also given is an instance of the target word with the (sentential) context it appears, and the task goal is to rank the paraphrase candidates by their appropriateness in the light of the given context. No training data is provided, so the system is allowed to use external resources.

Following (Erk and Padó, 2008; Thater et al., 2010; Erk and Padó, 2010; Dinu and Lapata, 2010), we adapt the SemEval-2007 English lexical substitution (ELS) dataset (McCarthy and Navigli, 2007) for a paraphrase ranking task. The dataset consists of 205 target words (59 nouns, 54 verbs, 57 adjectives, and 35 adverbs), each with at most 10 instances of sentential contexts. For each target instance, gold standard paraphrases are annotated and ranked by annotators' votes. Notice that although we use this dataset to organize a paraphrase ranking task, the task setting is different from the original SemEval-2007 ELS task. In SemEval-2007, paraphrase candidates are not provided, and hence the system is required to generate them before ranking. Here in the paraphrase ranking task, we focus solely on ranking candidate paraphrases, which are predefined and given. To make this predefined list of candidate paraphrases from the SemEval-2007 ELS dataset, we pool all the gold standard paraphrases in the dataset for each target word. Now the goal is to rank these candidates for each target instance occurring in a specific context.

Notice that because we use BNC to collect contexts for candidate paraphrases (see Section 5.2.2), paraphrases occurring less than 100 times in the corpus are removed from the candidate lists; a similar filtering was done in (Thater et al., 2010). After this filtering, the average number of candidates for a target word becomes 14.0 in total (13.5 for nouns, 17.6 for verbs, 14.4 for adjectives, and 8.6 for adverbs).

5.2.2 Experimental procedure

Step 1. Collect candidate instances. Given an instance of a target word (i.e., target word in a specific sentential context), we rank its paraphrase candidates according to their contextual similarity to the target instance. To this end, we need the contexts in which candidate words appear, but candidates are provided without context. Hence, for each candidate word, we collect 100 sentential contexts from BNC.

Step 2. Compute bag-of-walks kernels. After collecting sentential contexts for candidate words in Step 1, we convert these sentences into the corresponding parse graphs using the Enju parser and the post-processing described in Section 3.1. The contextual sentences for target instances, which come from SemEval-2007 data, are also converted to parse graphs in the same way. We then apply the bag-of-walks kernels on these graphs to compute the kernel value $K(w, w')$ between a target instance w and each candidate instance w'. The similarity score of w' relative to w is then given by $K(w, w')/\sqrt{K(w, w), K(w', w')}$. In the bag-of-walks kernel computation, we used the same basic kernels K_{word} and K_{rel} as those used for the WSD experiment.

Step 3. Rank candidates. For a given target instance, we compute the score of each candidate word by averaging the similarity scores between the target instance and (a hundred) candidate instances, which we calculated in Step 2. The candidates are then ranked by their scores.

5.2.3 Evaluation

Following previous work (Erk and Padó, 2008; Thater et al., 2010; Erk and Padó, 2010; Dinu and Lapata, 2010), we evaluate the rankings output by each system by *generalized average precision* (GAP) (Kishida, 2005).

5.2.4 Compared methods

The baseline in this task is to rank candidates according to cosine similarity with a target instance using type vectors. Note that since type vectors are context-independent, rankings obtained from this baseline become identical for all instances of a target word regardless of the difference in context in which they appear.

We also compare the performance of bag-of-walks kernels against those reported in two previous studies (Erk and Padó, 2010; Dinu and Lapata, 2010). These studies conducted paraphrase ranking for all target words in the SemEval-2007 dataset, just like this experiment. However, notice that these results are just for reference, because detailed experimental settings, such as the way they built gold candidates for each target word, are probably not the same with ours.

5.2.5 Results

Table 2 shows the performance (GAP score) of the compared methods. For bag-of-walks kernels, we did not tune the parameters since no training data was provided. So the scores displayed

Method	ALL	Noun	Verb	Adjective	Adverb
cosine similarity	44.6	44.0	36.3	45.7	57.0
bag-of-walks kernel ($L = 1$)	46.7	45.2	39.1	47.5	60.1
bag-of-walks kernel ($L = 2$)	47.2	45.5	39.4	**48.7**	60.0
bag-of-walks kernel ($L = 3$)	**47.5**	45.2	40.6	48.6	**60.7**
bag-of-walks kernel ($L = 4$)	47.3	45.6	40.2	**48.7**	59.5
bag-of-walks kernel ($L = 5$)	47.4	45.3	40.8	48.6	59.6
bag-of-walks kernel ($L = 6$)	47.3	45.5	**40.9**	48.1	59.2
bag-of-walks kernel ($L = 7$)	47.0	45.3	40.7	47.6	59.0
bag-of-walks kernel ($L = 8$)	46.8	**45.9**	40.2	47.4	57.7
bag-of-walks kernel ($L = 9$)	46.6	**45.9**	39.9	46.9	57.9
(Erk and Padó, 2010)*	38.6	41.4	38.4	37.5	-
(Dinu and Lapata, 2010)*	42.9	-	-	-	-

Table 2: GAP scores on the paraphrase ranking experiment. Note that the results for the previous studies (*) are just for reference, as the detailed task setting is different from this experiment. Scores for the proposed methods are obtained with $\gamma = 0$.

are those when the walk termination probability γ is set to zero, because it gave the best results. According to Table 2, all the bag-of-walks kernels with maximum walk length L from 1 to 9 outperform the baseline cosine similarity in total ("ALL") as well as when the data is split by part-of-speech (noun, verb, adjective, and adverb). Also, better scores are obtained when $L \geq 3$, indicating that it is effective to take the structural co-occurrences consisting of more than two words into consideration.

Conclusion

We have proposed a new measure of semantic similarity between words in context. It captures structural collocation between the target words and multiple words in the context simultaneously. The proposed measure applies the bag-of-walks kernels, a variation of Desrosiers and Karypis' kernel between graph nodes, to the syntactic/semantic graph output by semantic parsers.

In the experiments on word sense disambiguation and paraphrase ranking, we verified that higher-order relations between words are effective; setting the maximum walk length of $L = 3$ steps achieved the highest performance in these tasks. And in the paraphrase ranking task, if the target words are limited to nouns only, walk length as long as $L = 9$ achieved the highest score.

While we tested our method only on English data, it does not rely on any language-specific features, and hence should work on any languages with sufficiently accurate dependency parsers. Such highly-accurate parsers are now available for many languages, as evidenced by the success of the CoNLL-X shared task (Buchholz and Marsi, 2006).

ABSTRACT
Sentence compression is important in a wide range of applications in natural language processing. Previous approaches of Japanese sentence compression can be divided into two groups. *Word-based methods* extract a subset of words from a sentence to shorten it, while *bunsetsu-based methods* extract a subset of bunsetsu (where a bunsetsu is a text unit that consists of content words and following function words). Basically, bunsetsu-based methods perform better than word-based methods. However, bunsetsu-based methods have the disadvantage that they cannot drop unimportant words from each bunsetsu because they have to follow constraints under which each bunsetsu is treated as a unit. In this paper, we propose a novel compression method to overcome this disadvantage. Our method relaxes the constraints using Lagrangian relaxation and shortens each bunsetsu if it contains unimportant words. Experimental results show that our method effectively compresses a sentence while preserving its important information and grammaticality.

TITLE AND ABSTRACT IN JAPANESE

ユニット制約の緩和による柔軟な日本語文圧縮

文圧縮は，自然言語処理の様々なアプリケーションにおいて重要である．日本語文に対する既存の圧縮手法は二種類に分けられる．単語ベースの手法は文から単語集合を選出し，圧縮文とする．一方，文節ベースの手法は文から文節集合を選出し，圧縮文とする．基本的には後者の方が良く機能する．しかし，文節ベースの手法は，文節をユニットとして扱うという制約があるため，個々の文節を圧縮できない．本稿では，この欠点を克服する新しい圧縮手法を提案する．提案手法はラグランジュ緩和を用いて上の制約を緩和し，各文節を圧縮する．実験の結果，提案手法によって原文の情報を多く保持する文法的な圧縮文を生成できることが分かった．

KEYWORDS: sentence compression, Lagrangian relaxation.

Proceedings of COLING 2012: Technical Papers, pages 1097–1112,
COLING 2012, Mumbai, December 2012.

1 Introduction

Sentence compression is the task of shortening a sentence while preserving its important information and grammaticality. This task is important in a wide range of applications such as automatic summarization (Jing, 2000; Lin, 2003; Zajic et al., 2007), subtitle generation (Vandeghinste and Pan, 2004), and displaying text on small screens (Corston-Oliver, 2001).

In this paper, we propose a novel compression method for a Japanese sentence. Like other languages, Japanese uses sentences composed of words. However, we can also say that a Japanese sentence is composed of *bunsetsu*. Bunsetsu is a text unit that consists of one or more content words and possibly one or more function words. For example, consider the following sentence.[1]

(1) *nihon to kanada no kokusai kyoudou kenkyuu guru-pu ga hakken shita*
Japan CNJ Canada GEN international collaborative research group NOM discover did

(An international collaborative research group between Japan and Canada made a discovery)

This sentence is composed of four bunsetsu: "*nihon to*", "*kanada no*", "*kokusai kyoudou kenkyuu guru-pu ga*", and "*hakken shita*". As seen in this example, a Japanese sentence can be viewed as a bunsetsu sequence as well as a word sequence.

This characteristic of the Japanese language has led researchers to take two compression approaches: *word-based methods* and *bunsetsu-based methods*. Word-based methods view a source sentence as a word sequence and generate a compressed sentence by selecting a subset of words from the source sentence (Hori and Furui, 2004; Hirao et al., 2009). However, the methods do not take account of bunsetsu, and it is thus difficult to generate grammatical compressions. For example, if only content words (or only function words) in a bunsetsu are selected, the grammaticality of the corresponding part in the compressed sentence would be poor.

We can avoid this problem using bunsetsu-based methods. Bunsetsu-based methods view a source sentence as a bunsetsu sequence and generate a compressed sentence by selecting a subset of bunsetsu from the source sentence (Takeuchi and Matsumoto, 2001; Oguro et al., 2002; Yamagata et al., 2006; Nomoto, 2008). Bunsetsu-based methods treat each bunsetsu as a unit. Thus, the methods do not suffer from the above problem and they can generate compressions that are more grammatically correct than those generated by word-based methods.

However, bunsetsu-based methods have a disadvantage in that they cannot shorten each bunsetsu in a source sentence. More precisely, when there is a compound noun in a bunsetsu and the noun contains unimportant words, bunsetsu-based methods cannot drop those words from the noun. Consider the above sentence (1) as an example. The third bunsetsu "*kokusai kyoudou kenkyuu guru-pu ga*" contains a compound noun "*kokusai kyoudou kenkyuu guru-pu*" (international collaborative research group). Suppose that we want to drop the word "*kokusai*" (international) from the noun and to shorten the bunsetsu to "*kyoudou kenkyuu guru-pu ga*". However, bunsetsu-based methods cannot perform such flexible word selection because they have to treat each bunsetsu as it is.

[1] This paper uses the abbreviations NOM (nominative), ACC (accusative), DAT (dative), ALL (allative), GEN (genitive), CMI (comitative), CNJ (conjunction), and TOP (topic marker).

In this paper, we propose a novel compression method to overcome the above disadvantage. As described above, the disadvantage results from a constraint for each bunsetsu under which the bunsetsu has to be treated as a unit (hereafter called the *unit constraint*). If we ignore unit constraints, we may be able to avoid the problem. However, if we do so, we again suffer from the problem of word-based methods (i.e., we will not generate grammatical compressions). We therefore do not ignore or adhere to unit constraints, but relax them using Lagrangian relaxation. That is, the proposed method basically follows the constraints and treats each bunsetsu as a unit. However, if a bunsetsu contains unimportant words, our method violates its unit constraint and drops those words from the bunsetsu. In this paper, we formulate this idea using integer linear programming (ILP) and report the effectiveness through experiments.

2 Word-based Method

We first describe word-based methods in detail. Although several word-based methods have been proposed (Hori and Furui, 2004; Hirao et al., 2009), the basic idea behind the methods is the same. We explain the idea in detail and discuss the advantage and disadvantage of word-based methods.

2.1 Idea

In word-based methods, a source sentence is viewed as a word sequence. Let w_i $(i = 1, \ldots, I)$ denote a word in a source sentence. The basic idea underlying word-based methods is that the compression is a subset of words with the maximum importance in a source sentence. Through ILP, this idea is formulated as follows.

Sentence Compression (Word-based Formulation)

$$\text{maximize} \quad \sum_{i=1}^{I} x_i \, Score(w_i) \tag{1}$$

$$\text{subject to} \quad \sum_{i=1}^{I} x_i \, Length(w_i) \leq L \tag{2}$$

$$x_i = 0 \text{ or } 1 \quad (i = 1, \ldots, I) \tag{3}$$

where x_i denotes a decision variable of w_i that is 1 if w_i is contained in a compressed sentence, and otherwise 0. $Score(w_i)$ represents the importance of w_i and $Length(w_i)$ represents the length of w_i. L is a predefined maximum length of a compressed sentence. According to Eq. (1), the optimal subset of words in a source sentence is selected as a compressed sentence. In addition, according to Eq. (2), the length of the compressed sentence shall be not more than L.

2.2 Advantage and Disadvantage

The advantage of word-based methods is that the methods can more freely select important words in a source sentence than bunsetsu-based methods. This is because word-based methods do not take account of bunsetsu in a source sentence and are not limited to unit constraints.

However, due to the freeness, word-based methods have the disadvantage that they tend to generate ungrammatical compressions. As described in Section 1, if only content words (or

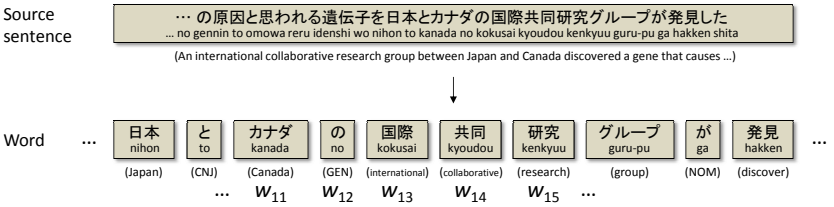

Figure 1: Word-based method. A source sentence is segmented into words and a subset of words in the sentence is selected as the compressed sentence.

only function words) in a bunsetsu are selected, the grammaticality of the corresponding part in the compressed sentence would be poor. Consider the sentence in Figure 1. There is, for example, the bunsetsu "*kanada no*" in the sentence (although word-based methods do not take account of it). If we select only the word "*kanada*" (Canada) from the bunsetsu and do not select the word "*no*" (GEN), the corresponding part of the compressed sentence would not make sense. As just described, it is difficult to generate grammatical compressions using word-based methods.

3 Bunsetsu-based Method

Like word-based methods, most previous bunsetsu-based methods (Oguro et al., 2002; Yamagata et al., 2006; Nomoto, 2008) are based on the same idea. In this section, we explain the idea and discuss the advantages and disadvantage of bunsetsu-based methods.

3.1 Idea

Word-based methods view a source sentence as a word sequence, while bunsetsu-based methods view the sentence as a bunsetsu sequence. Let b_j $(j = 1, \ldots, J)$ denote a bunsetsu in a source sentence. The basic idea underlying bunsetsu-based methods is that the compression is a subset of bunsetsu with the maximum importance in a source sentence. Through ILP, this idea is formulated as follows.

Sentence Compression (Bunsetsu-based Formulation)

$$\text{maximize} \quad \sum_{j=1}^{J} y_j \, Score(b_j) \tag{4}$$

$$\text{subject to} \quad \sum_{j=1}^{J} y_j \, Length(b_j) \leq L \tag{5}$$

$$y_j = 0 \text{ or } 1 \quad (j = 1, \ldots, J) \tag{6}$$

where y_j denotes a decision variable of b_j that is 1 if b_j is contained in a compressed sentence, and otherwise 0. $Score(b_j)$ represents the importance of b_j and $Length(b_j)$ represents the length of b_j. According to Eq. (4), the optimal subset of bunsetsu in a source sentence is selected as a compressed sentence. In addition, according to Eq. (5), the length of the compressed sentence shall be not more than L.

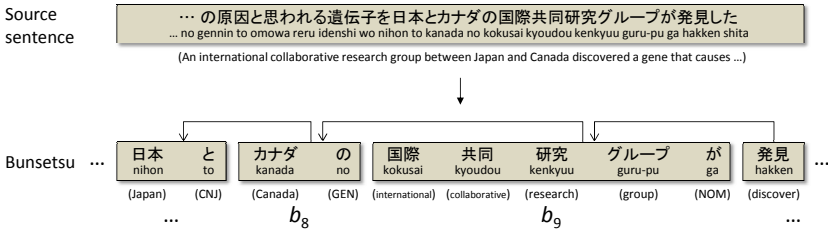

Figure 2: Bunsetsu-based method. A source sentence is segmented into bunsetsu and a subset of bunsetsu in the sentence is selected as the compressed sentence. Bunsetsu-based methods have the advantage in that they are able to use dependency information.

3.2 Advantages and Disadvantage

One advantage of bunsetsu-based methods is that the methods can generate compressions that are more grammatical than compressions generated by word-based methods. Bunsetsu-based methods select each bunsetsu in a source sentence just as it is. Therefore, the methods do not suffer from the problem of word-based methods (see also Section 2.2).

Bunsetsu-based methods have the another advantage in that they are able to use dependency information in a source sentence. In Japanese, a dependency relation is generally defined between not a pair of words but a pair of bunsetsu. Consider the source sentence in Figure 2. In the sentence, there is the example that bunsetsu b_8 depends on bunsetsu b_9. Bunsetsu-based methods can use this information by adding the following simple constraint to the above formulation.

$$\text{subject to} \quad y_8 \leq y_9 \tag{7}$$

This constraint ensures that if b_8 is contained in a compressed sentence, b_9 is also contained in the sentence. In this way, bunsetsu-based methods can easily use dependency information in a source sentence. On the other hand, there is a word-based method that defines dependency relations between words in a source sentence and uses the information (Hori and Furui, 2003). However, as described above, a dependency relation is generally defined between a pair of bunsetsu. In the method, bunsetsu dependencies in a source sentence and complex rules are necessary to define the word dependencies, and it is not easy to use the information.

On the other hand, as described in Section 1, the disadvantage of bunsetsu-based methods is that they cannot shorten each bunsetsu in a source sentence. More precisely, when there is a compound noun in a bunsetsu and the noun contains unimportant words, bunsetsu-based methods can not drop those words from the noun. Consider again the sentence in Figure 2. Bunsetsu b_9 contains a compound noun "*kokusai kyoudou kenkyuu guru-pu*" (international collaborative research group). Suppose that we want to drop the word "*kokusai*" (international) from the noun and to shorten the bunsetsu to "*kyoudou kenkyuu guru-pu ga*". However, bunsetsu-based methods cannot perform such flexible word selection because they are limited to unit constraints.

4 Proposed Method

Bunsetsu-based methods basically perform better than word-based methods, especially in terms of the grammaticality of a compressed sentence. However, bunsetsu-based methods have the disadvantage that they cannot shorten each bunsetsu in a source sentence. In this section, we describe a novel compression method that overcomes this disadvantage.

4.1 Idea

The point of our method is to relax unit constraints responsible for the disadvantage. Under the constraints, we have to treat each bunsetsu as a unit. If we ignore the constraints, we may be able to avoid the problem. However, if we do so, we again suffer from the problem of word-based methods (i.e., we will not generate grammatical compressions). Therefore, we select a set of bunsetsu, each containing unimportant words, and relax their unit constraints. Note that each bunsetsu that contains a compound noun (e.g., b_9 in Figure 3) is selected as a bunsetsu that may contain unimportant words. Conversely, we do not shorten each bunsetsu that does not contain a compound noun (e.g., b_8 in Figure 3) because such a bunsetsu has only one content word and does not need to be shortened.

First, let us rewrite the bunsetsu-based formulation in Section 3.1. Using w_i and x_i instead of b_j and y_j, the formulation can be rewritten as follows.

Sentence Compression (Bunsetsu-based Formulation 2)

$$\text{maximize} \quad \sum_{i=1}^{I} x_i \, Score(w_i) \tag{8}$$

$$\text{subject to} \quad \sum_{i=1}^{I} x_i \, Length(w_i) \leq L \tag{9}$$

$$x_i = 0 \text{ or } 1 \quad (i = 1, \ldots, I) \tag{10}$$

$$x_{First(b_j)} = x_{First(b_j)+1} = \cdots = x_{Last(b_j)} \quad (w_{First(b_j)}, \ldots, w_{Last(b_j)} \in b_j, \; j = 1, \ldots, J) \tag{11}$$

where $First(b_j)$ represents a function that returns the index of the first word in b_j, while $Last(b_j)$ returns that of the last word in b_j (e.g., in Figure 3, $First(b_9) = 13$ and $Last(b_9) = 17$). In addition, we set $Score(b_j) = \sum_{w_i \in b_j} Score(w_i)$ and $Length(b_j) = \sum_{w_i \in b_j} Length(w_i)$.

The notable aspect of the above formulation is Eq. (11), which is the set of unit constraints. Equation (11) ensures that if we select one word from a bunsetsu in a source sentence, we also select the other words from the bunsetsu. Likewise, if we do not select one word from a bunsetsu, we must also not select the other words from the bunsetsu.

The proposed method does not ignore or adhere to unit constraints but relaxes them. To do this, we use Lagrangian relaxation, which is a classical technique for combinatorial optimization. The technique moves problematic constraints into the objective function and penalizes the function if those constraints are not satisfied. Using the technique, we remove unit constraints for each bunsetsu that contains a compound noun.

Let B_{CN} denotes a subset of bunsetsu, each containing a compound noun. In addition, let us decompose a unit constraint for b_j in B_{CN} (i.e., $x_{First(b_j)} = x_{First(b_j)+1} = \cdots = x_{Last(b_j)}$) into

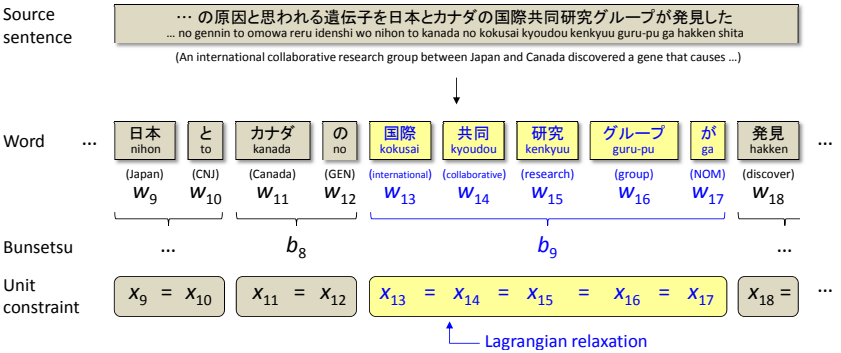

Figure 3: Proposed method. Bunsetsu b_9 contains a compound noun "*kokusai kyoudou kenkyuu guru-pu*" (international collaborative research group). The proposed method relaxes the unit constraint for the bunsetsu using Lagrangian relaxation.

a set of constraints: $x_{First(b_j)} = x_{Last(b_j)}$, $x_{First(b_j)+1} = x_{Last(b_j)}$, …, and $x_{Last(b_j)-1} = x_{Last(b_j)}$. Our new formulation is given below.

Sentence Compression (Proposed Formulation)

$$\text{maximize} \quad \sum_{i=1}^{I} x_i \, Score(w_i) + \sum_{b_j \in B_{CN}} \sum_{w_i \in b_j \setminus w_{Last(b_j)}} \mu_{i,Last(b_j)}(x_i - x_{Last(b_j)}) \tag{12}$$

$$\text{subject to} \quad \sum_{i=1}^{I} x_i \, Length(w_i) \leq L \tag{13}$$

$$x_i = 0 \text{ or } 1 \quad (i = 1, \ldots, I) \tag{14}$$

$$x_{First(b_j)} \leq x_{First(b_j)+1} \leq \cdots \leq x_{CLast(b_j)} = \cdots = x_{Last(b_j)}$$
$$(w_{First(b_j)}, \ldots, w_{Last(b_j)} \in b_j, \; j = 1, \ldots, J) \tag{15}$$

where $\mu_{i,Last(b_j)}$ is a Lagrangian multiplier provided for a constraint $x_i = x_{Last(b_j)}$. $CLast(b_j)$ in Eq. (15) returns the index of the last content word in b_j (e.g., in Figure 3, $CLast(b_9) = 16$).

A notable aspect is the second term in Eq. (12). For a bunsetsu b_j in B_{CN} (e.g., b_9 in Figure 3), the term penalizes the objective function if a decision variable of a word in b_j (denoted as x_i) is not equal to that of the last word in b_j (denoted as $x_{Last(b_j)}$). For example, if $x_i = 0$ and $x_{Last(b_j)} = 1$, the term penalizes the objective function. Thus, the proposed method basically treats words in b_j as a unit similarly to bunsetsu-based methods. However, now there is no constraint under which $x_{First(b_j)} = x_{First(b_j)+1} = \cdots = x_{Last(b_j)}$. In other words, although we have to consider the penalty, we can set a different value for each decision variable. Suppose that w_{13} in b_9 in Figure 3 have little importance, while the rest words in b_9 have great importance. Unlike bunsetsu-based methods, the proposed method can set $x_{13} = 0$ and the rest decision variables to 1.

Equation (15) represents a constraint that sets the order of preference of the selection of words in a bunsetsu. As described above, for each bunsetsu in B_{CN}, each decision variable

  end for
end for
return $\boldsymbol{x}^{(T)}$

can take a different value from other variables. However, care must be taken in setting each variable. More precisely, latter words in a bunsetsu generally should not be dropped before the earlier words are dropped. One reason for this is that function words are located in the latter part of a bunsetsu. Another is that former words within a Japanese compound noun basically modify the latter words (i.e., the latter words are syntactically more important than the former words). We thus add a constraint to our formulation under which we prioritize latter words in a bunsetsu.

We set $x_{CLast(b_j)} = \cdots = x_{Last(b_j)}$ in the latter part of Eq. (15). The purpose is to treat function words in a bunsetsu in B_{CN} as a unit and select at least one content word from the bunsetsu. Furthermore, using this equation, we can retain a unit constraint for each bunsetsu that does not contain a compound noun (i.e., for such bunsetsu, Eq. (15) is the same as Eq. (11)).

Of course, there are exceptions to Eq. (15), especially proper nouns. For example, if we drop the first word from the compound noun "*murayama tomiichi syusyou*", an unlikely noun "*tomiichi syusyou*" would be generated ("*murayama*", "*tomiichi*", and "*syusyou*" meaning Murayama, Tomiichi, and prime minister, respectively). In this case, we need to recognize the family name ("*murayama*"), the last name ("*tomiichi*"), and the title ("*syusyou*") and drop the words in the following order: last name, family name, and title. In our experiments described in the following section, we handle this exception for person names. However, we do not handle exceptions about other proper nouns such as organization names. We leave this for our future work.

Finally, we present an algorithm to solve our formulation in Algorithm 1. In the algorithm, T denotes the number of iterations and $\alpha^{(t)}$ denotes a parameter that determines a step size to update each Lagrangian multiplier (see (Korte and Vygen, 2008) for detail). Using this algorithm, each multiplier is updated and a subset of words in a source sentence is selected so that a compression produced by our method is as similar to that produced by bunsetsu-based methods as possible. However, as described in the previous paragraphs, if bunsetsu contain unimportant words, our method prioritizes to violate their unit constraints and drop the unimportant words.

4.2 Advantages

Compared with word-based and bunsetsu-based methods, the proposed method has at least three advantages. First, our method can generate compressions that are more grammatical than compressions generated with word-based methods. This is because our method is loosely based on bunsetsu-based methods and basically treats each bunsetsu in a source sentence as it is.

Second, unlike word-based methods, our method can easily use dependency information in a source sentence. This is again because our method is loosely based on bunsetsu-based methods. For example, bunsetsu b_8 in Figure 3 depends on bunsetsu b_9 (see also Figure 2). We can use this information employing the following constraint.

$$\text{subject to} \quad x_{12} \leq x_{17} \tag{16}$$

That is, we introduce a constraint between the last words of the bunsetsu. In this way, when b_8 is contained in a compressed sentence, we can ensure that b_9 is also contained in the sentence regardless of whether the bunsetsu are shortened.

Third, unlike bunsetsu-based methods, our method can shorten a bunsetsu in a source sentence. Since bunsetsu-based methods are limited by unit constraints, they have to treat each bunsetsu as a unit. Thus, even if there are unimportant words in a bunsetsu, the methods do not drop those words from the bunsetsu. On the other hand, our method relaxes unit constraints using Lagrangian relaxation. Thus, our method has the ability to drop unimportant words from a bunsetsu, even though it is loosely based on bunsetsu-based methods.

5 Experiments

In this section, we report two experiments conducted to evaluate the proposed method.

5.1 Test Set

There is no standard test set for Japanese sentence compression. We therefore constructed a test set to evaluate the proposed method. The construction process is as follows.

First, we extracted 240 sentences from Kyoto University Text Corpus (Kurohashi and Nagao, 1998),[2] a parsed corpus of Mainichi Shimbun 1995. More precisely, we extracted sentences that satisfied all of the following three conditions. (1) The sentence was a lead sentence (the first sentence of an article). Lead sentences are often used in experiments for sentence compression because they can be compressed without consideration of their context. (2) The length of the sentence was not too short and not too long. We employed the number of characters in a sentence as the sentence length and extracted sentences not shorter than 51 characters and not longer than 100 characters. (3) The sentence did not contain parentheses. This condition was considered because we found that even human subjects often could not compress content in parentheses (typically speech). From the 409 extracted sentences that satisfied these three conditions, we randomly selected 240 sentences for our experiments.

For each of the 240 sentences, two subjects produced compressed versions. The compression ratio was set to 0.7. For example, if the length of a sentence was 100 characters, each subject was asked to produce a compressed sentence whose length was not longer than 70 characters.

Avg. # of characters per source sentence	75.1
Avg. # of words per source sentence	44.6
Avg. # of bunsetsu per source sentence	14.5
Avg. # of bunsetsu with a compound noun per source sentence	5.3

Table 1: Statistics of our test set.

Finally, from the 240 groups of a source sentence and its two compressed versions, we randomly selected 160 groups as our test set. We used the remaining 80 groups as a development set to tune the proposed method. The statistics of our test set are given in Table 1.

5.2 Methods

In our experiments, we compared the outputs of the following methods.

WORD (RANDOM) Word-based method. This method randomly selected a subset of words from a source sentence as the compressed sentence.

WORD Word-based method described in Section 2.1. The optimal subset of words in a source sentence was selected using ILP.

BNST (RANDOM) Bunsetsu-based method that randomly selected a subset of bunsetsu from a source sentence as the compressed sentence.

BNST Bunsetsu-based method described in Section 3.1. The optimal subset of bunsetsu in a source sentence was selected using ILP.

BNST w/ DPND Bunsetsu-based method. We added dependency constraints to BNST.

PROP Proposed method described in Section 4.1. Using Lagrangian relaxation, unimportant words were dropped from a compound noun in a bunsetsu.

PROP w/ DPND Proposed method. We added dependency constraints to PROP.

HUMAN Human compression. For each source sentence in our test set, one of the two compressed sentences produced by subjects were randomly selected.

For WORD, BNST, BNST w/ DPND, PROP, and PROP w/ DPND, we used lp_solve (a mixed ILP solver[3]). In addition, we set $Score(w_i)$ and $Score(b_j)$ as follows. First, from articles in the newspaper Mainichi Shimbun from 1991 to 2002, we extracted pairs of a lead sentence and a title that could be viewed as a source sentence and its pseudo compression. Note that articles in 1995 were excluded because they overlapped with our test set. Moreover, we viewed a lead sentence and a title as a source sentence and its pseudo compression if the lead sentence contained more than 80% of content words in the title. We then calculated the rate of occurrence of a word in the titles to that in the lead sentences. For example, if a word appeared 50 times in the titles and 100 times in the lead sentences, the rate of occurrence of the word was 0.5. We used this rate as $Score(w_i)$ and set $Score(b_j) = \sum_{w_i \in b_j} Score(w_i)$.

Furthermore, we set $\alpha^{(t)} = \alpha^{(0)}/t$ for PROP and PROP w/ DPND. Note that $\alpha^{(0)}$ was set to 0.02 according to our development set. T was set to 100.

BNST	0.745	0.615
BNST w/ DPND	0.772†	0.653†
PROP	0.751	0.616
PROP w/ DPND	0.796†‡	0.671†‡

Table 2: Information content in a compressed sentence. † and ‡ mark statistically significant improvement over BNST and BNST w/ DPND with $p < 0.01$, respectively.

5.3 Information Content of a Compressed Sentence

In the first experiment, we examined how well our method performed in preserving important information in a source sentence. Using the methods described in the previous section, we compressed each source sentence in our test set. The compression ratio was set to 0.7. We then computed Recall-Oriented Understudy for Gisting Evaluation (ROUGE) scores (Lin, 2004) for each of the methods. That is, we measured the *n*-gram overlap between the outputs of each method and those of human subjects. In the calculation of ROUGE, stopwords were not removed. In addition, each word in a compression was normalized using the Japanese morphological analyzer JUMAN (Kurohashi et al., 1994).

Table 2 gives the results. We can see that PROP significantly outperformed WORD, especially in terms of ROUGE 2. The reason for this is that unlike WORD, PROP basically selected words in each bunsetsu in a source sentence as a unit.

When dependency constraints were not considered, PROP performed better than BNST. However, the performance differences between them were small and only the difference in ROUGE 1 was statistically significant (Wilcoxon signed-rank test, $p < 0.05$). On the other hand, when dependency constraints were considered, PROP significantly outperformed BNST. This time, the differences in ROUGE 1 and ROUGE 2 were both statistically significant ($p < 0.01$).

We found that the differences between PROP w/ DPND and BNST w/ DPND were due to the number of available bunsetsu that each method could select. More precisely, PROP w/ DPND selected 4.6% more (shortened) bunsetsu in a source sentence than BNST w/ DPND. Suppose that bunsetsu b_j is located at a deep node in a dependency tree of a source sentence (i.e., b_j depends on $b_{j'}$ and $b_{j'}$ depends on $b_{j''}$ and ... depends on b_J). To select b_j, both methods first have to select from $b_{j'}$ to b_J owing to the dependency constraints. However, since there is a length constraint, it is usually difficult to select b_j at such a deep node even if b_j contains important words. However, PROP w/ DPND has more chance of selecting b_j than BNST w/ DPND. This is because PROP w/ DPND can make room to select b_j by dropping unimportant words from other bunsetsu. In this way, PROP w/ DPND selected more bunsetsu that contained important words and achieved higher performance than BNST w/ DPND.

In contrast, when dependency constraints were not considered, the number of (shortened) bunsetsu that PROP selected was not so different from the number of that BNST selected (the difference was 2.4%). This is because PROP ignored dependency constraints and almost greedily selected bunsetsu that were composed of many important words. In other words, PROP had less opportunity to drop unimportant words. As a result, the differences between the performances of the two methods were not so large.

	Grammaticality
WORD	1.50
BNST	2.23
BNST w/ DPND	4.15
PROP	2.18
PROP w/ DPND	4.14
HUMAN	4.85

Table 3: Grammaticality of a compressed sentence. The score ranges from 1 to 5: 1 (very poor), 2 (poor), 3 (average), 4 (good), and 5 (very good).

5.4 Grammaticality of a Compressed Sentence

In the second experiment, we examined how well our method performed in producing grammatical compressions. We randomly selected 50 source sentences from our test set and obtained the outputs of six methods for those sentences. Note that the six methods were WORD, BNST, BNST w/ DPND, PROP, PROP w/ DPND, and HUMAN. Then, for each of the 50 source sentences, we presented the six outputs to five subjects and asked them to rate the outputs in terms of grammaticality. The subjects were all native Japanese speakers and did not include the two subjects who constructed our test set. They were told that all outputs were automatically generated. For each of the source sentences, the order of the outputs was randomized.

Table 3 presents the results. From the table, we can confirm that PROP produces compressions that are more grammatically correct than the compressions produced by WORD. This is because PROP was loosely based on bunsetsu-based methods and basically selected each bunsetsu as a unit.

For the same reason, PROP achieved comparable performance with BNST. Note that the performance of PROP was slightly worse than that of BNST. This is because words that should not be dropped from a bunsetsu were dropped by PROP. For example, PROP shortened the bunsetsu "*unyu syou wa*" to "*shou wa*" ("*unyu*", "*syou*", and "*wa*" mean transport, ministry, and TOP, respectively). In Kyoto University Text Corpus, which we used in our experiments, "*shou*" (ministry) was tagged as a noun. However, unlike usual nouns, the word cannot be located at the beginning of a bunsetsu. This is because in Japanese, the word has a strong suffix nature. Thus, we must not drop "*unyu*" (transport) from the bunsetsu and we should treat "*unyu*" (transport) and "*syou*" (ministry) as a unit. We found that most errors arising when employing our method related to such words, which could be viewed as both a noun and suffix (e.g., "*kai*" (meeting), "*jin*" (-ese)). As a future work, we need to properly handle these words.

PROP achieved good performance when we added dependency constraints to the method. The score of PROP w/ DPND was 4.14. This result indicates that the grammaticality of the compressions produced by PROP w/ DPND was generally good. The reason why the performance of PROP w/ DPND was slightly worse than that of BNST w/ DPND is the same as the reason described in the previous paragraph. As seen in the first experiment, dependency constraints were also effective in preserving important information. Thus, we can say that there is no reason for not using the constraints in sentence compression.

To verify that the grading was consistent, we computed correlation coefficients between every pair of our five subjects (i.e., between subjects 1 and 2, 1 and 3, ..., and 4 and 5). Consequently, we found that the average of the coefficients was 0.45 and those coefficients were all statistically significant (t-test, $p < 0.01$). These suggest that the grading was consistent.

Source sentence
中米ホンジュラスの/軍司令官は/１５日、/４０年間に/わたり/管轄してきた/警察部隊を/文民の/指揮下に/置くと/発表した。[52]
(On the 15th, an army commander of Honduras, located in Central America, announced that the police divisions that the army had controlled for 40 years would be placed under civilian control.)

WORD
中米ホンジュラスの軍司令官は日、４０年間に管轄警察部隊を文民の指揮下にと [36]
Ungrammatical sentence

BNST w/ DPND
中米ホンジュラスの/軍司令官は/警察部隊を/文民の/指揮下に/置くと/発表した。[34]
(An army commander of Honduras, located in Central America, announced that the police divisions would be placed under civilian control.)

PROP w/ DPND
ホンジュラスの/軍司令官は/１５日、/警察部隊を/文民の/指揮下に/置くと/発表した。[36]
(On the 15th, an army commander of Honduras announced that the police divisions would be placed under civilian control.)

HUMAN
ホンジュラスの/軍司令官は/１５日、/警察部隊を/文民の/指揮下に/置くと/発表した。[36]
(On the 15th, an army commander of Honduras announced that the police divisions would be placed under civilian control.)

Figure 4: Example of the outputs. For explanation purposes, we inserted slashes between bunsetsu in each of the outputs except for WORD. The values in square bracket denote sentence lengths.

5.5 Example of the Outputs

Figure 4 gives an example of the output of our method (PROP w/ DPND). For comparison, we also show the outputs of WORD, BNST w/ DPND, and HUMAN. In this example, the source sentence comprises 52 characters. Thus, each method was required to produce a compressed sentence whose length was not more than 36 characters ($52 \times 0.7 = 36.4$).

In this example, WORD produced a completely ungrammatical compression. In contrast, BNST w/ DPND produced a good compression, which was grammatical and preserved much information in the source sentence. However, in the output of HUMAN, the first bunsetsu “中米ホンジュラスの” in the source sentence was shortened to “ホンジュラスの” (“中米”, “ホンジュラス”, and “の” mean Central America, Honduras, and GEN, respectively). BNST w/ DPND could not perform such an operation because the method has to treat each bunsetsu as it is.

On the other hand, PROP w/ DPND could shorten the bunsetsu by dropping word “中米”, which had less importance, from the bunsetsu ($Score$(“中米”) was 0.119). Additionally, using the room that was made by dropping the word, the method could add another bunsetsu “１５日、” to the compression (“１５”, “日”, and “、” mean 15, day, and comma, respectively). Although there are other bunsetsu that contain compound nouns (e.g., “軍司令官は”), our method did not drop any words from those bunsetsu and selected them as a unit similarly to BNST w/ DPND (“軍”, “司令” + “官”, and “は” mean army, commander, and TOP, respectively). This is because the words in the bunsetsu had great importance (e.g., $Score$(“軍”) was 0.378). In this way, PROP w/ DPND could produce the same compression as HUMAN.

6 Related Work

Sentence compression has been widely studied since the early 2000s. For the English language, Jing used multiple knowledge resources to decide which phrases in a source sentence to remove (Jing, 2000). Knight and Marcu modeled a generative process of a source sentence based on a noisy-channel framework and generated a compressed sentence using the model (Knight and Marcu, 2002). Turner and Charniak presented semi-supervised and unsupervised variants of the Knight and Marcu's model (Turner and Charniak, 2005). McDonald employed a discriminative model to learn which words in a source sentence should be dropped (McDonald, 2006). Clarke and Lapata recasted previous methods as ILP and extended those with various constraints (Clarke and Lapata, 2008). Our work differs from these efforts in that we focus on Japanese sentence compression.

For the Japanese language, previous compression methods can be divided into two groups: word-based methods and bunsetsu-based methods. Hori and Furui proposed a word-based method to summarize speech (Hori and Furui, 2004). They extracted a set of important words from an automatically transcribed sentence. Hirao et al. also proposed a word-based method (Hirao et al., 2009). They extended Hori and Furui's method using novel features. Unlike these methods, our method is loosely based on bunsetsu-based methods, and thus easily generates grammatical compressions.

Previous bunsetsu-based methods are given below. Takeuchi and Matsumoto used a support vector machine to acquire rules for dropping unimportant bunsetsu in a source sentence (Takeuchi and Matsumoto, 2001). Oguro et al. and Yamagata et al. defined varying importance of bunsetsu and dependency and extracted the optimal subset of bunsetsu from a source sentence (Oguro et al., 2002; Yamagata et al., 2006). Nomoto generated candidates for a compression by removing bunsetsu from a source sentence and selected the best candidate using a conditional random field (Nomoto, 2008). Our work differs from these efforts in that our method has the ability to drop unimportant words from a bunsetsu.

In our method, we used Lagrangian relaxation to relax unit constraints. Lagrangian relaxation is a well known technique for combinatorial optimization and it has recently been successfully applied to various natural language processing tasks (Koo et al., 2010; M.Rush et al., 2010; Chang and Collins, 2011; M.Rush and Collins, 2011). However, to the best of our knowledge, this is the first work to use the technique for sentence compression.

Conclusions and Future Work

We presented a novel compression method for a Japanese sentence. The proposed method was loosely based on bunsetsu-based methods. Thus, unlike word-based methods, it could easily produce grammatical compressions. Additionally, using Lagrangian relaxation, the proposed method relaxed constraints that troubled bunsetsu-based methods. In this way, unlike bunsetsu-based methods, our method could shorten each bunsetsu if it contained unimportant words. Experimental results showed that the proposed method could preserve more information in a source sentence than word-based and bunsetsu-based methods. Furthermore, we confirmed that our method could produce grammatical compressions similarly to bunsetsu-based methods.

In future work, as described in Section 4.1, we plan to explore a technique to handle proper nouns such as organization names. Additionally, as described in Section 5.4, we need to develop a method to handle words that can be viewed as both a noun and suffix.

ABSTRACT
Testing a theory against real world data can sometimes be helpful in figuring out the shortcomings of your current theory. In this paper, we test a theory about the syntax-semantics interface of German *nach*-particle verbs against data from a web corpus in order to see if we can use our automatic NLP machinery to corroborate the predictions of the theory. We use state-of-the-art parsers to automatically annotate our data with the features predicted by the theory and then apply a standard clustering approach to approximate the *nach*-particle verb classes of the theory. The results of our experiment not only help us highlighting the more problematic parts of the theory but also teach us about the strengths and weaknesses of our automatic analysis tools.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE, L_2 (OPTIONAL, AND ON SAME PAGE)

Corpusbasierte Überprüfung einer semantischen Klassifikation deutscher *nach*-Partikelverben

Um Unzulänglichkeiten einer Theorie auszumachen ist es mitunter vonnöten, Hypothesen gegen echtes Textmaterial abzugleichen. In diesem Beitrag soll diskutiert werden, wie Vorhersagen einer Theorie zum syntaktischen und semantischen Verhalten deutscher *nach*-Partikelverben gegen Netztexte abgeglichen werden können und wie dabei eine automatische Textverarbeitung unterstützend zum Tragen kommt. Es werden Parser des letzten Stands der Forschung verwendet um die Daten mit den von der Theorie vorhergesagten Merkmalen zu annotieren bevor ein standardisiertes Clustering-Verfahren angewandt wird um die theoretischen *nach*-Partikel-Verb-Klassen nachzubilden. Die Resultate des Experiments unterstreichen nicht nur Problemfälle der Theorie sondern zeigen auch die Stärken und Schwächen der automatischen Analyse.

1 Introduction

We test a theoretically well-motivated hypothesis about the syntax-semantics interface of German *nach*-particle verbs (*nach*-PV) on data from the "real world", to gain insight into the strengths and weaknesses of the theory as well as the limitations of our NLP-methodology. The theory we want to test is a word-syntactic approach to *nach*-PVs implemented in a generative framework. The analysis of five different readings of *nach* in combination with a verb makes different predictions on the argument structure of the complex verb, in particular with respect to dative and marginally to accusative arguments: the verb semantics (especially the *nach* particle) determines the argument structure of the verb. In order to test this assumption, we will turn the argumentation around: to what extent can we use automatically gained syntactic information to recreate the *nach*-PV classes. For this, we automatically annotate large amounts of data with their syntactic structure and identify the argument structure of each verb. Based on this information, we then apply a standard clustering technique to recreate the *nach*-PV classes proposed by the theory. As syntactic indicators for the clustering, dative and accusative arguments seem to be ideal candidates, as they are partially in the scope of the theoretical description. But we also incrementally add further features of potential relevance for the *nach*-PV reading classification: the form of arguments, prepositional phrases (form of preposition, governed case, form of embedded object), adverbials (adverbs and predicative adjectives), as well as clausal objects.[1].

Although automatic parsers are high quality and reliable tools nowadays, their performance degrades when applied to unrestricted all-domain data. Since we work on web text, we apply two very different parsers, which we then combine for a more reliable annotation. For a small subset of the *nach*-PV data, we use a manually created gold standard for dative and accusative arguments. Evaluating the parsers against this gold standard enables us to pinpoint the advantages of each parser and develop a combination scheme.

The paper is structured as follows. In Section 2, we introduce the theory about the *nach*-PV classes and their related argument structures. In Sections 3 to 5, we present the study in which we apply the theoretical approach to the real world data. In Section 3, we present the data we use: a German web corpus, a small gold standard, and a manual classification of all *nach*-PV lemmas from the corpus according to the theory from Section 2. The gold standard is for the evaluation and combination of the parsers, which extract syntactic features related to the *nach*-PVs (Section 4). The classification of *nach*-PV lemmas is used for the evaluation of the clustering based on the extracted syntactic features (Section 5). We conclude by discussing the lessons learned from each step of this study.

2 Phenomena and linguistic modeling

The German verb particle *nach* (≈ 'after') shows a range of different meanings. Haselbach (2011) provides a partial classification of *nach* into five readings that behave differently with respect to licensing a dative argument:

1. ⊕DAT: direction reading (DIR)
2. ⊕DAT: copy manner reading (MAN)
3. ⊖DAT: copy creation reading (CRE)
4. ⊖DAT: once-more/restitution reading (OMR)
5. ⊖DAT: continuation reading (CONT)

This classification does not cover yet e.g. an intensifying reading such as in *nachdenken* ('to reflect') or a prove/check reading such as in *nachprüfen* ('to recheck').

[1]For similar work on the German verb particle *an* (≈ 'on') see Springorum et al. (2012)

2.1 Modeling at the syntax-semantics interface

(Haselbach, 2011) provides a syntactico-semantic modeling of the five readings of *nach* in terms of Discourse Representation Theory (e.g. Kamp and Reyle, 1993; Roßdeutscher and Kamp, 2010), combined with word-syntactic principles from Distributed Morphology (Halle and Marantz, 1993). Haselbach (2011) implements them by means of the extended VP-shell hypothesis (Larson, 1990). His syntactico-semantic modeling comes close to Nicol's (2002) implementation who argues that verb particles are spelled out instances of functional heads in the verbal domain. Precisely, Haselbach (2011) argues that (i) *nach* either represents the head of a functional projection *w*P which is above VP and projects a dative argument in its specifier, cf. (1-a); or (ii) it is the realization of the head of a functional projection *x*P, which is also above VP however does not project a dative argument in its specifier, cf. (1-b).

(1) a. [$_{wP}$ DP$_{DAT}$ [$_{w'}$ *w*=“*nach*” VP]]
b. [$_{xP}$ *x*=“*nach*” VP]

The idea is that *nach* adds a second eventuality to the semantics by presupposition. The functional difference between *w* and *x* is that *w*, i.e. if a dative is present in the structure, allows *nach* to access event properties in the underlying VP, whereas *x* allows *nach* to access state properties in the underlying VP. Accessing event properties here means that properties of the event in the VP are assigned to the event presupposed by *nach*. Accessing event properties can either be the direction (class DIR) or the manner (class MAN) of an event. By presupposing a second **event** in the semantics, a slot for a further argument is created in the specifier of the functional projection headed by *nach*, i.e. in Spec,*w*P. This argument, which surfaces as dative, is interpreted as a participant in the presupposed event. Accessing state properties, on the other hand, means that properties of a state, if present, within the VP are assigned a presupposed **state**. These can be result or progression state properties. A result state property can either be the existence of an object, i.e. for creation verbs (class CRE), or predicational states contributed by a deadjectival or denominal verb (class OMR). Progressive state properties are stative run-time properties of an event, i.e. the state that can be described by means of the event taking place (class CONT). In these cases, no additional argument slot is semantically present, and thus no dative is licensed.

2.1.1 Five readings of *nach* and the dative

Distinguishing two groups of *nach* reading (plus vs. minus dative), Haselbach (2011) claims that *nach* expressing the meaning “following NP$_{DAT}$” (**directional**: DIR; cf. (2-a)) and *nach* expressing the meaning “do such as NP$_{DAT}$” (**manner**: MAN; cf. (2-b)) take a dative argument.

(2) a. Der Hund rannte dem Hasen nach.
the dog ran the.DAT hare after
“The dog ran after the hare.”
b. Das Mädchen betete der Mutter (den Psalm) nach.
the girl prayed the.DAT mother (the.ACC psalm) after
“The girl copied the mother's praying (of the psalm).”

As opposed to the two readings of *nach* in the context of which a dative is present, there are three readings of *nach* where no dative is present. The first reading is the creation, or copy object reading which can be paraphrased as “making a copy of Y” (**creation**: CRE; cf. (3-a)). The second one is the **once-more/restitution** reading (OMR), which itself has two sub-meanings: a repetitive (once-more) and a restitution reading; cf. (3-b). Haselbach (2011) groups these two readings together as it is not *nach* that is liable for the semantic distinction,

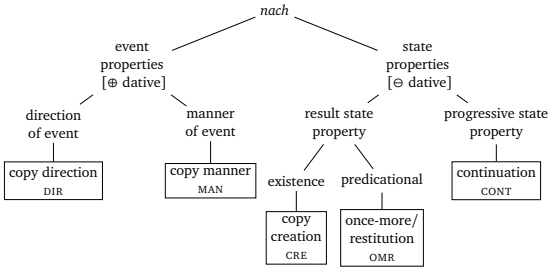

Figure 1: Classification of *nach* readings

but it is considered to be a discourse effect of how the eventualities emerging in the derivation are ordered temporally. The third reading without dative is the **continuation** reading (CONT; cf. (3-c)). In this reading, *nach* conveys a meaning that can be roughly paraphrased as "do something longer than expected". Figure 1 gives an overview of all readings.

(3) a. Der Junge baute den Eiffelturm nach.
the boy built the.ACC Eiffel Tower after
"The boy made a copy of the Eiffel Tower."
b. Der Schmied schärfte das Messer nach.
the blacksmith sharpened the.ACC knife after
"The blacksmith re-sharpened the knife."
c. Die Banane reifte nach.
the banana ripened after
"The banana continued ripening."

2.1.2 Five readings of *nach* and the accusative

Haselbach (2011) stays agnostic about the role of direct objects (i.e. accusative NPs) with respect to the readings of *nach*. With the DIR class, an accusative object may be present or absent, the latter being preferred, cf. (4).

(4) a. Der Hund rannte dem Hasen nach.
the dog ran the.DAT hare after
"The dog ran after the hare."
b. Der Lausbub warf ihr den Ball nach.
the scallywag threw her.DAT the.ACC ball after
"The scallywag threw the ball after her."

For the MAN reading, we encounter both predicates with and without an accusative object, as in (5). Thus, an accusative object does not correlate with the MAN-reading.

(5) Homer tanzte Marge (den Tango) nach.
Homer danced Marge.DAT (the.ACC tango) after
"Homer copied Marge's dancing (of the tango)."

For both the CRE and OMR classes, an accusative object seems to be obligatory. If no dative is present (which is fundamental for these readings), the accusative in (6-a) for CRE, and (7) for OMR cannot be left out. Thus, we consider the direct object to be crucial for these two classes. Replacing the accusative by a dative argument, cf. (6-b), also leads to grammaticality. Then, *nach* is considered to belong to the MAN class.

(6) a. Die Oma strickte *(die Mütze) nach.
the grandmother knitted the.ACC cap after
"The grandmother copied the cap by knitting."
b. Die Oma strickte der Uroma nach.
the grandmother knitted the.DAT great granny after
"The granny copied the great granny's knitting manner."

(7) Der Opa salzte *(die Suppe) nach.
the grandfather salted the.ACC soup after
"The grandfather added more salt to the soup."

The continuation reading of *nach* is not compatible with an accusative argument. This is because this reading seems to correlate with verbs where the verb-internal argument surfaces as subject, i.e. with anti-causative verbs such as in (8). In combination with a verb such as *reifen* ('to ripen') as in (8), neither an accusative, nor a dative, nor both can be present.

(8) Die Banane reifte (*dem Apfel) (*den Pfirsich) nach.
the banana ripened the.DAT apple the.ACC peach after
"The banana continued ripening."

2.1.3 MAN and CRE: one or two classes?

As we already saw in example (6-a) in Section 2.1.2, the *nach*-PV readings MAN and CRE are quite close. Now one could ask whether these two classes are really distinct. Note that the *nach*-PV classes discussed by Haselbach (2011) are interpretation-driven, i.e. in the context of a particular verb, the particle *nach* can evolve a certain interpretation with respect to the nature of the verb. This does not mean that each and every verb does only allow one interpretation. On the contrary, there are many verbs in the context of which *nach* exhibits several of the readings presented above. For example, the complex verb *nachtanzen* (derived from *tanzen*, 'to dance') shows at least three readings: (i) a DIR reading ("follow someone dancing"), (ii) a MAN reading ("copy somebody's dancing manner"), and (iii) a CRE reading ("copy a dance"). DIR and MAN require a dative, i.e. the "somebody" followed or copied, while CRE does not. Nevertheless, the interpretations of MAN and CRE are quite close to each other; verbs expressing the manner of process, such as *stricken* ('to knit', i.e. to produce with wool), *sprechen* ('to speak', i.e. to produce speech), or even *tanzen* ('to dance', i.e. to produce a dance), can also be interpreted as verbs of creation if used with an accusative object (mostly incremental theme, cf. Dowty 1991). Thus, we expect that these two classes are empirically not easily ascertainable.

2.2 Indicators of semantic readings observable in corpus data

In principle, dative and accusative could function as indicators for an automatic approximation of the *nach*-PV readings. However, they are problematic as there is no 1-to-1 relation between indicators and readings, cf. Table 1: datives seem to be better indicators (separating DIR/MAN from the rest) than accusatives, which are unevenly distributed. However, the discriminative power of dative is weakened by the closeness of MAN and CRE, cf. Section 2.1.3. Given this situation, we will check to what extent the use of further features will improve the result of an automatic classification. We will use, incrementally, details of the dative and accusative arguments, PPs, adverbials, as well as clausal complements.

3 Data

As our real world data, we use a fragment of a cleaned version of the German web corpus deWaC (Baroni and Kilgarriff, 2006). We automatically extracted 270k sentences containing at least one *nach*-PV.

indicator	DIR	MAN	CRE	OMR	CONT
dative	+	+	−	−	−
accusative	(−)	?	+	+	−

Table 1: Argument structure indicators for *nach*-PV classes

3.1 Manual gold standard for syntactic criteria for *nach*-PV

From this 270k *nach* sub-corpus, we extracted 270 sentences containing *nach* verbs (i) of each reading (i.e. DIR, MAN, CRE, OMR, and CONT) and (ii) of the frequency ranges high, middle, and low frequency. The set of 270 sentences functions as the gold standard, which we use to evaluate the automatic dependency parsers.[2]

Each *nach*-PV token was annotated by five annotators: two linguistically trained, three untrained. The annotation contains the dative argument and/or the accusative argument of each *nach*-PV token, if present. The linguistically untrained annotators only indicated the presence of a dependent dative or accusative argument. The linguistically trained annotators marked the extension of the argument under consideration, i.e. they annotated the entire textual string. Table 2a shows the inter-annotator agreement. The identification of dative and accusative (Boolean feature) is feasible even for untrained annotators (substantial agreement[3] on all annotators); the linguists even achieved an almost perfect agreement on the extension of the arguments. For the gold standard, the longest extension possible, i.e. a dependent NP containing all modifiers such as adjoined relatives clauses, etc., was taken.

3.2 Interaction of indicators with syntactic constructions

The syntactic features dative and accusative interact with certain "argument-structure-changing" constructions found in the corpus, which will impact on parsing. Basically, we encounter two types of construction that interfere with the argument structure of the verb: constructions that "reduce" the argument structure at the surface and constructions that seemingly "extend" it.

Argument structure reduction. The diatheses passive and middle, as well as null instantiations[4] (NI) "reduce" the argument structure of the verb. In passives (eventive, stative, impersonal, etc.) the subject of the verb is demoted and the direct object surfaces as subject, marked with nominative case. Eventive passives which are indicated with the auxiliary *werden* are identifiable, however other types of passives such as adjectival passives, which are identical with predicative adjective constructions, cannot be identified by the parsers. Middles, e.g. (9), behave similar to the passive with respect to subject and object. In middles, the internal object, which is marked with accusative in the standard active form, surfaces as nominative. The true external subject is demoted. However, middles are usually not identifyed by automatic parsers.

(9) Die Rumba tanzt sich leicht nach.
the rumba dances REFL easy after
"The rumba dances easily."

Another issue that arises is the pragmatically context-driven demotion of arguments. In a sentence such as (10-a), a direct object is clearly expected for verb *schärfen* ('to sharpen') to

[2] In the original gold standard set, there were 277 sentences. However, seven did not contain a *nach*-PV. The parser erroneously identified *nach* and verb as a *nach*-PV; e.g. *Falten Sie das Papier der Länge nach* ('Fold the paper lengthwise').

[3] Significance according to Landis and Koch (1977).

[4] Cf. Fillmore et al. (2003).

predicate over. However, in operating instructions for things that need to be sharp and that are operated manually, e.g. a knife or a pair of scissors, it seem perfectly fine to leave out the direct object. Similarly, in (10-b), the theory would predict a dative argument of *nachtanzen*, which seems to be correct if the *nachtanzen*-clause would occur in isolation. However in this example, the dative can be omitted easily as the reference of the dancing manner can be identified locally in the same sentence with the dance instructor.

(10) a. Wenn Sie mehr Druck ausüben müssen, sofort Ø nachschärfen!
if you more pressure exert must immediately Ø.ACC after-sharpen
"If you have to exert more pressure, re-sharpen (the knife) immediately!"
b. Der Tanzlehrer tanzte genau vor und ich tanzte Ø nach.
the dance instructor danced exactly before and I danced Ø.DAT after
"The dance instructor showed how to dance and I followed his dancing manner."

Argument structure extension. On the other side, there are constructions that seemingly "extend" the argument structure: ACI-constructions (*Accusativus cum infinitivo*), dative benefactives, and accusative temporal adverbials increase the number of accusative- or dative-marked NPs recognized by a parser. These constructions mentioned above do not extend the argument structure of the verb, however they change the observable amount of argument-like phrases by raising the subject of an embedded clause to the object of the matrix clause (ACI-construction as in (11)), or by adding a noun phrase that could erroneously be identified as an argument of the verb (dative benefactive as in (12-a) and accusative temporal adverbial as in (12-b)).

(11) Ich höre die Glocke nachklingen.
I hear the.ACC bell after-sound
"I hear the bell linger on."

(12) a. Die Oma strickte dem Baby die Mütze nach.
the grandmother knitted the.DAT baby the cap after
"The grandmother made a knitted copy of the cap for the baby."
b. Die Banane reifte eine Woche nach.
the banana ripened a.ACC week after
"The banana continued ripening for one week."

Table 2b shows the agreement of the linguistically trained annotators on the valency-changing constructions and their frequencies in the gold standard, where they affect 32.49 % of the *nach*-PV instances. Dative benefactives and accusative temporal adverbials are to be added.

a.

indicator	κ (all annot.)	κ (trained annot.)
accusative	0.699	0.967
dative	0.869	0.985

b.

phenomenon	κ	frequency
passive	0.971	67
middle	1.000	4
ACI	1.000	4
NI	0.774	15

Table 2: Inter-annotator agreement on a. indicators and b. valency-changing constructions

3.3 Manual *nach*-PV classification

To obtain a gold standard of the *nach*-PV lemmas with respect to the five *nach* readings described above, three annotators, who were familiar with the classes by Haselbach (2011), manually classified 475 *nach*-PV lemmas that where extracted from the corpus. Each annotator decided for each lemma (without context) if it exhibits one particular *nach*-reading, e.g. DIR. If at least two annotators labeled a lemma with a reading, the lemma was accounted to the *nach*-reading (majority decision). Multiple labels for one lemma were allowed (reflecting polysemy).

Table 3 shows the verb classes and verb class combinations of the *nach*-PV lemmas identified by the annotators. 246 of 475 *nach*-PV lemmas were classified as belonging to at least one of the five classes described by Haselbach (2011). Table 3 also illustrates that a manual classification of the *nach*-PV lemmas without context is a non-trivial task. Albeit the majority of *nach*-PV lemmas annotated with at least one of Haselbach (2011)'s classes clearly belong to one class (cf. rows 1 to 5 in Table 3) – or at least, as expected, to the mixed class {MAN,CRE} – there are many verbs that show different *nach* readings. This, of course, is not fatal for the theory, on the contrary, it is expected. However, for the automatic identification this might pose a problem. The ranks 1 to 5 (more than 10 lemma types) mostly cover single classes. Under the top-5 there is only one complex class, the MAN/CRE-class, which is expected as discussed in Section 2.1. Examples of the classes that are classified as expected are: *nachfetten* ('to regrease') or *nachsalzen* ('to add more salt') for OMR; *nachlaufen* ('to run after sb.') or *nachblicken* ('to gaze after sb.') for DIR; *nachbacken* (lit.: 'after'+'bake', to copy sth. by baking it/to copy sb.'s baking of sth.) for {MAN,CRE}; or *nachbluten* (lit.: 'after'+'bleed', to continue bleeding) for CONT.

Nevertheless, the verbs in the tail of list, i.e. from rank 6 on, seem randomly distributed. This shows that an *ad hoc* classification of the verbs without context is difficult because annotators might come up spontaneously with a reading that is rather coerced than predicted, or the other way around they might miss a reading because it is less common but perfectly grammatical. The unbalanced distribution of the verbs in the lower part of the list therefore also indicate that there might be verbs in the upper, apparently clear part of the table that might also be coerced to a particular reading of *nach*, and it might also have happened by accident that the annotators did not come up with a particular reading.[5]

rank	reading class	frequency	rank	reading class	frequency
1	OMR	67		{MAN,CRE,OMR}	6
2	DIR	58	9	{DIR,CONT}	5
3	{MAN,CRE}	26	10	{CRE,OMR}	4
4	MAN	20	11	{DIR,CRE}	3
5	CONT	19		{DIR,OMR}	3
6	{MAN,OMR}	8	12	{DIR,OMR,CONT}	2
	{DIR,MAN,CRE}	8		CRE	2
7	{DIR,MAN}	7	13	{MAN,CRE,CONT}	1
8	{OMR,CONT}	6		{DIR,MAN,CRE,CONT}	1
				overall	246

Table 3: Manual *nach*-PV classification

Additionally, the inter-annotator agreement of the classification is poor, cf. Table 4. The probability that all three annotators agreed on a particular class is not bad (P), however, as the distribution of the *nach*-readings over the lemmas is rather unbalanced the probability of an accidental match with the binary features is high (Pe). Thus κ is poor.

4 Tools and analyses of corpus data

To identify different classes of *nach*-PVs based on the corpus data, we make use of two dependency parsers and a relational database infrastructure (cf. Eckart et al., 2010), to extract

[5] An example in the data set is *nachlabern* (lit.: 'after'+'babble', paraphrase: derogatively reciting sth. in a babbling manner), which is labeled as exclusively belonging to the MAN class. A careful scrutiny however shows that *nachlabern* can also occur with the CRE reading.

nach-reading	P	Pe	κ
DIR	0.889	0.689	0.642
MAN	0.716	0.642	0.205
CRE	0.865	0.774	0.403
OMR	0.755	0.626	0.346
CONT	0.876	0.811	0.344

Table 4: Inter-annotator agreement on *nach* reading wrt. lemmas

syntactic features appearing with the *nach*-PVs. We chose two parsers based on different concepts to complement one another, i.e. by taking the individual strengths of each parser into account when extracting indicators from their results.

The **Bohnet-Parser** (BP), cf. Bohnet (2010), is a data-driven state-of-the-art dependency parser. It makes use of a rich feature model and a second order maximum-spanning-tree algorithm (McDonald and Pereira, 2006). The parser also includes its own processing pipeline containing statistical lemmatization, part-of-speech tagging, and morphological tagging on an already tokenized input. The output structure are non-projective dependency trees in the tabular representation format of CoNLL 2009's shared task. Regarding labeled syntactic accuracy in this shared task, the Bohnet-Parser was the second best system and the best system for English and German. The model we utilized in our experiments was trained on a dependency version of the German TiGer treebank (Brants et al., 2002), as described in Seeker and Kuhn (2012).

FSPar (FP), cf. Schiehlen (2003), is a rule-based dependency parser based on the approach by Abney (1996) of partial parsing by finite state cascades. FSPar also processes its own internal pipeline, which includes lexically informed tokenizing and lemmatizing and part-of-speech tagging with the TreeTagger, cf. Schmid (1994). Not only the tokenizing step but also the parsing makes use of a large integrated lexical knowledge base, e.g. including named entities. FSPar generates underspecified dependency graphs. Underspecification is applied with respect to head selection as well as dependency labels. If the attachment to a head is ambiguous for a specific token or if the head is part of a coordination or is a combined verb form, more than one head token is given. Multiple or underspecified dependency labels occur either because of mulitple head possiblilties or because of ambiguous dependency relations.

4.1 Parsing results: recognizing the indicators

Both parsers were evaluated against the test set described in Section 3.1. Three evaluation criteria were applied, each time taking all 277 sentences into account. The first evaluation is on *nach*-PV recognition, including cases where a sentence contains more than one or no *nach*-PV. The sentences that contain no *nach*-PV are difficult for the parsers as they contain the token *nach* and a verb for which the *nach* could denote a separable verb particle but does not so in the sentence under analysis. The other two criteria are the recognition of dative and accusative arguments, where in a correct case the parser extracted an argument of the expected case, and its head is contained in the argument string represented in the gold standard.

Table 5 shows the results of the evaluation. For the Bohnet-Parser, verbs are identified as *nach*-PVs, in case of *nach* being a part of the lemma, or having a token *nach* being the dependent of the verb, where the dependency label or the part-of-speech tag identified a separable verb particle. Accusative and dative arguments are identified by the respective dependency label on a relation having the *nach*-PV as its head.

Bohnet-Parser's *nach*-PV recognition suffers from the fact that the statistical lemmatizer sometimes produces a wrong lemma, even if the right token is recognized as a *nach*-PV. Dative recognition outperforms accusative recognition because dative arguments are morphologically marked more clearly. So although the Bohnet-Parser recognizes a dative only with a recall of 56.67, if it does annotate one, it is mostly correct with a precision of 87.18.

	Bohnet-Parser				FSPar		
	prec	rec	f1		prec	rec	f1
NPV recognition	93.62	95.65	94.62		97.53	100.0	98.75
dative recognition	87.18	56.67	68.69	upper bound	61.11	91.67	73.33
				lower bound	50.00	75.00	60.00
				chance	52.22	78.33	62.67
accusative recognition	53.12	67.11	59.30	upper bound	46.21	88.16	60.63
				lower bound	26.90	51.32	35.29
				chance	32.41	61.84	42.53

Table 5: Bohnet-Parser and FSpar on 277-sentences gold standard

Nach-PV recognition has a recall of 100.0 for FSPar, which is due to the facts that (i) we used the parser to identify sentences containing at least one *nach*-PV, so FSPar introduced all sentences including the sentences which contain no *nach*-PV and (ii) FSPar makes use of a huge lexicon so the correct lemma does not have to be generated. Due to the underspecified output of FSPar, three values are given for its argument evaluations. The first value results from a credulous interpretation of the underspecified output, constituting an *upper bound*, which takes all cases into account, where the right annotation could be derived from the underspecified one. The second value results from a strict interpretation and introduces a *lower bound*, as only those cases have been counted as correct where the right annotation was the only annotation by FSPar. The third value, called *chance* in the table, was calculated by randomly choosing an annotation from those proposed by FSPar.

4.2 More reliability by voting-based combination

To extract reading indicators from the large data set, we make use of our findings on the test set. The quality of the accusative and dative argument recognition is seen as an approximation of the overall parsing quality relative to the task of indicator identification. To extract more reliable indicators, we combine the results of FSPar and the Bohnet-Parser. By this approach, we trust in the hypothesis that the combined result exceeds the best single result, which has been confirmed for a set of speech recognition systems by Fiscus (1997), for a set of constituency-based parsers by Henderson and Brill (1999) and for a set of dependency parsers by Zeman and Žabokrtský (2005), among others. As our combination is task specific, we do not make use of complex heuristics or approaches handling the complete parse, but define some extraction rules based on the evaluation results from Section 4.1.

Tables 6 show the combination rules which we applied in the indicator extraction. Due to the underspecification representation of FSPar the combination rules distinguish between the two binary features "*nach*-PV has an argument of case X", where X is in {DAT,ACC}, and the feature denoting the argument form. Tables 6a and b show the combination rules for the binary features. $\oplus$DAT and $\oplus$ACC denote that the parser identified an argument in the respective case. For FSPar, this is split up in cases where the output of FSPar is not underspecified, i.e. where there was only a single result (*s*) and cases where the respecive annotation was one possibility

in a set of multiple annotations (*m*). ⊖DAT and ⊖ACC denote that the parser did not identify an argument of the respective case. In cases where both parsers agree, no further rule has to be applied. Where they disagree, we decided for the following rules depending on the results of the evaluation from Section 4.1:

a.

FP \ BP	⊕DAT	⊖DAT
⊕DAT **s**	⊕DAT	⊕DAT
m	⊕DAT	⊕DAT
⊖DAT	⊕DAT	⊖DAT

b.

FP \ BP	⊕ACC	⊖ACC
⊕ACC **s**	⊕ACC	⊖ACC
m	⊕ACC	⊕ACC
⊖ACC	⊖ACC	⊖ACC

c.

FP \ BP	⊕DAT	⊕ACC	0
⊕DAT **s**	⊕DAT	⊕DAT	⊕DAT
⊖ACC	⊕DAT	⊕DAT	0
⊕ACC **s**	⊕ACC	⊕ACC	⊕ACC
⊖DAT	⊕DAT	⊕ACC	0
⊕DAT ⊕ACC	⊕DAT	⊕ACC	0
0	⊕DAT	⊕ACC	0

Table 6: Combination rules for a. datives and b. accusatives per annotation and c. per argument

As the precision of Bohnet-Parser's dative recognition is high (87.18), we take the result of the Bohnet-Parser, whenever it identifies a dative. Regarding recall however, FSPar's result exedes the Bohnet-Parser even in the lower bound and has a very high value for the upper bound (91.67) which is an important value for the binary feature. Therefore we only decide for ⊖DAT in cases where both parsers agree on that.

For arguments in accusative case, the only high value in the evaluation was the upper bound recall of FSPar (88.16). This is not surprising, as arguments in accusative case are highly case syncretistic in German. We decided thus to let FSPar overwrite the decision of the Bohnet-Parser in the cases where an argument in accusative case was among the results of FSPar or where FSPar did not recognize an argument in accusative case at all. In cases where the Bohnet-Parser did not identify an argument in accusative case, but FSPar did so explicitly, i.e. the single case, we do not let FSPar overwrite because the values of FSPar's lower bound, which take exactly those single cases into account, are very low ($f1 = 35.29$).

Table 6 shows the rules we utilized in extracting the argument form. There we have the cases that the Bohnet-Parser specifies a form to be an argument in dative case (⊕DAT), in accusative case (⊕ACC), or neither (0). FSPar identifies a form as single dative (⊕DAT, *s*), as underspecified dative but from a representation of which no accusative can be derived (⊕DAT, ⊖ACC), as single accusative (⊕ACC, *s*), as underspecified accusative but no dative (⊕ACC, ⊖DAT), as underspecified between at least dative and accusative (⊕DAT, ⊕ACC), or as none of these (0).

Again we trust the dative recognition of each parser, which is only overwritten in two cases: (i) FSPar rules out a dative in favor of a single accusative and (ii) Bohnet-Parser neither annotates accusative nor dative and FSPar states the dative in a multiple result. These decisions deviate from the ones in the binary features. The latter decision takes into account that now a particular argument has to be decided upon and identifiying the respective dative argument drops FSPar to the chance value. The first decision is a more debatable one, and serves to balance the decisions for accusative arguments which are overall more frequent. The same applies for the other cases, in which FSPar proposes an accusative, while the Bohnet-Parser does not. If FSPar proposes ⊕DAT and ⊕ACC, or neither of them, we opt for the Bohnet-Parser. For all other clustering features, we use the Bohnet-Parser output as long as FSPar does not contradict it.

5 Automatic clustering of *nach*-PV lemmas into semantic classes

5.1 Experimental setup

As input data, we use the 270k sentences extracted from the SDeWaC corpus, which are automatically parsed by the Bohnet-Parser and FSPar. From these automatic syntactic structures we then extract five different types of features starting with the presence of dative and accusative arguments. In order to see the effect of features beyond argument structure, as described in Section 2.2, we successively add four other types of features: (i) the word form of the dative/accusative arguments, (ii) a combination of preposition form, case value, and prepositional object form for each prepositional dependent of the verb, (iii) the word form of adverbials depending on the verb, and (iv) the presence of clausal objects.

We use Ward's algorithm (Ward, 1963) to produce the clustering of the verbs in our gold standard with the number of output clusters set to 18.[6] In order to evaluate our clusters, we use the v-measure proposed in Rosenberg and Hirschberg (2007), which is defined as the harmonic mean of homogeneity and completeness. Both metrics are defined based on entropy of the clusters, where homogeneity measures the distribution of gold standard classes within each cluster and completeness measures the distribution of clusters within each gold standard class.[7]

features (added up)	homogeneity		completeness		v-measure	
	BP	FSPar	BP	FSPar	BP	FSPar
	combined		combined		combined	
dat,acc	32.96	37.62	28.20	30.11	30.39	33.45
	38.23		30.23		33.76	
⊕ datform,accform	33.24	33.53	30.27	28.19	31.68	30.62
	36.04		29.82		32.46	
⊕ pp-form-case-pobjform	34.40	35.18	30.65	29.56	32.42	32.13
	36.08		31.32		33.53	
⊕ adverbials	35.78	37.77	33.56	32.11	34.64	34.71
	41.76		34.89		38.02	
⊕ clausal objects	39.56	39.31	35.18	33.30	37.24	36.05
	41.49		35.09		38.02	

Table 7: Clustering: features extracted by Bohnet-Parser, FSPar, and their combination

5.2 Results and evaluation against human gold standard

Table 7 shows the result of the clustering broken down for the individual parsers as well as their combination. Focusing on the results for the Bohnet-Parser, we see that all features successively add to the overall performance. This shows that the additional features also contribute information to the formation of verb classes. If we check the results for FSPar and the combined feature extraction, we see a drop in performance when the word forms of the dative and accusative arguments are added, which is then compensated by the other three features which improve performance. The highest value is achieved if the combined feature

[6] Verbs can be in more than one of the theoretically predicted classes. Since the clustering algorithm does not allow for an instance to be in more than one cluster, we assume each combination of theoretical readings to be one class in the clustering. We however only consider those that appear in the gold standard and we also remove all verbs that belong to neither of the five *nach*-PV classes.

[7] The ideal case for homogeneity occurs when there is only one single class in each cluster whereas for completeness, the ideal case occurs when there is only one cluster for each of the gold standard classes.

extraction is applied. The reason for the drop for the first features is the ambiguous output of FSPar, that possibly adds more word forms to the features for the clustering than are actually correct. This is due to the fact that oftentimes FSPar gives more than one possibility for the dative or accusative argument and it is not possible to automatically choose between them without first disambiguating them. In the combined system, the drop is much smaller than for FSPar alone, because we can use the Bohnet-Parser to restrict the options that FSPar offers.

nach-reading	frequency	homogeneity	completeness	v-measure
CONT	10	78.53	66.30	71.90
{MAN,CRE}	24	42.82	58.45	49.43
OMR	51	45.35	44.82	45.08
MAN	16	28.02	56.85	37.54
DIR	51	37.05	37.19	37.12
{MAN,CRE,CONT}	1	65.95	100.00	79.48
{DIR,MAN,CRE,CONT}	1	44.05	100.00	61.16
{DIR,OMR,CONT}	2	45.17	86.83	59.43
{DIR,MAN}	4	44.32	78.85	56.75
CRE	1	39.61	100.00	56.75
{DIR,CRE}	2	40.59	86.83	55.32
{DIR,MAN,CRE}	5	44.53	73.28	55.40
{DIR,CONT}	3	38.95	79.12	52.20
{DIR,OMR}	3	36.65	79.12	50.09
{CRE,OMR}	3	33.17	86.74	47.99
{OMR,CONT}	5	31.96	79.36	45.56
{MAN,OMR}	7	31.72	72.20	44.08
{MAN,CRE,OMR}	4	25.58	73.66	37.98
overall	193	41.49	35.09	38.02

Table 8: Clustering: detail analysis: Bohnet-FSPar combination and all features

The other finding from the evaluation is the rather low overall performance. With a best value of 38.02 % v-measure it seems that we simply cannot recreate the classes that our theory predicts. However, it is worth taking a closer look at the results for the individual classes, since it turns out that the clustering quality varies greatly with the class that we are trying to produce. Table 8 shows the results of the clustering using the combined system, broken down for the individual classes. The table also splits the classes into high frequency and low frequency classes, showing the bigger classes first. As can be seen from the results, there are five classes that contain at least 10 lemmata, the biggest of them containing 51. It turns out that for three of them, we get much higher results than expectable from the average score (up to 35 % better for the CONT class). For the second and third class, we get results a little below 50 %, but for the MAN and DIR class, we get results slightly below the average. For the smaller classes with size less than 10, we mostly get results higher than the average, but these classes are too small to be really conclusive. In summary, we find that while the clustering works reasonably well for three of the bigger classes, the results are unsatisfactory for the other two. An explanation for the inferior performance on the MAN class can be found in the theory: as we discussed already in Section 2.1.3, the classes MAN and CRE are very closely related and could be considered one class since it is often not easy to distinguish the two meanings. The clustering seems to have similar problem singling them out. The performance on the DIR class can to a certain extent be explained by the argument structure of these verbs. As we show in Table 1, a DIR verb can have an accusative argument even though it would normally be avoided. That means that some of the features

that are available to the clustering are less informative than for other classes. As a point in case consider the CONT class, which comes out very nicely in the clustering. As shown in Table 1, this class has the most distinct argument distribution compared to all other classes.

One should also keep in mind that we are working with a tool chain of automatic tools that itself has several drawbacks, which influence the performance of the clustering. This includes the quality of the parsers, which although being state-of-the-art are still far from being perfect, and also the clustering algorithm, which can make incorrect decisions. Finally, one needs to take into account that our gold standard is not optimal because of the difficulties annotating our five verb classes.

Results and interpretation of the experiments: lessons learned

Theoretical results. The *nach*-PV class we were able to identify most precisely is the continuation class (CONT) for which no dative or accusative is predicted, cf. also Table 1. As assumed in Section 2.1.3, we saw that the theoretically motivated *nach*-PV classes MAN and CRE empirically collapse. We can conclude that argument structure, among others, is a fairly good indicator for automatically identifying the combined class {MAN,CRE}. However for the individual classes MAN and CRE, as well as for the directional class DIR, this is not the case. Here, more research is needed to pin down clear criteria for the selection of these classes.

Technological results. Regarding the NLP-methodology, our findings mainly address three topics: the quality of the single parsers, the combination of the parsing results and the application of a small high qualitiy sample as an approximation for the complete data set. We started with two single parsers, each evaluated against a small gold standard for *nach*-PV argument structures. Both parsers fell below expectations. The results of the state-of-the-art Bohnet-Parser decreased due to the unrestricted all-domain data. And FSPar, which preserves underspecified structures, did not reach an f-score higher than 73.33 even in the upper bound. While already the identification of *nach*-PVs was difficult due to sentences containing no *nach*-PV and due to complex lemmas, the creation of the gold standard also showed a lot of valency-changing constructions, most of them being difficult to annotate for the parsers. As we expect the gold standard to be representative for the whole data set, these difficult constructions should be found there in a similar distribution. This definitely has an impact on the features used in the clustering and therefore on the clustering results. So even by applying the best tools available their performace leaves much room for improvement. Nevertheless the parser combination showed the expected effect as the v-measure for the features from parser combination always exceeds the best single result. This also supports the applicabillity of the gold standard as approximation of the data set, as the combination rules were based on it.

Outlook. To benefit from this findings, we intend to add more parsers to the result combination and for example apply a majority voting scheme. While the two parsers we utilized were applicable right away, it might seem a good idea to complement our parsers with parsers that can be adapted to the task. Furthermore, one could try to apply other clustering techniques, e.g. fuzzy clustering to give greater emphasis on the fact that one lemma can be found in more than one class. Concerning the low agreement on the *nach*-PV lemma classification, we think that one could improve this by either taking more annotators into account or by classifying the *nach*-PV lemmas in expected and unexpected (coerced) contexts for each reading, and then measure their acceptability. This would rather approximate the conjectured continuum-like character of the distribution of the *nach* readings over the verb lemmas.

Bridging the Gap between Intrinsic and Perceived Relevance in Snippet Generation

ABSTRACT
Snippet generation plays an important role in a search engine. Good snippets provide users a good indication on the main content of a search result related to the query and on whether one can find relevant information in it. Previous studies on snippet generation focused on selecting sentences that are related to the query and to the document. However, resulting snippet may look highly relevant while the document itself is not. A missing factor that has not been considered is the consistency between the perceived relevance by the user in reading the snippet and the intrinsic relevance of the document. This factor is important to avoid generating a seemingly relevant snippet for an irrelevant document and vice versa. In this paper, we incorporate this factor in a snippet generation method that imposes the constraint that the snippet of a more relevant document should also be more relevant to the query. We derive a set of pairwise preferences between sentences from relevance judgments. We then use this set to train a gradient boosting decision tree to model a sentence scoring function used in snippet generation. Compared to the existing snippet generation methods and to the snippets generated by a commercial search engine, our snippets are more consistent with the true relevance of the documents. When the snippets are incorporated into a document ranking function, we also observe a significant improvement in retrieval effectiveness. This study shows the importance to generate snippets indicating the right level of relevance to the search results.

KEYWORDS: Search Engine Snippet, Query-biased Summarization, Document Retrieval.

Proceedings of COLING 2012: Technical Papers, pages 1129–1146,
COLING 2012, Mumbai, December 2012.

1 Introduction

The quality of a search engine is not only determined by its document ranking function, but also by the way the search results presented to the user (Turpin et al., 2009). In particular, good snippets can help the user select relevant documents to click on. Snippets can be considered as a type of extractive summary of the Web pages. It is thus important that a snippet reflects the main part of the document content related to the query topic. This is the traditional role that one assigns to a snippet. To this end, two main categories of approaches have been proposed for snippet generation: sentence retrieval (Sanderson, 1998; Han et al., 2000; Ko et al., 2007; Park and An, 2010; Daumé and Marcu, 2006) and query-biased document summarization (Conroy et al., 2006; Tombros and Sanderson, 1998; Varadarajan and Hristidis, 2005; Otterbacher et al., 2005; Wang et al., 2007; Kanungo et al., 2009).

The sentence retrieval approach finds the most relevant sentences (or text fragments) from a document and uses them as the snippet. One drawback of this method is that it does not consider the fidelity of the sentence to the content of the document, i.e., the extracted sentences may not reflect the main content of the document. There is a high risk of producing false positive snippets leading the user to click on an irrelevant document.

To solve this problem, query-biased document summarization aims to summarize the main content of a document for a specific query. The methods in this category consider both the query and the document. However, an implicit assumption in this method is that the document to be summarized is relevant to the given query. As a matter of fact, the training data used to train the extraction method usually consists of queries and relevant documents. The resulting method could reflect well the relevant part of a relevant document, but may also tend to generate "relevant" snippets for irrelevant documents.

The missing factor in the previous approaches to snippet generation is the consistency between the relevance that the user perceives in reading the snippet (perceived relevance) and the real relevance of the document (intrinsic relevance). The higher-than-intrinsic perceived relevance of snippets leads users to click on irrelevant documents (false positive), while the reverse case leads to not clicking on relevant documents (false negative).

In this paper, we propose a snippet generation method that tries to produce a snippet reflecting the right level of intrinsic relevance of the document. The basic idea is to define a sentence ranking function for a query and a document in such a way that the snippet of a document with a higher intrinsic relevance has a higher perceived relevance. We cast the sentence ranking problem in a learning-to-rank framework (Liu, 2011) with the above constraint. A set of training data is derived from a TREC dataset in which the intrinsic relevance of documents is known. The perceived relevance of a snippet is approximated by a similarity score to the query. A set of features will be defined to reflect different aspects such as the sentence's fidelity to the document and relevance to the query. Finally, we define a cost function for the learning, and propose to use a gradient boosting decision tree model to minimize the cost of the training data set.

When a snippet can reflect the intrinsic relevance of a document, it could be useful to use it to help document ranking. Although some previous studies have examined this by replacing the documents by their snippets for the purpose of increasing efficiency (Sakai and Sparck-Jones, 2001; Wasson, 2002), the results are not conclusive as to whether combining snippets with the

document content can help document ranking. In this paper, we will also incorporate snippets into the document ranking function.

We evaluate the snippet generation methods by comparing the manually judged perceived relevance of the generated snippets to the intrinsic relevance of the corresponding documents, and find that our snippets can better reflect the intrinsic relevance. On F1 score, it improves 14.0% compared to a search engine's snippets, and 7.7% compared to the query-biased summaries. The experiment on document retrieval also shows that our snippets, when incorporated into the document function, are useful in boosting document retrieval.

The remainder of the paper is organized as follows: we first present related work in Section 2. Our snippet generation method is described in Section 3. The experiments are shown in Section 4 and we conclude the paper in Section 5.

2 Related Work

A snippet is usually used as a surrogate for the content of the document in the search engine, and it helps the user determine whether the document contains relevant information (Tombros and Sanderson, 1998; White et al., 2002, 2003).

2.1 Snippet Generation Methods

There are two main categories of methods for generating snippets: sentence retrieval and query-biased summarization.

The sentence retrieval approach finds the most relevant sentences from a document using an IR method, and takes them as a snippet (Sanderson, 1998; Han et al., 2000; Ko et al., 2007; Park and An, 2010; Daumé and Marcu, 2006). One drawback of the approach is that it does not consider the fidelity of sentences to documents, i.e., their relation with the main content of the document. As a consequence, a snippet of an irrelevant document may consist of marginal sentences from the document and appear highly relevant. This problem can be partly tackled by the query-biased summarization method described below.

Query-biased document summarization approaches aim to summarize the content of a document around a specific query. In these approaches, both the document and query are considered in the snippet generation. (Conroy et al., 2006) used query terms and significant terms to select the sentences as snippets. (Tombros and Sanderson, 1998) also considered features such as a sentence's position (title, opening sentence, head, etc.) in weighting. Some work models a document as a graph, in which a sentence is presented as a vertex and the relation between the sentences is presented as a weighted edge. The goal is then to select a minimal spanning tree (Varadarajan and Hristidis, 2005) or a set of central sentences using PageRank-like algorithm as a snippet (Otterbacher et al., 2005).

The query-biased summarization problem can also be thought as a problem of ranking sentences according to their goodness to be a summary, so the learning-to-rank methods such as SVM classifier, SVM-rank (Wang et al., 2007), GBDT (Metzler and Kanungo, 2008) and GBRank (Kanungo et al., 2009) can be used. To build the training data for these methods, human subjects are asked to generate the manual snippet for documents or to judge the snippet's goodness. However, a "good" snippet in this case can reflect the content of a document, but may fail to help users distinguish relevant and irrelevant documents. In this paper, we will incorporate a criterion of consistency between the perceived relevance of the snippets and the intrinsic relevance of the documents in the learning-to-rank framework.

2.2 Snippet Evaluation

It is important to measure the quality of a snippet. The ultimate measure is to put snippet directly in a search task and evaluate how well they can help accomplish the task (Tombros and Sanderson, 1998; White et al., 2003). However, this method is very expensive and not reusable, and the utility measure is influenced by both the retrieval performance and the quality of snippets. Most work targeting the construction of indicative summaries relies on task-based evaluation where the summaries are evaluated as surrogates of the document content (Murray et al., 2009; Kushniruk et al., 2002). Some researchers also proposed to evaluate these two components together (Turpin et al., 2009; He et al., 2010).

Since the snippet generation problem is usually cast as a query-biased summarization problem, evaluation methods in summarization are also used for snippets. In this method, it is assumed that there is a gold-standard summary, and the automatically generated snippet can be compared to it (Wang et al., 2007; Bando et al., 2010). However, (Bando et al., 2010) found this method usually overestimates the quality of the snippets. Alternatively, some work evaluated a snippet by its judged goodness (Kanungo et al., 2009) or readability (Kanungo and Orr, 2009). Users' interaction with the search engine such as clickthrough, dwelling time and eye tracking are also used to evaluate the quality of the snippets (Savenkov et al., 2011; Cutrell and Guan, 2007).

For the task of search, we argue that the quality of a snippet should be primarily evaluated by whether the *perceived relevance* from it can reflect the *intrinsic relevance* of the corresponding document. In SUMMAC evaluation, (Mani et al., 1999) compared the relevance judgments on snippets and on documents, and found the users can make reasonable relevance based on snippets. In the INEX 2011 snippet retrieval task, a measure was used to explicitly examine the consistency between the perceived relevance of the snippets and the intrinsic relevance of the documents (Trappett et al., 2012). However, this measure was only used in the evaluation and none of the participating system used it in the snippet generation process. We believe that we are among the first researchers to use this criterion to train a snippet generator.

2.3 Using Snippets for Retrieval

Since a summary of a document can be considered as a surrogate for the document, it can be used in the document retrieval. Some previous work (Sakai and Sparck-Jones, 2001; Wasson, 2002) tested the utility of snippets for retrieval by replacing the document content by a summary, finding that it can achieve similar precision but worse recall. In this paper, we also test the use of snippets by applying them during the document retrieval. Instead of replacing the document content, we combine the snippet with the document content. This will lead to a higher retrieval effectiveness.

3 Generating Informative Snippets

In this section, we present the method for generating snippets whose relevance is consistent to the documents' relevance. We will first define the problem, and then propose to address this problem in a learning-to-rank framework.

3.1 Problem Definition

(Rose et al., 2007) found that text choppiness and sentence truncation is not good for the readability of search results, and it is better to use complete sentences in snippets. Following

this observation, we define snippet generation as a process of extracting a subset of complete sentences from a document.

A good snippet should of course reflect the main content of the document related to the query topic. It should also provide a good indication on how the document could be relevant, or how two documents compare with respect to relevance. In other words, the comparison between the perceived relevance of two documents should be consistent with their intrinsic relevance. Let's use $R_d(q,d)$ and $R_s(q,S)$ to denote respectively the intrinsic relevance of a document d to a query q and the perceived relevance of the document's snippet S to the query q. The consistency can be defined as follows: Given a query q and a document pair (d_1,d_2) with intrinsic relevance $R_d(q,d_1) > R_d(q,d_2)$, a snippet pair (S_1,S_2) is consistent with the relevance of the documents if and only if $R_s(q,S_1) > R_s(q,S_2)$.

Compared to previous approaches, our additional problem is to find a snippet generation function g^* so that the snippet pairs generated are as consistent with the relevance of the documents as possible. Formally, we need to find a snippet generator g^* that can maximize the expected ratio of the snippet pairs with consistent perceived relevance:

$$g^* = \arg\max_g \{\mathrm{E}_{q,d_1,d_2}[R_s(q,g(q,d_1) > R_s(q,g(q,d_2))|R_d(q,d_1) > R_d(q,d_2)]\} \quad (1)$$

In this paper, a set of judged queries will be used to train g^*. That is, for the training queries, we have document relevance judgments $R_d(q,d)$. The perceived relevance of a snippet $R_s(q,g(q,d))$ will be approximated by a similarity score between the query and the snippet. Even though we used the similarity between queries and snippets to approximate the perceived relevance, the same formalism can use real perceived relevance assessed by human subjects, an approach we might pursue in future work.

We use the learning-to-rank framework to address this problem due to its capability to utilize many different features. The previous work on snippet generation showed that pairwise learning methods perform better than pointwise methods (Kanungo et al., 2009; Wang et al., 2007), and that the methods based one gradient boosting decision tree (GBDT) outperform SVM based methods (Metzler and Kanungo, 2008). In this work, we use GBDT to generate the snippets.

3.2 Gradient Boosting Decision Tree (GBDT)

GBDT is a state-of-the-art learning-to-rank method, which can be learned in a pointwise or pairwise manner (Zheng et al., 2007; Friedman, 2001, 2002; Li et al., 2007; Kanungo et al., 2009; Metzler and Kanungo, 2008).

For pointwise learning, the training data containing N samples can be presented as $\{(x_i,y_i)|x_i \in \mathbb{X}, y_i \in \mathbb{Y}\}_{i=1}^N$, where x_i is a set of extracted features of an item, and y_i is the value of the independent variable, e.g., relevance of a document in the information retrieval task. A ranking function can produce a score for a feature vector $f : \mathbb{X} \to \mathbb{Y}$. Given a loss function $L(y,f(x))$ (we use least-squares loss) defined on the predicted value $f(x)$ and the real value y, the goal is to learn a function f^* in a function class $\mathbb{F}$ that can minimize the sum of loss function on the training dataset, i.e.,

$$f^* = \arg\min_{f\in\mathbb{F}} \sum_{i=1}^N L(y_i,f(x_i)) = \arg\min_{f\in\mathbb{F}} \sum_{i=1}^N \frac{1}{2}(y_i - f(x_i))^2$$

It is an optimization problem, and it can be solved using gradient descent. At iteration k the function $f^{(k)}$ can be updated by $f^{(k+1)}(x) = f^{(k)}(x) - \alpha_k \nabla L(f^{(k)}(x))$, where $\nabla L(f^{(k)}(x))$ is the gradient of $f^{(k)}$ at the point x, and α_k is a coefficient that can be set by line search or at a predefined value.

The gradient descent is implemented in GBDT as follows: At iteration k, we calculate the negative gradient $y_i - f^{(k)}(x_i)$ for each point in the training data, and these points as well as their negative gradients form a new gradient training data $\{x_i, y_i - f^{(k)}(x_i)\}_{i=1}^N$. We can fit a regression decision tree for this gradient training data. For a new point x, we can predict its gradient by the decision tree.

When GBDT is used in pairwise learning (Zheng et al., 2007), the training data is a set of ordered paired items: $\{(x_{i1}, x_{i2}) | y_{i1} > y_{i2}\}_{i=1}^N$. It is expected to produce the predicted values whose pairwise ranking is consistent with that in the training data. We can define a least-squares loss function as follows

$$L(f) = \sum_{i=1}^{N} \frac{1}{2} (\max\{0, f(x_{i2}) - f(x_{i1}) + \sigma\})^2, \sigma > 0 \tag{2}$$

In this formula, the loss is zero when $f(x_{i1}) \geq f(x_{i2}) + \sigma$. A small positive value σ is used to prevent from learning a constant function which produces an identical value for all the points.

Similarly, we can use gradient descent method to solve the problem of optimizing $L(f)$ in this pairwise setting. The negative gradient of one pair of items in the training data can be calculated as:

$$-\nabla L(f^{(k)}(x_{i1}), f^{(k)}(x_{i2})) = \begin{pmatrix} \max\{0, f^{(k)}(x_{i2}) - f^{(k)}(x_{i1}) + \sigma\} \\ \max\{0, f^{(k)}(x_{i1}) - f^{(k)}(x_{i2}) - \sigma\} \end{pmatrix} \tag{3}$$

That is, for one sample of pair of items, we add two samples in the gradient training data $(x_{i1}, \max\{0, (f^{(k)}(x_{i2}) - f^{(k)}(x_{i1}) + \sigma)\})$ and $(x_{i2}, \max\{0, (f^{(k)}(x_{i1}) - f^{(k)}(x_{i2}) - \sigma)\})$, aiming to increase $f^{(k+1)}(x_{i1})$ if $(f^{(k)}(x_{i1}), f^{(k)}(x_{i2}))$ is inconsistent with (y_{i1}, y_{i2}).

3.3 Learning GBDT for Ranking Sentences

In this section, we will propose a method to rank the sentences using the GBDT model.

3.3.1 Training Data

We need training data to learn an informative snippet generator, i.e., $R_d(q, d)$ for a set of queries $\{q\}$ and a set of documents $\{d\}$. Ideally, we would also like to have $R_s(q, S)$ for a snippet S, but this is usually unavailable given the large number of possible snippets for a document. In our implementation, we approximate the perceived relevance by the query-sentence similarity.

3.3.2 Loss Function

Since our objective function is defined on preferences, we can transform the relevance judgments in the training data to a preference data set: $\{(q, d_1, d_2) | q \in Q, d_1 \in D_q, d_2 \in D_q, R_d(q, d_1) > R_d(q, d_2)\}$, where D_q is the set of retrieved documents for q. For a snippet generation function g, we can get a pair of snippets for a given sample of the training data:

$(g(q,d_1),g(q,d_2))$. The perceived relevance is $(R_s(q,g(q,d_1)),R_s(q,g(q,d_2)))$. Similarly to the general GBDT pairwise loss function (Eq 2), we can define the loss function here as

$$L(g)=\sum_{q,d_1,d_2}\frac{1}{2}(\max\{0,R_s(q,g(q,d_2))-R_s(q,g(q,d_1))+\sigma\})^2,\sigma>0 \quad (4)$$

3.3.3 Sentence Scoring Function

It is difficult to train the snippet generator function g directly. Instead, we define a sentence scoring function, and then derive the snippet generator function from the sentence scoring function. A sentence scoring function can be defined as $f:\mathbb{X}\rightarrow\mathbb{R}$, where the input is a vector of extracted features about a sentence s in a document d for a query q, and the output is a predicted score for the sentence. Given the sentence scoring function, the snippet generator function g can be applied to a document d and a query q by: (1) ranking the sentences $s\in d$ by their scores, and (2) selecting the top-n sentences as the snippet up to some predetermined length. Thus, the problem of learning a snippet generation function g can be cast as learning a sentence scoring function f.

3.3.4 Learning Method

We use the GBDT method to learn a sentence scoring function in an iterative manner. At iteration k, we have the sentence scoring function $f^{(k)}$ and the derived snippet generator function $g^{(k)}$. In each iteration, there are two cases:

- Case 1: If the perceived relevance of the snippet of document d_1 is larger than that of d_2, the sentence ranking function should not be modified;
- Case 2: If the perceived relevance of the snippet about document d_2 is larger, then we should modify the sentence ranking function so that the snippet of d_1 becomes more relevant and that of d_2 less relevant;

In Case 2, the modification of sentence ranking function f is achieved by adding new sentence preference pairs into the training set. In particular, for document d_1, we should rank higher the sentences that are more relevant than the snippet of d_2:

$$S^{(k)+}_{q,d_1}=\{s|s\in d_1',R_s(q,s)>R_s(q,g^{(k)}(q,d_2))$$

In our implementation, d' is a subset of d_1 composed by the sentences that contain at least one non-stop query term. As such, we have a preference dataset about d_1:

$$\{(s_1,s_2)|s_1\in S^{(k)+}_{q,d_1},s_2\in g^{(k)}(q,d_1)\}$$

Therefore, the gradient training set for the sentence scoring function can be defined as:

$$(x_1,f(x_2)-f(x_1)+\sigma),(x_2,f(x_1)-f(x_2)-\sigma)$$

where x_1 and x_2 are feature vectors for s_1 and s_2 respectively. Similarly, for the sentences in d_2, we should create

$$\{(s_1,s_2)|s_1\in S^{(k)-}_{q,d_2},s_2\in g^{(k)}(q,d_2)\}$$

where

$$S_{q,d_2}^{(k)-} = \{s | s \in d_2', R_s(q,s) < R_s(q, g^{(k)}(q,d_1))$$

The above process for each iteration has a complexity of $O(|Q| \cdot |D|^2 \cdot |d|)$, where $|Q|$ is the number of queries, $|D|$ is the number of retrieved documents, and $|d|$ is the number of sentences in a document. This complexity is high. We use the more efficient stochastic GBDT method (Friedman, 2002). The algorithm is presented in Algorithm 1.

Input: Parameters: N, M, σ, α
Training Data: Query Set Q, Document Set $\{D_q | q \in Q\}$, Intrinsic Relevance Judgment $\{R_d(q,d) | q \in Q, d \in D_q\}$, Perceived Relevance Judgment $\{R_s(q,s) | q \in Q, s \in d, d \in D_q\}$.
Output: Sentence Scoring Function: f
begin
  Initial $f^{(1)}$ as a constant function
  for $k = 1, \ldots, N$ **do**
    GD = {}
    for $j = 1, \ldots, M$ **do**
      Sample a query $q \in Q$, a pair of documents $d_1, d_2 \in D_q, s.t. R_d(q,d_1) > R_d(q,d_2)$
      Generate snippets $g^{(k)}(q,d_1)$, $g^{(k)}(q,d_2)$
      if $R_s(q, g^{(k)}(q,d_1) > R_s(q, g^{(k)}(q,d_2)$ **then**
        Sample a sentence $s_{11} \in g^{(k)}(q,d_1)$ and a sentence $s_{12} \in d_1 - g^{(k)}(q,d_1)$
        GD.add($\{(x_{11}, 0), (x_{12}, 0)\}$)
        Sample a sentence $s_{21} \in g^{(k)}(q,d_2)$ and a sentence $s_{22} \in d_2 - g^{(k)}(q,d_2)$
        GD.add($\{(x_{21}, 0), (x_{22}, 0)\}$)
      else
        Sample a sentence $s_{11} \in S_{q,d_1}^{(k)+}$ and a sentence $s_{12} \in g^{(k)}(q,d_1)$
        GD.add($\{(x_{11}, f(x_{12}) - f(x_{11}) + \sigma), (x_{12}, f(x_{11}) - f(x_{12}) - \sigma)\}$)
        Sample a sentence $s_{21} \in S_{q,d_2}^{(k)-}$ and a sentence $s_{22} \in g^{(k)}(q,d_2)$
        GD.add($\{(x_{21}, f(x_{22}) - f(x_{21}) + \sigma), (x_{22}, f(x_{21}) - f(x_{22}) - \sigma)\}$)
      end
    end
    Fit a regression decision tree $t^{(k)}$ to the gradient training data GD
    Update the sentence scoring function $f^{(k+1)} = f^{(k)} + \alpha t^{(k)}$ and the corresponding snippet generator function $g^{(k+1)}$
  end
  $f = f^{(N+1)}$
end

Algorithm 1: Training GBDT Sentence Scoring Function

3.3.5 Features

We use four categories of features in the learning methods (see Table 1): Query-Sentence Relevance (QSR), Document-Sentence Fidelity Features (DSF), Sentence Informativeness Features (SI), Query-Document Relevance Features (QDR). The features about the relevance between the query and the document (QDR) are not commonly used in query-biased summarization.

Category	Description	Features
QSR	the relevance between the query and the sentence	- Cosine similarity of TFIDF vectors
DSF	the fidelity of the sentence's content to the document	- Cosine similarity of TFIDF vectors - Number of significant words - Is the sentence the title/heading?
SI	how much information contained in the sentence	- KL-divergence to the collection model - Averaged IDF of the words
QDR	the relevance between the document and the query	- Cosine similarity of TFIDF vectors - BM25 score

Table 1: Features

Since our goal is to generate snippets that can reflect the query-document relevance, these features can help in snippet generation.

4 Experiments

We carried out two experiments to test our snippet generation method. The first experiment compared the perceived relevance of the generated snippets with the intrinsic relevance of the documents. The second experiment use the generated snippets in document retrieval.

4.1 Experiment Setup

4.1.1 Dataset

We use the dataset of TREC Web track 2010 and 2011. There are 100 queries in the dataset (98 of them have relevance judgments), and these queries were extracted from search engine logs. For each query, we were given a short query string, a detailed description and a list of description about the subtopics. We use short queries in the study. The document collection is ClueWeb09B, which contains 428M documents. The dataset also contains relevance judgments. The relevance judgment for a (query, document) pair is in grades {0,1,2,3}, with larger values indicating higher relevance. In our experiment, we took the 50 queries of TREC 2011 for training the sentence ranking function, and the other 48 queries of TREC2010 as test. The information of the training dataset is shown in Table 2. The test dataset will be further pruned due to lack of some baseline results and selection for judgment, discussed in Section 4.1.2 and Section 4.1.3.

Statistics	Dataset		
	Training	Test	Pruned Test
#query	50	48	47
#document	13081	15849	754
#sentence/doc	64.2	66.4	51.1
#word/sentence	10.1	10.3	12.0

Table 2: Experimental Dataset

4.1.2 Tested Snippet Generating Methods

Two baselines are used in our experiment: a commercial search engine (SE) and a query-biased summarizer (SUM). The use of a commercial search engine is to see how other snippet generation methods compare to the current state-of-the-art search engines. In order to collect the snippets for a query-document pair, we send a search query containing the query string and the site of the document's URL. For example, for the query "horse hooves" and the document whose URL is "http://www.snopes.com/military/statue.asp", we construct a query "horse hooves site:www.snopes.com". We then look for the result whose URL is exactly same as the document's URL. The content of some Web pages may change, and search engine generates the snippet based on a document with different content. So we only keep the documents whose content is very similar (cosine value > 0.95) to that in ClueWeb09B dataset.

For many (query, document) pair, we cannot find the snippets generated by the search engine. For a fair comparison, we only use the (query, document) pairs whose snippets can be found in the search engine in our evaluation, and the statistics of this pruned test dataset is shown in Table 2. We also limited the length of generated snippets comparable to the search engine's snippets, the average snippet length of SE, SUM, our method is 153, 130, 142, respectively.

For query-biased snippets, we used the MEAD summarizer (Radev et al., 2004). MEAD clusters sentences and chooses sentences most similar to the centroid of the cluster, discarding sentences too similar to already picked sentences. We also can use an external query file as an extra feature for ranking. For our snippet generation method, we approximate the perceived relevance of the snippet by the query-sentence similarity. Specifically, we use cosine similarity between the TFIDF vectors of sentences and queries. There are four parameters in the learning method (see Algorithm 1): iteration number N, sample size M for each iteration, the predefined cost for identical predicted relevance σ and the shrinking parameter α. We tune these parameters by five-fold cross validation on the training dataset and get $(N = 200, M = 10,000, \sigma = 0.01, \alpha = 0.2)$.

4.1.3 Judgments

For earh query in the dataset, we randomly select up to 20 Web pages and generate the snippets for them (Some topics may have less than 20 documents).

We ask human assessors to judge the perceived relevance of these snippets. For each query, the assessors were given the query string, the description and a list of subtopics. For each snippet, the assessors were asked whether they thought the document behind the snippet can provide relevant information for the query. Each snippet is judged as "relevant" or "irrelevant". Every snippet and query pair was judged first by two assessors, and a third assessor was invited to judge if the previous two assessors disagree. The final judgment used for the evaluation is determined by voting. We found the agreement rate of the first two assessors quite high (86.7%), and the Cohen's kappa value is 0.699.

4.1.4 Measures

We use the evaluation measures used in the INEX 2011 snippet retrieval task (Trappett et al., 2012). Denote the number of true positive, false positive, true negative and false negative snippets for all the test queries are TP, FP, TN, FN respectively. Recall (R) and negative recall (NR) reflect the percent of the relevance/irrelevant documents that can be detected by their snippets. The geometric mean score (GM) of these values are used as the primary measure

in INEX 2011 snippet retrieval task. In addition, the precision (P), F-1 values (F1) and the accuracy (ACC) are used for the evaluation. All measured used are shown in Table 3

Measure	Definition
Precision	$P = \frac{TP}{TP+NP}$
Recall	$R = \frac{TP}{TP+FN}$
F1 Rcore	$F1 = \frac{R \cdot P}{R+P}$
Negative Recall	$NR = \frac{TN}{FP+TN}$
GM	$GM = \sqrt{R \cdot NR}$
Accuracy	$ACC = \frac{TP+TN}{TP+FP+TN+FN}$

Table 3: Definition of Measures

4.2 Results

The results are shown in Table 4. Each row corresponds to one measures, and each column one snippet generation method. For the our snippet generation methods, we also show in the parentheses the improvement rate compared to the baselines (SE and SUM). We found that the scores of our method are higher than both the search engine's snippets and the query-biased document summarization on most measures with an exception on recall. The query-biased summarization method also performs better than the search engine's snippet.

Measure	Snippet Generation Method		
	SE	SUM	Our Method
P	0.412	0.506	0.531(28.9%,4.9%)
R	0.605	0.539	0.596(-1.5%,10.6%)
F1	0.493	0.522	0.562(14.0%,7.7%)
ACC	0.617	0.693	0.714(15.7%,3.0%)
NR	0.622	0.764	0.782(25.7%,2.4%)
GM	0.613	0.642	0.676(10.3%,5.3%)

Table 4: Evaluation Results for the Snippet Generation Methods

For the snippets generated by the search engine, its recall value is the highest of the methods tested, but its precision score is the lowest. In other words, the snippet generator of search engines tends to select sentences with higher perceived relevance, and this way attract the users to click on the snippets. Specifically, 30.8% of the documents within the test collection are relevant, but 44.8% of the snippets from the search engine are assessed as relevant, compared to 33.0% and 34.5% from SUMM and our method, respectively.

For the snippets generated by SUM and our method, the negative recall value is much larger than that of the search engine. This means that those methods can better reflect irrelevant search restuls. Both our method and SUM methods perform worse than SE for the recall metric, but the our method's performance doesn't drop so much (-1.5% and not significant worse) compared to the others.

As an illustration, Table 5 shows two examples of generated snippets. The second column in the table is the labeled intrinsic/perceived relevance. SUM method generates a false-negative

snippet in the first example, and SE and SUM generate false positve snippets in the second example. In both cases, the snippets generated by our method can better indicate if the document is relevant.

Table 5: Two Examples of Snippets

We have used four categories of features in our experiment in Section 3.3.5. Here we examine the importance of these features. The importance of each category of feature can be evaluated by testing the loss after removing a category of features. If the loss increases much after removing a category of features, it indicates that these features are important for learning. The results are shown in Figure 1. It shows that these four categories of features are all useful for learning our snippet generator. In particular, the features that reflect the relevance between queries and documents (RQD) should be taken into account in generating snippets.

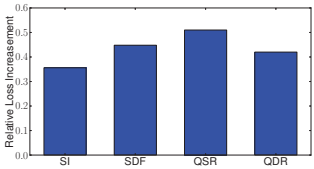

Figure 1: Feature Importance in Our Snippet Generating Method

4.3 Using Snippets for Document Retrieval

In this section, we investigate the role of snippets in document retrieval. We have found that the our snippets can help the users to determine the intrinsic relevance of the documents. Then a natural question is whether the snippets can also be useful to help a search engine determine the relevant documents.

In this experiment, we use a language modeling approach to IR, in which the document model is extended by the snippets as follows:

$$Pr(t|\theta_{d+S}) = \alpha Pr(t|\theta_{d_{\text{LM}}}) + \beta Pr(t|\theta_{S_{\text{LM}}}) + (1-\alpha-\beta)Pr(t|\theta_C)$$

where $\theta_{d_{\text{LM}}}$ and $\theta_{S_{\text{LM}}}$ are maximum likelihood model for the document and the snippet respectively, θ_C is the collection language model for smoothing, α and β are smoothing parameters. These parameters are tuned by grid search in our experiment. Given the new document language model, we use KL-divergence to score the document for a query:

$$KL(\theta_q||\theta_{d+S}) = \sum_t Pr(t|\theta_q) \log \frac{Pr(t|\theta_q)}{Pr(t|\theta_{d+S})}$$

The retrieval performance of the different snippet generation methods is shown in Table 6. The numbers in the parentheses show the improvement compared to retrieval based on the document model without combining with the snippet (NO). Since the snippets of only a subset of documents can be obtained from the search engine, we use the relevance judgments of this subset only in our evaluation. We also test the statistical significance using paired t-test, and † and ‡ indicate the difference is significant with p-value 0.1 and 0.05 respectively.

We can see that the snippets by SUM and our methods can significantly improve the retrieval effectiveness. This result clearly indicates that good snippets can be used to help document ranking. The improvement on top-ranked documents (ERR@10 and NDCG@10) is higher than MAP. This means that these methods have a higher impact on top retrieval results. On the other hand, we did not observe a significant difference when the snippets of the search engine are used. Overall, the rank of the retrieval performance with different snippet generation methods is the same as the perceived relevance accuracy: our method > SUM > SE.

However, we did not observe a significant difference between SUM and our method in IR, as in the experiment on perceived relevance. A possible reason is that both methods generate snippets that are related to the query and to the main content of the document, and the subtle difference is perceived by humans, but not by the simple retrieval model based on bag of words. It is possible that using a more sophisticated retrieval model, the difference between the two methods can be materialized on retrieval effectiveness. This is part of our future work.

Our experiment is different from that of (Sakai and Sparck-Jones, 2001; Wasson, 2002) in which snippets were used as replacement of documents. Their results showed that the retrieval recall decreases while precision remains in doing this. This is predictable as snippets are much shorter than documents, thus contain less less information. However, the short segment of text selected in a snippet is usually highly related to the query. They may provide useful position information about the document content, which can hardly emerge if we look at the whole content of the document. This may be the reason why snippets helped in our experiment on IR.

5 Conclusion and Future Work

In this paper, we addressed the problem of generating informative snippets for search results. A snippet is deemed informative not only because it reflects the part of content of the document related to the query topic, but also because it provides useful indication about the document's relevance. Generating a snippet that is perceived relevant for an irrelevant document is misleading, so is the opposite situation. We specifically addressed the problem of consistency

Measure	Snippet Generation Method			
	NO	SE	SUM	Our Method
MAP	0.328	0.328(0.0%)	0.335(2.1%†)	0.336(2.4%†)
ERR@10	0.109	0.112(2.8%)	0.114(4.6%†)	0.118(8.3%‡)
NDCG@10	0.290	0.293(1.0%)	0.304(4.8%‡)	0.309(6.5%‡)

Table 6: Retrieval Performance of Taking the Snippet as a Field

between the perceived relevance of the snippet and the intrinsic relevance of the document. To our knowledge, this is the first time that such a criterion is incorporated into a snippet generation process.

In this paper, we cast the snippet generation problem as the one to learn a sentence ranking function. The training data are pairwise sentence preference pairs, which are created according to the consistency between their perceived relevance and the real relevance of the documents. We used gradient boosting decision trees to model the sentence ranking function. Our experiments showed two facts: 1) Our method that generates snippets by considering the consistency criterion can provide better indication on the relevance of the documents to users; 2) The snippets of search results can provide useful information for document ranking.

We have explored one possible avenue to generate information snippets using a pairwise learning-to-rank method. Other methods could be explored in the future, such as SVM-rank, etc. Our focus in this paper was on consistency, and we used a simple method to determine the candidate sentences to be included into the training data. It may be better to select sentence candidates by also considering their fidelity to the document and relevance to the query.

On the use of snippets in document ranking, we used a bag-of-word approach, which failed to cope with the subtle differences between snippets. Those differences may emerge in the retrieval results if we use more sophisticated retrieval methods, e.g., by considering the possible relations between terms and by considering more complex units such as phrases. These are the problems that we will address in our future work.

ABSTRACT
Sequence labeling models like conditional random fields have been successfully applied in a variety of NLP tasks. However, as the size of label set and dataset grows, the learning speed of batch algorithms like L-BFGS quickly becomes computationally unacceptable. Several online learning methods have been proposed in large scale setting, yet little effort has been made to compare the performance of these algorithms. Comparison is often carried out on a few datasets with fine tuned parameters for specific algorithm. In this paper, we investigate and compare several online learning algorithms for sequence labeling with datasets varying in scale, feature design and label set. We find that Dual Coordinate Ascent (DCA) is robust across datasets even without careful tuning of parameter. Furthermore, a recently proposed variant of Stochastic Gradient Descent (SGD), Adaptive online gradient Descent based on feature Frequency information (ADF), has very fast training speed compared with plain SGD, but fails to converge under certain conditions. Finally, We propose a simple modification of ADF, which bears comparable convergence speed with ADF, and is consistently better than plain SGD.

TITLE AND ABSTRACT IN CHINESE

序列标注在线学习算法的比较和改进

序列标注模型，如条件随机场，已广泛用于自然语言处理的很多任务中。但随着数据规模和标记集的增大，批量学习算法（如L-BFGS）的训练时间复杂性变得越来越不可接受；于是，出现了多个大规模环境下的在线学习算法。这些算法有各自的特点，但对这些算法的比较研究很少有报道。通常情况下都是针对几个数据集，通过对特定算法细致调整参数来比较最后的测试结果。本文针对几个典型的序列标注在线学习算法，在不同规模、特征设计和标记集合的数据集上进行了比较研究。结果发现，即使没有特别对参数调优，对偶坐标上升算法（DCA）在不同数据集上也能有很好的表现；而随机梯度下降算法（SGD）的一个变种算法——基于特征频度的适应性在线梯度下降法（ADF）与普通的SGD相比，训练速度更快，但不能保证总收敛。最后，本文还对ADF提出了一种简单的改进，改进后的算法好于普通的SGD，与ADF 收敛速度接近。

1 Introduction

Sequence labeling models have been widely used in a variety of NLP tasks, such as word segmentation, part-of-speech tagging, chunking, and named entity recognition. Various sequence labeling models have been proposed, like hidden Markov models (HMM) (Rabiner, 1989), structured perceptron (Collins, 2002), conditional random fields (CRFs) (Lafferty et al., 2001) and SVM-HMM (Tsochantaridis et al., 2006). In recent years, discriminative models gain significant popularity over generative models on these tasks, and achieve state-of-the-art performance on most above tasks. Their strength and flexibility come from their ability to incorporate arbitrary declarative features.

CRFs is one of such discriminative models for sequence labeling built upon maximum entropy principle. The learning algorithms of CRFs can be divided into batch methods and online methods. Batch methods update parameters by estimating gradient over the entire training data, while online methods estimate noisy gradient with a small portion of the training data, and update parameters frequently. Among all the batch methods, L-BFGS is the most widely used and outperforms others by a substantial margin (Malouf et al., 2002); Conjugate-gradient (CG) method with proper preconditioner can converge as fast as L-BFGS (Sha and Pereira, 2003). However, discriminative models for typical sequence labeling tasks are very large and may involve hundreds of thousands of features, rendering even fastest batch learning methods very slow and impractical for large scale datasets.

Several online learning algorithms have been proposed to speed the training process of structured prediction problems, such as Passive-Aggressive (PA) algorithm (Crammer et al., 2006), Dual Coordinate Ascent (DCA) (Martins et al., 2010) and Stochastic Gradient Descent (SGD). SGD is known for its performance in the back propagation training of neural network. It also shows extremely good performance on machine learning tasks such as SVM (Bordes et al., 2009), CRFs (Vishwanathan et al., 2006), and Markov Logic Networks (Poon and Vanderwende, 2010). It may reach optimal performance even before it sees the whole training data on large datasets (Bottou and Bousquet, 2008). SGD takes typically 5-10 iterations to converge when training a multiclass Maximum Entropy (ME) model, while it takes over 50 iterations when training CRFs, much slower than training its unstructured counterpart, multiclass ME. We show how simple feature frequency adaptive strategy may help accelerate training of CRFs within 10 iterations.

Despite recent progresses in online learning algorithms, little effort has been made to compare these algorithms thoroughly. In this paper, we focus on several online learning algorithms for sequence labeling. More specifically, we investigate PA, DCA, SGD and SGD's variant ADF (Sun et al., 2012). We perform comparison on several standard datasets with diverse settings of feature design and label set. We make it as close as possible to real application scenarios whenever resources are available. Experiment reveals distinct behavior of these algorithms under different settings.

Our contributions are threefold. First, we make a fair and extensive comparison of state-of-the-art online learners for sequence labeling and characterize the strength of each algorithm. Second, we confirm the effectiveness of ADF on most datasets despite its lack of theoretical convergence guarantee for now; inspired by ADF, we propose Modified ADF (MADF), which guarantees convergence and converges as fast as ADF. Finally, we explore the use of Tongyici Cilin (Extended) as a semantic lexicon in Chinese named entity recognition, which remains unexplored for this task in previous work.

The remaining of this paper is organized as follows: in Section 2, we describe in detail the online learning algorithms, and propose MADF; in Section 3 we evaluate performance of these algorithms, and present novel usage of Tongyici Cilin (Extended) in Experiment 2; we review related work in Section 4; finally we conclude.

2 Online Learning Algorithms for Sequence Labeling

A sequence labeling task is defined as follows: given an observation sequence $\mathbf{x} = \{x_1, x_2, \ldots, x_n\}$, output its corresponding label sequence $\mathbf{y} = \{y_1, y_2, \ldots, y_n\}$, one label for each x_i. The output space is $|Y|^n$ where Y is the label set that each individual y_i takes values from, and n is the length of $\mathbf{y}$.

In discriminative sequence labeling models, feature functions are used to describe interdependency between observed and hidden variables. Under first order Markov assumption, the feature function can be divided into transition features $\phi(\mathbf{x}, y_i, y_{i+1})$ and emission features $\phi(\mathbf{x}, y_i)$. These can be combined to $\phi(\mathbf{x}, \mathbf{y})$.

Dynamic programming technique like viterbi decoding is often employed during inference:

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} \theta^T \phi(\mathbf{x}, \mathbf{y}) \tag{1}$$

where θ are model parameters. Next we will describe how to estimate parameters θ with different online algorithms. Table 1 shows a list of denotations for convenience.

$\mathbf{x}$	input sequence
$\mathbf{y}$	output label sequence
θ	parameter vector
$\phi(\mathbf{x}, \mathbf{y})$	feature function that maps sequence to feature vector
η_t	learning rate for the t-th sample
λ	regularization weight of $\frac{\lambda}{2}\|\theta\|_2^2$
M	number of training samples (sequences)
$l(\hat{\mathbf{y}}, \mathbf{y})$	cost function given the predicted and gold sequences

Table 1: Denotations

2.1 Passive-aggressive algorithm (PA)

Passive-Aggressive (PA) algorithm (Crammer et al., 2006) is a family of margin based online learning algorithms. This algorithm updates the parameter to satisfy the constraint imposed by the current example (aggressively), and does nothing if the current example is correctly classified (passively). Equation 2 defines the objective function for PA algorithm (referred by the author as PA-I):

$$\theta^{(t+1)} = \arg\min_{\theta} \frac{1}{2}\|\theta - \theta^{(t)}\|^2 + C\xi \quad \text{s.t.} \quad l(\hat{y}, y) < \xi \text{ and } \xi \geq 0 \tag{2}$$

where ξ is a non-negative slack variable that copes with wrongly labeled data; C controls the aggressiveness of parameter updating, and is a trade-off between convergence speed and model

quality. The update rule of parameter is as follows:

$$\theta^{(t+1)} = \theta^{(t)} - \eta(\phi(\mathbf{x}^{(t)}, \hat{\mathbf{y}}^{(t)}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})) \tag{3}$$

$$\text{where} \quad \eta = \min\{C, \frac{\theta^T(\phi(\mathbf{x}^{(t)}, \hat{\mathbf{y}}^{(t)}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})) + l(\mathbf{y}^{(t)}, \hat{\mathbf{y}}^{(t)})}{\|\phi(\mathbf{x}^{(t)}, \hat{\mathbf{y}}^{(t)}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})\|^2}\} \tag{4}$$

$$\text{and} \quad \hat{\mathbf{y}}^{(t)} = \arg\max_{\mathbf{y}} \theta^T(\phi(\mathbf{x}^{(t)}, \mathbf{y}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})) + l(\mathbf{y}^{(t)}, \mathbf{y}) \tag{5}$$

where $l(\mathbf{y}^{(t)}, \hat{\mathbf{y}}^{(t)})$ is the penalty we incur if our prediction is $\hat{\mathbf{y}}^{(t)}$ and the true label is $\mathbf{y}^{(t)}$. $\hat{\mathbf{y}}^{(t)}$ can be solved with cost augmented decoding, which can be efficiently accomplished if $l(\mathbf{y}^{(t)}, \hat{\mathbf{y}}^{(t)})$ decomposes the same way as the feature vector function (Smith, 2011). This is referred to as a max-loss update in (Crammer et al., 2006).

When applied to sequence labeling PA is a special case of the general algorithm where output $\mathbf{y}$ is a label sequence. Hamming loss (Eq. 6) is often used. However, other loss can also fit when one faces with task specific needs (Song et al., 2012) (Mohit et al., 2012).

$$l(\hat{\mathbf{y}}, \mathbf{y}) = Hamming(\hat{\mathbf{y}}, \mathbf{y}) = \sum_{i=1}^{n} \delta_{y_i \neq \hat{y}_i}(\hat{y}_i, y_i) \tag{6}$$

2.2 Dual coordinate ascent (DCA)

(Martins et al., 2010) present a general framework for online learning of structured classifiers. It bears some resemblance to the PA algorithm in that it shares the passive-aggressive property of PA. This algorithm applies to a wide class of loss functions; CRFs, SVM, structured perceptron can all be deemed as its special cases. Furthermore, learning rate is automatically determined for each instance, hence pesky learning rate tuning is no longer needed. The learning objective is the sum of loss on datasets plus a regularization term:

$$\min_{\theta \in \mathbb{R}^d} \lambda R(\theta) + \frac{1}{m} \sum_{t=1}^{m} L(\theta; \mathbf{x}^{(t)}, \mathbf{y}^{(t)}) \tag{7}$$

The update rule 8 is very similar to the PA algorithm in large margin setting (Eq. 3), if we divide Equation 7 by λ, replace $\frac{1}{\lambda m}$ with C, and set $\nabla L = \phi(\mathbf{x}^{(t)}, \hat{\mathbf{y}}^{(t)}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})$. The update rule for DCA is:

$$\theta^{(t+1)} = \theta^{(t)} - \eta_t \nabla L(\theta; \mathbf{x}^{(t)}, \mathbf{y}^{(t)}) \tag{8}$$

$$\text{where} \quad \eta^{(t)} = \min\{\frac{1}{\lambda m}, \frac{L(\theta^{(t)}; \mathbf{x}^{(t)}, \mathbf{y}^{(t)})}{\|\nabla L(\theta^{(t)}; \mathbf{x}^{(t)}, \mathbf{y}^{(t)})\|^2}\} \tag{9}$$

As for sequence labeling problem, CRFs is derived by setting the loss function to the negative log-loss with no cost function, i.e. $L_{CRF} = -\log P(\mathbf{y}_t|\mathbf{x}_t)$. The loss function of CRFs is just a special case of the general loss function L.

2.3 CRFs with SGD learning and its variants

Linear chain conditional random fields (CRFs) (Lafferty et al., 2001) is widely used model for sequence labeling. It predicts the output sequence $\mathbf{y}$ by its conditional probability $P(\mathbf{y}|\mathbf{x})$:

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp \theta^T \phi(\mathbf{x}, \mathbf{y}) \tag{10}$$

where $Z(\mathbf{x}) = \sum_{\mathbf{y}} \exp \theta^T \phi(\mathbf{x}, \mathbf{y})$ is normalization term which ensures that the probability sums to 1. The training objective is to maximize the likelihood on the training data (often accompanies a prior over parameters to get max-a-posterior estimation), which is equivalent to minimizing a negative log loss over all data points plus a regularizer:

$$L = \sum_{i=1}^{m} -\log P(\mathbf{y}|\mathbf{x}) + \lambda m \|\theta\|^2 \tag{11}$$

Here we multiply the regularizer by m to keep it consistent with Equation 7. This way λ has the same meaning as in Equation 7. Minimizing this objective gives the gradient for one instance in online setting:

$$\frac{\partial}{\partial \theta} L(\theta; \mathbf{x}^{(t)}, \mathbf{y}^{(t)}) = E_{P(\mathbf{y}|\mathbf{x};\theta^{(t)})} \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}) - \phi(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}) + \lambda\theta \tag{12}$$

where the expectation of feature vector given current example $\mathbf{x}^{(t)}$ is taken over all possible sequences of $\mathbf{y}$, and can be efficiently computed using forward-backward algorithm.

Generally regularizer is added to avoid overfitting. Various regularizers have been proposed. L_2 regularizer, $R(\theta) = \frac{\lambda}{2}\|\theta\|_2^2$, which is used by various CRF based tools, often leads to superior performance and can be numerically optimized. L_1 regularizer, $R(\theta) = \sigma\|\theta\|_1$, known as Lasso, encourages sparse parameter. Elastic net, a linear interpolation of L_1 and L_2 regularizer, is used by (Lavergne et al., 2010) to regularize CRFs, and performs as good as L_2 regularizer, while still retaining compact model.

2.3.1 SGD and its variants

Stochastic gradient descent (SGD) is known for its fast convergence on machine learning tasks (Bottou and Bousquet, 2008) (Vishwanathan et al., 2006) (Shalev-Shwartz et al., 2007). Every time the algorithm randomly draws one sample (or small batch of samples in mini-batch setting), and performs update according to the gradient of this sample. In general, SGD has the following simple update rule:

$$\theta^{(t+1)} = \theta^{(t)} - \eta^{(t)} \mathbf{B} \nabla L \tag{13}$$

where $\eta^{(t)}$ is a scalar learning rate, $\mathbf{B}$ is a matrix; $\mathbf{B} = \mathbf{I}$ for a plain SGD and $\mathbf{B} \approx \mathbf{H}^{-1}$ for second order SGD. Despite its ease of implementation, it's generally hard to tune and schedule the learning rate properly.

(Murata, 1998) shows that with a $1/t$-annealing learning rate it can be asymptotically as effective as batch learning in terms of generalization error. (Bottou and Bousquet, 2008) further shows that utilizing second order information by setting $\eta\mathbf{B} = \frac{1}{t}\mathbf{H}^{-1}$, optimal asymptotic convergence rate is achieved. With $\eta = 1/t$ and fixed $\mathbf{B}$, convergence is guaranteed based on the theory of stochastic approximation (Murata, 1998).

Various ways of approximating the inverse of Hessian have been proposed (Hsu et al., 2009) (Vishwanathan et al., 2006). But these methods are much slower than plain SGD in terms of execution time of one pass over the entire dataset, so the speed up is very limited. Full approximation of $\mathbf{H}^{-1}$ is quite expensive , so low rank approximation and diagonal approximation (Bordes et al., 2009) is very appealing. The next two algorithms is closely related to diagonal rescaling.

2.3.2 ADF

In ADF, instead of a single global learning rate in plain SGD, each dimension of parameters has its own learning rate. The learning rate decays periodically according to its associated feature frequency, with high frequency decaying faster. This adaptive strategy is based on the intuition that frequent observed features are more adequately trained so smaller learning rates are needed. The author shows its high convergence speed compared with plain SGD in Chinese word segmentation task.

The method works well in most of our experiments, except for a few datasets. As we observed in our experiments in several other sequence labeling tasks, despite its speed of convergence and of reduction in training set error rate, it might fail to generalize well to testset and its parameters fluctuate a lot with different random shuffling of data. Moreover, it is not clear how to tune the upper bound and lower bound of the decay factor. In fact, ADF can be seen as diagonal approximation of the inverse of Hessian with exponential decrease learning rate based on frequency adaptive information. Unfortunately, this decrease in learning rate does not have theoretically convergence guarantee for now, although it works well in practice. (Murata, 1998) shows that SGD with $1/t$-annealing learning rate guarantees convergence.

2.4 Modified ADF (MADF)

Second order SGD (2SGD) uses an approximation of inverse of Hessian by setting $\eta\mathbf{B} = \frac{1}{t}\mathbf{H}^{-1}$ in order to achieve the optimal learning rate. Inspired by ADF and current theory foundation of 2SGD, we propose to use feature frequency information to approximate $\mathbf{H}^{-1}$, while still keeping a $\eta = 1/t$ annealing factor, so convergence is guaranteed (Eq. 14).

Our method works as follows: at the beginning of the algorithm, we compute the diagonal scaling matrices $\mathbf{B}$ using Equation 15, which is of the same size as the parameter vector. For each dimension of θ, we use a separate learning rate $\frac{1}{t}B_{ii}$.

$$\theta^{(t+1)} = \theta^{(t)} - \frac{1}{t}\mathbf{B}\nabla L(\theta) \tag{14}$$

$$\mathbf{B}_{ii} = \frac{1}{\beta + (\alpha - \beta) \times \frac{\#\phi(x,y)}{\#tokens}} \quad \text{where} \quad a = \frac{1}{\alpha}\ b = \frac{1}{\beta} \tag{15}$$

where a and b serve as lower and upper bounds of diagonal scaling element $\mathbf{B}_{ii}$. We keep $\mathbf{B}$ constant during the training process. $\#\phi(x,y)/\#tokens$ is the relative feature frequency associated with i-th dimension.

There are two main differences of our method compared with ADF. The first is how the frequency is counted. In ADF, frequency is counted as $\sum_y \phi(x,y)$ per sentence and is the same for each predicate x with different y. Our method counts $\phi(x,y)$ per token in the training set and use separate learning rate for predicate x with different y. Another difference is that we keep an annealing learning rate $\eta^{(t)} = 1/t$ with fixed diagonal scaling matrix $\mathbf{B}$, while ADF can be seen as exponential decaying $\mathbf{B}$ with constant η.

It is difficult to set the upper and lower bounds of scaling factor $\mathbf{B}_{ii}$. One solution is to grid search a and b with held-out dataset. In this paper, we find it works surprisingly well by setting $a = 0.001$ and $b = 1$ on almost all datasets.

It is easy to interpret our method in the view of input rescaling. In the back propagation learning of neutral network, mapping a too large input to a relatively small output would result in a small learning rate in order to ensure stable convergence, leading to slow convergence speed [1]. (LeCun et al., 1998) suggest simply to normalize the input to combat this problem. Furthermore, input scaling is closely related to diagonal approximation of the inverse of Hessian (Bordes et al., 2009). However, scaling input feature value in sparse dataset is not realistic. Our idea is that in batch setting, the update of parameters associated with frequent features tend to be larger than those associated with rare features, so we scale the learning rate by the inverse of its associated relative feature frequency.

We show in Section 3 how this simple adaptive learning rate can significantly speedup the learning process while still is equipped with convergence guarantee. It runs as fast as plain SGD in terms of per iteration execution time, without the penalty of approximating the inverse of Hessian. The speedup is attributed to a proper estimation of initial learning rate, especially on datasets with more skewed feature frequency distribution.

3 Evaluation and Analysis

3.1 Implementation

There are several implementation issues on how to obtain good performance with different algorithms.

Weight averaging: averaged perceptron, PA and DCA can get much better performance by weight averaging. We only have to maintain two weight vectors $\theta^{(t)}$ and $\hat{\theta}^{(t)}$; each time we perform update $\theta^{(t+1)} = \theta^{(t)} - \nabla L$ and $\hat{\theta}^{(t+1)} = \hat{\theta}^{(t)} - t\nabla L$. Finally the average weight is obtained by $\bar{\theta} = \sum_{t=0}^{T} \theta^{(t)} = \theta^{(T)} - \hat{\theta}^{(T)}/T$.

Randomize data: if we have to pass the dataset multiple times, it's better to randomize the dataset. This can get better performance on all online algorithms in our experiments, not only SGD variants.

Regularization with L_2: In NLP tasks, the feature vector is typically sparse. The gradient ∇L (see Eq. 12) consists of two parts, one corresponds with the loss and the other with the regularizer. The first part is often sparse and can be efficiently carried out. The update of the regularizer part is dense and quite expensive if done for every sample.

There are two methods that can combat this problem. (Shalev-Shwartz et al., 2007) propose to represent the weight vector θ by the product of one scaling factor and one vector. We can see the reason by a simple rearrangement of the formula $\theta^{(t+1)} = \theta^{(t)} - \eta(\nabla l + \lambda\theta^{(t)}) = (1 - \eta\lambda)\theta^{(t)} - \eta\nabla l$. The first term can be done efficiently with a scalar product. (Bordes et al., 2009) propose in SVMSGD2 another method in which the regularizer term is treated as a special example and updated periodically. The method works on both first order and second order SGD. We will use this method in our experiment if not particularly mentioned.

Initial learning rate for SGD: The initial learning rate of SGD plays a critical role in the whole process of learning. It is chosen by heuristic method. We can sample a subset of the training data, run SGD algorithm for one pass over the subset and pick the learning rate with smallest training objective value as the initial guess of learning rate. This method is generally helpful for all SGD variants. We use this setting for all variants of SGD.

3.2 Datasets settings

We compare the performance on several sequence labeling tasks, namely Chinese word segmentation, Chinese named entity recognition, CoNLL 2000 chunking, CoNLL 2003 NER, and Chinese part-of-speech tagging. The datasets vary across tasks in label set size and feature design. We inject as much knowledge as possible to mimic real application scenarios. For under-resourced tasks, we simply use token based n-gram features. Table 2 gives a brief view of features used. Table 4 shows the statistics after feature generation.

Tasks	Type	Features
Chinese word segmentation	basic	character unigram $w_{-2}, w_{-1}, w_0, w_1, w_2$, character bigram $w_{-2}w_{-1}, w_{-1}w_0, w_0w_1, w_1w_2$, whether w_j and w_{j+1} are identical and whether w_j and w_{j+2} are identical in windows of 2 characters on the left and 2 characters on the right; unigram/bigram dictionary features as described in (Sun et al., 2012)
	extended	accessor variety and mutual information (Sun and Xu, 2011)
Chinese named entity recognition	basic	character unigram and bigram in the context window of size 2; bigram of previous character and next character; whether character is word,letter,digit or punctuation in windows of size 1
	extended	basic features plus Tongyici Cilin (extended) derived word boundary and semantic type, entity list derived from Baidu Baike, in windows of size 2; whether the current character is a single character word or multiple character word through forward maximum matching and backward maximum matching;
Chunking	basic	word unigram in windows of size 2, word bigram in windows of size 1; part-of-speech unigram,bigram,trigram in windows of size 2;
English named entity recognition	basic	word unigram in windows of size 2, word bigram in windows of size 1; part-of-speech unigram,bigram,trigram in windows of size 2; character shape unigram and bigram in windows of size 2
	extended	basic features plus word cluster code prefix with length 4,10,16,20, both unigram and bigram in windows of size 2; gazetteer list feature of the current token;
Chinese POS tagging	basic	word unigram and bigram in windows of size 2; current word prefix and suffix of size up to 3, which is the baseline of (Sun and Uszkoreit, 2012).

Table 2: Features used for different tasks. For basic features, I refer to most simple token based feature and word type (letter,digit,punctuation) within a window of certain size. Extended features vary with available resources.

1. **Chinese Word Segmentation (CWS)** SigHan 2005 dataset is used for CWS [2].

2. **Chinese Named Entity Recognition (NER)** Named entity recognition requires large amount of world knowledge. List lookup features from gazetteer, lexicon and dictionaries can greatly enhance an NER system (Nadeau and Sekine, 2007). So for extended features, we explore the use of Baidu Baike and Tongyici Cilin (Extended) [3] as two knowledge

[2] http://www.sighan.org/bakeoff2005/

[3] http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE_user_op=view_page&PAGE_id=162

sources. Table 3 gives a brief view of Tongyici Cilin. The first column gives the category

Category	Word Cluster
Af10B05#	省长(governor of province) 市长(mayor) 县长(county head) 区长 乡长 村长 ...
Ae13A10#	**教授**(professor) 副教授(associate professor) 讲师(instructor) 助教(teaching assistant) ...
Hg05A01=	讲课 授课 讲授 讲解 **教授**(teach) 教书 ...
Dm01A46#	安全部(ministry of security) 财政部(ministry of finance) 参谋部 电力部 ...

Table 3: A Snippet from Tongyici Cinlin (Extended)

one word belongs to. The category codes with prefix of different lengths give different levels of abstraction of its semantic meaning. Some of the clusters are good indicators of named entities. For instance, the first row is a good indicator of previous word being a location, and the first and second row is a good indicator of next word being a person. This categorized lexicon is quite similar to word cluster features in (Ratinov and Roth, 2009), but is more precise. However, to our certain knowledge, this resource remains unexplored in previous Chinese NER tasks.

Words in Chinese do not have space like in English. In Chinese NER task, texts are given without word boundaries, so segmentation is an essential preprocessing step. But this will bring segmentation error to the system, especially most named entities are out-of-vocabulary words. On the other hand, if we perform inference at character level directly, we quickly loss the meaning of words . We propose two simple strategies to alleviate these problems: first, while still performing inference at character level, we do forward maximum matching and backward maximum matching to provide basic word boundary features; second, word meaning is injected with the category of the matching word in Tongyici Cilin. The class of a word also serves as a mechanism of word cluster, which holds similar words together. Hence Tongyici Cilin serves as both word clusters and a lexicon when performing maximum matching.

Finally, we use entity list extracted from Baidu Baike as additional entity list features. The datasets we use are SigHan 08 Chinese NER dataset and one month of People Daily.

As our main concern is to build a resource rich feature design for Chinese named entity recognition, we do not make further comparison with other algorithms. Other approaches typically use complex model combinations, which are not directly comparable to our single model based method.

3. **CoNLL English NER and Chunking** (Ratinov and Roth, 2009) perform an extensive study on NER and extract valuable resources, which can be readily incorporated into any existing NER system. We use the word class hierarchy and gazetteer lists from their package[4]. We do not use other features for simplicity. Word class features are derived from brown clustering algorithm and intended for bridging the gap of unseen text . The brown algorithm hierarchically clusters the words, and paths with different lengths to the root represent different levels of abstraction. Gazetteers are dictionaries of named entities and injected to the system to provide world knowledge. We use these two features as described in (Ratinov and Roth, 2009).

   For English chunking task, we use the template provided with CRF++ [5], this template is

[4]http://l2r.cs.uiuc.edu/cogcomp/software.php
[5]http://crfpp.googlecode.com/svn/trunk/doc/index.html

also used in the benchmark of CRFSGD [6].

4. **Chinese part-of-speech(POS) tagging** The setting follows the baseline of (Sun and Uszkoreit, 2012). As we do not have access to the more complex features, we just use this baseline, which performs reasonably good on a different datasets.

Dataset	#tokens	#unigram	#bigram	#labels	cutoff	max %freq
CWS MSR	4,050,469	1,852,255	1,852,255	3	1	0.0428
CWS CITYU	2,403,024	1,594,695	1,594,695	3	1	0.0456
CWS PKU	1,822,380	1,202,381	1,202,381	3	1	0.0407
CWS PKU(e)	1,826,448	365,254	1	4	5	0.9954
NER MSRA	1,089,050	332,989	1	10	3	0.8763
NER CITYU	1,772,202	505,185	1	10	3	0.9143
NER PD(e)	1,811,931	744,396	1	10	3	0.8782
CoNLL2000	211,727	76,328	1	23	3	0.1424
CoNLL2003(e)	203,621	860,462	1	17	1	0.8526
CoNLL2003ned	202,644	366,086	1	9	1	0.6847
POS PKU	1,116,754	2,252,374	1	103	1	0.0667
POS CITYU	1,092,687	2,257,166	1	44	1	0.0614

Table 4: Statistics on different datasets. The meanings of each field are as follows: number of tokens, unigram features, bigram features and class labels; we use features with frequency no less than `cutoff`; `max%freq` refers to maximum relative frequency (ref. Eq. 15), a larger value means a more skewed feature frequency distribution.

3.3 Experiments

As for plain SGD, we replicate CRFSGD implementation for fair comparison. For all variants of SGD, we use the regularizer proposed by (Bordes et al., 2009). All learning rates are searched by subsampling, except for PA and DCA, which do not need to specify learning rates. For ADF, we use the same setting as (Sun et al., 2012). We run SGD for 50 iterations and other online methods for 30 iterations. This setting is suffice for most algorithms to reach a stable state.

Also note PA and DCA need to specify an aggressive parameter C, which controls how aggressively the parameter perform updates. PA seems to be very sensitive to this parameter, and the algorithm leads to bad results if C is not properly set. The algorithm converges fast with a larger C, but may not provide good generalization performance. In our experiment, we set $C = 0.01$ for PA, which is a trade-off between convergence speed and an accurate model. DCA is not very sensitive to this parameter so we set C to 1.

For every task we also plot the final performance of CRF++ and Wapiti [7] at the beginning of iterations. We do not plot the learning curves because they use different learning methods (Wapiti does contain online learners but needs to switch to L-BFGS to fine tune the model parameter, so we only report results of L-BFGS learner). For POS tagging we do not plot the results of CRF++, because CRF++ will run for weeks. CRF++ uses L-BFGS for parameter estimation, and we use default stop condition. Wapiti (Lavergne et al., 2010) uses elastic net regularizer, and does feature selection automatically while training. The resulting model is

[6] http://leon.bottou.org/projects/sgd
[7] http://wapiti.limsi.fr/

compact and small, and still retains performance comparable to L_2-regularizer. We use the default setting of regularizer weights and a stop condition that error rate of development set does not further decrease in window of size 10.

For other variants of SGD, PSA (Hsu et al., 2009) and SMD (Vishwanathan et al., 2006) are out of our consideration because they are typically more than 10 times slower than plain SGD in execution time of one pass over the dataset, despite their theoretical appealing one pass over the data. We tried averaged SGD (ASGD) (Xu, 2011) on two of our datasets, but it did not perform so well even if we tried several switch time between SGD and ASGD.

For Chinese word segmentation, we evaluate F-score using the script for SigHan 2005 bakeoff. For all NER and chunking tasks, we report phrase based F-score with the script provided by CoNLL. For POS tagging, we report token based accuracy. Results are listed in Table 5.

Datasets	CWS MSR	CWS CITYU	CWS PKU	CWS PKU(e)	NER MSRA	NER CITYU	NER PD(e)	Chunking	CoNLL 2003 Eng(e)	CoNLL 2003 Ned	POS PKU	POS CITYU
PA	96.60	94.10	94.80	95.60	87.84	**80.91**	91.60	93.26	85.15	**75.57**	94.09	89.09
DCA	**97.00**	94.10	**95.20**	95.50	**89.45**	80.39	91.78	93.76	86.66	75.33	**94.24**	**89.21**
SGD	96.90	94.10	95.10	95.60	88.91	80.05	92.05	93.71	86.60	74.77	94.04	88.98

CRF++	96.70	94.40	94.70	95.70	88.91	79.80	92.09	93.74	86.50	74.64	na	na

Table 5: Results on all datasets. Note that PA and Wapiti have different model/regularizer from other CRFs models, hence not directly comparable to other CRFs-based models. (e) means extended feature set.

3.4 Discussion

Differences across datasets: For well resourced tasks, i.e. CWS pku(e), NER People Daily(e), CoNLL 2003 English NER(e) (4,7,9 in figure 1), SGD and its variants give better performance than PA and DCA, with faster convergence speed; while PA and DCA give very robust performance on under-resourced tasks despite the presence of only simple token based features, partly attribute to their weight averaging mechanism. Another observation is that small or under-resourced datasets often make the learning curve of SGD and its variants fluctuate a lot.

For simple datasets with only token based features, e.g. 6,10,11,12, PA and DCA performs relatively good or even better than other methods. PA is a margin based method and may generalize well to unseen data under such circumstances. Moreover, PA and DCA all use weight averaging for better generalization, which proves useful under simple feature set. In other cases, DCA performs as good as other training methods and converges as fast as SGD, but are always more stable. This may ease the selection of stopping criterion, as a non-stable learning curve may stop accidentally at a bad point. (Lavergne et al., 2010) suggest it is good practice to use a separate development set to determine a stop criterion, but this set is not always available. Note also that the aggressiveness parameter C for PA is critical for a reasonably good performance, as in chunking (8) and English NER (9) tasks, PA gets very poor results.

Effect of η_0: As we observe in our experiments, the high convergence speed is largely determined by a good choice of initial learning rate. For plain SGD, high frequency features cause the initial estimate of learning rate to decrease, resulting in a low convergence speed. In datasets

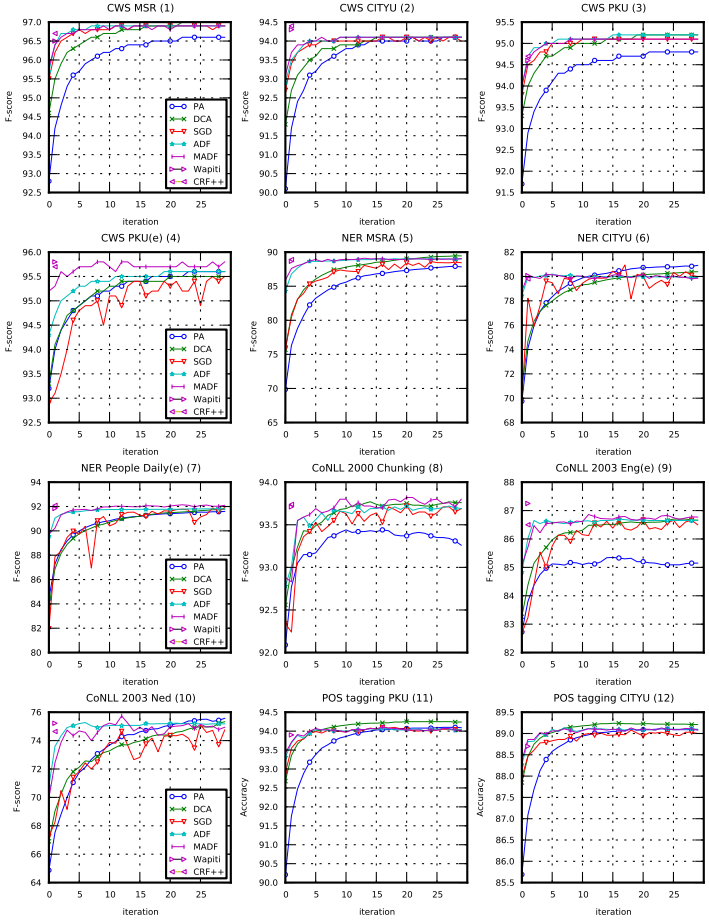

Figure 1: F-score (for CWS, NER, chunking) or accuracy (for POS tagging) on various datasets.

4,5,6,7,9,10, the initial estimations of η_0 in MADF are several times larger than that in SGD, which explains the convergence speed differences. (note the feature frequency in table 4 and convergence speed difference of SGD and MADF in figure 1.) In datasets with feature frequency not so skewed, SGD converges as fast as ADF and MADF.

ADF and MADF always converge faster than plain SGD and often achieve top performance within 10 iterations. ADF is more stable than MADF because of its fast decay of learning rate. But this effect comes at the price that ADF cannot reach top performance on some datasets. For instance, in the CWS PKU (4), Chinese NER People Daily (7) and English NER tasks (9), ADF reaches an F-score 0.1% to 0.3% lower than MADF; SGD can also performs better than ADF on these datasets after 100 iterations which I do not plot. But this is not without exception, in CoNLL 2003 Dutch NER task, where I use simple context token based features, ADF performs better than other methods. This dataset is small compared with others. The result implies ADF is more stable and suitable in most situations. MADF suffers from fluctuation on small datasets, but is still more stable, better, and faster than SGD on most datasets.

Running time: All online algorithms are 5-30 times faster than CRF++ to achieve comparable performance. ADF and MADF typically need a mere 10 iterations, and other online methods need several dozens iterations to get competitive result. In terms of one pass time over the dataset, PA clearly outperforms others because it does not have to compute normalization factor and expensive `log/exp` operations; DCA is only a little slower than SGD; ADF and MADF run as fast as SGD, while give more stable learning curve and faster convergence.

Batch vs. online: We plot the results of CRF++ and Wapiti, which can be seen as the near optimal solution to the optimization problem, we can see online methods provide as good as or even better performance than batch method. The elastic net regularizer of Wapiti is very competitive compared with L_2 regularizer. Except on CoNLL 2003 English NER data, in which Wapiti exceeds L_2 regularizer by a large margin, they gives similar results on all datasets.

Batch learning method (i.e. CRF++) rarely gives the best generalization performance. This implies that expensive batch optimization methods are not necessary for large learning tasks. Online methods will suffice. One exception is CITYU CWS task, in which CRF++ performs better than all online methods. We find the problem is how a feature fires when it is false. Both CRF++ and Wapiti treat it as a feature "F" and we omit it when we fire this feature. After adding this the F-score on testset goes up from 94.1% to 94.4% for SGD and MADF, 95.5% for ADF, comparable to CRF++. However, on a different dataset CWS PKU, adding this "F" feature decreases F-score by 0.1%, still higher than CRF++ by 0.3%.

Summary: PA is competitive with properly chosen aggressiveness parameter on under-resourced tasks. DCA converges as fast as SGD and is more stable, and is often as good as or even better than SGD variants. ADF and MADF are consistently faster than plain SGD and often reach reasonably good performance after a mere 10 passes over the datasets. ADF sometimes gets suboptimal results and losses the opportunity to further refine the parameters because of a too fast decay of learning rate; while MADF has convergence guarantee but may have a little more fluctuation in small datasets. Finally, online methods are generally several dozens times faster and get better performance than batch method.

4 Related Work

In many NLP related tasks, the data distribution is skewed, and generally only a small number of features are fired in each example, resulting in a sparse distribution. Skewed feature frequency

can affect speed of SGD algorithms, resulting in a conservative small initial guess of learning rate, which slows down the convergence speed. (Sun et al., 2012) utilize feature frequency information to speed up training of CRF model. It is simple and fast compared with other Hessian approximation methods. The sparse distribution can greatly accelerate training speed of models through clever regularization as described in (Vishwanathan et al., 2006) (Bordes et al., 2009), or through sparse forward-backward decoding (Lavergne et al., 2010).

Stochastic gradient descent (SGD) is well known for its performance on machine learning tasks (Bottou and Bousquet, 2008). Its recent successes in learning CRFs (Vishwanathan et al., 2006) and SVM (Shalev-Shwartz et al., 2007) show its advantage over batch learning algorithms in both convergence speed and generalization performance. It is particularly suitable in a large scale setting, and may achieve top performance even before seeing the whole dataset.

Various methods based on SGD have been proposed to accelerate training of CRFs. Several variants of SGD aim at theoretically one pass over the training data to get optimal performance (Hsu et al., 2009). The core idea of these methods is approximating the inverse of Hessian in order to accelerate training (and is why they are called second order SGD). However, the approximation is expensive and much slower than a plain SGD in terms of per iteration running time. (Xu, 2011) proposes averaged SGD (ASGD) that is as fast as SGD and converges within several iterations. However, in several datasets we tested, the testset performance is below standard SGD even after we tried several switch time of SGD and ASGD.

Besides the regularizer mentioned above, group Lasso has recently been proposed to regularize a structured classifier (Martins et al., 2011). The author encodes prior structural knowledge of the feature space by grouping different features into M groups and using separate regularizer weight for each group. The resulting model is compact and avoids the problem of overfitting with large number of free parameters.

Conclusion

We investigate several online learning algorithms for sequence labeling and empirically show how each algorithm performs on datasets with distinct feature design and label set. This will ease the selection of algorithms in similar tasks in future. Our experiments show that most online algorithms outperform batch method (CRF++) at both speed and generalization performance. We can gain further speedup by adopting simple strategy as ADF and MADF do.

We propose our own algorithm inspired by ADF, which is a variant of SGD. We confirm the effectiveness of ADF on several datasets. While ADF works in most situations, sometimes it leads to suboptimal solutions. Our algorithm performs consistently better than SGD, and converges as fast as ADF. These simple frequency adaptive methods can greatly accelerate training speed under skewed feature frequency distribution. As many NLP tasks involve the cycle of training the model and refining features then retraining the model, fast training methods are particularly useful, especially on large dataset with a large label set. It is also interesting to see how these two simple frequency adaptive approaches help in other structured learning problems in future.

ABSTRACT
Automatic methods to create entity dictionaries or gazetteers have used only a small number of entity types (18 at maximum), which could pose a limitation for fine-grained information extraction. This paper aims to create a dictionary of 200 extended named entity (ENE) types. Using Wikipedia as a basic resource, we classify Wikipedia titles into ENE types to create an ENE dictionary. In our method, we derive a large number of features for Wikipedia titles and train a multiclass classifier by supervised learning. We devise an extensive list of features for the accurate classification into the ENE types, such as those related to the surface string of a title, the content of the article, and the meta data provided with Wikipedia. By experiments, we successfully show that it is possible to classify Wikipedia titles into ENE types with 79.63% accuracy. We applied our classifier to all Wikipedia titles and, by discarding low-confidence classification results, created an ENE dictionary of over one million entities covering 182 ENE types with an estimated accuracy of 89.48%. This is the first large scale ENE dictionary.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (JAPANESE)

Wikipedia を用いた拡張固有表現辞書の構築

従来の固有表現辞書では，少ない数（最大で 18）の固有表現タイプが用いられてきたため，ピンポイントな情報抽出に適用することが難しいという問題があった．そこで，本稿では，200 の拡張固有表現タイプを用いた固有表現辞書の構築を目指す．具体的には，教師あり学習による多クラス分類器を用い，Wikipedia の見出し語を拡張固有表現タイプに分類することで辞書を構築する．特徴量として，見出し語そのもの，本文，そして，カテゴリ等のメタデータに関するものを数多く列挙し用いた．結果として，見出し語を，79.63%の精度で，拡張固有表現タイプに分類できることが分かった．学習された多クラス分類器を，Wikipedia のすべての見出し語に適用し，また，信頼度の低い分類結果については除外するようにしたところ，推定分類精度が 89.48%で，また，182 の拡張固有表現タイプをカバーする，百万以上のエントリを持つ拡張固有表現辞書を構築することができた．この辞書は，初の大規模な拡張固有表現辞書である．

KEYWORDS: Extended Named Entity, Dictionary, Wikipedia.

KEYWORDS IN JAPANESE: 拡張固有表現，辞書，Wikipedia.

1 Introduction

For information extraction, it is important to recognize named entities (NEs) in texts. NEs are typically recognized by such techniques as support vector machines (SVMs) (Isozaki and Kazawa, 2002) and conditional random fields (Suzuki et al., 2006), using words surrounding a target entity as cues to determine if that entity belongs to a certain NE type. The limitation is that it is difficult to recognize NEs when there are few contextual cues, such as in search queries and snippets of web search results. In such cases, an NE dictionary, or a gazetteer, is particularly useful. Here, an NE dictionary means a list of entities associated with their NE types (e.g., Tokyo → LOCATION, Barack Obama → PERSON). Such a dictionary is also useful for deriving gazetteer features for training an NE recognizer (Kazama and Torisawa, 2008).

A number of studies have focused on automatically creating NE dictionaries; e.g., (Toral and Muoz, 2006; Saleh et al., 2010). Such studies generally use a small number of entity types, mostly adopting those defined in the Message Understanding Conference (MUC) (Grishman and Sundheim, 1996) or Information Retrieval and Extraction Exercise (IREX) (Sekine and Isahara, 2000). To enable more fine-grained information extraction, some attempted to cover more NE types: (Chang et al., 2009), (Watanabe et al., 2007), and (Tkatchenko et al., 2011), using up to 18 NE types. Still, we consider the current granularity of the NE types used to be too coarse, especially for tasks such as question answering (Voorhees and Dang, 2005), where systems need to pinpoint exact entities requested by users.

This paper proposes to create a dictionary of **extended NEs** (**ENEs**). An ENE hierarchy was proposed by Sekine et al. (2002); Sekine and Nobata (2004), and it defines three levels of NE types. At the leaf level, it has 200 ENE types. We aim to create an ENE dictionary that covers all these 200 types. In our approach, using Wikipedia as a basic resource, we classify Wikipedia titles into ENE types to create an ENE dictionary. We perform supervised learning; we derive a large number of features for Wikipedia titles and train a multiclass classifier. The features encode various aspects of Wikipedia titles, including those related to the surface string of a title, the content of an article, and the meta data, such as categories and infoboxes. We devise an extensive list of features for accurate classification into a large number of ENE types. The idea of using Wikipedia for creating an NE dictionary is not new; however, no work has sought to use such a large number of NE types. We want to verify whether it is possible to create an NE dictionary covering such a large number of NE types. We also want to know what types of features are useful in classifying entities into fine-grained ENE types. Note here that this work uses Japanese Wikipedia. Although we want to make our features as language-independent as possible, we introduce some possibly language-specific features for better accuracy.

In the next section, we describe related work. Section 3 describes our proposed method and shows the complete list of features used for training a classifier. Section 4 describes our experiments to verify our proposed method, the effect of the size of training data, and how to refine the acquired dictionary by using probability estimates of the learned classifier. Section 5 summarizes and mentions future work.

2 Related Work

The work to create NE dictionaries has centered around Wikipedia, with the focus on classifying Wikipedia titles (articles) into NE types. As far as we know, the earliest work is by Toral and Muoz (2006). They focused on the first sentence of a Wikipedia article (generally a definition statement) and counted the number of nouns related to three NE types, namely, Location, Organization, and Person, and applied heuristic rules that take into account the numbers in order to determine the article's NE type. Bhole et al. (2007) followed and proposed a super-

vised machine learning approach to the same task, involving the training of an SVM classifier. The features used were the bag-of-words of Wikipedia articles.

In addition to the texts of articles, there are rich meta data in Wikipedia, which can be helpful in distinguishing the NE types of articles. In addition to the nouns of first sentences, Nothman et al. (2008) used head nouns of categories assigned to articles and used heuristic rules to map them to one of four NE types; namely, LOC, PER, ORG, and MISC. Dakka and Cucerzan (2008) trained an SVM classifier by using features related to the structure of Wikipedia articles. Specifically, they introduced bag-of-words features of abstracts (Wikipedia provides short abstracts for articles), tables (infoboxes and contents boxes), and links to other articles. As NE types, they used five: LOC, PER, ORG, MISC, and COMM (common object). Saleh et al. (2010) also used features derived from abstracts, infoboxes, and categories to train their SVM classifier. A similar feature set was also used by (Tardif et al., 2009) who worked on six NE types. Richman and Schone (2008) exploited the multilingual nature of Wikipedia. By using links to articles in other languages, they classified non-English articles into NE types by using their English counterparts, whose NE types can be estimated by using their category information. They used four NE types: DATE, GPE (geographical and political entity), ORG, and PERSON.

The above studies used a relatively small number of NE types, but there are also studies that aimed to cover a larger number of NE types. Chang et al. (2009) used nine NE types (person, act, communication, location, animal, artifact, time, object, and group), which are a subset of supersenses defined in WordNet. To cope with the larger number of NE types, they introduced new features, such as the supersenses of the head nouns of first sentences and the synsets of category names, for training their maximum entropy classifier. Watanabe et al. (2007) worked on 13 NE types taken selectively from the ENE hierarchy. They had to avoid using the full 200 ENE types because of a sparseness problem for their graph-based algorithm. Tkatchenko et al. (2011) used 18 NE types taken from the BBN's question answering taxonomy (Brunstein, 2002). The features used for their SVM and naive Bayes classifiers were conceptually identical to those in (Tardif et al., 2009).

Our work is similar to the previous literature in that we use Wikipedia to create an NE dictionary, but different in that we aim to deal with a much larger number of NE types: 200 ENE types. We want to verify the feasibility of creating such a fine-grained NE dictionary and want to explore useful features for the classification into ENE types. To this end, we make an extensive list of features, adopting those previously proposed and also proposing new ones, for training our classifier. We describe our features later in Section 3.2.

Although not directly related to creating an NE dictionary, there is a good body of work that aims at constructing an ontology (a hierarchy of words or concepts connected with relations such as *is-a* and *has-a*) from Wikipedia (Ponzetto and Strube, 2007; Suchanek et al., 2008; Nagata et al., 2010). Since ontologies are useful resources for the deep processing of texts, such as the inference, once we have created our ENE dictionary, our next step would include constructing an ontology by relating the ENEs.

3 Proposed Method

Following the previous studies, we also propose to use supervised learning and learn a classifier that classifies Wikipedia titles (articles) into ENEs. We have three steps: the creation of training data, extraction of features, and training of a classifier. Since we deal with many NE types (200 ENE types), we place a special emphasis on the extraction of features for accurately distinguishing the ENE types. In what follows, we describe each step in detail.

3.1 Creating training data

As our training data, we need Wikipedia titles tagged with ENE types. However, since there are many ENE types and we need a reasonable amount of training data for each ENE type to avoid data sparseness, the manual creation of training data will be very costly.

Therefore, to facilitate the creation of training data, our basic idea is to turn to an existing corpus annotated with ENE types. In Japanese, there is one such corpus publicly available (Hashimoto et al., 2008). The corpus contains newswire articles in which entities are annotated with ENE tags. From such a corpus, we can extract entities together with their ENE tags to create what we call a **seed dictionary**, whose entries can be matched against Wikipedia titles to take an intersection so that Wikipedia titles can be automatically annotated with their ENE types. Of course, when there are other corpora or gazetteers available, they can also be exploited to augment the seed dictionary. The approach we employ here is similar to (Bhole et al., 2007) and (Zhang and Iria, 2009) in that entries of external dictionaries/gazetteers are intersected with Wikipedia titles to create training data. The difference is that we use an annotated corpus to create such entries. Below, we enumerate the steps we performed to create our seed dictionary and training data.

1. From the Hashimoto corpus (Hashimoto et al., 2008), we extracted all tagged sections. There are 8828 newswire articles (Mainichi Shimbun newspaper '95) in the corpus with 255407 tagged sections. Since some tags are not related to ENE types, we first discarded such tagged sections. We also discarded entities that were annotated with multiple ENE tags because such entities can be ambiguous and would introduce noise. For example, the entity "Rakuten" is a company but also a sports organization owned by the same company; hence it is given Company in one context and Pro_Sports_Organization in the other. By retaining only the unambiguous entities, we obtained 59318 unique entities with their ENE tags.
2. We performed the same procedure as above on our in-house corpus, which we have been maintaining and consists of newswire articles and blogs annotated with ENE types. There are 7184 documents with 118051 ENE tagged sections, from which we extracted 40231 unique entities with their ENE tags.
3. We maintain gazetteers of ENEs for evaluating our ENE recognizer. From the gazetteers, we first removed ambiguous entities (some entities are listed in multiple gazetteers) and then extracted 35858 unique entities with their ENE tags.
4. We merged the results of steps 1–3 to create a seed dictionary. After removing overlaps and ambiguous entities (NB. different tags can be given to the same entity depending on the source of the entity), we created a seed dictionary that contains 128213 unique entities with their ENE tags.
5. The entries of the seed dictionary were matched against Wikipedia titles to take an intersection. We used the Japanese Wikipedia dump of 2012-08-06, which contains 1411994 titles (we use this dump of Wikipedia throughout the paper). The titles here contain all entries including redirects, categories, and disambiguation pages. We found 51576 Wikipedia titles whose surface forms exactly matched the entries in the seed dictionary. We then removed, matched titles that consisted only of a single character, bare numbers, or two or less Hiragana/Katakana (Japanese phonologic characters) because they are potentially vague; their ENE tags could have been incidentally unique due to the lack of instances in the corpus or gazetteer; e.g., bare numbers can be of any ENE type concern-

Rank	ENE type	Count	Ratio	Accum
1	Person	9456	18.93%	18.93%
2	City	1897	3.80%	22.73%
3	Position_Vocation	1827	3.66%	26.38%
4	Product_Other	1805	3.61%	30.00%
5	Company	1725	3.45%	33.45%
6	Doctrine_Method_Other	1380	2.76%	36.21%
7	Date	1070	2.14%	38.35%
8	Dish	786	1.57%	39.93%
9	Book	736	1.47%	41.40%
10	Character	723	1.45%	42.85%
11	Broadcast_Program	618	1.24%	44.08%
12	School	601	1.20%	45.29%
13	Food_Other	600	1.20%	46.49%
14	Movie	594	1.19%	47.68%
15	GOE_Other	556	1.11%	48.79%
16	Show_Organization	554	1.11%	49.90%
17	Music	542	1.08%	50.98%
18	Corporation_Other	537	1.07%	52.06%
19	Station	458	0.92%	52.98%
20	Game	454	0.91%	53.89%

Table 1: Top 20 ENE types in our training data.

ing a number, such as Date, Age, or N_Person. This process left us with 49956 Wikipedia titles (3.54% of all titles), and this becomes our training data.

Our training data (49956 titles) cover 191 ENE types; unfortunately, we could not cover all 200 ENE types, because some ENE types, especially those related to numeric expressions, were scarcely seen in Wikipedia titles. The ones that could not be covered were Address_Other, Weight, Email, URL, Calorie, Intensity, Postal_Address, Seismic_Magnitude, and Volume. Table 1 shows the top-20 ENE types in the training data. We can see that, although Person is by far the most frequent, the decreasing pace of the frequencies of the subsequent types is slow. See Fig. 1 for the relationship between the ranks of ENE types and their counts. We can observe that, for a large proportion of ENE types, we have a reasonable number of training data, with a median around 100.

3.2 Feature Extraction

For each Wikipedia title in the training data, we extract features. We created an extensive list of features to cope with the many ENE types, covering many of the previously proposed features and also introducing new ones that we thought would be useful for distinguishing fine-grained types. Some features can be specific to Japanese. We propose to use 22 kinds of features in all. They are divided into three categories: surface string of a title, content of an article, and meta data of Wikipedia. It should be noted here that when a title has a redirect to another title, we extract features for both titles and merge them to create its features.

3.2.1 Features related to the surface string of the title of an article

The surface string of a title could be greatly indicative of its ENE type. For example, a title that ends with “shi (city)”, is likely to be the name of a city and therefore should be given

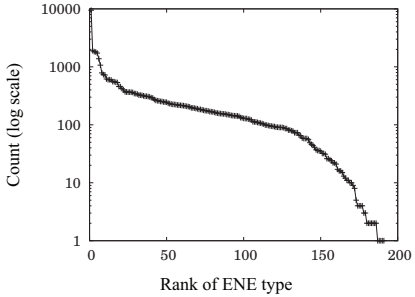

Figure 1: Relationship between the ranks of ENE types and their counts in the training data.

City as its ENE type. Rivers and Mountains, especially in Japanese, have names that end with "kawa (river)" or "yama (mountain)"; therefore, such names can be easily classified into River and Mountain ENE types. We have 16 features (T1–T16: 'T' stands for title) regarding various aspects of the surface string of a title. As far as we know, conventional studies have never put an emphasis on the surface string of a title, probably because most previous work worked with the English language. One exception is (Tardif et al., 2009) that used bag-of-unigrams in the title, corresponding to our T1. T2 through T16 are our newly introduced features. We enumerate the features below.

(T1-T2) Word unigram/bigram We first run the title in question through a morphological analyzer and separate it into words. Note that there are no marked word boundaries in Japanese. Then, we extract word unigrams and bigrams as features. Here, the features are bag-of-words features, indicating the existence of particular unigrams or bigrams with a binary value (i.e., 1 or 0). As a morphological analyzer, we use JTAG (Fuchi and Takagi, 1998).

(T3-T4) Character unigram/bigram We split a title into character tokens and then create bag-of-words features of character unigrams and bigrams. We have this feature since characters, especially Kanji (Chinese-origin) characters in Japanese, have individual meanings even when they form part of a word.

(T5-T6) POS unigram/bigram Using the results of the morphological analysis, we create bag-of-words features for the unigrams and bigrams of part-of-speech (POS) tags. Japanese POS taggers, including JTAG, generally output POS tags that correspond to subcategories for proper nouns, which can be useful in distinguishing ENE types. Other POS information, such as the existence of numbers, could also be useful.

(T7) Last common noun or noun/counter suffix We create a feature from the last word of a title whose POS tag is either a common noun or noun/counter suffix. This is a binary feature, indicating the existence of such a word. The rationale for using the last word of a title is that it is usually the head in Japanese. We chose to use common nouns and noun/counter suffixes because they denote general conceptions or entity categories in Japanese, and are hence more suitable than other POS tags. Here, the idea of using common nouns is similar to using the plural form of nouns in English (Suchanek et al., 2008).

(T8) Semantic category of the last common noun or noun/counter suffix JTAG outputs semantic categories for words. Here the semantic categories are those defined in the Japanese Goi-Taikei ontology (Ikehara et al., 1997). There are 2715 semantic categories in all. We extract features that indicate the existence of semantic categories for the last common noun or noun/counter suffix. It is natural to use these categories because they can be directly indicative of certain ENE types. The semantic categories can also provide abstract meanings for some words, which can be useful when there is sparseness in training data.

(T9-T11) Last one/two/three character(s) We have three features that use the last characters of a title because some characters alone could indicate certain ENE types in Japanese, especially when they are found at the end of a word. For example, words "ninja" and "geisha" both end with the Kanji character "sha", which by itself indicates a person. We use the existence of the last characters (one to three characters) of a title as features. We decided to use up to three characters to increase the coverage of subwords.

(T12) Semantic categories We extract semantic categories for all words in the title by using JTAG and create bag-of-words features. We use this feature to compensate for any possible lack of information that arises from using only the semantic categories of the last common noun or noun/counter suffix.

(T13) Proper noun semantic categories JTAG outputs special semantic categories for proper nouns. They are defined in the Goi-Taikei ontology and there are 130 such categories. Since proper nouns are conceptually similar to NEs, these categories will be useful for the classification of ENE types. We extract proper noun semantic categories for all words in a title and create their bag-of-words features.

(T14) IREX-based NEs We run an off-the-shelf NE recognizer, NameLister (Saito and Nagata, 2003; Suzuki et al., 2006), and extract IREX-based NEs in the title, from which we create bag-of-words features, indicating the existence of each of eight NE types in IREX. Here, the granularity of NEs is coarse; we regard this feature as a complement to other semantic category related features.

(T15) Last character type Japanese has several characters types, and certain types can be indicative of certain NE types. For example, Katakana characters are likely to be used for entities of a foreign origin such as cars and products, whereas Hiragana characters are likely to be used for Japanese entities. Here, we distinguish five types of characters: Hiragana, Katakana, Kanji, Alphabet, and Other, and use the type of the last character of a title as a feature.

(T16) Character type construction In addition to the last character type, this feature focuses on how character types constitute a title. We first split the title into character tokens and converted them into character types. Then, we concatenated the character types as a single string that represents the title's character type construction. For example, "London" is written with four consecutive Katakana characters in Japanese. Therefore, we have "K-K-K-K" (K stands for Katakana) as a binary feature.

3.2.2 Features related to the content of an article

The content of the article of a title obviously has important information about the entity. In this paper, we use two features (C17–C18, where 'C' stands for content) about the content of an article. We do not use all the words of an article because it would make the feature space too sparse and could cause over-fitting to the training data. We focus on the representative

parts of an article; namely, the first sentence and headings (section titles). These features have been used in previous studies (Toral and Muoz, 2006; Dakka and Cucerzan, 2008; Tkatchenko et al., 2011).

(C17) Last common noun or noun/counter suffix of the first sentence It is widely known that the first sentence of an article in Wikipedia is a definition statement. To obtain the first sentence of an article, we first obtain the abstract text of the article from the abstract data provided with a Wikipedia dump and then select its first sentence by selecting a text span from the beginning to the first punctuation mark. Here, we use the abstract data to facilitate our extraction of the initial part of an article. Then, we analyze the sentence with JTAG to extract the last common noun or noun/counter suffix in the first sentence. Finally, we create a binary feature indicating the existence of the last common noun or noun/counter suffix.

(C18) Headings Headings or section titles summarize what is written in an article. For example, the article of "Nobunaga Oda", a famous warlord in Japan, has section titles such as life, personality, portrait, and policies, which clearly indicate that this article is about a person. Therefore, we create bag-of-words features of section titles, each of which indicates the existence of a particular section title. Here, we only use top-level section titles. We ignore such section titles as "links to other articles" and "references" because they can be found in arbitrary articles and therefore would not be useful for distinguishing NE types. We extract section titles from the XML dump of Wikipedia by locating texts enclosed by "==" (section title markers in the Wiki format).

3.2.3 Features related to the meta data of an article

Ever since the work of Nothman et al. (2008), meta data in Wikipedia have been vigorously used for the classification of articles into NE types and have proved their usefulness. In this paper, we extract four features (M19–M22: 'M' stands for meta data) regarding the meta data of an article. Here, M20 and M22 are our newly introduced features.

(M19) Direct categories Categories are one of the most widely used features for distinguishing NE types. We analyze each category assigned to an article with JTAG and extract the last common noun or noun/counter suffix to create a bag-of-words feature. This is similar to using head nouns of categories (Nothman et al., 2008).

(M20) Upper categories In Wikipedia, categories have a network (mostly hierarchical) structure where articles are the sub-nodes of the categories. Starting from the article in question, we find the shortest path to the root category ("Main Category") and use the categories on the path. Such categories can be regarded as the upper categories for the article, and can be useful for distinguishing NE types especially when the direct categories are too specific. For each category on the path (except for the root), we extract the last common noun or noun/counter suffix to create a bag-of-words feature. We use Wik-IE (Mori et al., 2009) to create the network structure, which calculates the distance between nodes in Wikipedia using the Dijkstra's algorithm.

(M21) Infobox attributes Infoboxes provide tabular data for articles. Since the attributes (attribute names) of a table generally indicate the attributes of the entity in question, in a similar manner to (Saleh et al., 2010), we use the infobox attributes to create our features. For each attribute in the infobox, we create a bag-of-words feature indicating the existence of that attribute. We used the Japanese version of DBPedia (http://ja.dbpedia.org/), which offers the infobox data for Japanese articles as triples.

(M22) Instance types Inspired by Richman and Schone (2008), who used the English version of Wikipedia for non-English articles, we also turn to the English version for useful information. We noticed that the English version is heavily linked with the English version of DBPedia (http://en.wikipedia.org/wiki/DBpedia), which offers instance types for English articles. The instance types are given in the vocabulary of various ontologies, such as the DBPedia ontology, schema.org, and Friend of a Friend (FOAF), and are likely to be helpful in distinguishing NE types. For example, "Paris" has Place, PopulatedPlace, Settlement, and Thing as instance types. To create this feature, we first search for the English version of an article by using the external language links and find its instance types by looking up DBPedia. Then, for each instance type, we create a bag-of-words feature. Note that Japanese DBPedia currently does not provide instance type data.

3.3 Training a classifier

For each title in the training data, we extract the features and train a multiclass classifier that classifies the title into one of the ENE types. Here, we employ logistic regression as a learning algorithm. We first create binary logistic regression classifiers for all ENE types. Then, in classifying a title, we find the classifier that outputs the best probability estimate for that title, and use the ENE type for that classifier as an output ENE type.

Although previous studies have extensively used SVMs for NE type classification, we chose logistic regression because of its capability to output probability estimates. Such estimates can be used as confidence scores and can be used to refine the classification results by discarding low-confidence entries with a threshold (See Section 4.4). Note that the scores output by SVMs cannot be directly used as confidence scores because they denote distances from hyperplanes whose absolute values cannot be compared with a fixed threshold. For training the classifiers and calculating probability estimates, we use the LIBLINEAR toolkit (http://www.csie.ntu.edu.tw/~cjlin/liblinear/).

4 Experiments

We performed a series of experiments to verify our method. First of all, we created two sets of data by dividing our training data into two: one for training a classifier (TRAIN SET) and the other for testing (TEST SET). From the 49956 titles in our training data, we randomly sampled 10000 titles as TEST SET and made the rest TRAIN SET (39956 titles). TRAIN SET and TEST SET cover 190 and 179 ENE types, respectively.

We performed four experiments. The first experiment examined the classification accuracy when only one of the features is employed. The purpose of this experiment is to verify the effectiveness of each feature. Then, in the second experiment, we combined the features to maximize the classification accuracy. In the third experiment, we examined how the classification accuracy is affected by the size of training data. In the last experiment, we examined how the obtained ENE dictionary can be refined by discarding low-confidence entries. As an evaluation metric, we mainly use the classification accuracy, which is the rate of accurately classified ENE types in TEST SET. At the end of this section, we also describe our final ENE dictionary that we created by applying the trained classier to all titles in Wikipedia.

4.1 Results by individual features

Table 2 shows the classification accuracy when the classifiers were trained by using one of the features. Since some features can only be extracted for certain titles and since it is impossible

Feature		Acc	Rise in Acc
(T1)	Word unigram (BASE)	50.63%	0.00%
(M19)	Direct categories	72.54%	21.91%
(C17)	First sentence common noun	65.95%	15.32%
(T12)	Semantic categories	63.51%	12.88%
(M20)	Upper categories	63.40%	12.77%
(M21)	Infobox attributes	62.28%	11.65%
(C18)	Headings	62.08%	11.45%
(T4)	Character bigram	61.38%	10.75%
(M22)	Instance types	59.12%	8.49%
(T8)	Semantic category of last common noun	58.78%	8.15%
(T3)	Character unigram	58.39%	7.76%
(T9)	Last character	57.75%	7.12%
(T6)	POS bigram	56.99%	6.36%
(T5)	POS unigram	56.03%	5.40%
(T10)	Last two characters	55.37%	4.74%
(T13)	Proper noun semantic categories	54.06%	3.43%
(T14)	IREX NEs	53.37%	2.74%
(T11)	Last three characters	52.39%	1.76%
(T16)	Character type construction	51.94%	1.31%
(T15)	Last character type	51.59%	0.96%
(T2)	Word bigram	51.21%	0.58%
(T7)	Last common noun	50.94%	0.31%

Table 2: Classification accuracy for the individual features. All features are sorted by their performance except for the word unigram feature, which is used as a base feature.

to learn classifiers without a feature, we trained classifiers by using each of the features with an obligatory use of the word unigram as a base feature. As can be seen in the table, all features contribute to the improvement in the classification accuracy. The features related to the content and meta data, which proved their usefulness for a smaller number of NE types, also proved their effectiveness for ENE types. The direct category feature was by far the most effective. We have two title-related features, T12 and T4, that contributed to the rise of more than 10% over the base feature, suggesting the usefulness of using the title information for the classification into ENEs. We find it interesting that character bigrams contribute greatly to the classification accuracy, suggesting the importance of characters/subwords in Japanese.

4.2 Results by the combination of features

We use a backward selection method to find the best combination of features; that is, we first use all the features and then remove one feature at a time whose removal improves the performance the most. As a result, we removed seven features: (T3) Character unigram, (T4) Character bigram, (T5) POS unigram, (T10) Last two characters, (T13) Proper noun semantic categories, (T16) Character type construction, and (T7) Infobox attributes.

The feature selection improved the classification accuracy from 79.10% to 79.63%, the best accuracy we attained in this work. See Table 3 for the results. We believe the classification accuracy of 79.63% is reasonably high when considering the large number of ENE types. The table also shows the drop in performance when other features are individually eliminated from the best combination, which shows that even when we remove the most influential feature, i.e.,

Feature		Acc	Drop in Acc
	Best combination (w/o T3–T5, T10, T13, T16, M21)	**79.63%**	0.00%
(T11)	w/o Last three characters	79.50%	-0.13%
(T7)	w/o Last common noun	79.49%	-0.14%
(T14)	w/o IREX NEs	79.44%	-0.19%
(T8)	w/o Semantic category of last common noun	79.44%	-0.19%
(T2)	w/o Word bigram	79.38%	-0.25%
(T12)	w/o Semantic categories	79.35%	-0.28%
(T6)	w/o POS bigram	79.35%	-0.28%
(C18)	w/o Headings	79.33%	-0.30%
(T15)	w/o Last character type	79.31%	-0.32%
(M22)	w/o Instance types	79.29%	-0.34%
(T1)	w/o Word unigram	79.29%	-0.34%
(M20)	w/o Upper categories	79.23%	-0.40%
(T9)	w/o Last character	79.02%	-0.61%
(C17)	w/o First sentence common noun	78.93%	-0.70%
(M19)	w/o Direct categories	77.83%	-1.80%

Table 3: Classification accuracy for the best combination and when one of the features is removed from the best combination. The features are sorted by their performance.

Feature set	Acc
T (T1–T16)	69.37%
C (C17, C18)	68.57%
M (M19–M22)	75.40%
T+C	76.14%
T+M	78.64%
C+M	75.90%
T+C+M	**79.10%**
Previous work only (T1, C17, C18, M19, M21)	75.11%
Newly introduced only (T2–T16, M20, M22)	75.09%

Table 4: Classification accuracy for the combinations of feature sets. When the word unigram (T1) is not included in a feature set, we had it included as a base feature.

(M19) Direct categories, from the best combination, the drop is small (1.80%). This indicates that most of the features possess complementary information. The magnitude of a drop can be considered as the specific information carried by a certain feature. We consider it interesting that (T9) Last character has the third largest drop, indicating again the effectiveness of using characters in Japanese.

Table 4 shows the classification accuracy for some combinations of feature sets. We can see that, when we use the features of all three categories (T+C+M), the best accuracy is achieved. The contribution of the newly introduced features is clear, raising the accuracy from 75.11% to 79.10%.

Table 5 shows the precision, recall, and F-measure for the most frequent 20 ENE types in TEST SET (the feature set used is the best combination in Table 3). We can see that the performance varies greatly depending on the ENE types. For some ENE types, such as Product_Other, Doctrine_Method_Other, Character, and GOE_Other, our method performs very poorly. We suspect

Rank	ENE type	Precision		Recall		F
1	Person	0.851	(1840/2162)	0.952	(1840/1933)	0.899
2	City	0.859	(371/432)	0.907	(371/409)	0.882
3	Product_Other	0.525	(255/486)	0.646	(255/395)	0.579
4	Company	0.756	(301/398)	0.820	(301/367)	0.787
5	Position_Vocation	0.766	(301/393)	0.875	(301/344)	0.817
6	Doctrine_Method_Other	0.501	(177/353)	0.697	(177/254)	0.583
7	Date	0.887	(197/222)	0.956	(197/206)	0.921
8	Dish	0.809	(127/157)	0.789	(127/161)	0.799
9	Book	0.723	(102/141)	0.646	(102/158)	0.682
10	School	0.948	(127/134)	0.907	(127/140)	0.927
11	Character	0.639	(62/97)	0.449	(62/138)	0.528
12	Broadcast_Program	0.735	(83/113)	0.654	(83/127)	0.692
13	Food_Other	0.644	(76/118)	0.650	(76/117)	0.647
14	Show_Organization	0.876	(85/97)	0.746	(85/114)	0.806
15	GOE_Other	0.653	(49/75)	0.450	(49/109)	0.533
16	Movie	0.745	(70/94)	0.648	(70/108)	0.693
17	Music	0.772	(71/92)	0.676	(71/105)	0.721
18	Station	0.942	(81/86)	0.880	(81/92)	0.910
19	Corporation_Other	0.673	(72/107)	0.791	(72/91)	0.727
20	Game	0.892	(74/83)	0.831	(74/89)	0.860

Table 5: Precision, recall, and F-measure for the most frequent 20 ENE types in TEST SET.

this low performance is partly attributable to the variation of their names. We leave it to our future work to improve the accuracy for these hard-to-guess ENE types.

4.3 Learning curve

We split TRAIN SET into blocks of 1000 (1K) titles, and examined how the performance improves when each block is added to the training data. TEST SET was used for testing. Figure 2 shows the learning curve. We can see a steady improvement until we reach around 10K. The classification accuracy at 10K is 75.07%. However, after that, the pace of improvement is very gradual. From 30K on, the gradient is just 0.14% per K. Even were this gradient to continue, to reach 100%, we would need an additional 145K of training data, which would be too hard to create manually. For further improvement, it would definitely be necessary to devise new useful features. In addition, it would be helpful to bring in external gazetteers and link them with ENE types so that they can be used to augment our seed dictionary. The idea of linking with other gazetteers has been successful in the linked data community (http://linkeddata.org/), which makes this approach promising. We would like to pursue this approach in the future.

4.4 Refinement by using probability estimates

Our choice of logistic regression was motivated by its capability to output probability estimates so that low-confidence results can be discarded. We examined how this discarding process improves the accuracy. We set up a variable t for a cut-off threshold and moved it from 0 to 1 by increasing it by 0.05. When t becomes larger, erroneous (low-confidence) results would be discarded, and the classification accuracy would improve. However, the improvement in accuracy would come at the cost of decreased coverage (the number of retained samples over the total number of samples). Figure 3 shows how the accuracy and coverage change as

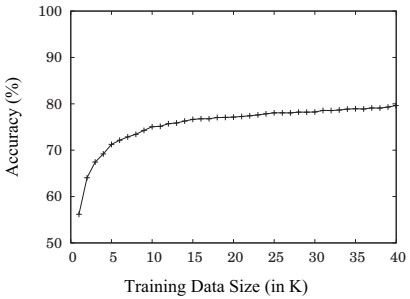

Figure 2: Learning Curve.

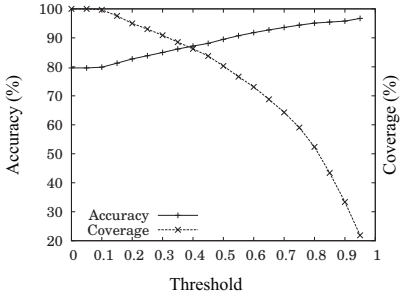

Figure 3: Accuracy and coverage by a varying threshold.

t increases. One can see that the improvement of accuracy is gradual between 80% to 95%, whereas that of the coverage is rather sharp. We also see a clear trade-off between the accuracy and coverage. We use this finding in the creation of our ENE dictionary in the next section.

4.5 Creating the final ENE dictionary

We apply our ENE classifier to all titles in Wikipedia in order to create our ENE dictionary. For this purpose, we newly trained an ENE type classifier using all of our training data (49956 titles). Then, we extracted the features (best combination in Table 3) for all Wikipedia titles (1411994 titles). Using the extracted features, we classified the titles into ENE types with their probability estimates. The result becomes our initial ENE dictionary.

As a dictionary resource, a weight should be given to accuracy over coverage. According to Fig. 3, when t is 0.5, about 90% accuracy (89.48%) can be achieved with over 80% coverage (80.29%). Since we viewed this as a fair setting, satisfying the requirements of a good dictionary, we decided to use 0.5 for t for refinement. After the refinement, 1015563 (71.92%) entries remained. Althouth the number of retrained entries were slightly smaller than the expected 80.29%, we could still retain over one million entries. Here, from Fig. 3, the estimated accuracy of the entries is 89.48%. The final dictionary covers 182 ENE types.

Table 6 shows the top 20 ENE types in the created ENE dictionary. Although Person occupies a good proportion of the entries, we also see large numbers of entities of other ENE types. Compared to the statistics of the training data (Table 1), the orders of the ENE types had some changes, reflecting the differences between the ENE corpus and Wikipedia. Although we cannot show the relationship between the ranks of ENE types and their counts by a figure similar to Fig. 1 for lack of space, the shape of the curve is nearly identical. Up to the 148th rank, we have over 100 entries, suggesting that we have a reasonable number of entities even when the ENE type is rather rare. A fine-grained ENE dictionary such as this one would be greatly helpful for various information extraction tasks.

5 Summary and Future Work

Using Wikipedia as a basic resource, we classified Wikipedia titles into ENE types to create an ENE dictionary. We derived a large number of features for the titles and trained a multiclass classifier. The features used encode various aspects of Wikipedia titles, such as those related

Rank	ENE type	Count	Ratio	Accum
1	Person	301625	29.700%	29.700%
2	Product_Other	53751	5.293%	34.993%
3	School	42179	4.153%	39.146%
4	Company	36462	3.590%	42.737%
5	City	34139	3.362%	46.098%
6	Road	32252	3.176%	49.274%
7	Music	29262	2.881%	52.155%
8	Position_Vocation	27712	2.729%	54.884%
9	Broadcast_Program	26759	2.635%	57.519%
10	Doctrine_Method_Other	24616	2.424%	59.943%
11	Station	21408	2.108%	62.051%
12	Book	15638	1.540%	63.591%
13	Game	14033	1.382%	64.972%
14	Movie	12956	1.276%	66.248%
15	Show_Organization	11778	1.160%	67.408%
16	Worship_Place	11076	1.091%	68.499%
17	Train	11014	1.085%	69.583%
18	Date	10624	1.046%	70.629%
19	Province	10213	1.006%	71.635%
20	GOE_Other	10190	1.003%	72.638%

Table 6: Top 20 ENE types in the created ENE dictionary.

to the surface string of a title, the content of the article, and the meta data provided with Wikipedia. By experiments, we successfully showed that it is possible to classify Wikipedia titles into ENE types with a reasonable accuracy of 79.63%. We also showed that, by applying the classifier to all Wikipedia titles and by discarding low-confidence entries, it is possible to create an ENE dictionary of over one million entities covering 182 ENE types with an estimated accuracy of 89.48%. Our main contributions are as follows: (1) We created the first large-scale ENE dictionary; no work has attempted to classify entities into such fine-grained types. (2) We made clear the features that are useful for the classification into ENE types; we ascertained the effectiveness of the previously proposed features regarding the content and meta data and newly found useful title-related features, such as the semantic categories found in the title and character bigrams.

Our method has a number of limitations. First, the classification accuracy is still low. As shown in Table 5, the accuracy for some ENE types are very poor. We want to devise new features and also find ways to augment our training data. Second, some features, e.g., character-based features, could be dependent on the Japanese language. We need to examine whether our method is applicable to other languages, especially English. Third, we could not cover all ENE types in our dictionary; many ENE types especially those related to numerical expressions were not included in the dictionary. This is mainly because Wikipedia titles do not cover such expressions. We want to investigate other resources to enrich our dictionary with currently scarce ENE types. Fourth, we want to evaluate our dictionary extrinsically, for example by using it in such information extraction tasks as question answering. We also want to use the dictionary to derive gazetteer features for our ENE recognizer that is under development. Finally, we want to extend our dictionary to ontologies so that it can be used for more intelligent tasks. Since ENE types themselves form a hierarchy, we will be able to use this structure to relate the ENEs in our created dictionary.

ABSTRACT
This paper develops a new statistical method of building language models (LMs) of Japanese dialects for automatic speech recognition (ASR). One possible application is to recognize a variety of utterances in our daily lives. The most crucial problem in training language models for dialects is the shortage of linguistic corpora in dialects. Our solution is to transform linguistic corpora into dialects at a level of pronunciations of words. We develop phoneme-sequence transducers based on weighted finite-state transducers (WFSTs). Each word in common language (CL) corpora is automatically labelled as dialect word pronunciations. For example, *anta* (Kansai dialect) is labelled *anata* (the most common representation of 'you' in Japanese). Phoneme-sequence transducers are trained from parallel corpora of a dialect and CL. We evaluate the word recognition accuracy of our ASR system. Our method outperforms the ASR system with LMs trained from untransformed corpora in written language by 9.9 points.

KEYWORDS: spoken language, dialect, language model, weighted finite-state transducer (WFST).

Proceedings of COLING 2012: Technical Papers, pages 1179–1194,
COLING 2012, Mumbai, December 2012.

1 Introduction

Automatic speech recognition (ASR) systems for spoken language are yet far from practical use. ASR systems for written sentences have been widely studied, and recognition accuracy has rapidly improved. In contrast, recognition accuracy is drastically lower for spontaneous speech (Anusuya and Katti, 2009, p. 194). People in their daily lives do not actually speak in a stable way like written sentences. Their speeches include casual expressions, fillers, and even vocabulary specific to dialects.

This paper especially handles improving Japanese dialect ASR. Most previous application systems with speech interface have assumed well-formed sentences in the common language (CL), although they have assumed non-expert speakers. Non-expert speakers will obviously utter informal expressions other than those in written language, and even words specific to their own dialect; dialect ASR systems have difficulty in recognition accuracy or scalability.

Dialects in the world have various kinds of differences (Benincà, 1989). The major differences between dialects and the CL are categorized into the following types: 1) pronunciation, 2) vocabulary, and 3) word order. The first type belongs to the difference in acoustic features, while the second and third belong to that in linguistic ones. Canadian English contains all of three types; 1) /tu/ is pronounced as /tju/, 2) 'high school' is called 'collegiate institute', and 3) 'next Tuesday' is changed into 'Tuesday next' (Woods, 1979). Many North American varieties of French have a tendency to take SVO (subject-verb-object) word order (Gadet and Jones, 2008). In Japanese dialects, the difference of vocabulary is characteristic, e.g., *tabe n* is used instead of *tabe nai* (do not eat) (Gottlieb, 2005).

Our method in this paper focuses on differences in pronunciation of vocabulary between dialects, which correspond to the first and second types. Vocabulary is a set of word entries used in a language or a dialect. We process pronunciation as the corresponding phoneme sequence to reduce the problem to text processing.

The main difficulty with dialect ASR lies in the shortage of linguistic corpora on dialects because they are spoken rather than written. This prevents us from building statistically reliable language models (LMs) including characteristic vocabulary for dialect ASR.

In this paper, we overcome the shortage of dialect corpora by training a vocabulary transformation system that gives labels of dialect expressions to each word in large CL linguistic corpora. (The LMs for ASR is trained based on the output of the above vocabulary transformation system.) The vocabulary transformation system is implemented as a weighted finite-state transducer (WFST) (Allauzen et al., 2007; Neubig et al., 2009). WFSTs model probabilistic transformation rules extracted from dialect-CL parallel corpora.

The three main advantages of our strategy are as follows. First, our system improves the recognition of dialect utterances even with a limited amount of dialect corpora. Second, our method dispenses with the manual enumeration of dialect transformation rules. Therefore, it enables us to build ASR systems for various dialects in the principled manner. Third, statistical corpus transformation gives a solution to how to choose one of multiple candidates for output by taking the contexts of parallel corpora into account.

This paper is organized as follows. Section 2 reviews related work on dialect ASR. Section 3 states major elements of our system, and describes our method of recognition of dialect utterances. Section 4 discusses our evaluation of the system in terms of word recognition accuracy, and finally conclusions summarize this paper and describe future work.

2 Related work

Most studies have focused on acoustic aspects in developing ASR systems for dialects, Ching et al. (1994) described the phonological and acoustic properties of Cantonese, one of the major dialects of Chinese language, based on energy profiles, pitch, and duration. Miller and Trischitta (1996) studied the phonetic features of Northern and Southern US dialects in linearly classifying each dialect. Their experiment achieved error rates of 8% in distinguishing Northern US dialect from those in the the South. Lyu et al. (2006) developed an ASR system for two Chinese dialects, Mandarin and Taiwanese. Dialect-mixed utterances could be recognized with combined character-to-pronunciation mapping in their system.

These systems had two main problems:

1. difficulty of collecting acoustic corpora of dialects
2. incapability of incorporating vocabulary difference

The first problem means that many dialect speakers are necessary for reliable analyses. These systems would work well for major dialects whose corpora were abundant, whereas it was not realistic to collect large corpora even for relatively minor dialects. The second problem prevented these systems from being in general use. Phonological methods are effective for the situation that variation of dialects mainly stems from differences of their phonemes, while these systems do not cover difference of vocabulary. If target dialects have large difference of vocabulary, these systems are less effective. The strategy of classifying dialects and selecting LMs is effective only if the vocabulary of target dialects are almost the same, but actually, dialect vocabulary is rather likely to differ between dialects (Wolfram, 2009, p. 144). The strategy of classifying dialects and next selecting LMs is possible, of course, but effective case is limited; classification would not work well if vocabulary dominates difference of target dialects and these dialects have similar phonological characteristics.

Instead of studying acoustic aspects of dialects containing the problems above, some studies focused linguistic aspects. Zhang (1998) described dialect machine translation (MT) between dialects in the Chinese language. Since dialect sentences were only represented in sound and had not been written down, his translations were between *pinyin* representations of two dialects, which is similar to those in our study. Munteanu et al. (2009), related to the correction of ASR results, tried to correct ASR results in the lecture domain by using a transformation model trained from correct sentences and the corresponding outputs. The scoring for each rule was based on how much the word error rate (WER) could be reduced by applying the rules. These studies still had problems. Zhang (1998) created translation dictionaries manually, and dealing with various dialects required the same process for each dialect. Munteanu et al. (2009) assumed that ASR results were correct; if much vocabulary specific to a target domain were not covered, e.g., for dialects, these methods would not work well. These problems indicates that the key to successful ASR systems is automatic building of LMs in dialects.

This paper deals with dialect ASR as follows. We develop a dialect ASR system by building LMs instead of analyzing acoustic features, because vocabulary is more characteristic in Japanese dialects, as mentioned in Section 1. This enables an ASR system to recognize vocabulary specific to each dialect. Translation dictionaries, transformation rules in other words, are automatically extracted from dialect-CL parallel corpora. The extracted rules are probabilistic based on the statistical analysis of parallel corpora; using large CL corpora, we can simulate dialect linguistic corpora including variations in word choices. This strategy is applied to transformations between spoken and written language (Akita and Kawahara, 2010; Neubig

et al., 2012). Since our transformation targeted dialects, it is more advanced than that for mere spoken language. Our transformation model is simpler than those in these studies, due to our assumption that the word order does not change.

3 ASR for Japanese Dialects

This section describes our method in detail. First, we enumerate elements of our system. Next, we explain how to develop the vocabulary transformation system based on WFST. Finally, we introduce examples of corpora to transform.

The inputs are utterances in dialects and the outputs are recognized word sequences in the CL. We make the following three assumptions behind the problem setting. First, dialects would have no effect on the word order; in other words, it would be only necessary to merely transform pronunciation. Second, dialects of input utterances are known and parallel corpora corresponding to the dialects are available. Third, one-to-many sentence correspondence for CL and dialect sentences, i.e., one CL sentence may be transformed into various dialect sentences by dialect speakers, while these dialect sentences have only one corresponding CL sentence. This problem setting has advantages that 1) we prefer that ASR systems output a CL sentence as its meaning instead of simple dialect transcription given a dialect utterance, and because 2) CL sentences are easy to handle as a canonical representation for applications such as speech dialogue systems.

3.1 Main idea underlying ASR for Japanese dialects

We simulate large dialect corpora to build a statistically reliable LM by transforming large CL corpora. The main problem in building a dialect ASR system is the shortage of large linguistic corpora in dialects due to rare transcriptions of sentences. The transformation produces large dialect corpora even if few actual dialect corpora are available. Each word in the new corpora contains the corresponding pronunciation in the dialects and the original word itself so that the dialect utterances can be recognized as CL sentences. This eliminates the cost of having to transform the ASR results again; we only need CL-to-dialect transformation for linguistic corpora and do not need reverse transformation. We can assume that only phoneme sequences are different because 1) as mentioned above, we handle dialects in structure of text processing, and because 2) Additionally, as we describe at the end of Section 2, we assume that the word order does not change. The vocabulary transformation system focuses on transformation at a level of phoneme sequences; it is called 'phoneme-sequence transducer' afterward.

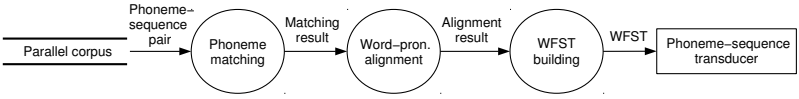
Our solution is composed of two steps:

1. training phoneme-sequence transducers
2. training LMs from corpora transformed with phoneme-sequence transducers

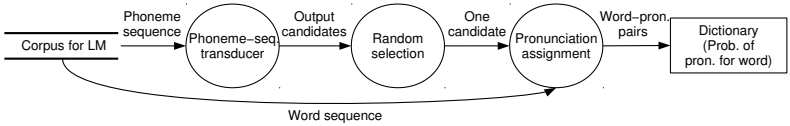
Figure 1 outlines data flow for our method.

Phoneme-sequence transducers are trained from CL-dialect parallel corpora in the first stage (Figure 1(a)). Units of *phonemes* are matched to corresponding sentences in parallel corpora. Next, pronunciations are aligned in units of *words*. Finally, *n*-gram models for phoneme-sequence transducers are trained from the results of alignment as sequences of phoneme-sequence pairs.

The second stage (Figure 1(b)) takes inputs from pronunciations of sentences in the CL corpora to phoneme-sequence transducers to obtain the corresponding pronunciations in the dialects.



(a) Training phoneme-sequence transducers.



(b) Training language models.

Figure 1: Data flow of our method.

After all sentences have been processed, the pronunciations that have been obtained are counted for each CL word entry, and the probabilities for each pronunciation are calculated.

The process involves four main steps:

1. phoneme-sequence transducer
2. random selection
3. pronunciation assignment
4. pronunciation dictionary

In the first step, the pronunciation of all sentences is transformed into dialects. This transformation is probabilistic; phoneme-sequence transducers output multiple candidates together with their probability. These probabilities are determined by the frequencies of transformation patterns in parallel corpora. If a transformation pattern frequently appear in parallel corpora, the phoneme-sequence transducers assign high probability to the pattern.

In the second step, to avoid only candidates with the maximum probability from being output, output is decided randomly from one of the candidates based on their probability. This is a kind of simulation of randomness of word choice. If only candidates with the maximum probability are output, only one pronunciation can be recognized for each CL word.

In the third step, phoneme-sequence transducers process pronunciations, not sentences themselves. This process deals with matching the output phoneme sequence to the original CL sentences (word sequences). After this process, each word in the original CL corpora will have its dialect pronunciation.

In the fourth step, pronunciation dictionaries in an ASR system contain each word entry and corresponding pronunciation as a phoneme sequence. Pronunciation dictionaries can contain multiple pronunciations together with their probabilities (LMs are treated as class n-gram models, in which each CL word entry corresponds to a class). Pronunciations and the corresponding probability is decided by the frequency of each pronunciation in the output of the previous process. These pronunciations make it possible to recognize dialect pronunciation as a word in the CL.

Our solution requires parallel corpora and linguistic corpora to train LMs. Parallel corpora are composed of pairs of phoneme sequences in a dialect and the CL. Our system uses the parallel

i	1	2	3	4	5	6	7	...																			
x	a	n	a	t	a	w	a	d	o	k	o	n	i	s	u	N	d	e	i	r	u	n	o				
y	a	N		t	a			d	o	k	o			s	u	N	d	e		r	u	N					
z	C	S	D	C	C	D	D	C	C	C	C	D	D	C	C	C	C	C	D	C	C	S	D				

(a) Example of alignment of phoneme-sequence pairs in parallel corpora. The first line is in the CL and the second line is in a dialect in the Kansai area (including Osaka). The third line is the matching result; `C` is a correct phoneme, `S` is a substitution error, and `D` is a deletion error.

```
a+a n_a+N t+t a+a w_a+NULL d+d o+o k+k o+o n_i+NULL
s+s u+u N+N d+d e+e i+NULL r+r u+u n_o+N
```

(b) Representation of transformation rules by using sequences of phoneme-sequence pairs. Symbol `+` separates two phoneme sequences in the CL and a dialect. `NULL` represents empty sequences.

Figure 2: Main idea in building rules for phoneme-sequence transducers.

corpus (National Institute for Japanese Language and Linguistics, 2008) composed of dialect sentences and the corresponding CL translations. They contain spoken sentences in various areas (prefectures) of Japan. The corpora for training LMs are sets of dialect sentences. They are created as explained in Section 3.1 using phoneme-sequence transducers.

3.2 Developing phoneme-sequence transducers

The rules for developing phoneme-sequence transducers are created from the parallel corpora previously mentioned. Briefly, the rules are created in two steps:

1. match of each pair of pronunciations,
2. obtain pronunciations in a dialect for each word in the CL.

First, each pair of pronunciations in parallel corpora is processed by matching based on the method of dynamic programming (DP-matching) using the minimum Levenshtein distance to create phoneme-pair sequences (Figure 2(a)), which describe what part of each pair of sequences corresponds to each other. Figure 3 outlines how to create sequences of pairs of the phoneme-sequences described in Figure 2(b) from the two phoneme sequences in Figure 2(a). Let `x[i]` be a phoneme sequence in the CL, and `y[i]` be that in a dialect. We have assumed that they have already been obtained by DP-matching together with the matching result, `z[i]`. Each element of `x` and `y` is a phoneme or empty. Each element of `z` is one of the following: `C` (correct phoneme), `S` (substitution error), `D` (deletion error) or `I` (insertion error).

We adopt WFSTs to build phoneme-sequence transducers. Phoneme-sequence transducers are represented as WFST $T = T_1 \circ L \circ T_2$ (The operation $\circ$ denotes the composition of (W)FSTs. See Allauzen et al. (2007) for more details), T takes phoneme sequences in the CL as input and the corresponding phoneme sequences in dialects together with their likelihoods as output. Figure 4 lists the roles of each (W)FST T_1, T_2, and L. T_1 is the FST for transforming a phoneme sequence in the CL into a sequence of phoneme-sequence pairs, in other words, enumerating sequences of phoneme-sequence pairs whose concatenation at the left is equal to the original phoneme sequence (see Figure 5(a)). T_2 is the FST for transforming a sequence of phoneme-sequence pairs into a phoneme sequence in a dialect, in other words, cutting down the left of each

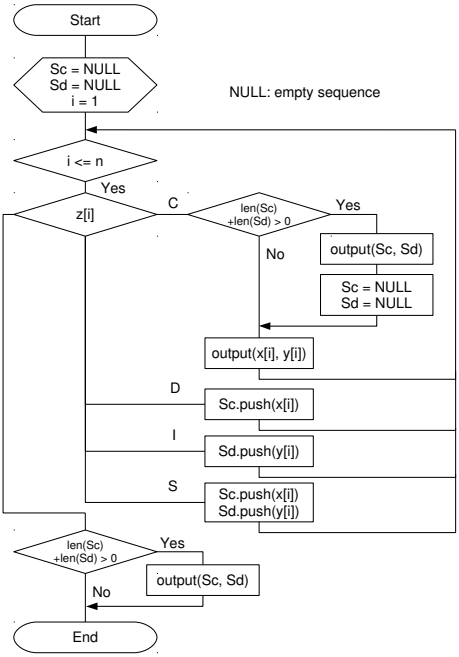


Figure 3: Creating sequences of phoneme-sequence pairs based on DP-matching results. Here 'Sc.push' append the symbol specified in the parameter to the end of sequence 'Sc'.

phoneme-sequence pair (see Figure 5(b)). L is the WFST of a 3-gram model of phoneme-sequence pairs (Chen, 2003) with the method of Kneser-Ney smoothing. L gives a likelihood value to each candidate and it can model phoneme transformation depending on the context. In this paper, OpenFst (Allauzen et al., 2007) is used for creating these (W)FSTs, and additionally Kylm is used for creating L.

We input phoneme sequence $\boldsymbol{x}$ in the CL to WFST T to obtain phoneme sequences in dialect $\boldsymbol{y}_1, \boldsymbol{y}_2, ...$ together with their likelihoods $L(\boldsymbol{y}_1|\boldsymbol{x}), L(\boldsymbol{y}_2|\boldsymbol{x}), ...$ (If $i < j$, $L(\boldsymbol{y}_i|\boldsymbol{x}) \geq L(\boldsymbol{y}_j|\boldsymbol{x})$). It is not efficient to calculate $L(\boldsymbol{y}_i|\boldsymbol{x})$ for all possible $\boldsymbol{y}_i$ since some of $\boldsymbol{y}_i$ have very small likelihoods and the number of candidates is sometimes very large. We only consider the n-best results $\boldsymbol{y}_1, ..., \boldsymbol{y}_n$ for the possible candidates, and cut off candidates from $\boldsymbol{y}_{n+1}$. Likelihoods $L(\boldsymbol{y}_i|\boldsymbol{x})$ for the possible candidates determine the probability of choosing $\boldsymbol{y}_i$; these probabilities $P(\boldsymbol{y}_i|\boldsymbol{x})$ are regularized likelihoods whose sum is equal to one:

$$P(\boldsymbol{y}_i|\boldsymbol{x}) = \frac{L(\boldsymbol{y}_i|\boldsymbol{x})}{\sum_{j=1}^{n} L(\boldsymbol{y}_j|\boldsymbol{x})}. \quad (1)$$

Next, we obtain pronunciation in a dialect for each word. One problem occurs here. The way pronunciation is transformed depends on its context, e.g., whether a given phoneme sequence

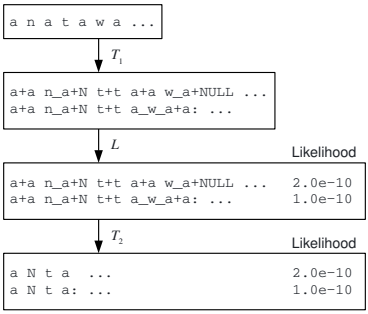

Figure 4: Roles of each (W)FST T_1, T_2, and L.

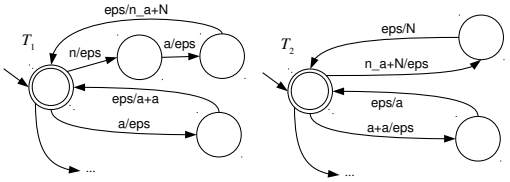


(a) Structure of T_1. (b) Structure of T_2.

Figure 5: Structure of FST T_1 and T_2. Each transition has a pair of input and output symbols delimited by symbol '/'. Symbol 'eps' represents a transition with no input or output symbols.

is itself a word or part of a word; viz., only given a pronunciation in the CL, some of the outputs of the phoneme-sequence transducers may be not suitable as pronunciation of the original word. We introduce word boundaries to the phoneme-sequence transducers. The modified phoneme-sequence transducers take phoneme sequence $\boldsymbol{x}$ containing some word boundaries in the CL and output at most n candidates of phoneme sequences containing word boundaries in a dialect. The modified phoneme-sequence is trained in three steps (see Figure 6).

1. extract what parts of given sequences correspond from phoneme-sequence pairs of pronunciations (Figure 6(a)) *without* word boundary information (Figure 6(b)).
2. align phoneme sequences to each word based on the extracted information (Figure 6(c)).
3. train word-based transformation rules from corresponding sequences *including* word boundary information (Figure 6(d)).

In the second step, we regard phoneme-sequence pairs crossing word boundaries as alignment of multiple ($m \geq 2$) CL words to a single dialect word, and insert $m-1$ symbol(s) representing boundary crossing before the next word boundary. The word-based transformation rules include identity transformations of a single phoneme such as a in the CL to a in dialects, so that the transducers can accept sequences containing a word that does not appear in parallel corpora. The transducers only output the same phoneme sequences for such words in input sequences.

Now, we are ready to transform the corpora. We segment words and estimate pronunciations for each sentence in large linguistic corpora in the CL to create input data for the modified

```
a n a t a | w a | d o k o | n i | s u | N | d e | i | r u | n o
a N t a d o k o s u N d e r u N
```

(a) Example pairs in parallel corpora. The first line is in the CL and the second line is in a dialect of the Kansai area. Symbol | represents word boundaries automatically decided by a morphological analysis tool.

```
a+a n_a+N t+t a+a w_a+NULL d+d o+o k+k o+o n_i+NULL
s+s u+u N+N d+d e+e i+NULL r+r u+u n_o+N
```

(b) Align two sentences at the phoneme level without word boundaries and express them with pairs of phoneme sequences. (Same as figure 2(b))

```
a n a t a | w a | d o k o | n i | s u | N | d e | i | r u | n o
a N   t a |     | d o k o |     | s u | N | d e |   | r u | N
```

(c) Align two sentences at the word level. This represents how each word is pronounced in a dialect.

```
a_n_a_t_a_|+a_N_t_a_|  w_a_|+|  d_o_k_o_|+d_o_k_o_|  n_i_|+|
s_u_|+s_u_|  N_|+N_|  d_e_|+d_e_|  i_|+|  r_u_|+r_u_|  n_o_|+N_|
```

(d) Transformation rules of phoneme sequences based on word-level alignment. Symbol | represents word boundaries.

Figure 6: Way in which word-level transformation rules were developed.

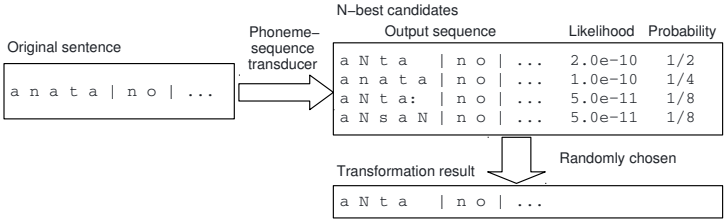
phoneme-sequence transducers. The modified phoneme-sequence transducers output phoneme sequences including word boundary information in a dialect. The transformed sequences are randomly chosen from the corresponding n-best results.

Figure 7 lists the process of building class n-gram LMs, in which each word entry is a class, from the transformed sentences. Class n-gram LMs allow many kinds of pronunciations to be manipulated without increasing the number of word entries of LMs. After all sentences have been transformed, the frequencies of pronunciations for each word entry are counted. We define the frequencies divided by the frequency of the word as the in-class probability of the pronunciation. Let $\#(\boldsymbol{x})$ be the number of CL word $\boldsymbol{x}$ that appears in the original sentences and $\#(\boldsymbol{y}|\boldsymbol{x})$ be the number of pronunciations $\boldsymbol{y}$ given to word $\boldsymbol{x}$; then the in-class probability, $P_c(\boldsymbol{y}|\boldsymbol{x})$, is written as

$$P_c(\boldsymbol{y}|\boldsymbol{x}) = \frac{\#(\boldsymbol{y}|\boldsymbol{x})}{\#(\boldsymbol{x})} = \frac{\#(\boldsymbol{y}|\boldsymbol{x})}{\sum_{\boldsymbol{y}} \#(\boldsymbol{y}|\boldsymbol{x})}. \quad (2)$$

3.3 Linguistic corpora to transform

The transformation method previously mentioned, of course, requires large linguistic corpora to transform. A former study (Lee et al., 2002) adopted 75 months of newspaper articles for a corpus, which is typical in studies on language models. Newspaper articles are relatively formal and in consistent style; therefore, they are suitable for recognizing speech in written articles, while not for spoken sentences including expressions that are characteristic of spoken language. One candidate for corpora in spoken language is the academic presentation speech corpora included in the *Corpus of Spontaneous Japanese* (CSJ) (Maekawa, 2003). This corpus consists of



(a) Transformation of sentences using phoneme-sequence transducers.

a n a t a | n o | ...	a N t a | n o | ...
a n a t a | w a | ...	a N t a: | ...
a n a t a | t o | ...	a N t a | t o | ...
a n a t a | k a r a | ...	a: t a | k a r a | ...
... | w a | a n a t a | ...	... | w a | a N t a | ...

In–class probabilities: P(a N t a | a n a t a) = 3/5, P(a N t a: | a n a t a) = 1/5, P(a: t a | a n a t a) = 1/5.

(b) Way in which in-class probabilities are determined. Phoneme-sequence transducers transform sentences including word **a n a t a** in the CL (at left) into sentences in a dialect (at right).

Figure 7: Way in which a corpus is transformed.

sentences including many technical terms, which are also not very suitable for spoken language.

This paper adopts corpora available on the Web, especially the Yahoo! *Chiebukuro* (Q&A) corpus. This corpus is presented by Yahoo! Japan Corporation and National Institute of Informatics (NII). Since corpora on the Web are created by various users, they contain various and some informal expressions like spoken language. The Yahoo! Q&A corpus contains sentences together with categories and subcategories to which each sentence belongs. It is possible to build LMs from sentences belonging to some specific categories near the target topics.

We adopt a corpus filtering method (Misu and Kawahara, 2006) in the Yahoo! Q&A corpus to build LMs. The major disadvantage of Web corpora is that some sentences are too inconsistent or not even in the form of sentences, e.g., Internet slang and ASCII arts. Speech recognition does not require these sentences and they are need to be excluded from corpora for training LMs. Corpus filtering is based on perplexity; we choose sentences with small perplexity on an LM from a set of sentence examples. These sentence examples were blog articles in the Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa, 2008) core data. Words were segmented and pronunciations were estimated in BCCWJ core data these were manually checked by humans. Blog articles in the BCCWJ core data contained sentences that were close to those in spoken language including informal words and expressions.

4 Experiment

Our experiment evaluated the recognition accuracy of ASR. Dialect utterances were recognized as CL sentences and compared to referential CL sentences. We collected utterances in the CL and Kansai dialects. People from the Kansai area (Osaka, Hyogo, Nara and Shiga Prefectures in this experiment) read these sentences in their own dialects. The LMs for the CL were simply trained from the Yahoo! Q&A corpus. The LMs for the Kansai dialect were trained from the

	Data set	# of persons	# of sentences	# of words

pronunciation-transformed corpus based on the Yahoo! Q&A corpus mentioned in Section 3.2.

4.1 Conditions

Here we describe the training data for the phoneme-sequence transducers and LMs. Table 1 summarizes the size of corpora. Each LM had a common vocabulary size of 10,000.

This experiment adopted the parallel corpus (National Institute for Japanese Language and Linguistics, 2008) of the Kansai area (Osaka, Kyoto and Hyogo Prefectures). Each dialect sentence in this corpus was represented as pronunciation while each CL sentence was in plain text. We segmented CL sentences into words and estimated pronunciations of the words with KyTea (Neubig and Mori, 2010) so that the two kinds of sentences would have the same format in pronunciation.

We transformed the pronunciation of the Yahoo! Q&A corpus into that of the Kansai dialect to train the LMs. We chose 23,600 out of 335,685 questions in the category of daily life with the filtering method mentioned in Section 3.3, which has approximately the same number of words as the BCCWJ core data. One of at most the five-best dialect pronunciations was randomly chosen in the transformation, with the probability of their normalized likelihoods, and determined the probability of each pronunciation by using Equation 1.

Spoken sentences were translated into Kansai dialect by each speaker so that speakers would utter sentences clearly, since each speaker's dialect was slightly different. Each speaker read 100 sentences from blog articles in the BCCWJ. The spoken sentences and sentence examples for the filtering method did not overlap. We adopted Julius (Lee et al., 2001) as the ASR engine in this experiment, and the acoustic model was a phonetic tied-mixture (PTM) trigram model for Japanese language available at the Julius website.

4.2 Evaluation

This experiment evaluated ASR by recognition accuracy, Acc, calculated as

$$Acc = \frac{N - S - I - D}{N} \tag{3}$$

Language model		#1	#2	#3	#4	Average
Y	(Untransformed)	53.6	47.0	57.0	45.4	50.8
Y	(Dialect-transformed)	60.5	51.8	64.4	52.6	**57.3**
B	(Untransformed)	53.5	43.4	54.8	43.3	48.8
B	(Dialect-transformed)	60.1	49.4	63.9	49.4	55.7

Table 2: Word recognition accuracy of Kansai dialect [%]. Y and B stand for Yahoo! Q&A and BCCWJ, respectively.

Language model		#1	#2	#3	Average
Y	(Untransformed)	71.8	64.0	71.5	69.1
Y	(Dialect-transformed)	62.4	55.1	62.3	59.9
B	(Untransformed)	72.1	64.5	72.5	**69.7**
B	(Dialect-transformed)	62.0	56.3	58.7	59.0

Table 3: Word recognition accuracy of the CL [%]. Y and B stand for Yahoo! Q&A and BCCWJ, respectively.

where N, S, I, and D correspond to the sum of the lengths of referential word sequences, substitution errors, insertion errors, and deletion errors.

Tables 2 and 3 summarize word recognition accuracy for the Kansai dialect and CL, for LMs trained from transformed and untransformed corpora of Yahoo! Q&A and BCCWJ core data. The LMs from the Yahoo! Q&A corpus had better recognition accuracy than the LMs from the BCCWJ. As explained in Section 3.3, the Yahoo! Q&A corpus contained more sentences that had the characteristics of spoken sentences, which matched the blog articles of spoken sentences. The Yahoo! Q&A corpus made it easy to match specific kinds of topics by category filtering. These characteristics of the Yahoo! Q&A corpus made a difference despite the same size of the two corpora. Additionally, the LMs from transformed corpora resulted in better word recognition accuracy for the Kansai dialect than those from untransformed corpora (the opposite characteristics appeared for the CL). This means that the ASR system actually recognized some dialect-specific expressions like spoken language with LMs from transformed corpora. This demonstrated our method's effectiveness.

Dialect transformation was proved to reduce the effect of pronunciation-estimation errors, seeing the created dialect corpora. Automatic pronunciation estimation causes some errors, and these errors affect the recognition accuracy. Dialect transformation was proved to output correct pronunciations for inputs of mistakenly-estimated pronunciations, by training this "mistaken" transformation rules. Since dialect pronunciation in parallel corpora is correct, words with mistaken pronunciation in corpora for LMs are transformed into the correct dialect pronunciation if errors occur in a consistent way.

We interpolated the in-class probabilities of pronunciations of a dialect and the CL to recognize both pronunciations. The interpolation of probabilities is defined as follows; let P_c of Equation (2) for dialect d be rewritten as $P_{c,d}$, then

$$P_{c,mix}(\boldsymbol{y}|\boldsymbol{x}) = \sum_d \alpha_d P_{c,d}(\boldsymbol{y}|\boldsymbol{x}), \quad (4)$$

$$\text{s.t.} \quad \sum_d \alpha_d = 1, \ \alpha_d \geq 0$$

Transformation ratio			#1	#2	#3	#4	Average
Y	0%	(Untransformed)	53.6	47.0	57.0	45.4	50.8
Y	25%		60.8	52.6	66.1	52.2	57.9
Y	50%		61.3	51.9	65.9	51.1	57.6
Y	75%		62.0	53.8	66.0	52.9	**58.7**
Y	100%	(Completely transformed)	60.5	51.8	64.4	52.6	57.3

Table 4: Word recognition accuracy of Kansai dialect [%] with interpolated pronunciation dictionaries.

Language model		#1	#2	#3	#4	Average
Y	(75% transformed)	66.0	56.6	68.9	55.6	**61.8**

Table 5: Word recognition accuracy [%] after ignoring variation of expressions in spoken language.

gives the interpolated in-class probabilities, $P_{c,mix}$. Table 4.2 lists the recognition accuracy with interpolated pronunciation dictionaries.

Word recognition accuracy with a transformation ratio of 75% (i.e., $\alpha_{\text{dialect}} = 0.75$, and $\alpha_{\text{CL}} = 0.25$) scored the best (58.7%), which is 9.9 points higher than the result for LMs trained from the BCCWJ, and 7.9 points higher than that for LMs trained from the untransformed Yahoo! Q&A corpus. Dialect-transformed LMs have dialect pronunciations of words, but fewer kinds of CL pronunciations. Not all words in spoken language are characteristic of dialects; spoken language is composed of both dialect and CL pronunciations. The result showed that interpolated dictionaries was able to improve recognition accuracy more.

Word recognition accuracy depends on four components.

1. phoneme-sequence transducers and their parallel corpora
2. corpora with dialect-specific words
3. acoustic models
4. variation of expressions in spoken language

The first component, *phoneme-sequence transducers and their parallel corpora*, was the main idea presented in this paper. Parallel corpora determine what pronunciation ASR systems can recognize as dialect expressions. Phoneme-sequence transducers in this paper had word boundary features as well as phoneme sequences themselves. Pronunciation in a dialect can actually differ from words having the same pronunciation in the CL, depending on the part-of-speech (POS) tags of each word. One of possible improvement is including the POS tags of each word and its previous and next words to phoneme-sequence pairs in Figure 6(d).

The second component, *corpora with dialect-specific words*, is necessary to recognize actual dialogues in specific areas. Spoken sentences in this experiment did not include dialect-specific proper nouns. In other words, the problem was how to collect sentences containing such proper nouns. Corpus candidates are local pages in newspapers. Among major newspaper companies in Japan, Mainichi newspapers Co., Ltd. distributes data of local pages as well as national press.

The third component, *acoustic models*, is required to deal with acoustic features specific to dialects (e.g., changes in phonemes). Since the acoustic model in this experiment did not assume dialect speech recognition, acoustic features specific to dialects may affect word recognition accuracy.

The fourth component, *variation of expressions in spoken language*, makes non-essential errors affect recognition accuracy. Some words and phrases, especially those in spoken language, have the same meaning and role in sentence and are unnecessary to distinguish. It is important for ASR systems to rather recognize the meaning of sentences than strictly recognize sentences word by word. If they also have similar pronunciation, the variations in recognition results are likely to increase recognition errors. For example, *want to* and *wanna* in English language, even though not in all cases, can be regarded as the same phrases. In Japanese language, some particles (e.g., *na* and *ne* on the end of sentences, corresponding to tag questions in English) and verbs (...*teiru* and ...*teru*: progressive form) have similar variations.

We modified the results of the 75%-transformed Yahoo! Q&A corpus to correct errors related to the fourth component. Table 5 lists word recognition accuracy after modifications. We should regard these results to demonstrate the considerable accuracy of ASR systems. These were 3.1 points higher than that of the same LM in Table 2 (61.8%) on average.

Conclusions

This paper described how to develop an ASR system that could recognize utterances in Japanese dialects. The main idea behind our system was how to create dialect corpora, few of which are actually available. We developed phoneme-sequence transducers trained from dialect-CL parallel corpora to statistically model transformations of pronunciations between dialects and the CL. Each word in the linguistic corpora was labelled as dialect word pronunciations to simulate dialect corpora. The experiment with measuring of word recognition accuracy confirmed the effectiveness of our system in recognizing dialect utterances. We were able to obtain higher recognition accuracy by adopting sentences like spoken language as corpora for training LMs. Furthermore, interpolation of in-class (pronunciation) probabilities of the CL and dialects improved recognition accuracy a little more. Our method does not depend of language and dialects; an ASR system for another language could be developed as long as parallel corpora were available.

Even though this paper assumed dialects would have no effect on the word order, a little more work should be necessary to handle slight changes in the word order as mentioned in Section 1. One possible solution is to introduce a parameter of extraneous word generation probability, p_0, like IBM model 3 (Brown et al., 1993). If WFST L (see Section 3.2) is represented by larger n-gram models ($n = 3$ in this paper) than the length of phrases within which the word order changes, WFST would model a few changes in the word order.

Our next project will be developing an ASR system to recognize various dialects alone. One possible solution to recognize utterances in multiple dialects is interpolation of in-class probabilities of pronunciations of the dialects in the same way as Section 4.2. This treatment may be too simple to work well because it assumes independence of dialects of each word. Adjacent words are intuitively likely to belong to the same dialects, and its modeling will be the main problem of recognition of multiple dialects. After that, it will be a further step to train acoustic models from dialect utterances and develop a method of switching dialects.

ABSTRACT
We give a report on a detailed study of automatic lexical disambiguation of 30 sample English verbs. We were drawing on a lexicon of English verb patterns based on the Corpus Pattern Analysis (CPA), which is a novel lexicographic method that seeks to cluster verb uses according to the morpho-syntactic, lexical and semantic/pragmatic similarity of their contexts rather than to associate them with abstract semantic definitions. We have trained several statistical classifiers to recognize these patterns, using morpho-syntactic as well as semantic features. In this paper we mainly concentrate on the procedures for feature extraction and feature selection and their evaluation. We show that tailoring the features to the verbs respectively, as they are implicitly contained in the pattern definitions (explicitly described in the lexicon), has the potential to significantly improve the accuracy of supervised statistical classifiers.

TITLE AND ABSTRACT IN CZECH

Rysy šité na míru anglickým slovesům pro automatickou lexikální disambiguaci pomocí Corpus Pattern Analysis

Předkládáme detailní studii automatické lexikální disambiguace na pilotním vzorku třiceti anglických sloves za použití lexikonu vzorů slovesných užití (patterns), který vychází z Corpus Pattern Analysis (CPA). Tato inovátorská lexikografická metoda namísto na abstraktních definicích jednotlivých významů staví na souhře morfosyntaktické, lexikální a sémantické/pragmatické podobnosti slovesných užití. Natrénovali jsme několik statistických klasifikátorů na rozpoznávání těchto vzorů. Klasifikátory využívají jak morfosyntaktických, tak sémantických rysů. V naší studii se soustředíme na procedury pro extrakci rysů, jejich výběr a jejich evaluaci. Ukazujeme, že rysy na míru uzpůsobené jednotlivým slovesům, jež jsou implicitně obsaženy v definici každého vzoru v lexikonu, mají potenciál významně zvýšit přesnost statistických klasifikátorů s učitelem.

1 Introduction

This study focuses on the lexical semantics of English verbs and its automatic analysis based on contextual hints, morpho-syntactic as well as lexical. It is generally known that the manual annotation of verbs for Word Sense Disambiguation (WSD) tasks has to face the issue of inter-annotator confusion. The commonest verbs are often used to represent several events or aspects of an event at once. For instance, *throwing bread crumbs to the birds* comprises a number of different but interlinked events: propelling an object (typically humans with hands), targeting a propelled object, discarding an object, passing an object to someone else, passing it to an animal as food. Fine-grained lexicons would list all or many of these partial events, since there are good examples of contexts, where one of the aspects is outstanding: throwing missiles, throwing something away/in the sink, throw corn to chickens, etc. In contexts like the one mentioned above, where none of the partial events is dominating, the inter-annotator confusion is almost inevitable, since the instance matches several semantic definitions at once. Using a coarse-grained lexicon, on the other hand, would mean that *throwing darts* and *throwing sour milk in the sink* are similar events, with all the implications for inferencing or translations. Facing this issue, we became fascinated by the Corpus Pattern Analysis, a manual method of sorting corpus concordances according to their morpho-syntactic, lexical and semantic/pragmatic similarity, coined by Hanks (1994). Our current work has been inspired by its implementation, the Pattern Dictionary of English Verbs (PDEV) (Hanks and Pustejovsky, 2005). PDEV as a database has been practically developed at Masaryk University in Brno (Horák et al., 2008) and is publicly available at http://deb.fi.muni.cz/pdev/.

PDEV is a semantic concordance built on yet a different principle than FrameNet, WordNet, PropBank, or OntoNotes: the manually extracted patterns of frequent and normal verb uses are, roughly speaking, intuitively similar uses of a verb that express "in a syntactically similar form" a similar event in which similar participants (e.g. humans, artifacts, institutions, other events) are involved. Two patterns can be semantically so tightly related that they could appear together under one sense in a traditional dictionary. The patterns are *not* senses but syntactico-semantically characterized *prototypes*. Concordances that match these prototypes well are called *norms* while concordances that match them with a reservation (metaphorical uses, argument mismatch, etc.) are called *exploitations* (Hanks, forthcoming). The PDEV corpus annotation indicates the norm-exploitation status for each concordance. Compared to other semantic concordances, the granularity of PDEV is high and thus discouraging in terms of expected inter-annotator agreement. However, selecting among patterns does not really mean disambiguating concordance but rather determining to which pattern it is most similar — a task easier for humans than WSD is. This principle seems particularly promising for verbs as words expressing events, which resist the traditional word sense disambiguation the most.

2 Lexicon of Verb Semantic Patterns

Each lexical entry in the PDEV scheme consists of numbered categories (an example is given in Table 1). Each category consists of a *pattern* and an *implicature*. The pattern represents the morphological, syntactic and lexical characteristics of the verb used in a certain context. The meaning is represented by the implicature. The pattern takes the form of a predication. The pattern-defining verb complements are represented by *semantic types* or *lexical sets*. A lexical set is a list of characteristic collocates, whereas semantic types are items in Hanks' ontology.

Verb	No.	Pattern / Implicature
gleam	1	**[[Physical Object | Surface]] gleam [NO OBJ]** [[Surface]] of [[Physical Object]] reflects occasional flashes of light
gleam	2	**[[Light | Light Source]] gleam [NO OBJ]** [[Light Source]] emits an occasional flash of [[Light]]
gleam	3	**{eyes} gleam [NO OBJ] (with [[Emotion]])** {eyes} of [[Human]] shine, expressive of [[Emotion]]
wake	3	**[no object] [Human] wake ({up}) AdvTime({from} {nightmare | dream | sleep | reverie}) ({to} Eventuality)** the mind of [[Human]] returns at a particular [[Time]] to a state of full conscious awareness and alertness after sleep
wake	4	**pv [phrasal verb] [[Human 1] ^ [Sound] ^ [Event]] wake [[Human 2] ^ [Animal]] ({up})** [[Human 1 | Sound | Event]] causes the mind of [[Human 2 | Animal]] to return to a state of full conscious awareness and alertness after sleep
wake	7	**[Anything] wake [Emotion] ({in} Human)** [[Anything]] causes [[Human]] to feel or become aware of [[Emotion]]
wake	9	**waking * ({up})** [Human|Animal]'s returning to a state of full conscious awareness and alertness after sleep

Table 1: Example patterns defined for the verbs *gleam* and *wake*.

2.1 Pilot Sample English Verbs

We have performed our experiments using a newly developed lexical resource called *VPS-30-En*, recently published by Cinková et al. (2012). *VPS-30-En* (Verb Pattern Sample, 30 English verbs, henceforth VPS) is a pilot lexical resource of 30 English lexical verb entries enriched with semantically annotated corpus samples. VPS is publicly available on the web page http://ufal.mff.cuni.cz/spr/pdev30verbs.[1] The data describes regular contextual patterns of use of the selected verbs in the BNC (2007). VPS has arisen as a practical result of previous studies published by Hanks, drawing on his PDEV, see e.g. (Hanks and Pustejovsky, 2005). VPS contains the verbs showed in Table 2.

VPS is a collection of 30 revised PDEV verbs in which the adjustments of the entries and the original concordance samples were driven by inter-annotator agreement (IAA) findings. The collection was designed as a small sample of PDEV that was revised and cleaned up as a gold-standard data set for statistical pattern recognition.

During the annotation, the annotators got a random 50-concordance sample along with the lexicographer-annotated reference sample and the entry. They matched each random concordance to the categories according to the similarity of implicatures, the similarity of the patterns and, not least, according to the overall similarity of the concordance to the concordance clusters associated with the respective categories.

[1]This language resource has been developed and/or stored and/or distributed by the LINDAT-Clarin project of the Ministry of Education of the Czech Republic (project LM2010013). In the LINDAT-Clarin repository the VPS data is available under the handle https://ufal-point.mff.cuni.cz/xmlui/handle/11858/00-097C-0000-0005-BF95-B.

Table 2: Basic characteristics of the 30 sample English verbs under study. For detailed explanation see Section 3.

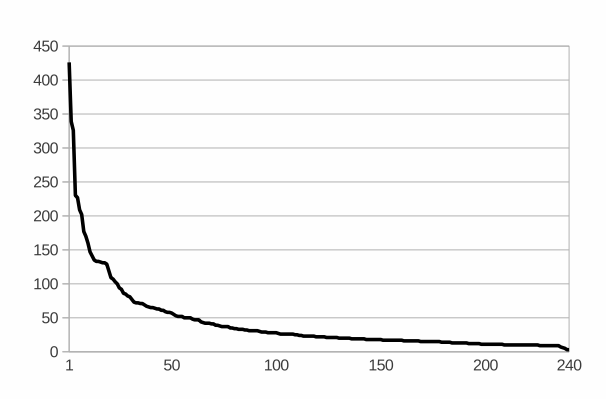

Figure 1: Number of examples of the classified tags in the training data set. The x-axis corresponds to the 240 pattern tags sorted by their frequency in the training data. The value on the y-axis is the number of the training example sentences. For example, only 55 pattern tags have more than 50 examples in our training data.

After each annotation round, IAA was measured and disagreements were manually analyzed. The disagreement analysis was supported by confusion matrices computed for each annotator pair. Provided the annotation of the random sample reached a satisfactory IAA, the disagreements were manually adjudicated by the lexicographer in a spreadsheet table: the lexicographer highlighted evident annotation errors, listed all acceptable values and "one best choice" in a separate column to each concordance. The "one best" annotation was typed back into the user interface as part of the gold standard data set.

The gold standard data set consists of the reference sample and of the adjudication table for the adjudicated sample. As a rule, it consists of 350 concordances (a 250-concordance original sample, one 50-concordance trial sample, and one 50-concordance adjudicated sample).

3 Experimental Data Set

To keep things simple we have neglected the norms and exploitations in this series of experiments. Also, we have, to a significant extent, preserved the classical WSD setup, i.e. both the annotators and the classifier are forced to pick one tag only.

Table 2 shows the most important characteristics of the verbs in the VPS data set. VPS contains about 450 different pattern tags. However, we reduced the number of patterns for classification task and accepted only those with more than 8 occurrences in the training data. The number of pattern tags that we use is 240. The verbs are divided into three frequency groups (A, B, C) according to their frequency in the corpus. Note that 6 most frequent verbs in the data set (*say, arrive, claim, deny, throw* and *tell*) cover 90% of our subcorpus.

The distribution of the number of examples per one tag in the training data set is shown in Figure 1. Unfortunately for most of the 240 tags that should be classified we have a small

Frequency Group	Weight	Perplexity	MFC Average Accuracy %
A	80.7	2.3	73.9 ±0.5
B	12.3	6.5	49.9 ±0.7
C	7.1	5.3	43.7 ±0.5
All	100.0	3.0	68.8 ±0.5

Table 3: Accuracy baselines (the accuracy of a MFC classifier) for all verbs and by frequency groups.

number of training examples (only 91 tags have more than 30 examples).

We also measure the perplexity of the verbs using a standard formula based on the entropy of a probabilistic distribution. The weighted average perplexity of verbs and the baseline accuracy by frequency groups are summarized in Table 3. MFC stands for a most-frequent-case classifier (i.e. the most frequent tag of the training set is used to classify all instances of the test set). The training set was randomly divided into 9 parts to perform a 9-fold cross-validation. In Tables 3 and 6 the AVG accuracy is displayed together with the confidence intervals based on the standard t-test at the significance level $\alpha = 5\,\%$.

The test sets contain 50 multi-annotated instances of each verb. The IAA values (measured as Fleiss' kappa) displayed in Table 2 were calculated using human annotations made independently by 4 annotators. In Table 2 we also indicate the values of "human accuracy", just to illustrate how difficult the classification task is for people.

4 Feature Extraction and Selection

We have identified the feature extraction for machine learning as a central issue, with great impact on the performance of automatic classifiers. Since we used only one-sentence contexts, we dealt only with *local* features. Each data instance to be classified consists of the target verb (TV) and some context words. Therefore the features that describe data instances are based on the observed characteristics of both the TV and the context words. Intuitively it seems to be a good idea to follow the structure of the defined patterns. Therefore we use two kinds of features for machine learning, the morpho-syntactic features and the semantic features. All features used in this study are binary, i.e. have only 0/1 values.

4.1 Types of features and feature sets

4.1.1 Morpho-syntactic features

We have considered three types of morpho-syntactic features: 1) morphological features of the target verb, 2) morphological features of words in a contextual window, 3) syntactic dependencies. By the morpho-syntactic feature set we were seeking to analyze collocates in relevant argument positions, negation and the modifiers of arguments. To alleviate the automatic parser errors, we formulated some features just based on part-of-speech tags. For instance, a (likely) direct object is also encoded as a noun following the target verb in a given window. We were also observing the tense, mood and voice of the target verb. Also, we were taking into account whether the verb is governed by or governs another verb. We were drawing on (Semecký, 2007), adapting the features to English.

First we tuned a model for pattern classification using only morpho-syntactic features, and only then we tried and improved it by using a set of semantic features.

4.1.2 Semantic features

Semantic features capture the semantics of nominal subjects and/or objects of the TV and/or prepositional phrases dependent on the TV, which exactly corresponds with semantic types and/or lexical sets indicated in the pattern definitions. For that purpose we use the system of *semantic prototypes* developed by Bick (first publicly mentioned in (Bick, 1996); the current documentation is available on the Web[2]). In fact, to create semantic features we take only the most coarse-grained level of the semantic prototypes, which is called "umbrella" categories. In Bick's system each of the 150–200 semantic prototypes is assigned to some of 40 umbrella categories, which are grouped into 22 "major umbrellas": *animal, botanical, human, location, vehicle, abstract concepts, actions/events/processes, anatomical, things (concrete/countable), clothes, materials, collectives/parts, domain concepts, features, food, perceptions and feelings, semantic/semiotic, state of affairs, time, tools/machines, units/quantities, weather*.

The semantic prototypes for English are drawing on similar systems for Portuguese and Danish. The original motivation for creating the semantic prototypes, such as <Hprof> (professional human), <tool> or <sem> (semantic/semiotic product) was the polysemy resolution for Portuguese-Danish machine translation in a Constraint Grammar context. Thus, context-driven rules are used to remove or select semantic categories for a given lemma, depending on its syntactic function, inflexion, definiteness and dependency relations. The granularity of the semantic prototypes was chosen to match linguistic usefulness, rather than for its descriptive value as such. Thus, tags should optimally be distinguishable with linguistic tests, such as the combinatorial potential, e.g. which prepositions are typically used with a noun in question, plural vs. mass determiners, or testing verbs: "you can eat it, drink it, write it . . . ". Too low a granularity (high level of abstraction) would reduce the distinctive power, too high a granularity (low level of abstraction) would make it impossible to express general contextual rules and not gain much compared to lexical rules targeting the individual lemma.

4.1.3 Universal and tailored feature sets

We developed and evaluated two kinds of feature sets. While *universal* feature sets are common to all verbs under study, *tailored* feature sets are verb-specific. The procedure for extracting the tailored features is fully automatic and is based on an automatic analysis of the pattern definitions. As we show in this paper, using tailored feature sets enables us to build automatic classifiers with a significantly better performance.

After many experiments we tuned and evaluated 5 models for feature extraction and selection. First, we started with a basic universal model that deals only with morpho-syntactic features (U1). Second, to evaluate the contribution of semantic features, we designed a more advanced universal model that also uses semantic features (U2). Then we focused on using the specific clues contained in the pattern definitions and developed 3 tailored models (T1, T2, and T3) that work with all kinds of features and differ in procedures for feature selection. An overview is given in Table 4.

[2] http://beta.visl.sdu.dk/semantic_prototypes_overview.pdf

Model	Number of features	Relation to verbs	Feature characteristics	Feature selection method
U1	58	universal	morpho-syntactic features only	selection using Decision Trees (Information Gain)
U2	65	universal	morpho-syntactic and semantic features	same as U1
T1	68-106	tailored	the U2 set + features based on pattern definitions	same as U1 and U2 + features tailored to verbs
T2	19-88	tailored	all morpho-syntactic, semantic, and pattern-based features	greedy forward selection to maximize SVM accuracy
T3	29-147	tailored	the union of the feature sets selected by T1 and T2	greedy backward elimination to maximize SVM accuracy

Table 4: Overview of the models used for feature extraction.

4.2 Morpho-syntactic Feature Extraction

Morpho-syntactic features are extracted from sentences using both a morphology analyzer based on the Penn TreeBank (PTB) morphological tagset (Santorini, 1990) and the Stanford parser with its Stanford dependencies representation (de Marneffe et al., 2006). In total we have established 79 fixed binary features and 4 lexicalized features. In fact the lexicalized ones generate a number of binary features, depending on the occurrence of certain auxiliary words (prepositions, particles, and conjunctions) in the training data. All morpho-syntactic features can be divided into 3 groups:

Characteristics of the TV
10 binary features: Passive voice, modality-1 (would, should), modality-2 (can, could, may, must, ought, might), negation, tense (PTB tags: VBN, VBD, VBG, VBP, VB), use in an infinite phrase (outside subject).

Characteristics of the context words that immediately precede or follow the TV
Context is limited to ± 3 words simply by the word order. 9 binary features have been established for each of the 6 closest context words (in total 54 binary features): nominal-like (NN, NNS, NNP, NNPS, DT, PDT, PRP, PRP$, POS, CD), adjective (JJ, JJR, JJS), verbs (VB, VBD, VBG, VBN, VBP, VBZ), modal (MD), adverbial (RB, RBR, RBS, RP, IN), *to* (TO), wh-pronoun (WDT, WP, WP$), wh-adverb (WRB), to_be (lemma = *be*).

Characteristics of the context words that syntactically directly depend on the TV
a) logical subjects (3 binary features: nominal subject, clausal subject, subject in the plural form); b) objects (8 binary features: direct object, indirect object, passive nominal subject, passive clausal subject, clausal complement, complementizer (typically the subordinating conjunction "that" or whether"), any object, any object in the plural form); c) particles (lexicalized); d) adverbials (4 binary features: adverbial modifier, adverbial clause modifier, purpose clause modifier, temporal modifier); e) preposition (lexicalized: prepositional modifier or prepositional clausal modifier); f) markers (lexicalized: subordinating conjunctions different from *that* or *whether*).

4.3 Morpho-syntactic Feature Selection

Feature selection was performed in two steps. First, we filtered out the features with useless value distribution. As a threshold we used the condition that the less frequent (binary) value should be detected in our training data at least 5 times. After that filtering we had 149 binary features. The second step was reducing the remaining feature set in order to "optimize" the classifier performance. After many experiments the following heuristic procedure won. For each of the 30 verbs separately we searched for a small subset of the features with the best performance using a decision tree classifier. We started with only one best feature and then greedily added further best features and tested the classifier performance. When it was not possible to improve the accuracy by adding any of the remaining features, the process stopped. Then all the "best" small sets for all 30 verbs were united and we got an overall feature set containing 58 morpho-syntactic features. We call this model "U1". Its accuracy for different verbs is shown in Table 5 and in Figure 2. We experimentally checked that U1 could be hardly beaten regarding the overall accuracy measured as a weighted average of all 30 verbs.

4.4 Semantic Feature Extraction and Selection

Our universal model U2 deals only with the umbrella prototypes (22 major + 40 subordinated) and observes only the semantic types of subjects and objects. As a starting point, the feature selection procedure takes the overall set of 124 (binary) semantic features (62 for the semantic type of subjects, and other 62 for objects). The final feature selection was done analogously as the previous selection of the morpho-syntactic features. We started with the union of the best 58 morpho-syntactic features and all 124 semantic features. First, we greedily searched for the "best" small feature subset for each of 30 verbs separately. Then we took the union of all small subsets. The result was a set of 65 features consisting of 21 semantic and 44 morpho-syntactic ones. We call this model "U2". Again, its accuracy for different verbs can be seen in Table 5 and in Figure 2. The overall average results for all 30 verbs are given in Table 6.

4.5 Tailored Feature Extraction and Selection

The extraction of the tailored features is based on contextual hints described in the patterns. This process is driven by 1) the presence of a member of a lexical set defined in patterns, 2) the verb forms indicated in patterns, 3) prepositions listed in prepositional phrases described in patterns, 4) particles dependend on the TV, 5) types of object clauses allowed in patterns, 6) the "no_object" attribute defined in patterns.

The tailored models differ in the feature selection method used. The T1 model simply uses the U2 feature set and all tailored featured corresponding to a given verb. The T2 model takes all possible features and greedily selects the best ones to maximize accuracy of an SVM classifier. The most advanced T3 model takes the union of the T1 and T2 feature sets and then reduces the whole set by greedy backward elimination, again to maximize accuracy of an SVM classifier.

5 Supervised Pattern Classification: Model Choice and Tuning

We experimented with several supervised machine learning methods, namely k-Nearest Neighbours (kNN), Decision Trees (DT), AdaBoost.M1 (ADA) based on DT, Support Vector Machines (SVM), and Naive Bayes classifier (NB). Our results are perfectly in line with the observation reported in (Màrquez et al., 2007) that the best results are obtained using SVM or ADA. We also observed that in case of small samples for different patterns, the SVM model tends to be

Verb	Average accuracy						Best tailored model				
	MFC	U1	U2	T1	T2	T3	M	#F	Acc	Imp-B	Imp-U

Table 5: Comparison of two universal and three tailored models. The best model is always one of T1, T2, or T3. #F is the number of the features selected by the best model. Imp-B and Imp-U stand for improvement over the baseline and over the best universal model U2, respectively.

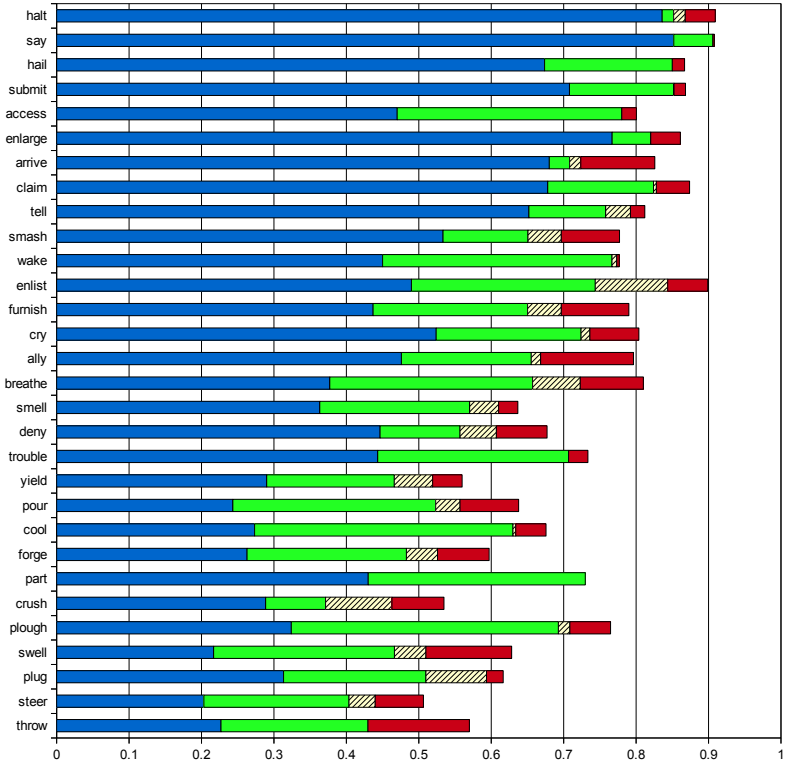

Figure 2: Accuracy improvement over the MFC baseline (in blue): the best models using universal feature sets U1 (green) and U2 (cream), and the best models using tailored feature sets (red).

Frequency Group	Best universal				Best tailored			
	AVG Accuracy %	Improvement %	ERR decrease %	Test Acc %	AVG Accuracy %	Improvement %	ERR decrease %	Test Acc %
A	87.9 ±1.9	10.4	38.2	86.4	88.9	11.8	41.5	83.1
B	63.9 ±2.1	38.3	27.1	58.8	72.3	60.6	45.6	66.6
C	68.7 ±0.9	72.0	42.8	66.9	74.1	87.8	53.4	69.6
All	83.6 ±1.6	18.2	37.1	81.6	85.8	23.1	42.8	80.1

Table 6: Accuracy of the best SVM models. *AVG Accuracy* is the result of the cross-validation test on the training data set. *Improvement* is the percentage difference between the AVG Accuracy and the Baseline Accuracy. *ERR decrease* stands for the percentage difference between the baseline error rate and the error rate of the respective model. *Test Acc* is the accuracy measured on the test sets.

better than ADA (cf. the overview article by Schapire (2003)). Finally we trained our best models (U1, U2, T1, T2, T3) using the SVM method and a grid search approach to parameter optimization. The results described in Table 5 and in Figure 2 show that tailored models almost always clearly outperform the universal ones. However, among the tailored models there is no absolute winner. Unfortunately, we have not yet developed one "best" method for feature selection that would universally lead to the best performance for any verb. Therefore we chose the best tailored model for each verb separately, according to the results of the cross-validation experiments performed on the training data.

6 Evaluation and error analysis

6.1 Universal models

Our overall result is that the "semantically enriched" model U2 slightly outperforms the "only morpho-syntactic" model U1, which can be observed in Table 5. However, only the difference for the low-frequent verb group is statistically significant. In Figure 2 the verbs are sorted according to the increasing perplexity; this figure also shows the decreasing accuracy tendency, which has naturally been expected.

The classifiers did not know the pattern definitions for the respective verbs. We made this decision in order to see to what extent the default feature set would do. This approach, along with the sparsity of our data, resulted in a few systematic errors. The most striking one is the misclassification of patterns that prescribe a participial form of the verb. When these patterns were not frequently assigned, the classifier did not learn the most important feature — that the verb should be a participle that is not used in an obvious passive voice, but is already a transition to an adjective or a noun (e.g. *cooling* in *cooling towers*). The classifier often assigned this tag to concordances in which the verbs did not have the form of a participle.

Another drawback of the classifiers is that they have not been fed a list of phrasemes. As the data is so sparse, idioms either remain unrecognized, or they are interpreted literally. For

Feature type	Frequency	%
All tailored	**283**	**16.1%**
Tailored – lexical sets	94	5.3%
Tailored – prepositions	68	3.9%
Tailored – particles	24	1.4%
Tailored – clauses	15	0.9%
Tailored – verb form	59	3.4%
Tailored – no object	23	1.3%
All semantic	**462**	**26.2%**
Semantic – Subj	118	6.7%
Semantic – Obj	304	17.3%
Semantic – PP	40	2.3%
All morpho-syntactic	**1016**	**57.7%**
All	**1761**	**100.0%**

Table 7: Overview of the structure of features used in best tailored feature sets.

instance the concordance *This organisation happily <ploughs> a furrow totally at odds with the notion of free trade* is interpreted as an agricultural context. This problem goes beyond just idioms, since many patterns with limited collocability are defined by lexical sets — lists of typical collocates. The nouns in these lists are often quite heterogeneous, encompassing several semantic types and the association with a semantic type is irrelevant. For instance *claim credit for something*. The data is too small for such lists to be learned directly.

Another interesting issue is semantic modulation in nouns. For instance, the verb *halt* distinguishes between abstract processes, such as financial crises, and vehicles or human groups in military contexts to be halted. In the following concordance, *advance* is a process, but what is really meant are the men and vehicles advancing. Semantic modulation is a typical cause of annotator confusion, often mimicked by the classifier: *And even Crown Prince Rupprecht, far removed from Verdun, had warned him days before the offensive began that the advance would be <halted> by flanking fire from the Left Bank.*

6.2 Tailored models

To some extent, tailored feature sets are able to provide a remedy for the errors described above. A summary is given in Table 6 to compare our best universal model U2 with the best tailored models (specific for each verb). Although tailored features cause the accuracy increase, Table 7 indicates the fact that the morpho-syntactic features dominate even in the best tailored models.

A glance at the results provided by the tailored models reveals a couple of observations. We have compared the results for the test data with the human confusion matrices and with the overall outcome of the universal models as we have described it in the previous section. We have identified four interesting points:

1) Participial patterns. The universal models did not learn that the confusion between a participial and a regular pattern is only acceptable when the target verb is in a participial form. The tailored models learned this successfully for most verbs where participial patterns occurred. There is only one major exception: cool 11 (participial) – confused for cool 1 (intransitive).

2) Patterns with a different number of objects. In several verbs, e.g. "deny something" (deny 9) confused for "deny somebody something" (deny 10), neither model learned to discriminate according to the number of non-prepositional objects, although the presence of the indirect object was among the features. We suspect this confusion to occur due to parsing errors.

3) Syntactically similar patterns with different implicatures or semantic types. The classifiers are in trouble whenever two pattern definitions are syntactically similar and the only difference lies in the semantic types of the collocates. Although the universal features contain the semantic types, this semantic information is not sufficiently granular. Unlike lexical sets, we do not have any detailed information on which words correspond to which semantic types.

4) Heterogenity of 'u' and 'x' tags. The most systematic error is in many verbs a pattern number assigned to a concordance classified as 'u' or 'x'. We speculate that learning these negative instances is extremely difficult. Their examples in the data are very heterogeneous, and each of them can be more similar to a positive instance, respectively, than they are among one another.

6.3 Future work

As a next step, we would like to exploit the potential of the semantic types determined in the patterns. We need to develop a robust method to "populate" the semantic types with lexical units. Also, we need to gain a better insight into the performance of parsers, since the most important features are inarguably the syntactic ones. A weak spot of the tailored features is that, in *some* cases, our best tailored models slightly overfit the training data (as can be observed in Table 6). So we need to make the proces of feature selection more robust. The main issue, however, that sets the limits on the performance of supervised classifiers seems to be the lack of sufficient amount of reliable training examples.

Conclusion

The two main goals of our research were to evaluate the usefulness of semantic prototypes if we use them directly as features for statistical learning, and to evaluate the power of features tailored to individual verbs and based on automatic analysis of pattern definitions. Our result is in line with previously published studies that usually agree on the fact that the morpho-syntactic features are the most important for statistically-driven semantic disambiguation. Nevertheless, for *some* verbs the use of semantic features plays an important role. The positive impact of tailored features is obvious.

Acknowledgments

This research work has been supported by the Czech Science Foundation (grant project no. P103/12/G084) and partly by the project META-NET (FP7-ICT-2009-4-249119 of the EU and 7E11040 of the Ministry of Education, Youth and Sports of the Czech Republic).

We thank our friends from Masaryk University in Brno for providing the annotation infrastructure and for their permanent technical support. We thank Patrick Hanks for his CPA method, for the original PDEV development, and for numerous discussions about the semantics of English verbs.

ABSTRACT
Scientific publications contain many references to method terminologies used during scientific experiments. New terms are constantly created within the research community, especially in the biomedical domain where thousands of papers are published each week. In this study we report our attempt to automatically extract such method terminologies from scientific research papers, using rule-based and machine learning techniques. We first used some linguistic features to extract fine-grained method sentences from a large biomedical corpus and then applied well established methodologies to extract the method terminologies.

We focus the present study on the extraction of method phrases that contain an explicit mention of method keywords such as (**algorithm, technique, analysis, approach and method**) and other less explicit method terms such as **Multiplex Ligation dependent Probe Amplification**. Our initial results show an average F-score of 91.89 for the rule-based system and 78.26 for the Conditional Random Field-based machine learning system.

KEYWORDS: terminology extraction, rule-based, machine learning, corpus, linguistic features.

COLING 2012, Mumbai, December 2012.

1 Introduction

The methods and techniques used during scientific experiments and reported in scientific papers are often expressed in different forms. They can be in the form of a semantic sequence (see (Hunston, 2008) containing the word *method ("rank-based normalization method" in Sentence 1)*, the word *technique ("Non-negative matrix factorization technique" in Sentence 2)*, the word *analysis ("discriminant analysis" in Sentence 3)*, and so on.

Sentence 1: *In order to compare U133A and U133 Plus 2.0 data we further normalized the data with a* ***rank-based normalization method****.*

Sentence 2: *In the Bioinformatics field a great deal of interest has been given to* ***Non-negative matrix factorization technique NMF*** *due to its capability of providing new insights and relevant information about the complex latent relationships in experimental data sets.*

Sentence 3: *The relative performance of the four IBDQ dimensions in distinguishing best patients with minor symptoms from those with severe was studied by* ***discriminant analysis****.*

A method mention can be a terminology term such as the phrase **Multiplex Ligation dependent Probe Amplification** in Sentence 4.

Sentence 4: *Recently* ***< Multiplex Ligation dependent Probe Amplification > < MLPA >*** *has also been used to quantify copy number classes.*

A method expression can also be a verb phrase referring to an action performed during an experiment, such as the verb phrase *to search for* in sentence 5.

Sentence 5: *These sequences were used* ***to search for*** *the nearly invariant nucleotides of the inverse core AAC and core GTT sites separated by a distance typical of previously identified attC sites to bp .*

In some cases, the context in which the method terminologies are used in the text can contain valuable information about the method mention, such as synonyms, definition, and other relations with entities in the text.

The automatic extraction of terminologies has been the focus of many studies in the past (Maynard and Ananiadou, 2000), (Zhang and Wu, 2012), but not many works have focussed on automatic extraction of method mentions. We believe that the extraction of method expressions from research papers can help to build lexical resources that can be used in various NLP tasks on research papers.

For example, the automatic recognition of method expressions can help to easily detect method sentences and classify them into their rhetorical categories as in (Agarwal and Yu, 2009).

In addition, the automatic extraction of method mentions and the information surrounding them can be useful in dictionary building, ontology population and glossary creation. Also, it can help in the task of knowledge discovery from scientific papers, as any mention of methods and techniques used in that paper can easily be presented to readers without them having to read the whole text.

The extraction of contextual information around the method mentions can be useful in building Question-answering and focussed text summarization systems.

In this study, we present our attempt to extract method terminologies from sentences. Also we showed how we can use a terminology context to extract other relevant information about the term. We define "other relevant information" to be the syntactic and semantic relationship between the term and other words. It may be a definition, a variant terminology and so on.

This study doesn't take into account the extraction of verbs as method mention in scientific research papers.

The contribution of our work is twofold. First we used some linguistic filters to automatically select thousands of fine-gained method sentences that have a high probability to contain methodology terminologies; then we used the context of such sentences to extract terminologies and other information about them.

The rest of this paper is organized as follow. The next section reviews some related works. In Section 3, a detailed methodology of method mentions extraction techniques is presented. In Section 4, the results are described. We conclude the paper by a summary and directions for future work.

2 Related work

Automatic term extraction is an important component of many natural language processing systems. It is often used in applications such as knowledge discovery, knowledge management, automatic text indexing, and so on. Many studies have been conducted on the recognition of terminologies from research papers, especially in the biological domains where new terms are created constantly. These studies primarily focussed on the extraction of domain specific concepts such as nouns and collocations. But it is hasn't been possible to apply a general rules to extract all the terms.

Previous studies on automatic term extraction have been made possible with the availability of many language resources and large electronic corpora. Three main approaches are used in terminology extraction, namely, linguistics-based approaches, statistical approaches and hybrid approaches.

2.1 Linguistics-based approach

A term from a terminology is often a unit of meaning related to a specific field or domain of study. It can be a single word, such as *clustering*, or a compound expression made up of individual terms, such as *Hidden Markov Model*. Some terms in a terminology can follow comprehensive rules which can help with their generalization.

With the linguistics-based approach, candidate terminology is filtered by linguistic features using morphological analysis, such as part of speech (POS). Complex terms are extracted using shallow parsing and dependency analysis between words in the sentence (Bourigault, 1992). (Dagan and Church, 1994) limited the candidate terminology to a string that represents the pattern of noun sequences. Good results can be achieved in small corpora using linguistic methods, but due to the shortage of patterns, recall can be low and it is difficult to generalize these techniques across fields and languages.

2.2 Statistical approach and machine learning approach

Statistical approaches are based on statistical information, such as the frequency of terms appearing in the corpus. As already noted in (Zhang and Wu, 2012), statistical features can include term document frequency and inverse document frequency TF*IDF (Maedche and Staab, 2000), KF*IDF (Xu et al., 2002), C-value/NC-value (Frantzi et al., 2000) and so on. Term extraction is based on the computation of the Unithood – i.e. a degree of strength or stability of syntagmatic combinations or collocations, and Termhood – i.e. the degree that a linguistic unit is related to a domain-specific concept (Kageura and Umino, 1996) of the terminology.

Termhood calculation is often based on the frequency of the term in the paper or a given baseline corpus.

(Church and Hanks, 1990) used Mutual Information (MI) to compute Unithood, (Dunning, 1993) used LogL , and (Patry and Langlais, 2005) computed left/right entropy to extract unithood candidates. When computing termhood, methods such as TF*IDF (Maedche and Staab, 2000), DR-D (Velardi et al., 2001), C-value/NC value (Frantzi et al., 2000)) and Domain Component Feature Set (DCFS) (Zhang and Sui, 2007) are employed, as reported in (Zhang and Wu, 2012).

2.3 Hybrid approach

Linguistics-based and statistical approaches have their own advantages and disadvantages. They are often integrated to extract terminology. There are two ways to combine them. One way is to extract candidate terms with linguistics methods and then if no terms are found then the statistical methods are applied. (Daille, 1996) used the linguistic methods to get candidate terms and set them as the input of statistical models. Then statistical methods such as MI and LogL are used to get final terms.

The other way is to obtain candidate terms using statistical methods first and then use linguistic methods to discard those terms that are inconsistent with linguistic patterns. (Maynard and Ananiadou, 2000) extracted multi-word terms using a thesaurus and the semantic Web concept to get the semantic and category information, and then integrated it with the statistical and syntactic information in the corpora. Different terminology extraction toolkits can also be integrated to extract terminology besides the integration of linguistics and statistics methods. (Vivaldi and Rodriguez, 2001) integrated different term extraction tools using simple voting and the results were better than that with single term extraction tools. (Vivaldi et al., 2001) improved the previously mentioned voting approach, got the best integration strategy with Boosting algorithm and improved the performance of terminology extraction based on the hybrid approach.

3 Methodology

3.1 Corpus creation

The goal of this study is to extract the methods and techniques used in biomedical research papers in order to build a lexical resource comprising the name, the variants and definition of such methods and techniques as they are mentioned and used in research articles. The first task consists of the gathering of a comprehensive corpus that is large enough to contain an important number of method mentions and information about how they are used in the papers. One way is to select some research papers and scan through each of them to extract candidate

"method sentences" manually. Another way is to use filters to automatically select in a large repository of papers, "method sentences" that we believe are about the methods or techniques used in the paper as well as the context of such sentences. We define the context of a "method sentence" to be a window of sentences coming after or before them. The first option has proved in the past to be more precise, but very difficult to implement. In fact, a manual information extraction task can be tedious and time-consuming and requires many specialized skills and domain experts. It is therefore recommended to use automatic extraction techniques whenever it is possible. Since our purpose is to find as many relevant sentences as possible, it is obvious that we cannot rely on existing corpora to achieve our goal.

Some recent works have focussed on the classification of sentences from biomedical articles into the IMRAD (Introduction, Methods, Research, and, Discussion) categories. In their attempt to classify biomedical research papers into these categories (Agarwal and Yu, 2009) used a corpus of 1131 sentences. Of these sentences, 389 were labelled Introduction, 363 were labelled Methods, 273 were labelled Results and 106 were labelled Discussion. Even though the corpus contained "method" sentences, very few contain the mention of the techniques used in the paper. Also, the context of the sentence was not retrieved. (Liakata et al., 2012) used a corpus of 265 articles from biochemistry and chemistry annotated at the sentence level by experts in the domains. Even though the corpus contains 8404 method sentences, many sentences belong to the same papers and are about the same methods or techniques. For instance 10 consecutive sentences can be annotated to belong to the method category. Those sentences usually refer to the same method or technology and some of them may not even contain any mention of a method. Besides, few of the sentences contain a definition of the techniques used in the papers.

Based on the study of the corpora mentioned above, we deemed it necessary to build a different corpus that contains as many method sentences as possible and a definition or a usage context of the method mention.

We relied on some linguistic concepts such as anaphoric relations to produce our fine-grained method corpus.

In fact, most demonstrative noun phrases are anaphoric; therefore a sentence that begins with the demonstrative noun phase "This method" is anaphoric and its antecedents are likely to be found in previous sentences. (Torii and Vijay-Shanker, 2005) reported their work on anaphora resolution of demonstrative noun phrases in Medline abstracts, and found that nearly all antecedents of such demonstrative phrases can be found within two sentences. On the other hand, (Hunston, 2008) reported that interpreting recurring phrases in a large corpus enables us to capture the consistency in meaning as well as the role of specific words in such phrases. So, the recurring semantic sequence "this method" in the Pubmed corpus can help us to capture valuable information in the context of their usage.

To build our corpus we therefore search for sentences starting with "This method" in the PubMed article repository as well as the sentences immediately preceding them. Then we collected the pairs of sentences.

Sentence 6 in Example 1 contains the mention of the method and Sentence 7 contains its usage and definition context.

Example 1

Sentence 6 *: The Ortholuge method reported here appears to significantly improve the specificity*

(precision) of high-throughput ortholog prediction for both bacterial and eukaryotic species .

Sentence 7 *: This method , and its associated software , will aid those performing various comparative genomics-based analyses , such as the prediction of conserved regulatory elements upstream of orthologous genes .*

We can see that Sentence 6 is talking about the method and Sentence 7 is a reference to the method mention and how it is used. Combining both sentences we therefore have sufficient information to extract the "method" mention, its usage and its benefits.

We can then derive such information to fill lexical components such as:

- Method Mention: ***Ortholuge method***
- Usage/Role: ***comparative genomics-based analyses/ prediction of conserved regulatory elements upstream of orthologous genes.***

Example2

Sentence 8 *: An alternative method for predicting protein function is the Phylogenetic profile method, also known as the Co-Conservation method , which rests on the premise that functionally related proteins are gained or lost together over the course of evolution [4] .*

Sentence 9 *: This method predicts functional interactions between pairs of proteins in a target organism by determining whether both proteins are consistently present or absent across a set of reference genomes.*

In Example 2, it is possible to extract the following information:

- Method : ***Phylogenetic profile method***
- Variant/ also known as:***Co-Conservation method***
- Usage: ***for predicting protein function / predicts functional interactions between pairs of proteins***
- How: ***by determining whether both proteins are consistently present or absent across a set of reference genomes.***

The information that we can derive from this pair is sufficient enough to create lexical resources that can be used in many natural language processing tasks.

Using the retrieval technique mentioned above, we have been able to retrieve about 6500 such pairs of sentences from 189 different journals and 2000 papers.

We limit the scope of this study to the extraction and recognition of the method terminologies, due to time constraints.

3.2 Gold Standard datasets

We created 2 sets of gold standards with sentences taken only from BiomedCentral journals. The first gold standard comprises 918 pairs of sentences containing the first category of method mention – i.e. terminology units ending with a method keyword. The second gold standard comprises 122 pairs of sentences of method mentions that don't contain a method keyword. In

each gold standard, we assumed that the method mention is in the first sentence and the other information about its usage is in the second sentence.

We used grammatical rules to extract the first category (method mentions that contain keywords, such as algorithm, technique, analysis, approach and method) and machine learning techniques to extract the second category of method mention (those that don't contain the above keywords).

When a method keyword is not explicitly mentioned in a sentence containing a method mention, it is not obvious to apply general grammatical rule to recognize it as the words composing it can be of various forms. In the following sentences:

Sentence 10 : Enault and colleagues proposed an improved **< phylogenetic profile >** based on a **< normalized Blastp bit score >**.

Sentence 11 : Another way to obtain suboptimal solutions from a **< HMM >** is to do **< HMM sampling >**.

Sentence 12 : In this paper we introduce a **< Bootstrap procedure >** to test the null hypothesis that each gene has the same relevance between two conditions where the relevance is represented by the Shapley value of a particular coalitional game defined on a microarray data set .

we can notice that the different method mentions - *< phylogenetic profile >, < normalized Blastp bit score > < HMM >, < Bootstrap procedure >* are all of different word shapes. Also when most of them are nouns phrases, they can be confused with other noun phrases in the sentence. We thus believed that the extraction of this type of method mentions can be viewed as a named entity recognition task (Maynard et al., 2001), (Palmer and Day, 1997).

For this second task, we transformed each sentence into the BIO format (Table 1). There are 284 manual-tagged terms, 122 sentences, 2871 words and punctuations.

In Table 2 we shows the number of sentences in each dataset.

Enault and colleagues proposed an improved **< phylogenetic profile >** based on a **< normalized Blastp bit score >**	Enault	O
	and	O
	colleagues	O
	proposed	O
	phylogenetic	B-method
	profile	I-method
	based	O
	on	O
	a	O
	normalized	B-method
	Blastp	I-method
	bit	I-method
	score	I-method
	.	O

Table 1: Representation of a method sentence in the BIO format.

Category (keywords)	Number of sentences	Proportion
Method	439	42%
Analysis	200	19%
Model	63	6%
Algorithm	73	7%
Approach	145	14%
Other (Machine learning corpus)	122	12%
Total	1040	100%

Table 2: Corpus statistics (combining both datasets).

3.3 Rule-based extraction

Most of the method mentions in the first category can be represented by the following examples:

1. *rank-based normalization method*
2. *HRV power spectral analysis*
3. *Non-negative matrix factorization technique*
4. *linear regression analysis*
5. *Newton-type algorithm*
6. *tube group amplification approach*
7. *progressive alignment algorithm*
8. *metabolite profiling approach coupling mass spectrometry*
9. *profile-based HMM method*
10. *multifactor-dimensionality reduction MDR method*

As we can notice these are simple grammatical patterns that can be extracted with simple rules.

1. They can start and continue either with an adjective or a noun.
2. They can continue either with an adjective or a noun.
3. They end with a method keyword.

These rules can be represented by the following regular expression:

(Adjective | Noun)+(method | analysis | algorithm | approach| model)

To extract such patterns, we first used the Genia tagger (Tsuruoka et al., 2005), a Part-of-Speech tagger trained on a biomedical corpus, to tag every word in the sentence. Then, we used the rules to extract all phrases and terminologies that correspond to the above mentioned patterns. The results are presented in the Result section.

3.4 Machine learning and feature extraction

3.4.1 Feature extraction

The feature pool includes:

1. Word feature

   The word itself.

2. Part-of-speech tags

   We used a POS tagger (the Genia tagger) to tag each word in the sentence.

3. Word-shape features

   We check whether the word is lower case, upper case or has both lower case and upper case letters.

   These features include: isAllCaps, StartWithCap, isAllLowerCase, isMixedCase.

4. Position features

   We checked if the word is at the beginning of sentence (BOS), at the end of sentence (EOS), Not Beginning of Sentence (!BOS), Not Ending of Sentence (!EOS).

5. Token prefixes and suffixes features

   We extract the prefixes and suffixes for each word. These include the first four prefixes and the last four prefixes for each word.

6. Bigram features

   For each sentence we extracted bigrams containing only nouns and adjectives.

3.4.2 Conditional Random Field (CRF)

To train the model, we used Conditional Random Field machine learning on 90 % of the dataset and we tested on 10 % of the dataset.

CRF is a machine learning model proposed by (Lafferty et al., 2001). It is widely used in word segmentation, part-of-speech tagging, chunking recognition, named entity recognition and so on.

Conditional Random Fields (CRF) model is a state-of-the-art sequence labeling method, which can use the features of documents more sufficiently and effectively. As we said earlier, non-explicit method mention extraction can be considered as a task of entity recognition to which string labeling techniques can be successfully applied.

4 Results and Discussion

The experimental results used 924 for the rule-based task and 122 sentences for the machine learning task. Table 3 shows the performance of the two tasks. As we could expect recall is very high (100 %) for the rule-based task because every sentence in the dataset contains a method keyword. Our rules were able to recognize every noun phrase and adjective phase ending with a method keyword. Precision is 85.40, which is not bad. Some of the errors came from the tagger. We have spotted these errors and we will remove them in future study For the machine learning task, precision is 81.8 percent, recall is 75 and F-score is 78.26 percent. Features such as word shape, POS, and noun-bigrams performed better than the position features. Also some of the errors came from the all-lower-case terms as they tend to be confused with similar words in the sentence. Table 3 shows the performance of both systems. We believe that the scores can be improved with better linguistic filters in the case of the first task and a better feature selection for the second task.

System	Precision	Recall	F-Measure
Rule-based	85.40	100	91.89
Machine Learning	81.8	75.00	78.26

Table 3: Precision, Recall, F-measure of the Various Methods.

Our work can be compared to (Zhang et al., 2008) which uses CRF for automatic keyword extraction from documents; they reported promising results (F-score of 51.25 percent) on a Chinese corpus.

It can also be compared to (Zhang and Wu, 2012), which uses a multi-level termhood method to extract terminology candidates from a bilingual corpus. Their system achieves an F-score of 79.6% with CRF. Both works use similar techniques to ours, but most of the terminology extraction tasks are performed using a Chinese corpus.

5 Conclusions and future work

In this paper we have first presented a simple approach to extract fine-grained method sentences from large scientific corpora. We have also explored two established techniques to automatically extract method terminologies from method sentences. Our results showed that we can extract most of these terms using simple grammatical patterns. A few other terms can be extracted with machine learning techniques. A brief study of the corpus showed that the context of the method mentions can help in the extraction of important information about the method term. Our future work will then be to use the whole corpus to extract such information that is essential in the building of NLP resources such as glossaries, ontologies and specialist lexicons.

ABSTRACT

This work investigates an interesting and challenging task in summarization, i.e., personalized social summarization, which aims to adapt summarization result of a specified document to an intended user based on his interests inferred from social context implicitly. Most existing summarization systems generate a uniform version of summary for different users no matter who is reading or generate personalized summaries employing only the local information in the document and the user profile. This paper proposes a novel unsupervised approach by making use of enhanced social context to aid personalized summary generation. In the proposed method, document expansion, user expansion, and implicit induction of the intended user's interest aspects are achieved simultaneously by adopting a fuzzy tripartite clustering algorithm. And both the informativeness of sentences and the user's interest aspects are incorporated in a unified ranking process. Preliminary experimental results on a social tagging dataset validate the effectiveness of the proposed approach.

KEYWORDS: Personalized social summarization, social context, fuzzy tripartite clustering

Proceedings of COLING 2012: Technical Papers, pages 1223–1238,
COLING 2012, Mumbai, December 2012.

1 Introduction

With the dramatic growth of the Internet, people are overwhelmed by a large number of accessible documents. In recent years, document summarization has become one of the most important research topics, which aims to address such dilemma by automatically capturing the essential content from document(s) and presenting it to a human reader in a succinct and friendly form. However, most existing summarization methods generate the same summary for different users, regardless of the interests of the readers for whom they are intended. These "one size fits all" methods may perform well in general but may not meet the needs of individuals.

Now with the rapid growth of social networking services like Delicious[1], CiteULike[2], and Flickr[3], users are no longer passive consumers of web contents. They can create contents and add metadata. Similarly, web documents no longer exist on their own and they are naturally associated with other documents and diverse users. All these information can be considered as the potential data source for document understanding and personalization.

For generating a personalized summary, traditional methods usually require that a user explicitly provides his interest aspects, such as specifying the categories he prefers (Díaz and Gervás, 2007) or clicking a subset of sentences in a document according to his interests (Yan et al., 2011). However, most users are reluctant to provide such information, thus it is more meaningful to infer a user's interests implicitly.

To address these concerns, we present an unsupervised approach for personalized summarization. The underlying assumption is that it is beneficial to understand both a single document and a single user better if appropriate social context can be leveraged under some constraints. In this work, the expanded social context used to infer users' interests and enrich document's content is highly selective, which comes from the most similar users and documents. We explored how the size of social context influences the summarization performance, and further demonstrated that appropriate contextual information can ensure better quality and personalization of summaries.

To the best of our knowledge, implicitly exploiting social contextual information to collaboratively summarize single document in a personalized way has been rarely investigated in the summarization community. In this work, we propose a novel personalized summarization approach which benefits from three important elements: the interests of like-minded users, the contents of topic-related documents, and semantically-related tags. In the approach, a fuzzy tripartite clustering algorithm is proposed and a multi-manifold ranking algorithm is adopted to generate personalized summary by considering both the informativeness of sentences and the intended user's interests.

The main contribution of this paper is summarized as follows:

1. we investigate an interesting and challenging summarization task, i.e., personalized social summarization.
2. we propose a novel approach making use of expanded social context to capture the intended user's interests, enrich the target document's content, and collaboratively summarize the document in a personalized way.

[1] http://delicious.com/
[2] http://www.citeulike.org/
[3] http://www.flickr.com/

3. we conduct preliminary experiments to validate the effectiveness of the proposed approach on a social tagging dataset and investigate how the expanded social context improves the performance of personalized summarization.

The remainder of the paper is organized as follows. The related work is introduced in Section 2. The proposed summarization approach is described in Section 3. Experimental results are shown in Section 4. Section 5 is our conclusion and future work.

2 Related work

Document summarization has been widely studied for many years. To date, various approaches have been proposed, and our work is under the framework of extractive summarization.

The vast majority of extractive methods identify which sentences are important by making use of unsupervised or supervised learning techniques. In unsupervised methods, feature-based ranking methods are usually based on a combination of linguistic and statistical features such as term frequency, sentence position, cue words, stigma words, lexical chains, rhetorical structure, topic signatures (Luhn, 1969; Lin and Hovy, 2000), etc. Clustering-based methods usually select one or more representative sentences from each subtopic to produce a summary with minimized redundancy and maximized coverage (Nomoto and Matsumoto, 2001). Graph-based methods have been shown to work well and are becoming more and more popular. LexRank (Erkan and Radev, 2004) and TextRank (Mihalcea and Tarau, 2004) are representative methods adopting models like PageRank and HITS to estimate the importance of sentences via the computation of the stationary distribution of a Markov chain or a mutual reinforcement process (Zha, 2002).

For supervised methods, summarization is often regarded as a classification task or a sequence labeling task at sentence level, and many supervised learning algorithms have been investigated including Hidden Markov Models (Conroy and O'leary, 2001), Support Vector Regression (You et al., 2011), Factor Graph Model (Yang et al., 2011), etc. However, such a supervised learning paradigm often requires a large amount of labeled data, which are not available in most cases.

With the rapid growth of online information, some work has began to employ context to aid summarization, such as contents from external documents (Wan and Yang, 2007) or cited papers (Mei and Zhai, 2008; Qazvinian and Radev, 2010), click-through data or search logs (Sun et al., 2005), and social tags (Qu and Chen, 2009; Hu et al., 2011), comments (Hu et al., 2008) or discussing tweets (Yang et al., 2011), etc.

However, such methods so far are usually designed for generic summarization and do not take into account the impact of users' interests on summary generation. Besides, in the existing studies, personalized summarization is often conducted with the help of a query (Sun, 2008; You et al., 2011) or a static user profile (Díaz and Gervás, 2007), and most studies only use the local content from target document(s) or the user profile, with little attention paid to the rich social contextual information affiliated with them.

Currently, an increasing number of social websites allow users to enrich the source content. Many documents are now presented together with various feedback information in the form of social tags, comments, or ratings, etc. These usage data can be exploited for personalized summarization since they provide a natural channel to reveal users' interests implicitly.

Based on the analysis above, we investigate a challenging task in summarization, i.e., personalized social summarization, and propose an unsupervised approach for this task. The characteristic of our proposed approach is that it can leverage topic-related documents, like-minded users, and semantically-related tags to infer the intended user's interests implicitly and collaboratively summarize the target document in a personalized context-aware way.

3 Personalized social summarization

3.1 Overview

Given a user u ($u \in U$), a document d ($d \in D$), and related social tagging data G (G = (D, U, T, R)), personalized social summarization aims to generate a tailored summary of d for u. Here D, U, and T are documents, users, and tags respectively. R is a ternary relation between them, which denotes the set of annotations of each tag in T to a document in D by a user in U.

In most social tagging sites, many documents have been annotated by few tags and most users have only annotated few documents. In this case, existing tag-based summarization methods will fail to produce a personalized summary (Boydell and Smyth, 2007; Zhu et al., 2009), since the user-related tags may be absent for that document. To address it, we propose to expand both the target document and the intended user with appropriate social context so that the important parts in the document that the intended user may care about can be identified from context.

The general framework of our proposed approach consists of three major steps.

Step1. Social context identification by document expansion and user expansion

In this step, the given document d is expanded to a small document set $D_d^{(c)}$ by adding a small number of topic-related documents, and the intended user u is expanded to a small user community $U_u^{(c)}$ by adding a small number of like-minded users. Here $D_d^{(c)}$ and $U_u^{(c)}$ are identified as the expanded social context, which is based on the intuition that we would better know a user if we know more like-minded users close to him and we would better understand a document if we read more topic-related documents close to it.

Step2. User interest discovery

In this step, the interest aspects of the intended user u are inferred from the social context $D_d^{(c)}$ and $U_u^{(c)}$ by making use of the social tagging information that the like-minded users gave to the topically related documents.

Step3. Personalized summary generation

In this step, given the expanded document context $D_d^{(c)}$ and the inferred interest aspects, the relationships of all sentences in $D_d^{(c)}$ against each interest aspect are incorporated in a unified ranking process to extract personalized informative sentences from document d.

3.2 Social context identification

In this study, the related social tagging data G, which the target document d and the intended user u belong to, is firstly collected. Then it is used to identify the social context, which can be demonstrated by the example in Figure 1.

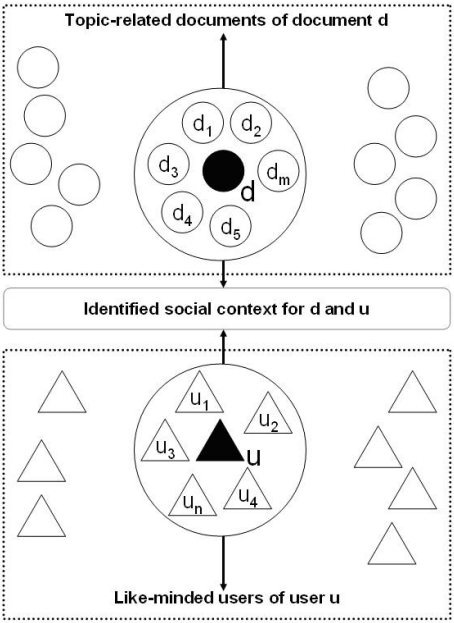

FIGURE 1 – Social context for document d and user u.

Since content-related documents are usually annotated with semantically-related tags by users with similar interests, it is feasible to find topic-related documents, like-minded users, and semantically-related tags simultaneously by clustering them collaboratively (Lu et al., 2009). Therefore, we propose a fuzzy tripartite clustering algorithm to solve the fuzzy partition issues peculiar in personalized social summarization: a document may cover different subtopics, a user may have diverse interest aspects, and a tag may be a polysemy. The potential benefit of our algorithm is that it can make use of the inherent cluster structure and interactions among the different types of objects to cluster them simultaneously and flexibly. By the algorithm, an object can have a fuzzy membership across clusters and each cluster can be represented by a committee, i.e., a small number of objects with the highest membership for the cluster.

Before clustering, each type of object (e.g., document, user, and tag) is first represented by a combined vector. A document d_i is represented by D_i consisting of two components with one denoting user link vector and the other denoting tag link vector. $D_i = (D_i^{(U)}, D_i^{(T)})$, $D_i^{(U)} = (x_{ij}^{(U)} \mid j=1,2,...,|U|)$, $D_i^{(T)} = (x_{ik}^{(T)} \mid k=1,2,...,|T|)$, where $x_{ij}^{(U)}$ denotes the times that d_i is annotated by user u_j, $|U|$ denotes the total number of users, $x_{ik}^{(T)}$ denotes the times that d_i has been annotated with tag t_k, and $|T|$ denotes the total number of tags. User and tag can be represented likewise. Accordingly, the similarity between any two objects of the same type can then be computed by the linear combination of the similarity between their combined vectors. Our proposed fuzzy tripartite clustering algorithm is shown as follows.

Algorithm 1: The fuzzy tripartite clustering algorithm.

Input:

G=(D, U, T, R): the related social tagging data that document d and user u belong to;

N_{dc}, N_{uc}, N_{tc}: the predefined number of document clusters, user clusters, and tag clusters.

Output:

The fuzzy cluster assignments of documents, users, and tags: M_d^*, M_u^*, and M_t^*, where each object is affiliated with a list of membership values with respect to various clusters.

Method:

Initialize the fuzzy partition matrices of documents, users, and tags $M_d^{(0)} = \left[u_{(d)_{i,j}}\right]_{|D|\times N_{dc}}$, $M_u^{(0)} = \left[u_{(u)_{i,j}}\right]_{|U|\times N_{uc}}$ and $M_t^{(0)} = \left[u_{(t)_{i,j}}\right]_{|T|\times N_{tc}}$ randomly, such that $0 \leqslant u_{(d)_{i,j}}$, $u_{(u)_{i,j}}$, $u_{(t)_{i,j}} \leqslant 1$ and $\sum_p u_{(d)_{i,p}} = 1$, $\sum_p u_{(u)_{i,p}} = 1$, $\sum_p u_{(t)_{i,p}} = 1$. And then generate the initial committee of each cluster and set k = 1.

Repeat:

For each type of object (e.g. document, user, and tag) **do**

Calculate the centroid vector $c^{(k)}$ of each cluster based on the current committee of this cluster according to formula (1).

For each object **do**

Update the object's membership values $u_{i,j}^{(k)}$ to $u_{i,j}^{(k+1)}$ by the normalized Cosine similarity value between the i-th object and the centroid of the j-th fuzzy object cluster formed in the k-th iteration. Here the computation of the similarity value can be considered as the membership function.

End For

Regenerate the committee of each cluster.

End For

k = k + 1

Until $\max_{i,j}\{|u_{i,j}^{(k+1)} - u_{i,j}^{(k)}|\} < \varepsilon$ or k>specified threshold.

In the algorithm, $u_{i,j}$ denotes the membership value for the i-th object in the j-th cluster, ε is the termination criterion, which is set as 0.01 in this study. The threshold of maximum iteration number is set at k=50. Since the 'true' numbers of document clusters, user clusters, and tag clusters are hard to predict in advance, we simply set N_{dc}, N_{uc}, and N_{tc} to the square root of the total number of documents, users, and tags in the related social tagging data respectively. The committee of each cluster is determined by selecting 30 percent of objects which have the highest membership values for the cluster from all the objects of the same type. In the following demonstration, we will take documents as examples of objects.

Let C_d represent a fuzzy document cluster and $C_d(c)$ represent the committee of C_d ($C_d(c) \subset C_d$). Since each document can be represented by a user link vector and a tag link vector, we will first consider the user link vectors of these documents. The value of the centroid vector of the document cluster C_d at the user dimension u_μ can be calculated by formula (1).

$$Centroid_{C_{d_u}}^{(U)} = \frac{\sum_{d_i \in C_d(c), u_j \in C_u(c)} x_{ij}^{(U)}}{|C_d(c)| * |C_u(c)|}, \ (u_u \in C_u(c)) \qquad (1)$$

where $C_u(c)$ is the committee of a fuzzy user cluster for which user u_u has its highest membership value, u_j is any user in $C_u(c)$, and d_i is any document in $C_d(c)$. $x_{ij}^{(U)}$ denotes the times that d_i is tagged by u_j. The value of the centroid vector at the tag dimension can be calculated similarly. Accordingly, the similarity between a document d_i and the centroid of a fuzzy document cluster C_j can be calculated by the linear combination of the Cosine similarity between their user link vectors and tag link vectors.

After clustering, we get the cluster assignments of documents, users, and tags, where each document (user, tag) gets a membership value for each cluster. Next, the given document d is expanded to the document context $D_d^{(c)} = \{d, d_1, d_2, ..., d_m\}$ by adding m topic-related documents with highest membership value for the cluster that d belongs to most likely. Similarly, the intended user u is expanded to the user context $U_u^{(c)} = \{u, u_1, u_2, ..., u_n\}$ by adding n like-minded users with highest membership value for the cluster that u belongs to most likely. $D_d^{(c)}$ and $U_u^{(c)}$ are identified as the expanded social context, aiming to boost information shared by topic-related documents and users with similar interests for personalized summary generation. We will further discuss the variation of performance with different assignment of m and n in Section 4.

3.3 User interest discovery

As a common form of users' online behavior, users' social tagging activities are good at reflecting their interests about document's contents and expressing the general concepts of documents. Previous work has studied the utility of social tags for user interest modeling (Li et al., 2008) and confirmed that a set of semantically related tags can characterize users' interests well (Zhou et al., 2010).

Considering that a user may have diverse interest aspects on a given document and the combination of topic-related documents and like-minded users can provide rich global contextual clues, we propose to model the interests of a user u about a document d by the social tags which have been used to annotate the documents in the document context $D_d^{(c)}$ by the users from the user context $U_u^{(c)}$. The intuitive idea is that users who annotate similar documents may have common interests on the topic shared by these documents, so the tags used by these like-minded users may reveal the latent interests of the intended user about this kind of topic.

According to the output of the fuzzy tripartite clustering algorithm, the tags on $D_d^{(c)}$ annotated by $U_u^{(c)}$ may belong to different tag clusters with varying degrees of membership. So we assign these tags into the clusters for which they have highest membership values, and then we can model the intended user's interests by the tag clusters with each indicating one unique interest aspect of the user. Here each cluster consists of one or more semantically-related tags, corresponding to the committee of the relevant tag cluster.

Formally, the intended user's interests on the given document can be represented as UM_u, which can be regarded as multiple subtopics for modelling user's interest aspects. $UM_u = \{p_i \mid 1 \le i \le N_{tu}\}$, where N_{tu} is the number of interest aspects for user u, and p_i is the user's i-th interest aspect for the given document.

3.4 Personalized summary generation

Based on the identified interest aspects, we further adopt multi-manifold ranking algorithm to fuse the sentence relationships against different aspects in a unified ranking process, which has

performed successfully in the multi-subtopic summarization task (Wan, 2009). In this study, we collaboratively summarize the target document by multiple topic-related documents within the document context, since topic-related documents can provide more clues from global context to aid extracting salient summary sentences from the specified document.

Formally, given the sentence set $S=\{s_i \mid 1\le i\le n\}$ of the document context $D_d^{(c)}$ for document d and the k-th interest aspect p_k of user u, an affinity matrix $W_k = \left[w_{(k)_{i,j}}\right]_{(n+1)\times(n+1)}$ can be built firstly to represent both the relationships among all the n sentences in $D_d^{(c)}$ and the relationship between each sentence and p_k. Then W_k is symmetrically normalized by $S_k = D_k^{-1/2} \cdot W_k \cdot D_k^{-1/2}$. Here $w_{(k)_{i,j}}$ is computed by the Cosine similarity between the i-th sentence and the j-th sentence. D_k is the diagonal matrix with the (i,i)-element equal to the sum of the i-th row of W_k. In this study, there will be N_{tu} affinity matrices in total since the number of discovered interest aspects for user u is N_{tu}.

Let F represent a ranking function that assigns each element s_i ($0\le i\le n$) a ranking score f_i. It can be regarded as a vector $F = [f_0,\ldots, f_n]^T$. We also define a prior vector $Y = [y_0,\ldots, y_n]^T$, in which $y_0=1$ for the k-th interest aspect p_k and $y_i=0$ ($1\le i\le n$) for all the remaining sentences.

Next, we can rank all the sentences by adopting the multi-manifold ranking algorithm (Wan, 2009), in which the ranking function F is to be learned from W_k ($1\le k\le N_{tu}$) and Y. In this study, the constraints from S_k ($1\le k\le N_{tu}$) and Y are naturally fused in a regularized optimization framework defined by the following cost function.

$$Q(F) = \sum_{k=1}^{N_{tu}} \left[u_k \cdot \sum_{i,j=0}^{N_{tu}} \left(w_{(k)}\right)_{ij} \left| \frac{1}{\sqrt{(D_k)_{ii}}} f_i - \frac{1}{\sqrt{(D_k)_{jj}}} f_j \right|^2 \right] + \eta \cdot \sum_{i=0}^{n} |f_i - y_i|^2 \quad (2)$$

where u_k ($1\le k\le N_{tu}$) and η ($0<\eta\le 1$) are the trade-off between the smoothness constrains. $0<u_k$, $\eta<1$ and $\sum_{k=1}^{N_{tu}} u_k + \eta = 1$.

Based on the optimization framework, the optimal ranking function F^* can be achieved when Q(F) is minimized. In practice, the following iterative form shown in the formula (3) is more commonly used to get the ranking function, in which $F^{(0)}$ is set to Y and we have $F^{(*)} = \lim_{t\to\infty} F^{(t)}$.

$$F^{(t+1)} = \sum_{k=1}^{N_{tu}} u_k S_k F^{(t)} + (1 - \sum_{k=1}^{N_{tu}} u_k) Y \quad (3)$$

Through the above ranking process, the ranking scores, which denote the user-biased informativeness of sentences, can be obtained. Finally, those sentences highly overlapping with other informative sentences are penalized to remove redundancy (Wan and Yang, 2007), and the sentences with high overall scores are chosen from document d into the summary.

4 Experiments

4.1 Dataset

Since there is no benchmark dataset available for the task of personalized social summarization, we collected data from Delicious, one of the most popular social tagging websites. Specifically, we extracted a set of web documents, bookmark tags, and the users who bookmarked these documents to serve as the experimental dataset.

Starting with predefined seed tags, we extracted the top bookmarked documents for each tag and extracted the users and tags used to annotate each of the documents. The result is a collection consisting of 204 bookmarked documents and 2186 unique social tags that were used to annotate these documents by 1696 users. To guarantee the genre consistency, all the documents were crawled from news sources such as CNN, BBC, New York Times, etc.

4.2 Evaluation methods

In this paper, both manual evaluation method and automatic evaluation method are adopted. For each document in the dataset, we randomly select one to five users as the intended users from all the users who annotated the document with multiple social tags.

4.2.1 Manual evaluation

First, we must admit that it would be better to use personalized reference summaries for evaluation. However, it would be quite difficult to get personalized summaries from the actual users of Delicious. The alternative way is to get the external judgments from several judges and take average of their ratings so that we know that multiple people would consider that this summary is relevant or tailored for the intended user to a certain extent. How to develop a better test collection for personalized summarization from the perspective of social context is an important future direction of our research.

In this study, three evaluators are requested to express their judgments over all automatically generated summaries based on both the content they deem to be important for the target document and how "personal" each one is according to the interests of the intended user. We provide each evaluator the intended user's background knowledge collected by calling the official Delicious.com API and parsing its RSS feeds. The provided information includes all the open document bookmarks of intended users and all the tags they used to annotate the documents including the target document to be summarized. Evaluators can also access the content of the corresponding document by clicking the URL in each bookmark.

In the evaluation process, evaluators are instructed to give an overall score to each summary. The overall score reflects the comprehensive quality of a summary including not only the evaluation for the general content of the generated summary but also the degree of compliance with the intended user's personalized interests and foci.

All the judgment scores are rated in a 5-point scale, where "1" for "very poor", "2" for "poor", "3" for "barely acceptable", "4" for "good", and "5" for "very good". Evaluators are allowed to judge at any scores between 1 and 5, e.g. 3.5.

4.2.2 Automatic evaluation

Considering that manual evaluation is generally time consuming and labour-intensive, we also adopt automatic evaluation strategy.

For each intended user of the target document, we randomly divide the social tags he assigned to the document into two approximately equal parts: a training set and a test set. The former is used to generate personalized social summary on the document for the user, and the latter is used to evaluate the generated summary based on the recall against the tags in the test set, making sure to remove the tags occurring in the training set from the test set.

The idea of this kind of evaluation strategy is to look for overlaps between the generated personalized social summary and those unseen tags used by the intended user on the given document, since the tags in the test set correspond to an alternative, but previously unseen, point of interests for the intended user with respect to the target document.

The automatic evaluation experiments were conducted in the cross validation procedure, and the average recall score was recorded. Intuitively, the higher the average recall score is, the more the generated summaries are in line with the interests of the intended users.

4.3 Baselines

In the experiments, we compare our proposed approach with several baseline methods. For fair comparison, we conduct the same preprocessing for all the methods including sentence segmentation, word stemming, and redundancy removing.

Random: It extracts sentences randomly from each document.

OTS: It is an open source summarizer integrating shallow NLP techniques with statistical word frequency analysis for sentence scoring (Nadav, 2003).

MEAD: It ranks sentences according to the combination of features including centroid value, positional value, and first-sentence overlap (Radev et al., 2000).

LexRank: It first constructs a sentence affinity graph based on the Cosine similarity between sentences in a document, and then extracts a few informative sentences based on eigenvector centrality (Erkan and Radev, 2004).

DcontextLexRank: It is an extension of the original LexRank method by firstly ranking sentences on the document context which the target document belongs to, and then extracting sentences with highest ranking scores from the target document.

PSocialSum: It is our proposed approach using expanded social context to capture the intended user's interests, enrich the target document's content, and collaboratively summarize the target document in a personalized way.

4.4 Overall comparison results

4.4.1 Parameter settings

The parameters m and n, i.e., the number of expanded topic-related documents in the document context $D_d^{(c)}$ and the number of expanded like-minded users in the user context $U_u^{(c)}$, are set as

the number of elements in the corresponding committee of the cluster that document d or user u belongs to most likely.

In the multi-manifold ranking process of our approach, parameters u_k and η are the smoothness constraint and fitting constraint respectively, which control the trade-off between the impact from S_k (i.e., both the relationships among all the sentences in the document context and the relationship between each sentence and the k-th interest aspect of user u) and the impact from Y (i.e. the prior vector set for the k-th interest aspect and all the remaining sentences). In the following experiments, the regularization parameter η for the fitting constraint is fixed at 0.01, the same as in (Wan, 2009), and u_k is set to the normalized Cosine similarity between the corresponding vectors of p_k and $D_d^{(c)}$.

4.4.2 Experimental results

In the experiments, for each document, we generate multiple different personalized summaries for each of the intended users by our approach. For comparison purpose, each document in the dataset is also summarized using all the baseline methods described in Section 4.3.

First, we conducted the manual evaluation and the average overall scores of multiple evaluators on all the generated summaries are listed in Table 1.

Method	Average Overall Score
Random	1.2
OTS	2.1
MEAD	2.2
LexRank	2.3
DcontextLexRank	2.4
PSocialSum	3.5

TABLE 1 –The average overall scores of multiple evaluators.

From Table 1, it can be found that Random has the worst summarization performance.

LexRank and DcontextLexRank perform better than those of MEAD and OTS. This is mainly because both LexRank and DcontextLexRank make use of the inter-relationship between sentences to rank them globally, while MEAD and OTS only depend on the combination of some local features.

DcontextLexRank outperforms LexRank in our experiments, which indicates the use of appropriate document context for sentence ranking is an improvement over the use of single document alone which lacks the support of external clues from the similar documents.

Note that all these baseline methods generate the summary based on either the given document itself or the document context, regardless of the intended user's interests. Our proposed approach shows significantly better performance on evaluators' ratings. And the rating difference between PSocialSum and other baselines is significant at the 95% statistical confidence level in all cases. This indicates that consideration of user's interests is critical for generating a better personalized

summary, and the improvement achieved is mainly attributed to the personalization aspect as well as informative content.

We also find that the evaluator judgments on MEAD, LexRank, and DcontextLexRank are of little significant difference at the 95% confidence interval, which illustrates that the general summaries generated by these comparable baselines can convey the important information of a document, and different evaluators may have some agreement on the quality of its content, although all of these methods do not consider the intended user's interest at all.

Next, we conducted the automatic evaluation by computing the average recall scores against the tags in the corresponding test set for all the resulting summaries. The process is repeated across multiple different random splits of training and test set. The average recall scores are reported in Table 2.

Method	**Average Recall Score**
Random	0.194
OTS	0.282
MEAD	0.287
LexRank	0.292
DcontextLexRank	0.294
PSocialSum	0.338

TABLE 2 – The average recall scores.

From Table 2, we see that the summarization performance of PSocialSum is consistently better than those of other baselines. Such results also demonstrate that by leveraging part of the social tagging information of the intended users, we can generate better summaries which are more in accordance with the latent interests of them, compared to other summarizers which generate the static summaries ignoring the social contextual information.

4.5 Impact of parameters

In this section, to investigate how the size m and n of the expanded topic-related documents and the expanded like-minded users influence the performance of PSocialSum, we conduct the following experiments with different values.

Considering that m and n in this study are dynamically related to the predefined percentage of objects which have the highest membership values for the cluster from all the objects of the same type, in the experiment, we set the predefined percentage value related with m and n ranging from 10% to 80% with step length 10%, indicating the corresponding percentage of documents or users are selected for the expanded document set or user set.

Figure 2 shows the average recall scores against the tags in the test set for PSocialSum with different percentage values.

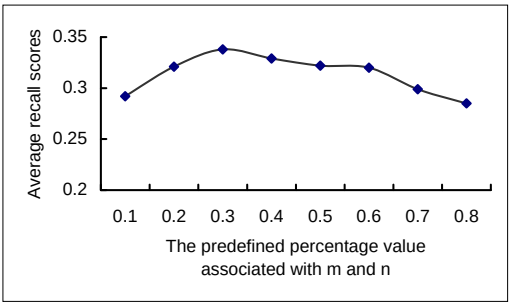

FIGURE 2 –The average recall scores of PSocialSum
vs. the predefined percentage value related with m and n.

From Figure 2, it can be seen that when the percentage value increases from 10% to 30%, the recall increases gradually, and reaches the global maximum when it is set to 30%. When we adjust the percentage value from 30% to 80%, the recall starts to decay. The result demonstrates that appropriate document context and user context are beneficial for improving personalized summarization performance, yet a large size of the expanded context may deteriorate the performance because it may include a lot of irrelevant information even noise.

Conclusion

In this paper, we present a study of personalized social summarization, and propose a novel unsupervised approach. The approach makes use of expanded social context to capture the intended user's interests, enrich the target document's content, and collaboratively summarize the target document in a personalized context-aware way. Preliminary experimental results demonstrate the effectiveness of the proposed approach.

In practice, the dimensions and variability of users, documents, and tags from most social network websites may be quite high, so in future work, we plan to combine link structure association analysis and feature selection to effectively deal with high-dimensional online tripartite clustering dynamically. And more social contextual information such as social relationships among users will also be investigated. For simplicity, this method represents each object with a vector of two sets of features, and this kind of representation would inevitably result in information loss to a certain extent. Therefore, we plan to try better alternatives such as hypergraph or tensor model, and make effort to improve the existing work on content or social network-based user interest modeling. Furthermore, it would be more convincing to resort to crowdsourcing technique to evaluate the proposed approach by a large number of real users on the social tagging websites and on larger-scale social data set.

Abstract

Ranking tweets is a fundamental task to make it easier to distill the vast amounts of information shared by users. In this paper, we explore the novel idea of ranking tweets on a topic using heterogeneous networks. We construct heterogeneous networks by harnessing cross-genre linkages between tweets and semantically-related web documents from formal genres, and inferring implicit links between tweets and users. To rank tweets effectively by capturing the semantics and importance of different linkages, we introduce Tri-HITS, a model to iteratively propagate ranking scores across heterogeneous networks. We show that integrating both formal genre and inferred social networks with tweet networks produces a higher-quality ranking than the tweet networks alone. [1]

Title and Abstract in Chinese

基于异构网络的微信息排序

微信息排序是一个可以过滤由用户分享的大量信息的根本任务。在这篇文章中，我们探索利用异构网络来排序微信息。我们利用来源于正规类型并且与微信息语义相关的网络文本的跨类型联接,和推理微信息和用户之间的潜在联系来构造异构网络。为了有效地捕获不同联接的语义和重要性，我们提出了Tri-HITS, 一个能够跨网络循环传播排序分数的模型。我们证明了结合来自正规类型的信息，和推理隐含的社交网络可以取得比仅靠微信息网络本身更高的排序质量。[2]

1 Introduction

Twitter has become a popular service for online communication through short messages of up to 140 characters, known as tweets. Its users produce millions of tweets a day, enabling both individuals and organizations to disseminate information about current affairs and breaking news in a timely fashion. This information is sometimes posted by users on-site or in the vicinity of events, providing first-hand accounts from a wide variety of sources. However, the sheer volume of tweets sent during events of general interest is overwhelming and hence difficult to distill for the most relevant information, while also filtering out non-informative tweets.

To facilitate finding informative and trustworthy content in tweets, it is crucial to develop an effective ranking method. This is particularly useful in emerging situations. Eyewitnesses might be live-tweeting about anything happening at ongoing events (Diakopoulos et al., 2012) such as natural disasters. To assist in these situations, we aim to develop a ranking system that organizes tweets by informativeness, so that informative tweets are readily identified, while pointless and speculative observations are filtered out. However, the definition of informativeness might vary for different points of view. Twitter users can produce diverse content ranging from news and events, to conversations and personal status updates. While personal updates and conversations might be relevant to a specific group of people, we aim to find tweets on topics that are informative to a general audience, such as breaking news and real-time coverage of on-going events. For example, during Hurricane Irene in 2011, updates from a user living in New York City about her own safety might be very informative to her friends and relatives, but not so informative to others. To produce rankings that are as relevant to as many people as possible, we define informativeness as the extent to which a tweet meets the general interest of people involved with or tracking the event.

While previous research has relied on either the text of tweets or explicit features of social network such as retweets, replies, and follower-followee relationships, we believe that such networks can be enhanced by integrating information from a formal genre. On one hand, tweets from different sources tend to contain non-informative noise such as subjective comments and conversations. Therefore it is challenging to identify salient information from tweet content alone. On the other hand, events of general interest such as natural disasters or political elections are the topics of tweets sent by many users from multiple communities which are not connected to each other. In these situations, users are likely to be unaware of each other. As a result, they fail to connect with many others on topics of mutual interest. This lack of social interaction produces networks with few explicit linkages between users, and therefore between tweets and users. The sparsity of linkages would limit the effectiveness of features extracted from social network.

In this work, we introduce Tri-HITS, a novel propagation model that leverages global information iteratively computed across heterogeneous networks constructed from web documents, tweets, and users, to rank tweets on a topic by informativeness. The model addresses the two issues mentioned above (noisy tweets, limited social connections). Using Tri-HITS, we establish cross-genre linkages between tweets and web documents, filter informal writing and noise contained in tweets, and infer implicit tweet-user relations beyond the explicit ones, so that networks are enriched by connecting users that are sharing similar contents. We propose three high-level hypotheses that motivate the presented methods of constructing heterogeneous networks of tweets, users, and web documents. The proposed model, Tri-HITS, operates iteratively over all networks incorporating the semantics and importance of different linkages. By ranking tweets about the Hurricane Irene, we demonstrate that incorporating a formal genre such as web documents, inferring implicit social networks and performing effective ranking score propagation with the proposed model can significantly improve

the ranking quality.

2 Background

In this section, we describe the basic techniques used in the paper: information networks, the ranking approach TextRank, and a widely used method for redundancy removal.

2.1 Information Networks

We define an information network as a graph $G = (V, E)$ on $X = \{X_1, X_2, ..., X_Z\}$ for Z types of vertices, where $V(G) = X_1 \cup X_2 \cup ... \cup X_Z$ and $E(G) = \langle x_i, x_j \rangle$, for $x \in X$. An edge $\langle x_i, x_j \rangle$ is a binary relation between two vertices x_i and x_j. An information network is **heterogeneous** when the vertices are from multiple distinct types of sources ($Z \geq 2$). (Deng et al., 2011) defined a text-rich heterogeneous information network as an information network that integrates a set of text documents $D = \{d_1, d_2, ..., d_n\}$ with other types of vertices, so that $V(G) = D \cup X_1 \cup ... \cup X_{Z-1}$. In this work, we construct heterogeneous networks that include web documents, tweets, and users, as shown in Figure 1.

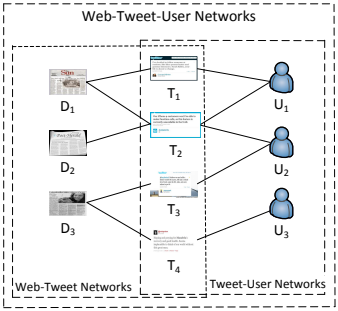

Figure 1: Web-Tweet-User heterogeneous networks

2.2 TextRank: Baseline Approach

Graph-based ranking algorithms have been widely used to generate rankings for vertices in graphs.. Adapted from PageRank (Page et al., 1998) to weighted graphs, TextRank (Mihalcea and Tarau, 2004) is a well-known ranking algorithm for homogeneous networks, which is defined as follows:

$$s(v_i) = (1-d) + d * \sum_{v_j \in In(v_i)} \frac{w_{ji} s(v_j)}{\sum_{v_k \in Out(v_j)} w_{jk}} \quad (1)$$

where v_i is a vertex with $s(v_i)$ as the ranking score, $In(v_i)$ as the set of incoming edges, and $Out(v_i)$ as the set of outgoing edges; w_{ij} is the weight for the edge between two vertices v_i and v_j. An edge exists between two vertices that represent text units when their computed shared content (cosine similarity) exceeds or equals a predefined threshold δ_{tt}.

Given its success when applied to sentence ranking for the task of extractive document summarization (Mihalcea, 2004), we choose TextRank as the **baseline** method to compute ranking scores in

tweet-only networks where edges between tweets are determined by their cosine similarity.

2.3 Redundancy Removal

Since users on Twitter can be tweeting similar information obliviously, and retweet and reply others' tweets, redundancy has been shown to be a pervasive phenomenon (Zanzotto et al., 2011). This issue has not been considered in previous works on tweet ranking (Duan et al., 2010; Huang et al., 2011). In this work, we perform a redundancy removal step to diversify top ranked tweets. To do so, we adopt the widely used greedy procedure (Carterette and Chandar, 2009; McDonald, 2007) to apply redundancy removal after the completion of each ranking method, as follows: tweet t_i in position i is removed when its cosine similarity with tweets $t_j \in [t_1, t_{i-1}]$ in more highly-ranked positions exceeds or equals a predefined threshold δ_{red}[3]

3 Motivations and Hypotheses

Next, we describe the motivational aspects and hypotheses in this work, which we aim to prove.

Hypothesis 1: *Informative tweets are more likely to be posted by credible users; and vice versa (credible users are more likely to post informative tweets).* (Duan et al., 2010; Huang et al., 2011) consider that users who have more followers, mentions, and retweets, and are listed more, are more likely to be authoritative. They used retweet, reply, user mention and follower counts to to compute the degree of authoritativeness of users; and showed that user account authority is a helpful feature for tweet ranking. However, for events of general interest involving multiple communities, users are more likely to be unaware of each other, and rarely interact. This makes it insufficient to rely on user-user networks constructed from retweet and reply interactions to compute user credibility scores. To overcome this problem, we apply a Bayesian approach to compute the credibility of users by incorporating the contents shared by them.

Hypothesis 2: *Tweets involving many users are more likely to be informative.* Having many users share similar tweets at the same time helps identify informative tweets. For example, in the context of Hurricane Irene, users were likely to share information about the Evacuation Zone when they found relevant news or events. The synchronization of information within groups has been successfully harnessed in other fields like financial trading, autonomous swarms of exploratory robots, and flocks of communicating software agents (Couzin, 2007; Saavedra et al., 2011). This idea has also been successfully exploited for event summarization from tweets (Zubiaga et al., 2012).

Hypothesis 3: *Tweets aligned with contents of web documents are more likely to be informative.* Tweets come from diverse sources, and can diverse content ranging from news and events, to conversations and personal status updates. Therefore, informative tweets tend to be interspersed with noisy and non-informative tweets. This differs from formal genres such as web documents, which tend to be cleaner. In the case of current events such as natural disasters or political elections, there are tight correlations between social media and web documents. Important information shared in social media tends to be posted in web documents. For example, the following informative tweets would rank highly because they are linked to informative web documents: " *New Yorkers, find your exact evacuation zone by your address here: http://t.co/9NhiGKG /via @user #Irene #hurricane #NY*" and "*Details of Aer Lingus flights affected by Hurricane Irene can be found at http://t.co/PCqE74V2̌01d*". As far as we know, this is the first work to integrate information from a formal genre such as web documents to enhance tweet ranking.

[3]We choose $\delta_{red} = 0.6$ as a threshold, obtained from our empirical studies with values from 0.1 to 1.0 in the development set.

4 Enhanced Approach: Tri-HITS

Based on the formulated hypotheses, we describe how Tri-HITS works.

4.1 Overview

Figure 2 depicts how Tri-HITS works. For a set of tweets on a specific topic, a rule-based filtering component is first applied to filter out a subset of non-informative tweets. For the remaining tweets, we define queries based on top terms in tweets, and use Bing Search API[4] to retrieve the titles[5] of the top m web documents for those queries ($m = 2$ for these experiments). Then we apply TextRank and a Bayesian approach that initialize ranking scores for tweets, web documents, and users. Finally, we iteratively propagate ranking scores for web documents, tweets, and users across the networks to refine the tweet ranking.

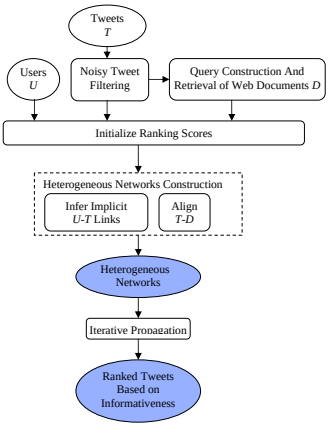

Figure 2: Overview of Tri-HITS

4.2 Filtering non-informative Tweets

Tweets are more likely to be shortened or informally written than texts from a formal genre such as web documents. Thus, a prior filtering step would clean up the set of tweets and improve the ranking quality. We observed that numerous non-informative tweets have some common characteristics, which help infer patterns to clean up the set of tweets. In our filtering method, we define several patterns to capture the characteristics of a non-informative tweet, i.e., very short tweets without a complementary URL, tweets with first personal pronouns, or informal tweets containing slang words[6]. These features have been shown to be effective in previous work on tweet ranking and information credibility (Duan et al., 2010; Castillo et al., 2011; Uysal and Croft, 2011). Our filtering component accurately filters out non-informative tweets, achieving 96.59% at precision.

[5] We rely on page titles, but it could be extended to the whole content of web documents straightforwardly.

[6] http://www.mltcreative.com/blog/bid/54272/Social-Media-Minute-Big-A-List-of-Twitter-Slang-and-Definitions

4.3 Initializing Ranking Scores

Initializing scores for tweets and web documents. For a set of tweets T, we first construct an undirected and weighted graph $G = (V, E)$. After removing stopwords and punctuations, the bag-of-words of each tweet t_i is represented as a vertex $v_i \in V$, and the weight for the edge between tweets is the cosine similarity using TF-IDF representations. Then, we use TextRank to compute initial scores. The same approach is used to initialize ranking scores for web documents.

Initializing user credibility scores. Based on Hypothesis 1, we define two approaches to compute initial user credibility scores. First, we construct a user network based on retweets, replies and user mentions as in (Duan et al., 2010). This results in a directed and weighted graph $G_d = (V, E)$, where V is the set of users and E is the set of directed edges. A directed edge exists from u_i to u_j if user u_i interacts with u_j (i.e., mentions, retweets, or replies to u_j). The weight of the edge is defined as N_{ij}, according to the number of interactions. In this case, we use TextRank to compute initial user credibility scores.

In addition, we also use the *Bayesian ranking* approach (Wang et al., 2011, 2012) that considers the credibility scores of tweets and users simultaneously based on Tweet-User networks. Given a set of users $U = \{u_1, u_2, ..., u_m\}$, and a set of claims $C = \{c_1, c_2, ..., c_n\}$ the users make (each claim corresponds to a cluster of tweets in this paper). We also define matrix W^{cu} where $w^{cu}_{ji} = 1$ if user u_i makes claim c_j, and is zero otherwise. Let u^t_i denote the proposition that *'user u_i speaks the truth'*. Let c^t_j denote the proposition that *'claim c_j is true'*. Also, let $P(u^t_i)$ and $P(u^t_i|W^{cu})$ be the prior and posterior probability that user u_i speaks the truth. Similarly, $P(c^t_i)$ and $P(c^t_i|W^{cu})$ are the prior and posterior probability that claim c_i is true. We define the credibility rank of a claim $Rank(c_j)$ as the increase in the posterior probability that a claim is true, normalized by prior probability $P(c^t_i)$. Similarly, the credibility rank of a user $Rank(u_i)$ is defined as the increase in the posterior probability that a user is credible, normalized by prior probability $P(u^t_i)$. In other words, we can get:

$$Rank(c_j) = \frac{P(c^t_j|W^{cu}) - P(c^t_j)}{P(c^t_j)} \quad (2)$$

$$Rank(u_i) = \frac{P(u^t_i|W^{cu}) - P(u^t_i)}{P(u^t_i)} \quad (3)$$

In our previous work, we showed that the following relations hold true regarding the credibility rank of a claim $Rank(c_j)$ and a user $Rank(u_i)$:

$$Rank(c_j) = \sum_{k \in Users_j} Rank(u_k) \quad (4)$$

$$Rank(u_i) = \sum_{k \in Claims_i} Rank(c_k) \quad (5)$$

where $Users_j$ is the set of users makes claim c_j, and $Claims_i$ is the set of claims the user u_i makes. From the above, the credibility of sources and claims can be derived as:

$$P(c^t_j|W^{cu}) = p^t_a(Rank(c_j) + 1) \quad (6)$$

$$P(u^t_i|W^{cu}) = p^t_s(Rank(u_i) + 1) \quad (7)$$

where p_a^t and p_s^t are initialization constants, which are the ratio of true claims to the total claims, and the ratio of credible users to the total users.

Then, Equation 7 is used to compute initial user credibility scores as our second approach.

4.4 Constructing Heterogeneous Networks

Next, we describe the two types of networks we build as constituent parts of heterogeneous networks:

Tweet-User networks. Based on Hypothesis 2, we expand the Tweet-User networks by inferring implicit tweet-user relations. If a user u_i posted a set of tweets T_i during a period of time, we say an implicit relation exists between u_i and a tweet t_j if the maximum cosine similarity between t_j and $t_i \in T_i$ exceeds or equals a threshold δ_{tu}.

Web-Tweet networks. Given a set of tweets T and a set of associated web documents D, we build a bipartite graph $G = T \cup D, E$, where an undirected edge with weight w_{ij}^{td} is added when the cosine similarity between $t_i \in T$ and $d_j \in D$ exceeds or equals δ_{td}. This approach creates cross-genre linkages between tweets and web documents on similar events (e.g., evacuation events).

In subsection 5.3, we will discuss the effects of parameters δ_{td} and δ_{tu}.

4.5 Iterative Propagation

We introduce a novel algorithm to incorporate both initial ranking scores and global evidence from heterogeneous networks. It propagates ranking scores across heterogeneous networks iteratively. Our algorithm is an extension of Co-HITS (Deng et al., 2009), which is limited to bipartite graphs. Co-HITS was designed to incorporate links of a bipartite graph with content from two types of objects. The intuition behind the score propagation is the mutual reinforcement to boost co-linked objects.

Let $G = (U \cup V, E)$ be a bipartite graph, in which the vertices are divided into two disjoint sets U and V, and each edge in E connects one vertex in U to another in V. We use w_{ij}^{uv} (or w_{ji}^{vu}) to denote the weight for the edge between u_i and v_j. To put all the weights between sets U and V together, we can use $W^{uv} \in \mathbb{R}^{|U|\times|V|}$ (or $W^{vu} \in \mathbb{R}^{|V|\times|U|}$) to denote the weight matrix between U and V. Note that $W^{uv} \in \mathbb{R}^{|U|\times|V|}$ is the transpose of $W^{vu} \in \mathbb{R}^{|V|\times|U|}$ as we have $w_{ij}^{uv} = w_{ji}^{vu}$. For each $u_i \in U$, a transition probability p_{ij}^{uv} is defined as the probability that vertex u_i in U reaches vertex v_j in V at the next step. Formally, it is defined as a normalized weight $p_{ij}^{uv} = \frac{w_{ij}^{uv}}{\sum_k w_{ik}^{uv}}$, such that $\sum_{j\in V} p_{ij}^{uv} = 1$. Similarly, we obtain the transition probability $p_{ji}^{vu} = \frac{w_{ji}^{vu}}{\sum_k w_{jk}^{vu}}$ and $\sum_{i\in U} p_{ji}^{vu} = 1$ for each $v_j \in V$. The Co-HITS algorithm is defined as follows:

$$s(u_i) = (1 - \lambda_u)s^0(u_i) + \lambda_u \sum_{j\in V} p_{ji}^{vu} s(v_j), \tag{8}$$

$$s(v_j) = (1 - \lambda_v)s^0(v_j) + \lambda_v \sum_{i\in U} p_{ij}^{uv} s(u_i), \tag{9}$$

where $\lambda_u \in [0, 1]$ and $\lambda_v \in [0, 1]$ are personalized parameters, $s^0(u_i)$ and $s^0(v_j)$ are initial ranking scores for u_i and v_j, and $s(u_i)$ and $s(v_j)$ denote updated ranking scores of vertices u_i and v_j. In this algorithm, the initial scores are normalized to $\sum_{i\in U} s^0(u_i) = 1$ and $\sum_{j\in V} s^0(v_i) = 1$, and the sum of updated $s(u_i)$ and $s(v_j)$ will be 1 as well.

The problem with Co-HITS in our experimental settings is the transition probability. As mentioned before, we choose cosine similarity as the weight for the edge between two vertices, and a similarity matrix W is obtained to denote the weight matrix where each entry w_{ij} is the similarity between vertex u_i and vertex v_j. Although the transition probability is a natural normalization for the weight between two vertices, it may not be suitable for similarity matrix. The reason is that the original similarity between different objects has already been normalized, so a further normalization from the similarity matrix to transition matrix may weaken or damage inherent meanings of the original similarity. For example, if a tweet u_i is aligned with one and only one document v_j with relatively low similarity weight, the transition probability w_{ij}^{uv} will be increased to 1 after normalization. Similarly, some higher similarity weights may be normalized to small transition probabilities.

By extending and adapting Co-HITS, we develop Tri-HITS to handle heterogeneous networks with three types of objects: users, tweets and web documents. Given the similarity matrices W^{dt} (between documents and tweets) and W^{tu} (between tweets and users), and initial ranking scores of $s^0(d)$, $s^0(t)$ and $s^0(u)$, we aim to refine the initial ranking scores and obtain the final ranking scores $s(d)$, $s(t)$ and $s(u)$. Starting from document $s(d)$, the update process considers both the initial score $s^0(d)$ and the propagation from connected tweets $s(t)$, which can be expressed as:

$$\begin{aligned} \hat{s}(d_i) &= \sum_{j \in T} w_{ji}^{td} s(t_j), \\ s(d_i) &= (1-\lambda_{td}) s^0(d_i) + \lambda_{td} \frac{\hat{s}(d_i)}{\sum_i \hat{s}(d_i)}, \end{aligned} \tag{10}$$

where W^{td} is the transpose of W^{dt}, and $\lambda_{td} \in [0,1]$ is the parameter to balance between initial and propagated ranking scores. Tri-HITS normalizes the propagated ranking scores $\hat{s}(d_i)$, while Co-HITS propagates normalized ranking scores by using the transition matrix instead of the original similarity matrix, potentially weakening or damaging the inherent meanings of the original similarity. Similarly, we define the propagation from tweets to users as:

$$\begin{aligned} \hat{s}(u_k) &= \sum_{j \in T} w_{jk}^{tu} s(t_j), \\ s(u_k) &= (1-\lambda_{tu}) s^0(u_k) + \lambda_{tu} \frac{\hat{s}(u_k)}{\sum_k \hat{s}(u_k)}, \end{aligned} \tag{11}$$

Each tweet $s(t_j)$ may be influenced by the propagation from both documents and users:

$$\begin{aligned} \hat{s}_d(t_j) &= \sum_{i \in D} w_{ij}^{dt} s(d_i), \\ \hat{s}_u(t_j) &= \sum_{k \in U} w_{kj}^{ut} s(u_k), \\ s(t_j) &= (1-\lambda_{dt}-\lambda_{ut}) s^0(t_j) \\ &\quad + \lambda_{dt} \frac{\hat{s}_d(t_j)}{\sum_j \hat{s}_d(t_j)} + \lambda_{ut} \frac{\hat{s}_u(t_j)}{\sum_j \hat{s}_u(t_j)}. \end{aligned} \tag{12}$$

where W^{ut} is the transpose of W^{tu}, λ_{dt} and λ_{ut} are parameters to balance between initial and propagated ranking scores. The λ variables define the networks being considered: (i) when λ_{dt} is

Input: A set of tweets (T), and users (U) on a given topic.
Output: Ranking scores (S_t) for T.

1: Use rule-based method to filter out noisy tweets (remaining $\hat{T}$ posted by users $\hat{U}$);
2: Retrieve relevant web documents D for $\hat{T}$;
3: Use TextRank and Bayesian Ranking to compute initial ranking scores S_t^0 for $\hat{T}$, S_d^0 for D and initial credibility scores S_u^0 for $\hat{U}$;
4: Construct heterogeneous networks across $\hat{T}$, $\hat{U}$ and D;
5: $k \leftarrow 0$, $diff \leftarrow 10e6$;
6: **while** $k <$ MaxIteration and $diff >$ MinThreshold **do**
7: Use Eq. (12) to compute S_t^{k+1};
8: Use Eq. (11) to compute S_u^{k+1};
9: Use Eq. (10) to compute S_d^{k+1};
10: Normalize S_t^{k+1},S_d^{k+1}, and S_u^{k+1};
11: $diff \leftarrow \sum(|S_t^{k+1} - S_t^k|)$;
12: $k \leftarrow k + 1$
13: **end while**

Algorithm 1: Tri-HITS: Tweet ranking using heterogeneous networks

set to 0, only Tweet-User networks are considered (Method 3 in Table 1); (ii) when λ_{ut} is set to 0, only Web-Tweet networks are considered (Method 4); (iii) when both λ_{dt} and λ_{ut} are different from 0, the entire heterogeneous Web-Tweet-User network is considered (Method 5). For methods relying on bipartite graphs, we define as *one-step propagation* when the propagation is performed in a single direction, while we call it *two-step propagation* when it is performed in both directions. The selection of one-step propagation and two-step propagation is controlled by λ parameters.

Model Convergence Proof: From Equation (10), and assuming $\lambda_{td} > 0$ (the ranking scores $s(d)$ for web documents would not change if $\lambda_{td} = 0$), we get:

$$\bar{s}(d_i) = \frac{1}{\lambda_{td}}[s(d_i) - (1 - \lambda_{td})s^0(d_i)] = \frac{\hat{s}(d_i)}{\sum_i \hat{s}(d_i)}. \quad (13)$$

$\bar{s}(d)$, the normalized score of $\hat{s}(d)$, is similar to the normalized authority or hub scores defined in HITS (Kleinberg, 1999), the difference being only the function to select vector norms. Kleinberg proved that $\bar{s}(d_i)$ converges as the iterative procedure continues, from which the convergence of the ranking scores $s(d)$ for web documents is guaranteed. The same assumption proves the convergence of ranking scores for tweets and users.

Algorithm 1 summarizes Tri-HITS.

5 Experiments

Next, we present the experiment settings and analyze the methods shown in Table 1.

Methods	Descriptions	Hypotheses
1. Baseline	TextRank based on tweet-tweet networks.	
2. 1+Filtering	Baseline with filtering included.	
3. 2+Tweet-User*	Propagation on explicit and implicit Tweet-User networks.	1 and 2
4. 2+Web-Tweet	Propagation on Web-Tweet networks.	3
5. 3+4 Web-Tweet-User*	Propagation on Web-Tweet-User networks.	all

Table 1: Description of methods (method with * make use of the Bayesian Approach to initialize user credibility scores.

Grade	5	4	3	2	1
Hour 1	65	48	93	119	847
Hour 2	135	159	255	164	458
Hour 3	129	102	162	123	602

Table 2: Tweet distribution by grade

5.1 Data

We use tweets on the Hurricane Irene from August 26 to September 2, 2011 for our experiments. Using the query terms *hurricane* or *irene* to monitor tweets, we collected 176,014 tweets posted by 139,136 users within that timeframe. For evaluation purposes, we segment the tweets into 153 hours with an average of 1,150 tweets in each hour.

We randomly chose tweets from three hours to be manually annotated as our reference. This subset contains 3,460 tweets posted on different days: August 27, 2011, August 28, 2011 and September 1, 2011. Following the annotation guidelines defined by (Huang et al., 2011), two annotators parallelly assigned each tweet a grade in a 5-star likert scale. Tweets with grade 5 are the most informative, while tweets with label 1 are the least informative. When the label difference between annotators was 1, the lower grade was selected. When the label difference was greater than 1, those tweets were re-annotated until the label difference did not exceed 1. Table 2 shows the distributions of all grades for each of the three hours of tweets.

5.2 Evaluation Metric

To evaluate tweet ranking, we rely on three-fold cross validation using *nDCG* as a measure (Jarvelin and Kekalainen, 2002), which considers both the informativeness, and the position of a tweet:

$$nDCG(\Phi, k) = \frac{1}{|\Phi|} \sum_{i=1}^{|\Phi|} \frac{DCG_{ik}}{IDCG_{ik}},$$

$$DCG_{ik} = \sum_{j=1}^{k} \frac{2^{rel_{ij}} - 1}{\log(1+j)},$$

where Φ is the set of documents in the test set, each document corresponding to an hour of tweets in our case, rel_{ij} is the human-annotated label for the tweet j in the document i, and $IDCG_{ik}$ is the DCG score for the ideal ranking. The average *nDCG* score for the top k tweets is: $Avg@k = \sum_{i=1}^{k} nDCG(\Phi, i)/k$. To favor diversity of top ranked tweets, redundant tweets are penalized to lower down the final score.

5.3 Effect of Parameters

We study the impact of different parameters on the training set. We present the most representative figures to show the effect, due to the lack of space. For TextRank, we explore δ_{tt} values from 0 to 1. For the enhanced approaches, we firstly perform one-step propagation of ranking scores from web documents to tweets by considering all pairs of δ_{td} and λ_{dt} from 0 to 1 with a step of 0.1. For each δ_{td}, the corresponding λ_{dt} and the best average nDCG scores for top 10 and 100 tweets are shown in Figure 3(a). We notice that when both initial tweet ranking scores and propagated ranking scores from web documents are considered (i.e., δ_{td} is set from 0 to 0.9 and $\lambda_{dt} > 0$), the ranking quality

outperforms that by simply considering initial ranking scores of tweets (i.e. $\delta_{td} = 1$). Secondly, for the ranking performance of double-step ranking scores propagation, we choose to set $\delta_{td} = 0.1$, $\lambda_{dt} = 0.4$ and test λ_{td} from 0 to 1. Figure 3(b) shows an encouraging improvement in the ranking quality, and more stable over the baseline and one-step propagation. This suggests that two-step propagation provides mutual improvement in the ranking quality. The reason is that the ranking of web documents may also be refined using tweet and user evidence thanks to the large volume and synchrony of tweeting (Zanzotto et al., 2011). Here, $\lambda_{td} = 0.2$ yields the best performance. The aforementioned process is followed for Tweet-User networks, finding the best performance for $\delta_{tu} = 0.1$, $\lambda_{ut} = 0.2$, and $\lambda_{tu} = 0.6$.

When validating on the test set, Method 4 based on Web-Tweet networks outperforms Method 3 relying on Tweet-User networks. Therefore, for Web-Tweet-User networks, we keep the above values, and explore λ_{ut} values from 0 to 0.6 (e.g., $1 - \lambda_{dt}$). Figure 3(c) shows that integrating web documents, tweets and users, the ranking quality improves over both Web-Tweet networks and Tweet-User networks.

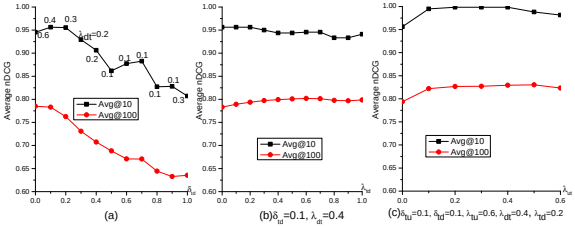

Figure 3: Effect of parameters: (a) δ_{td} and λ_{dt} for Web-Tweet networks, (b) λ_{td} for Web-Tweet networks, (c) λ_{dt} for Web-Tweet-User networks.

5.4 Performance and Analysis

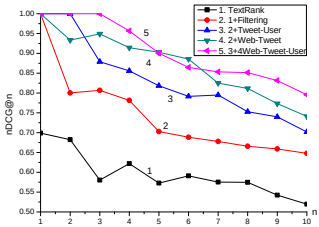

Figure 4: Performance comparison of ranking methods

Figure 4 shows the performance of ranking methods. The performance gain from Method 1 to Method 2 shows the need of filtering short and informal tweets. In this case, filtering reduced from 3,460 to 1,765 tweets ($\sim$ 49% reduction). Table 3 shows the distribution of labels for filtered tweets: a great majority of 91.75% had been annotated as 1, while only 0.11% had been annotated as 5.

Methods 3, 4 and 5, which integrate heterogeneous networks after filtering, outperform the baseline TextRank. When tweets are aligned with web documents (Method 4), the ranking quality improves

Grade	5	4	3	2	1
Percentage	0.11%	0.17%	3.13%	4.84%	91.75%

Table 3: Grade distributions for filtered tweets.

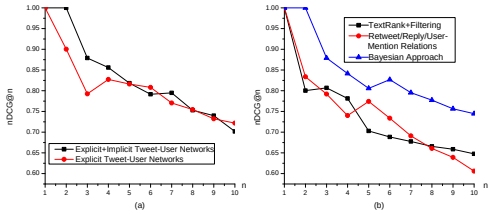

Figure 5: (a) Explicit vs Inferred Implicit Tweet-User Relations to Construct Tweet-User Networks; (b) TextRank vs One-step Propagation on Explicit Tweet-User Networks Using Bayesian Approach and Retweet/Reply/User Mention Relations.

significantly, proving that web documents can help infer informative tweets adding support from a formal genre. The fact that tweets with low initial ranking scores are aligned with web documents helps improve their ranking positions (Hypothesis 3). For example, the ranking of the tweet "*Hurricane Irene: City by City Forecasts http://t.co/x1t122A*" is improved compared to TextRank, helped by the fact that 10 retrieved web documents are about this topic.

Integrating users (Method 5) further improves performance. This indicates that Web-Tweet and Tweet-User networks may complement each other in improving ranking. For example, the tweet "*A social-media guide to dealing with Hurricane Irene http://t.co/0XBEnEJ*" is not top-ranked when only using Web-Tweet networks, since none of the retrieved web documents is related to it. However, similar tweets appear with high frequency in the tweet set. Hence, inferring implicit tweet-user relations and propagating information through the tweet-user network also improves the ranking.

Figure 5(a) shows that inferring implicit tweet-user relationships outperforms the only use of explicit tweet-user relations, especially for top positions. Looking into lower positions, we find that the redundancy removal performs better for the only use of explicit relations. However, both approaches can still perform similarly in positions $5 \sim 10$. This corroborates the synchronous behavior of users as an indicator of informative contents (Hypothesis 2). Since it is likely that a large set of users only tweet once within a short timeframe, limiting to explicit tweet-user relations results in sparse links, and ranking quality cannot be bootstrapped. Interestingly, inferring implicit tweet-user relations can capture synchronous behavior of users, which indicates subjects that users are concerned about.

Figure 5(b) shows that initializing user credibility scores with the Bayesian approach and performing one-step ranking score propagation from users to tweets based on the explicit tweet-user networks also outperforms TextRank. This corroborates our hypothesis that credible users are more likely to post informative tweets (Hypothesis 1). In addition, using only retweets, replies, and user mentions to compute initial user ranking scores, the performance does not improve over TextRank. The reason is that for an event of general interest like the Hurricane Irene, users from different communities rarely interact with each other.

Finally, Figure 6 shows that Tri-HITS significantly outperforms Co-HITS over bipartite graphs, with the only exception of position $n = 2$ for the Web-Tweet network. This corroborates that normalizing the similarity matrix weakens semantic relations between different objects, and that

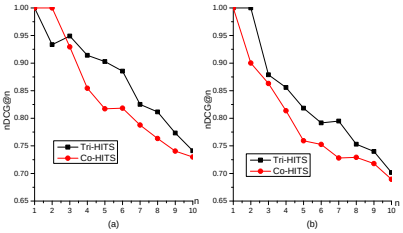

Figure 6: Co-HITS vs Tri-HITS on (a) Web-Tweet Networks, (b) Tweet-User Networks

capturing inherent meanings of cross-genre linkages is crucial for information propagation.

5.5 Remaining Error Analysis

Tri-HITS shows encouraging improvements in ranking quality with respect to a state-of-the-art model like TextRank. However, there are still some issues to be addressed for further improvements.

(i) Topically-relevant tweet identification. We tracked tweets containing the keywords "Hurricane" and "Irene". Using such a query to follow tweets might also return tweets that are not related to the event being followed. This may occur either because the terms are ambiguous, or because of spam being injected into trending conversations to make it visible. For example, the tweet "*Hurricane Kitty: http://t.co/cdIexE3*" is an advertisement, which is not topically related to Irene.

(ii) Non-informative tweet identification. Our rule-based filtering component achieves high precision (96.59%) on the identification of non-informative tweets, while there are still a number of false positives with a 70.7% recall. Performing deeper linguistic analysis, such as exploring subjectivity, might help clean up the tweet set by identifying additional non-informative tweets. For example, an analysis of writing styles would help identify the tweet "*Hurricane names hurricane names http://t.co/iisc7UY ;)*" as informal because it contains repeated phrases. And the tweet "*My favorite parts of Hurricane coverage is when the weathercasters stand in those 100 MPH winds right on the beach. Good stuff.*" is clearly subjective commentary that may entertain but will not meet the general interest of people involved with or tracking the event.

(iii) Deep semantic analysis of the content. Users may rely on distinct terms to refer to the same concept. More extensive semantic analyses of text could help identify those terms, possibly enhancing the propagation process. For example, information extraction tools can be used to extract entities and events, and their coreferential relations, such as "NYC" and "New York City", or "MTA closed" and "subway shutting down". Likewise, existing dictionaries such as WordNet (Miller, 1995) can be utilized to mine synonym/hypernym/hyponym relations, and Brown clusters (Brown et al., 1992) can be explored to mine other types of relations.

6 Related Work

We discuss relevant research on tweet ranking, information credibility for tweets, and the use of graphical models.

Previous research on tweet ranking has relied on the analysis of content (Sankaranarayanan et al., 2009), user credibility (Golder et al., 2009; Weng et al., 2010; Yamaguchi et al., 2010; Hannon et al., 2010; Uysal and Croft, 2011) and URL availability, or combinations of them (Duan et al., 2010;

Huang et al., 2011). In addition, (Huang et al., 2011) also exploited content similarity to propagate evidence within the tweet genre. Most work has been based on supervised learning models such as RankSVM, Naive-Bayes classifier, and Linear Regression. (Inouye and Kalita, 2011) compared various unsupervised methods to rank tweets for summarization purposes, but only used lexical-level content analysis features.

In analyzing the information credibility of tweets, (Castillo et al., 2011) relied on various levels of features (i.e., message-based, user-based, topic-based and propagation-based features) and supervised learning models for information credibility assessment in Twitter, which (Gupta et al., 2012) extended by capturing relations among events, tweets, and users. (Wang et al., 2011, 2012) proposed a Bayesian interpretation to assess tweet credibility. However, it remains as a preliminary approach due to the linear assumption made in the iterative algorithm of the basic fact-finding scheme. Intensive research has also been conducted on information credibility analysis (cf. (Gupta and Han, 2011)).

Graphical models have been effectively used in document summarization (Mihalcea, 2004; Sornil and Greeu, 2006; Sharifi et al., 2010) demonstrating their power of propagating information across linked instances. However, most of these models, such as TextRank (Mihalcea and Tarau, 2004), as originally developed apply only to homogeneous networks. In contrast to existing research, we introduce Tri-HITS, a novel method that incorporates evidence from multiple genres, by exploiting semantically-related links to external web documents and inferring the implicit tweet-user relations. Following a different method for linking tweets and web documents, (Dong et al., 2010) used outgoing links from tweets to improve recency ranking for a search engine.

7 Conclusions and Future Work

We have introduced Tri-HITS, a novel propagation model that makes use of heterogeneous networks composed of tweets, users, and web documents to rank tweets. To the best of our knowledge, this is the first approach to integrating tweets with formal genres that improves tweet ranking quality. Using propagation models to define ranking scores, we have shown that information from the formal genre of web documents can help improve the ranking quality. By introducing this new propagation model, studying the integration of different genres, presenting a way of inferring implicit tweet-user relations, and exploring the impact of parameters, this work sheds light on the challenging task of ranking tweets that are written informally by a diverse community of users.

Our next step is to develop metrics to predict ranking confidence so that we can remove low-confidence results and outliers from the evidence propagation. In addition, ranking tweets (and later, news) by their informativeness within a given time frame, will help in identifying elements of information for inclusion in a summary. More ambitiously, in future work, we plan to generate automatic summaries from the information jointly provided by tweets and web documents.

ABSTRACT

Combinatory Categorial Grammar (CCG) is an expressive grammar formalism which is able to capture long-range dependencies. However, building large and wide-coverage treebanks for CCG is expensive and time-consuming. In this paper, we focus on the problem of unsupervised CCG induction from plain texts. Based on the baseline model in (Bisk and Hockenmaier, 2012), we propose following two improvements: (1) we utilize boundary part-of-speech (POS) tags to capture lexical information; (2) we perform nonparametric Bayesian inference based on the Pitman-Yor process to learn compact grammars. Experiments on English Penn treebank demonstrate the effectiveness of our boundary model and Bayesian learning.

TITLE AND ABSTRACT IN ANOTHER LANGUAGE (CHINESE)

基于边界词和贝叶斯模型改进的组合范畴语法推导

组合范畴语法(CCG)是一种具有丰富表达能力的语法形式，它可以捕获长距离的依赖关系。但是，构建大规模、覆盖面广的组合范畴语法语料库既昂贵又耗时。在本文中，我们研究如何从普通文本中无监督地推导出组合范畴语法。基于现有的工作(Bisk and Hockenmaier, 2012)，我们提出以下两个改进：(1) 我们使用边界词的词性标记把词汇化信息引入模型中；(2) 我们使用基于Pitman-Yor过程的非参数贝叶斯模型来学习简洁的文法。在英语宾州树库上的实验结果显示了我们提出的边界词模型和贝叶斯模型的有效性。

1 Introduction

Unsupervised grammar induction has attracted research interests for a long time. The induced grammars can be used to construct large treebanks (van Zaanen, 2000), study language acquisition (Jones et al., 2010), etc. In recent years, numerous approaches have been introduced to automatically induce hierarchical structures from plain strings. Some approaches focus on the constituency grammar induction: the constituent-context model (Klein and Manning, 2002), the data-oriented parsing (Bod, 2006), the common cover link model (Seginer, 2007), and the tree-substitution grammars (TSG) (Cohn et al., 2009). The other mainstream is the dependency grammar induction: the dependency model with valence (DMV) (Klein and Manning, 2004; Headden III et al., 2009; Cohen and Smith, 2009), TSG model for dependency (Blunsom and Cohn, 2010), etc.

Among these grammar formalisms, the Combinatorial Categorial Grammar (CCG) is a lexicalized, mildly-context-sensitive model (Steedman, 2000). In the formal grammar theory, CCGs are known to be weekly equivalent to Linear Indexed Grammars, Tree-adjoining Grammars, and Head Grammars (Vijay-Shanker and Weir, 1994). The CCG formalism provides a transparent interface between syntax and semantics, such that the underlying semantics could be naturally defined over syntactical derivations, including the long-range dependencies, the coordination structure, and the extraction phenomenon (Bos et al., 2004; Zettlemoyer and Collins, 2007). As a mildly context-sensitive grammar, CCG can be efficiently parsed in polynomial time, which makes them practical in real parsing tasks[1]. The wide-coverage combinatorial categorial grammars have been used in many NLP tasks, such as the lexical acquisition (Blunsom and Baldwin, 2006), the parsing tasks (Hockenmaier and Steedman, 2002; Clark and Curran, 2003), and the statistical machine translation (Hassan et al., 2007; Zhang and Clark, 2011). These supervised CCG models highly depend on the annotated training corpus, e.g. the CCGbank (Hockenmaier and Steedman, 2007). However, building large and wide-coverage treebanks for CCG is expensive and time-consuming. Therefore, how to induce CCG lexicons and grammars from unlabeled sentences has great values.

Some unsupervised CCG induction models have been proposed (Osborne and Briscoe, 1997; Watkinson and Manandhar, 1999; Ponvert, 2007; Boonkwan and Steedman, 2011; Bisk and Hockenmaier, 2012). Most of these approaches define probabilistic models over CCG rules and use the Expectation-Maximization (EM) algorithm to estimate parameters. The generative process generates grammar rules independently given their parents, without regard to the lexical information. However, the constituents and contexts have been proven useful for grammar induction (Klein and Manning, 2002; Headden III et al., 2009). Another issue of the EM-based models is that the EM algorithm tends to overfit the training data, which requires carefully smoothing (Headden III et al., 2009).

In this paper, we propose to incorporate the lexical information in the unsupervised CCG induction in order to capture more complex language aspects. Specifically, an additional *boundary model*, which defines probability distributions over the boundary part-of-speech tags, is introduced during the probability calculation for parse trees. Furthermore, we present the nonparametric Bayesian inference to alleviate the overfitting problem of EM. The Pitman-Yor process (Pitman and Yor, 1997) is used to encourage rule reuse, resulting in compact grammars. Although the boundary words and Bayesian inference have been used in other grammar

[1] Given grammar G, the parsing complexity of CCG is $O(n^3|G|)$ for the sentences with length n. Clark and Curran (2007) report their supervised parser could parse $20-30$ sentences/second using the treebank grammar.

induction models, so far as we know they are used in CCG induction for the first time. Experimental results show that both the boundary model and the Bayesian inference outperform the baseline CCG induction system significantly.

This paper is structured as follows. First we give a brief overview of the combinatorial categorial grammars in Section 2. Then we present the grammar generation step in Section 3. In Section 4, we describe the baseline model and propose the boundary model and the nonparametric Bayesian learning framework. Experimental results and related work are shown in Section 5 and Section 6 respectively. We conclude our work in the final section.

2 Combinatory Categorial Grammar

Combinatory Categorial Grammar (CCG) is a linguistically expressive lexicalized grammar formalism (Steedman, 2000). In CCG, words and nonterminals are associated with rich syntactic categories which capture the basic word order and subcategorization. Specifically, the categories in CCG are defined recursively: (1) There are some atomic categories, e.g. `S`, `N`; (2) Complex categories take the form `X/Y` or `X\Y`, representing the syntactical function that takes the input category `Y` and outputs the result category `X`. The forward slash (`/`) and the backward slash (`\`) indicate the input category `Y` follows or precedes the complex category respectively. Note that `X` and `Y` themselves may be complex categories too. Parentheses can be used to specify the order of function applications if needed. By default, the slashes are left-associated, e.g. "`X\Y/Z`" is the shorthand of "`(X\Y)/Z`". If the order of categories is not important in some cases, we use the symbol "`|`" to represent either the forward slash or the backward slash. The following examples show some common categories in English grammars: `S` for sentences, `N` for nouns and noun phrases[2], `(S\N)/N` for transitive verbs, `N/N` for determiners and adjectives, etc.

The *derivation* of CCG is the sequence of CCG rule applications. There are a few kinds of rule templates defined in CCG. The simplest rules are the forward application (>) and the backward application (<), where the complex category consumes the whole input category:

`X/Y`	`Y`	$\Rightarrow$	`X`	(>)
`Y`	`X\Y`	$\Rightarrow$	`X`	(<)

The input category could be complex category as well, forming the composition rules:

`X/Y`	`Y|Z`	$\Rightarrow$	`X|Z`	(>B^1)
`Y|Z`	`X\Y`	$\Rightarrow$	`X|Z`	(<B^1)

Note that the above composition rules could reduce the categories `X/Y` and `Y\Z` to the category `X\Z`, using the so-called *cross composition rule*. These rules give CCG the ability to deal with the crossed dependencies in some languages such as Dutch or German[3].

Higher order composition rules can be defined similarly:

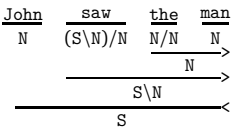
`X/Y`	$Y\|Z_1\|\ldots\|Z_n$	$\Rightarrow$	$X\|Z_1\|\ldots\|Z_n$	(>B^n)
$Y\|Z_1\|\ldots\|Z_n$	`X\Y`	$\Rightarrow$	$X\|Z_1\|\ldots\|Z_n$	(<B^n)

In a sense, the application rules (> and <) can be regarded as the zero-order case of composition rules (>B^0 and <B^0).

[2]In formal English grammars, `NP` is often used to represent noun phrases(Hockenmaier and Steedman, 2007). Following (Bisk and Hockenmaier, 2012), we do not distinguish noun phrase from nouns in this paper for efficiency. This simple treatment causes some problems, e.g. the determiners would be treated as adjuncts and then regarded optional, but actually they are needed for singular count nouns. We leave this problem to future work.

[3]See the example 71 (a German sentence) in (Steedman and Baldridge, 2011)

The following examples show the CCG derivations of a declarative sentence:



(1)

In this example, the lexical category (S\N)/N for the transitive verb "saw" restricts that the verb must first consume an object noun (N) on the right to become the intransitive verb category S\N, then take another noun (N) on the left as the subject to form the sentence S. We can see that the lexicons encode rich lexical information as well as the syntactic restrictions.

For coordination, only the same categories can be conjuncted to yield a single category of the same type in CCG. In detail, the CCG includes a ternary conjunction rule (&).

X conj X ⇒ X (&)

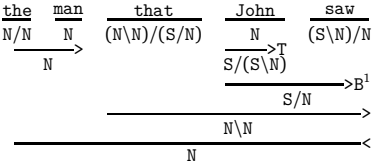
For the parsing algorithms (e.g. the bottom-up CKY algorithm) that require binary rules, we often use the binarized conjunction rules (>& and <&):

X X[conj] ⇒ X (>&)
conj X ⇒ X[conj] (<&)

The type-raising rules are also included in CCG, which turn arguments into functions over functions-over-such-arguments:

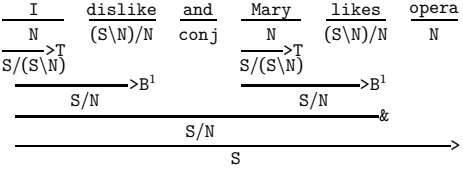
X ⇒ T/(T\X) (>T)
X ⇒ T\(T/X) (<T)

These rules are needed to form some unusual constituents, such as the constituent "John saw" in the example (2). In this example, there is no argument on the right to transitive verb "saw" due to the clause structure, so the noun "John" has to be type-raised.



(2)

Another example of type-raising is the uncommon coordination case (example (3)), in which the two uncommon subject-verb categories S/N are conjuncted.



(3)

In example (1) and (2), it should be emphasised that the same words have the same lexical categories, although the sentence structures are totally different. This elegant treatment for coordination and extraction structures in CCG allows easy recovery of the long-range dependencies and semantics.

Following (Bisk and Hockenmaier, 2012), we group the complex categories into the following two types according to their linguistic functions.

- **Modifier category**. Categories in the form of X|X are modifier categories. In other words, modifier categories take one category as input and output the same category as result. Some modifier category examples are the noun modifier "N/N", the sentence modifier "S\S", and the more complex category "(S\S)/(S\S)".
- **Functor category**. In contrast, the functor category takes one category as input but output a different category as result, i.e. in the form of X|Y, where X and Y are different categories. In the example (2), the follows are all functor categories: the transitive verb "(S\N)/N", the uncommon constituent "S/N", the type-raised category "S/(S\N)", and the relative pronoun "(N\N)/(S/N)".

The modifier categories and the functor categories play different linguistic roles. Using the dependency terminology, the modifier category X|X acts as the dependent and modifies its head X, while the functor category X|Y acts as the head of its dependent Y. We will revisit this issue in the CCG evaluation (section 5.1).

In this paper, we focus on the problem of unsupervised CCG induction, the task to infer meaningful grammars and tree structures from plain texts. We will first describe the grammar generation step in Section 3, and propose the boundary model and the Bayesian learning method in Section 4.

3 Grammar Generation

The combinatory categorial grammars explicitly encode the head-modifier and head-argument dependencies into rich syntactic categories. The first step of our CCG induction method is the lexicon generation step. Bisk and Hockenmaier (2012) propose a simple iterative lexicon generation algorithm from the golden part-of-speech tags. Due to the simplicity and effectiveness of this method, we adopt it to generate lexicons in our method. We rephrase their algorithm with minor modifications in this section.

Only two atomic categories, N (nouns or noun phrases) and S (sentences) are allowed in the grammar. Conjunction words (usually with part-of-speech tag CC in the Penn Treebank) are expanded from a special conjunction category conj. All trees are generated from a special start symbol TOP. Following (Bisk and Hockenmaier, 2012), we assume all strings are either nouns or sentences, i.e. they are generated from one of the following two unary rules:

$$\texttt{TOP} \rightarrow \texttt{N} \qquad\qquad \texttt{TOP} \rightarrow \texttt{S}$$

In addition, we restrict that: (1) strings containing at least one verb must be sentences, i.e. parsed with the TOP → S rule; and (2) strings without any verb must be parsed with the TOP → N rule[4]. Note that the above assumptions are not always true for real sentences. For instance, there exist some sentence fragments and exclamatory sentences in the English treebank. In this paper, we just follow previous work and have no special consideration on these cases for simplicity.

[4]Only the first restriction is used in (Bisk and Hockenmaier, 2012).

The initial CCG lexicon $\mathscr{L}^{(0)}$ is created manually. We associate the noun POS tags with the atomic category N, the verb POS tags with the atomic category S, and the conjunction POS tag with the special category conj. For the POS tag set of the English Penn treebank (Marcus et al., 1993), the initial CCG lexicons are shown as follows:

$$\begin{aligned} \texttt{N} &: \{\texttt{DT}, \texttt{NN}, \texttt{NNS}, \texttt{NNP}, \texttt{NNPS}, \texttt{PRP}\} \\ \texttt{S} &: \{\texttt{MD}, \texttt{VB}, \texttt{VBD}, \texttt{VBG}, \texttt{VBN}, \texttt{VBP}, \texttt{VBZ}\} \\ \texttt{conj} &: \{\texttt{CC}\} \end{aligned}$$

Note that the tag NNPS (representing plural proper nouns) and the tag VBP (representing verbs of non-3rd person singular and in present tense) are missed in (Bisk and Hockenmaier, 2012), but these two tags are found in the Penn treebank tag set.

The lexicon for atomic categories remains fixed after the initial lexicon $\mathscr{L}^{(0)}$ has been created. However, the POS tags may acquire more syntactic categories in the lexicon generation stage. In each induction step, we first assign each POS tag with the categories induced in the previous step, then create new candidates for adjacent POS tags of the training sentences.

- **Modifier category**. Assuming the i^{th} POS tag in some given sentence has been associated with category X, we create new modifier category X/X and X\X, if X satisfies one of the following conditions (items with [c]):
  [c] X is an atomic category;
  [c] X is a modifier itself.
  The newly created categories are inserted to the candidate set of the $(i-1)^{th}$ POS tag and the $(i+1)^{th}$ POS tag respectively.
- **Functor category**. For each pair of adjacent POS tags in the i^{th} and the $(i+1)^{th}$ position in each training sentence, and for each category X and Y associated with the two POS tags, we consider that X may take Y as argument to form the functor category X/Y, and Y may also take X as argument resulting in the functor Y\X. The new categories are valid if the head H (input category) and the argument A (result category) satisfy one of the following conditions (items with [c]) and violate none of the following restrictions (items with [r]):
  [c] H is a modifier or in the form of "(S|...)", and A is the atomic category "N" or "S";
  [c] H is "S" and A is "N", i.e. the categories "S/N" and "S\N" are allowed;
  [r] A is not a modifier, i.e. any non-modifier (atoms and functors) may be argument;
  [r] H is different from A, otherwise the result category is the modifier category rather than the functor category;
  [r] H is not "N", since the atomic category "N" is assumed to take no arguments.
  If the categories X/Y (or Y\X) passes the above tests, it is inserted to the candidate set of the i^{th} POS tag (and the corresponding $(i+1)^{th}$ POS tag).

After creating the lexicons for one sentence, we parse it with the created lexicons and remove categories that can not lead to a successful parse. The rest categories are inserted to the lexicon $\mathscr{L}^{(i)}$ for the i^{th} induction step. We perform this step twice to get the final lexicon $\mathscr{L}^{(2)}$.

The above induction procedure is almost the same as the algorithm described in (Bisk and Hockenmaier, 2012). One additional induction step they used is the "derived" induction step, in which adjacent constituents that can be derived from the existing lexicon are combined. However, their experiments do not show significant improvement of this lexicon generation method, so we omit this step in our experiments.

4 Improved CCG Induction Models

4.1 Basic Probabilistic Model

The *basic* model in this paper is the baseline model described in (Hockenmaier and Steedman, 2002), which is also used in (Bisk and Hockenmaier, 2012). There are four types of CCG rules:

1. the lexical (W) rules which generate terminal words;
2. the unary (U) rules which could be the root rules or the type-raising rules;
3. the left-headed (L) rules with the first child symbol as the head category, e.g. the forward composition rules;
4. the right-headed (R) rules with the second child symbol as the head category, e.g. the backward composition rules.

Binary trees are generated top-down recursively from the start symbol TOP. For each unexpanded nonterminal P, the basic model first generates the expansion type $\texttt{exp} \in \{\texttt{W},\texttt{U},\texttt{L},\texttt{R}\}$ according to $P_e(\texttt{exp}|\texttt{P})$. Then for each expansion type, the model generates either terminal word w or head child H and possible non-head child N:

$$\begin{aligned}
\text{Lexical:} \quad & P_e(\texttt{exp}=\texttt{W}|\texttt{P})\, P_w(\texttt{w}|\texttt{P},\texttt{exp}=\texttt{W}) \\
\text{Unary:} \quad & P_e(\texttt{exp}=\texttt{U}|\texttt{P})\, P_U(\texttt{H}|\texttt{P},\texttt{exp}=\texttt{U}) \\
\text{Left:} \quad & P_e(\texttt{exp}=\texttt{L}|\texttt{P})\, P_L(\texttt{H}|\texttt{P},\texttt{exp}=\texttt{L})\, P_l(\texttt{N}|\texttt{P},\texttt{H},\texttt{exp}=\texttt{L}) \\
\text{Right:} \quad & P_e(\texttt{exp}=\texttt{R}|\texttt{P})\, P_R(\texttt{H}|\texttt{P},\texttt{exp}=\texttt{R})\, P_r(\texttt{N}|\texttt{P},\texttt{H},\texttt{exp}=\texttt{R})
\end{aligned}$$

After the lexicon generation step, each POS tag acquires a lexicon of CCG categories. These lexicons and CCG rules are used to parse the training corpus. We use the Expectation Maximization (EM) algorithm to estimate model parameters for the basic model. The Inside-Outside algorithm (Lari and Young, 1990) is used to collect the expected counts in the E-step of the EM algorithm.

4.2 Boundary Models

Boundary POS tags have been proven useful for detecting phrase boundaries in the supervised setting (Xiong et al., 2010) and in the unsupervised grammar induction (Golland et al., 2012; Huang et al., 2012). We introduce this idea to the unsupervised combinatory categorial grammar induction. Since the system inputs are the golden POS tags in the treebank, we use the boundary words and the boundary POS tags interchangeably in this paper.

Particularly, in some parse tree T, we consider the boundary POS tags of each constituent and define the new probabilistic model as

$$\begin{aligned}
P(T) &= P_{CCG}(T) P_{BDR}(T) \\
&= \prod_{\text{rule:}r\in T} P_{CCG}(r) \prod_{\text{span:}\langle i,j\rangle\in T} P_{BDR}(\sigma_{\langle i,j\rangle}|B)
\end{aligned} \tag{4}$$

where distribution P_{CCG} is the basic CCG model defined in section 4.1, P_{BDR} is the proposed boundary model, $\sigma_{\langle i,j\rangle}$ means the boundary words of the constituent covered by span $\langle i,j\rangle$, and B is a special nonterminal representing the constituent spans. We denote this model as *basic+bdr*. Figure 1 shows a tree example. The boundary probability of this parse tree is

$$\begin{aligned}
P_{BDR}(T) = {} & P(\texttt{DT_DT}|B) \times P(\texttt{NNS_NNS}|B) \times P(\texttt{VBD_VBD}|B) \times P(\texttt{RB_RB}|B) \\
& \times P(\texttt{DT_NNS}|B) \times P(\texttt{VBD_RB}|B) \times P(\texttt{DT_RB}|B)
\end{aligned} \tag{5}$$

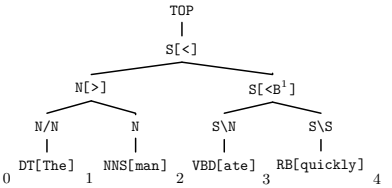


Figure 1: A tree example used to illustrate the boundary probability. The CCG rule types are given in the square brackets next to each nonterminal. Although only POS tags are considered in the induction model, we also show the words for clarity.

Currently, we restrict that the single special nonterminal B generates all boundary tag pairs. We have tried to let the boundary pairs depend on the category of tree nodes. For instance, for span $\langle 2,4\rangle$ of tree in Figure 1, we model $P(\texttt{VBD\_RB}|S)$ rather than $P(\texttt{VBD\_RB}|B)$. However, this category-dependent boundary model performs poor in experiments (not reported in this paper). The reason might be the data sparsity problem, since there are quite a lot of induced categories in the grammar.

4.3 Bayesian Models

The EM algorithm may overfit the training data, so we propose the Bayesian model to infer grammars and tree structures. In the Bayesian models, the generative process is often formulated as the Chinese Restaurant process (CRP) or the Pitman-Yor process (PYP) to encourage rule reuse and learn compact models (Teh et al., 2006; Pitman and Yor, 1997). Since the PYP is a generalization of the CRP and has more elegant and controllable behavior over the "long tail" of probability distributions, we focus on the PYP in this paper.

For each nonterminal category A in CCG, we maintain a cache to store the total number n of rules expanded with A as parent, the total number of different rule types m, and the counts n_k of each rule that has been generated for $k = 1,\ldots,m$. Initially, all caches are empty, i.e. with $n = m = 0$. The parse trees are generated in sequence. For each sentence, the PYP generates trees in the top-down fashion. For each nonterminal label to be expanded, we consult the cache associated with that nonterminal and decide whether to choose the k^{th} expanded rule in the cache, or generate a new rule. The probabilities of these two cases are

$$P_t(z|z_{i<n}) = \begin{cases} \frac{ma+b}{n+b} & \text{if } z_{n+1} = m+1 \\ \frac{n_k-a}{n+b} & \text{if } z_{n+1} = k, k \in \{1,\cdots,m\} \end{cases} \tag{6}$$

where z_i is the cache index of the i^{th} generated rule, $a \in [0,1]$ and $b \geq 0$ are two category-associated parameters naming the discount and concentration parameters respectively. Note that different labels may have different values of a and b. If we decide to generate a new rule, the new rule is sampled from the base multinomial distribution P_0. We also put a Dirichlet prior on the base distribution and sample the base rule probabilities from the Dirichlet distribution: $\boldsymbol{\theta} \sim \text{Dir}(\boldsymbol{\theta}|\boldsymbol{\alpha})$. The above sampling procedures are performed recursively down until all frontier labels have been expanded to terminals. For CCG induction models described in previous sections, PYP priors are put on all factored models, although they may have different hyperparameters.

The joint probability of a particular sequence of indexes $\boldsymbol{z}$ with cached counts $(n_1, \ldots, n_m)$ under the Pitman-Yor process is

$$PY(\boldsymbol{z}|a,b) = \frac{\prod_{k=1}^{m}(a(k-1)+b)\prod_{j=1}^{n_k-1}(j-a)}{\prod_{i=0}^{n-1}(i+b)}. \tag{7}$$

The above generative process demonstrates the "rich get richer" dynamics, i.e. previous sampled rules would be sampled more likely in following procedures. It is easy to verify that any permutation of $z_1, \ldots, z_n$ has the same probability in the Pitman-Yor process, so the Pitman-Yor process is *exchangeable*, resulting in efficient sampling methods. Given the parse tree set $\mathscr{T}$, we could integrate out the base distribution probabilities to get the joint PYP probability[5]:

$$P(\mathscr{T}|\boldsymbol{a},\boldsymbol{a},\boldsymbol{b}) = \prod_{\mathtt{X}\in\mathscr{N}} \frac{\mathrm{Beta}(\boldsymbol{a}_{\mathtt{X}} + \boldsymbol{f}_{\mathtt{X}})}{\mathrm{Beta}(\boldsymbol{a}_{\mathtt{X}})} PY(\boldsymbol{z}(\mathscr{T})|\boldsymbol{a},\boldsymbol{b}) \tag{8}$$

where $\mathscr{N}$ is the set of nonterminal categories, $\boldsymbol{f}_{\mathtt{X}}$ is the vector containing the number of occurrences that rules r with $\mathtt{X}$ as parent in $\mathscr{T}$, and Beta means the Beta function.

To infer trees and parameters of the PYP model, we apply the collapsed Metropolis-Hastings algorithm (Hastings, 1970; Johnson et al., 2007) to sample trees from the parse forests. In detail, we iteratively draw samples for each yield in training corpus in sequence. Assuming the current tree of the i^{th} sentence is T_i, we first remove this tree from the whole tree set to obtain $\mathscr{T}_{-i}$, the set of sampled trees except the i^{th} one. Then we draw new tree T_i' from some proposal distribution $Q(T_i'|\mathscr{T}_{-i})$, and accept the new sampled tree with probability

$$A(T_i, T_i') = \min\left\{1, \frac{P(T'|\alpha,\boldsymbol{a},\boldsymbol{b})\, Q(T_i|\mathscr{T}_{-i})}{P(T|\alpha,\boldsymbol{a},\boldsymbol{b})\, Q(T_i'|\mathscr{T}_{-i})}\right\}. \tag{9}$$

In theory, Q could be any distribution if it never assigns zero probability. In practice, the proposal distribution should be close enough to the true distribution to avoid high rejection rate. We use the following proposal distribution in experiments:

$$Q(T_i|\mathscr{T}_{-i}) = \frac{1}{Z(\mathscr{T}_{-i})} \prod_{\text{rule}:r\in T_i} P_t(z_r|z_{\mathscr{T}_{-i}})\, P_0(r|\alpha)^{\delta(r\notin\mathscr{T}_{-i})} \tag{10}$$

in which P_t is the conditional index probability in Equation 6, and the model needs to consult the base distribution P_0 if it encounters a new rule ($\delta(r \notin \mathscr{T}_{-i}) = 1$). We do not need to calculate the normalization constant $Z(\mathscr{T}_{-i})$ since it would be cancelled in Equation 9. The proposal distribution differs from the true distribution in the sense that: the caches are updated immediately after calculating probabilities of each rule in T_i under the true distribution, while the caches stay fixed in the proposal distribution evaluation. In experiments, we observe that only a tiny fraction (less than 1%) of proposals are rejected. This provides evidence that the proposal distribution works well enough. We use the sampling algorithm described in (Blunsom and Osborne, 2008) to draw a parse tree from the parse forest according to the proposal distribution Q.

[5]For simplicity, we omit probability factorization as if there is only one model. The complete probability expression is the product of multiple factored PYP probabilities.

5 Experiments

5.1 Datasets and Settings

We carry out experiments on the Wall Street Journal portion of the Penn English Treebank (Marcus et al., 1993). As the standard data split, we use sections 02-21 as the training set, section 00 as the development set, and section 23 as the final test set. We remove punctuations and null elements in treebank, as the standard preprocessing step in the previous unsupervised grammar induction approaches (Klein and Manning, 2002; Cohn et al., 2010; Bisk and Hockenmaier, 2012). For comparison, we build datasets with sentence lengths no more than 10 and 20 words after removing punctuations. As the standard machine learning pipeline, we perform learning and inference on the training set, select model with best performance on the development set, and report the result of the selected model on the test set. For efficiency, we only train and tune parameters on sentences with length no more than 10, but report performance on longer sentences as well. Table 1 gives the statistics of each dataset.

Dataset	Train		Dev		Test	
	# sent	# word	# sent	# word	# sent	# word
PTB10	5,899	41,701	265	1,875	398	2,649
PTB20	-	-	-	-	1,286	16,591

Table 1: Data statistics

For evaluation, the script of CoNLL 2008 shared task[6] is used to calculate the Unlabeled Attachment Score (UAS) of the system outputs, using the treebank dependency structures as golden standards. We perform the McNemar's significant test to compare our proposed models with the baseline model. Since the original treebank only has the phrase-structure trees, we use (Johansson and Nugues, 2007)'s code[7] to convert the treebank to dependency structures. In order to compare with existing approaches, we follow (Bisk and Hockenmaier, 2012) to convert the CCG trees to dependency trees: (1) the modifier categories are treated as the dependents of their heads; (2) the head of the sentence is treated as a dependent of a root node at position 0; (3) the left part of conjunction is treated as the head of `conj`, and the `conj` is treated as the head of the right part. Figure 2 shows an example.

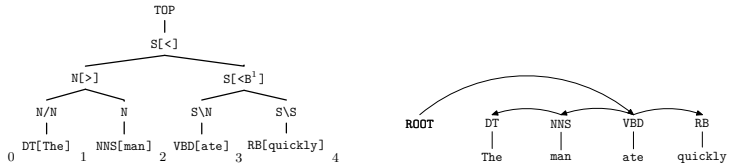

Figure 2: Left: a CCG tree example. Right: the converted dependency tree.

To reduce the model complexity, we restrict that the maximal order of composition rule is 2. The rule probabilities are initialized uniformly. For EM-based models (basic and basic+bdr), we add fixed value to expected counts in each E-step as smoothing. We perform maximal 40 EM iterations while stop earlier if the development score starts to drop. In the Bayesian

[6]Available at: `http://barcelona.research.yahoo.net/dokuwiki/doku.php?id=conll2008:software`
[7]Available at: `http://nlp.cs.lth.se/software/treebank_converter`

inference, we run sampler through the whole training sentences for 400 iterations and use the last sampled grammars to parse fresh sentences. To model the uncertainty of hyperparameters, we put an uninformative Beta$(1,1)$ prior on $\boldsymbol{a}$ and a "vague" Gamma$(10, 0.1)$ prior on $\boldsymbol{b}$ instead of setting them empirically. After each iteration, we resample each of hyperparameters from the posterior distribution of hyperparameters using a slice sampler (Neal, 2003).

5.2 Results

Before presenting the final results, we first examine the effect of smoothing values for EM models. We test smoothing values from $\{1, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100\}$ and evaluate the unlabeled attachment scores (UAS) of the basic model and the basic+bdr model on both the development set and the test set. Note the performance on the test set is only used for references, the final smoothing value is selected as the one with best performance on the development set. Experimental results are plotted in Figure 3. We can easily find that the best smoothing value (with highest dev-score) is 20 for both of these models. The basic+bdr model achieves significant (at $p < 10^{-3}$ level) better results (dev: 66.3, tst: 66.7) than the basic model (dev: 63.3, tst: 62.9) on both the development and test sets when the optimal smoothing values are selected.

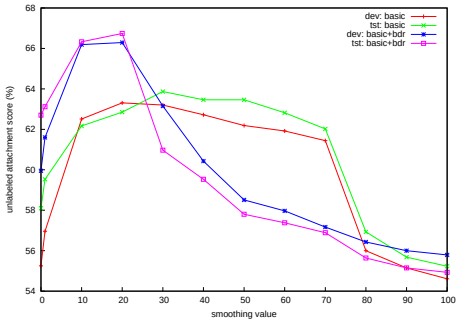

Figure 3: The effect of smoothing value on development and test set of PTB10

The final results of basic and basic+bdr models, using EM or Pitman-Yor process (PYP) are shown in Table 2 for comparison. Some existing results (copied from Figure 4(a) in (Bisk and Hockenmaier, 2012)) are also given in this table. Comparing within the four models described in this paper, we draw following conclusions:

1. The basic+bdr model achieves significant better results than the basic model under the EM learning. The boundary words capture lexical information about constituents and show complementary effectiveness for CCG induction.
2. The Bayesian framework outperforms the EM baseline significantly. This provides evidence that the compact models are preferred in the unsupervised CCG induction.
3. The combination of the boundary model and the Bayesian inference only show slightly better results than individual components. The reason might be that both the boundary words and the Bayesian model have the same effects and give high probabilities to those parse trees with more reused rules.

4. For longer sentences, the proposed methods still outperform baseline model with a large gap, demonstrating the robustness of our method.

Model		PTB10	PTB20
(Klein and Manning, 2004)		47.5	-
(Headden III et al., 2009)		68.8	-
(Spitkovsky et al., 2010)		65.3*	53.8*
(Cohn et al., 2010)		65.9	58.3
(Bisk and Hockenmaier, 2012)		71.5	60.3
(Naseem et al., 2010)		71.9	50.4*
EM	basic	62.9	49.9
	basic+bdr	66.7$^+$	54.0$^+$
PYP	basic	66.0$^+$	53.9$^+$
	basic+bdr	66.7$^+$	55.1$^+$

Table 2: Comparison results on the test set with various length limits. Results of existing approaches are copied from (Bisk and Hockenmaier, 2012). Results with (*) were obtained with additional training data. Results with ($^+$) outperform the baseline (basic with EM) results significantly at $p < 10^{-3}$ level according to the McNemar's significant test.

Compared with existing approaches, our models stay in the intermediate level. Headden III et al. (2009) use rich contexts, words as well as POS tags, and sophisticated smoothing techniques, which might explain their higher performance than ours on short sentences. Naseem et al. (2010) manually specify some dependency rules in experiments, while we only use some coarse restrictions on the lexicon and grammar generation. Our models are mainly based on the previous work (Bisk and Hockenmaier, 2012). The full-EM model in (Bisk and Hockenmaier, 2012) corresponds to the basic model in our paper. Their reported results of full-EM are around 55−60 on short sentences, lower than our implementation. However, the best model in their paper outperforms our models on both short and long sentences. They achieve the state-of-the-art performance using the k-best EM learning. It should be emphasised that the k-best EM learning strategy is still applicable to our proposed basic+bdr model, which we leave for future work.

5.3 Discussion and Future work

Our method and many previous approaches (Klein and Manning, 2002, 2004; Bisk and Hockenmaier, 2012) take the golden part-of-speech tags as input. This practice may reduce data sparsity problem caused by directly modelling words. However, this may also lose useful lexical information. As reported in (Headden III et al., 2009), incorporating words with high frequencies (greater than 100 times in their experiments) as well as the POS tags could improve the induction accuracy for dependency models. In CCG, words may also help to distinguish lexical categories. For example, the transitive verbs are often tagged as (S\N)/N and the intransitive verbs often have category S\N. However, these syntactic differences are not encoded in the Penn treebank POS tags, in which they may both have the POS tag $\texttt{VB}_x$ depending on the tenses. We leave this extension for future work.

Although the simple additive smoothing methods could improve EM results (see Figure 3), sophisticated smoothing schemes are also applicable (Headden III et al., 2009). Currently, the

final probability is the product of basic CCG model and boundary model. This simple strategy already shows effectiveness in our experiments. In future work, different interpolation or back-off methods will be investigated. In addition, the context words have been proved useful for constituency tree induction (Klein and Manning, 2002; Golland et al., 2012). We could also integrate the context information to help CCG induction.

The performance of Bayesian model is somehow below our expectation, especially for the basic+bdr model. Currently, we simply use the grammars sampled at the last iteration to parse test sentences. Johnson and Goldwater (2009) propose the *maximum marginal decoding* technique to obtain more stable results, which we will explore in the future. Furthermore, we do not elaborately tune hyperparameters of Bayesian model, such as the prior distribution of $\boldsymbol{a}, \boldsymbol{b}$, the value of $\boldsymbol{\alpha}$, etc. Finally, tree nodes tend to be labeled with common and simple categories in CCGbank (Hockenmaier and Steedman, 2007). We could define probability models over the number of the categories and the internal arity of categories, and put sparse priors to enforce compact model.

6 Related work

Unsupervised dependency grammar induction has attracted a lot of research interests. The dependency model with valence (DMV) (Klein and Manning, 2004; Headden III et al., 2009; Cohen and Smith, 2009) is one of representative work, in which the valence is explicitly modelled. In contrast, the CCG formalism encodes the functor arity and word orders via syntactic categories, providing a more syntax-meaningful representation especially for long-range dependencies (Steedman, 2000). Since our work is based on CCG induction, we only present CCG-related work.

Osborne and Briscoe (1997) propose an unsupervised learning model for CCG induction. They create a labeled binary tree for each part-of-speech tag sequences in a greedy, bottom-up, incremental manner. The label of each inner node is the label of either the left or right sub-node. To avoid overfitting, they apply the Minimum Description Length (MDL) principle to learn compact grammars with minimal length of hypothesis and minimal length of data encoded in the hypothesis. While our model uses the alternative Bayesian learning method to learn compact grammars. Watkinson and Manandhar (1999) describe a CCG induction model based on linguistic lexicon generation. The learner is provided with a set of manually defined English oriented CCG categories, such as the verb-subcategorization. Compared to their work, we initialize lexicons with more general categories and learn complex categories and grammar rules automatically. Ponvert (2007) presents a generic algorithm to learn CCG categories. However, the reported experiments do not show much promising results. Naseem et al. (2010) use manually-specified linguistic-motivated rules in dependency grammar induction. Variational Bayesian method is used to estimate the parameters.

The most related work is (Bisk and Hockenmaier, 2012). The grammar generation step described in our paper is almost the same as the one in their paper. They compare various EM settings (full EM, Viterbi EM, and k-best EM) and find that the k-best EM could achieve best performance. They report the state-of-the-art results for unsupervised dependency grammar induction. Instead of the k-best EM, we perform the Bayesian inference and use sampling to estimate parameters. In addition, we exploit the use of rich lexical information and propose the boundary model to improve CCG induction. It is worth noting that the k-best EM can be also used for our boundary model, which we leave for future work.

Conclusion

In this paper, we have proposed to incorporate lexical information in the unsupervised CCG induction. Specifically, an additional boundary model is defined to capture complex language aspects, in which boundary words are generated from a special symbol independently for each span covered by tree nodes. Furthermore, we describe the nonparametric Pitman-Yor process to encourage rule reuse, resulting in compact grammars. Experimental results demonstrate that both the boundary model and the Bayesian inference outperform the baseline CCG induction system.

Acknowledgments

We would like to thank Zhixiang Ren for insightful discussions. We would also thank Professor Julia Hockenmaier for her LaTeX package to draw CCG derivations. Thank the anonymous reviewers for their helpful comments and suggestions.

ABSTRACT
Recently, methods for mining graph sequences have attracted considerable interest in data-mining research. A graph sequence is a data structure used to represent changing networks. The aim of graph sequence mining is to enumerate common changing patterns appearing more frequently than a given threshold in graph sequences. Dependency analysis is recognized as a basic process in natural language processing. In transition-based parsers for dependency analysis, a transition sequence can be represented by a graph sequence, where each graph, vertex, and edge corresponds to a state, word, and dependency, respectively. In this paper, we propose a method for mining rules to rewrite states reaching incorrect final states to those reaching correct final states, from transition sequences of a dependency parser using a beam search. The proposed method is evaluated using an English corpus, and we demonstrate the design of effective feature templates based on knowledge obtained from the mined rules.

KEYWORDS: Dependency Parsing, Graph Sequence, Frequent Pattern Mining.

COLING 2012, Mumbai, December 2012.

1 Introduction

Data mining is the process of mining useful knowledge from large datasets. Recently, methods for mining graph sequences (dynamic graphs (Borgwardt et al., 2006) or evolving graphs (Berlingerio et al., 2009)) have attracted considerable interest from researchers in the field of data mining (Inokuchi and Washio, 2008). For example, human networks can be represented as a graph, where each vertex and edge corresponds, respectively, to a human and a relationship in the network. If a human joins or leaves the network, the numbers of vertices and edges in the graph increase or decrease, respectively. A graph sequence is one of the data structures used to represent a changing network. Figure 1(a) shows a graph sequence consisting of four steps, five vertices, and various edges between the vertices. The aim of graph sequence mining is to enumerate subgraph subsequence patterns, an example of which is shown in Fig. 1(b), appearing more frequently than a given threshold in graph sequences. Since the development of methods for mining graph sequences, these methods have been applied, for example, to social networks in Web services (Berlingerio et al., 2009), article-citation networks (Ahmed and Karypis, 2011), and e-mail networks (Borgwardt et al., 2006).

Dependency parsing is considered a basic process in natural language processing (NLP), and a number of studies have been reported (Kudo and Matsumoto, 2002; Nivre, 2008). One reason for the increasing popularity of this research area is the fact that dependency-based syntactic representations seem to be useful in many applications of language technology (Kubler et al., 2009), such as machine translation (Culotta and Sorensen, 2004) and information extraction (Ding and Palmer, 2004). Broadly speaking, dependency parsers can be categorized as transition-based, graph-based, and grammar-based dependency parsers. Transition-based dependency parsers, which are data-driven methods, transit between states in a deterministic way using local state information. If the parser adds an incorrect dependency between words once, it never reaches the correct final state. To reduce such incorrect decisions, the parser can keep track of multiple candidate outputs using the beam search principle, thus avoiding making decisions too early (Zhang and Clark, 2008).

In a transition-based parser, a transition sequence can be represented by a graph sequence, where each graph, vertex, and edge, corresponds to a state, word, and dependency, respectively. By mining characteristic patterns from transition sequences for sentences analyzed incorrectly by a parser, it is possible to design new parsers and generate effective feature templates in the machine learner of the parser to avoid incorrect dependency structures. In this paper, we demonstrate the application of graph sequence mining to dependency parsing in NLP.

We propose a method for mining rewriting rules from transition sequences of an arc-eager dependency parser integrated with the beam search principle for English sentences. The mined rewriting rules can shed light on why incorrect dependency structures are returned by this type of parser. We also present effective feature templates designed according to knowledge obtained from the mined rules, and show the improvement of the parser's attachment score, which is a measure of the percentage of words with the correct heads. To mine such rules, the rules should be human-readable, since they are to be used as inspiration for the engineering

2 Transition-based Dependency Parsing

In this paper, we focus on dependency analysis using an "arc-eager parser" (Nivre, 2008), which is a parser based on a transition system, for "English sentences". However, the principle of the method proposed in this paper can basically be applied to any parser based on a transition system for sentences in any language (Inokuchi et al., 2012).

The aim of dependency parsing of a sentence is to output its dependency graph.

Definition 1 *The dependency graph for a sentence* $x = \langle w_0, \cdots, w_n \rangle$ *is represented as a graph* $g = (V, E)$*, where* $V = \{0, \cdots, n\}$ *and* $E \subset V \times V$. ■

Definition 2 *A dependency graph* (V, E) *is well-formed, if the following conditions are satisfied:*

- $\nexists x \in V$ *such that* $(x, 0) \in E$ *(root condition),*
- $\nexists x \in V$ *such that* $(x, y) \in E \wedge x \neq x'$*, when* $(x', y) \in E$ *(single-head condition), and*
- $\nexists \{(v_0, v_1), (v_1, v_2), \cdots, (v_{l-1}, v_l)\} \subseteq E$ *such that* $v_0 = v_l$ *(acyclicity condition).* ■

A dependency graph satisfying these conditions is a forest. In addition, if a dependency graph is connected, the graph is a tree.

We define a transition-based dependency parser with input $x = \langle w_0, w_1, \cdots, w_n \rangle$ and output $g = (V, E)$.

Definition 3 *A transition-based parser consists of* $S = (C, T, c_s, C_F)$*, where*

- $C = \{(\sigma, \beta, A)\}$ *is a set of states, with* σ*,* β*, and* A *a stack, a buffer, and a set of edges, respectively,*
- T *is a set of transitions, with* $t \in T$ *a partial function such that* $t : C \rightarrow C$*,*
- c_s *is an initial function satisfying* $c_s(x) = ([0], [1, 2, \cdots, n], \emptyset)$*, and*
- $C_F \subseteq C$ *is a set of final states* $\{c \in C \mid c = (\sigma, [\,], A)\}$. ■

A transition sequence for $x = \langle w_0, w_1, \cdots, w_n \rangle$ on $S = (C, T, c_s, C_F)$ is represented as $C_{1,m} = \langle c^{(1)}, \cdots, c^{(m)} \rangle$, satisfying (1) $c^{(1)} = c_s(x)$, (2) $c^{(m)} \in C_F$, and (3) $\exists t \in T$ for $c^{(i)}$ $(1 \leq i < m)$, $c^{(i+1)} = t(c^{(i)})$. We denote β and A for state c as β_c and A_c, respectively.

Figure 2 gives the algorithm for a transition-based dependency parser, where o denotes an oracle for selecting $t = [o(c)]$ to transit to the next state in a deterministic way. In particular,

the arc-eager parser, which is a transition-based parser, selects either Left, Right, Reduce, or Shift to analyze sentences, as shown in Fig. 3, where the operator | is taken to be left-associative for the stack and right-associative for the buffer. If o selects Left or Right, then edge (j,i) or (i,j) is added to A to transit from c to $t(c)$, respectively. If o selects Reduce, then i is popped from the stack to transit from c to $t(c)$. Otherwise, j is popped from the buffer and j is pushed onto the stack to transit from c to $t(c)$. Since o is a function that determines the transition from Left, Right, Reduce, and Shift, it is implemented using a multi-class classifier for feature vectors characterizing the state c (Kubler et al., 2009).

Although we defined each state using a stack and buffer in a similar way to that reported in most of the literature, we now redefine it using a graph to link dependency parsing to graph sequence mining.

Definition 4 *A state* $c = (\sigma, j|\beta, A)$ *s.t.* $\sigma = [s_{|\sigma|}, s_{|\sigma|-1}, \cdots, s_1]$ *is represented as a graph* $c_g = (N, A, N')$*, where* $N = \{0, 1, \cdots, j\}$ *is a set of vertices,* A *is a set of edges, and* $N' = \{s_{|\sigma|}, s_{|\sigma|-1}, \cdots, s_1, j\} \subseteq N$.

The graph $c_g = (N, A, N')$ is a forest of ordered trees, where $N' \subseteq N$ are vertices that are not reduced on the rightmost path of each tree in the forest. If o selects Left or Right, then edge (j,i) or (i,j), where i and j $(i < j)$ are the largest vertices in N', is added to transit from c to $t(c)$, respectively. If o selects Shift, the smallest vertex that does not exist in N is added to c_g to transit from c to $t(c)$. Otherwise, the second largest vertex in N' is removed from N' to transit from c to $t(c)$. Since an arc-eager dependency parser is incremental (Kubler et al., 2009), the numbers of vertices and edges in c_g increase monotonically.

Example 1 *Figure 4 shows the transition sequence from the initial state to the final state for the sentence* $\langle \$, I, saw, him, . \rangle$*, where* $w_0 = \$$ *is a special root vertex. In the sequence, Shift, Left, Right, Right, Reduce, and Right are selected in order by o. In this figure, shaded vertices in each state belong to* N'.

Figure 5 shows the search space T for sentence $\langle w_0, w_1, w_2, w_3 \rangle$. The words in each state and all states whose final states are not trees are omitted owing to lack of space. The search space T for the algorithm given in Figs. 2 and 3 is depicted as a single-rooted directed acyclic graph, where states C on $S = (C, T, c_s, C_F)$ are nodes, initial state $c^{(1)}$ is the root node, final states $C_F \subseteq C$ are leaves, and transitions between the states are branches. As shown in Fig. 5, there is only one or a few transition sequences from the initial state to each leaf. Therefore, if an incorrect dependency is added between words once, the parser never reaches the correct final state. To reduce the possibility of such an incorrect decision, the parser can keep track of multiple candidate outputs using the beam search principle and avoid making decisions too early (Zhang and Clark, 2008). Nevertheless, an arc-eager parser incorporating the beam search principle sometimes reaches an incorrect final state.

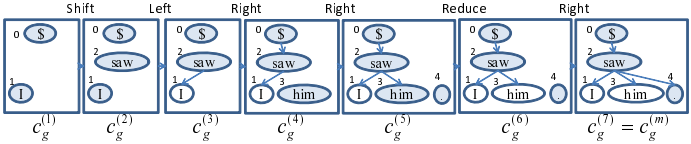

Figure 4: Transition sequence for the sentence $\langle \$, I, saw, him, . \rangle$

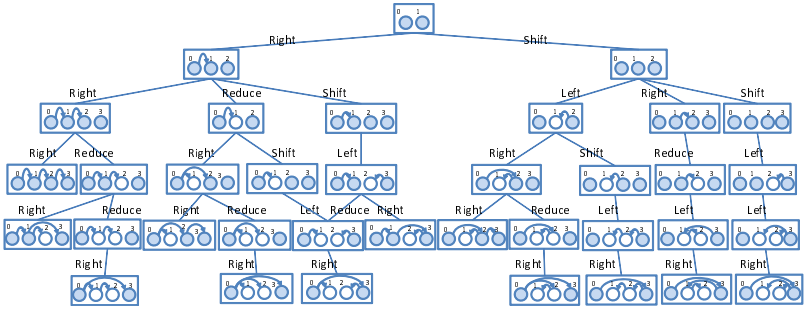

Figure 5: Search space for sentence $\langle w_0, w_1, w_2, w_3 \rangle$

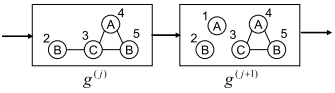


$g^{(j)}$ $g^{(j+1)}$

Figure 6: Change between two successive graphs

In this paper, we propose a method for mining rewriting rules from transition sequences of an arc-eager dependency parser incorporating the beam search principle for English sentences. The rewriting rules to be mined are human-readable rules for rewriting states reaching incorrect final states to those reaching the correct final states. The rewriting rules correspond to bypasses between states in the search space shown in Fig. 5. To describe the proposed method, we first discuss GTRACE for mining graph sequences corresponding to transition sequences in the next section.

3 Graph Sequence Mining

Figure 1(a) shows an example of a graph sequence. Graph $g^{(j)}$ is the j-th labeled graph in the sequence. The problem we address in this section is how to mine patterns that appear more frequently than a given threshold from a set of graph sequences. We proposed using transformation rules to represent graph sequences compactly under the assumption that "change is gradual" (Inokuchi and Washio, 2008). In other words, only a small part of the structure changes, while the other part remains unchanged between successive graphs $g^{(j)}$ and $g^{(j+1)}$ in a graph sequence. For example, the change between successive graphs $g^{(j)}$ and $g^{(j+1)}$ in the graph sequence shown in Fig. 6 is represented as an ordered list of two transformation rules $\langle vt^{(j)}_{[1,A]}, ed^{(j)}_{[(2,3),\bullet]} \rangle$. This list denotes that a vertex with ID 1 and label A is inserted (vi), and then the edge between the vertices with IDs 2 and 3 is deleted (ed). By assuming that the change in each graph is gradual, we can represent a graph sequence compactly, even if the graph in the graph sequence has many vertices and edges. We also proposed a method, called GTRACE (Graph TRAnsformation sequenCE mining), for mining all frequent patterns from ordered lists of transformation rules. A transition sequence in the dependency parser is represented as a graph sequence. In addition, since any change between two successive graphs in the graph sequence comprises at most two changes, the assumption holds.

A labeled graph g is represented as $g = (V, E, L, l)$, where $V = \{1, \cdots, n\}$ is a set of vertices, $E \subseteq V \times V$ is a set of edges, and L is a set of labels such that $l : V \cup E \to L$. In addition, a graph sequence is an ordered list of labeled graphs and is represented as $d = \langle g^{(1)}, \cdots, g^{(z)} \rangle$.

Table 1: TRs used to represent a graph sequence

Vertex Insertion $vi^{(j,k)}_{[u,l]}$	Insert vertex u with label l into $g^{(j,k)}$ to transform to $g^{(j,k+1)}$.
Vertex Deletion $vd^{(j,k)}_{[u,\bullet]}$	Delete an isolated vertex u in $g^{(j,k)}$ to transform to $g^{(j,k+1)}$.
Vertex Relabeling $vr^{(j,k)}_{[u,l]}$	Relabel the label of vertex u in $g^{(j,k)}$ as l to transform to $g^{(j,k+1)}$.
Edge Insertion $ei^{(j,k)}_{[(u_1,u_2),l]}$	Insert an edge with label l between vertices u_1 and u_2 in $g^{(j,k)}$ to transform to $g^{(j,k+1)}$.
Edge Deletion $ed^{(j,k)}_{[(u_1,u_2),\bullet]}$	Delete an edge between vertices u_1 and u_2 in $g^{(j,k)}$ to transform to $g^{(j,k+1)}$.
Edge Relabeling $er^{(j,k)}_{[(u_1,u_2),l]}$	Relabel a label of an edge between vertices u_1 and u_2 in $g^{(j,k)}$ as l to transform to $g^{(j,k+1)}$.

To represent a graph sequence compactly, we focus on the differences between two successive graphs $g^{(j)}$ and $g^{(j+1)}$ in the sequence.

Definition 5 *The differences between graphs $g^{(j)}$ and $g^{(j+1)}$ in d are interpolated by a virtual sequence $d^{(j)} = \langle g^{(j,1)}, \cdots, g^{(j,m_j)} \rangle$, where $g^{(j,1)} = g^{(j)}$ and $g^{(j,m_j)} = g^{(j+1)}$. The graph sequence d is represented by $d = \langle d^{(1)}, \cdots, d^{(z-1)} \rangle$.* ■

The order of graphs $g^{(j)}$ represents the order of the graphs in an observed sequence. On the other hand, the order of graphs $g^{(j,k)}$ is the order of graphs in the artificial graph sequences, and there can be various artificial graph sequences between graphs $g^{(j)}$ and $g^{(j+1)}$. We limit the artificial graph sequences to be compact and unambiguous by taking the one with the shortest length in terms of the graph edit distance to reduce both the computational and spatial costs.

Definition 6 *Let the transformation of a graph by either insertion, deletion, or relabeling of a vertex or an edge be a unit, and let each unit have edit distance 1. A graph sequence $d^{(j)} = \langle g^{(j,1)}, \cdots, g^{(j,m_j)} \rangle$ is defined as an artificial graph sequence in which the edit distance between any two successive graphs is 1 and the edit distance between any two graphs is the minimum.* ■

Transformations are represented in this paper by the following "transformation rule (TR)".

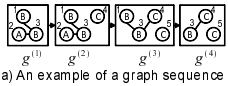
Definition 7 *A TR transforming $g^{(j,k)}$ to $g^{(j,k+1)}$ is represented by $tr^{(j,k)}_{[o_{jk},l_{jk}]}$, where*

- *tr is the transformation type that is either insertion, deletion, or relabeling of a vertex or edge,*
- *o_{jk} is the vertex or edge to which the transformation is applied, and*
- *$l_{jk} \in L$ is a label to be assigned to the vertex or edge in the transformation.* ■

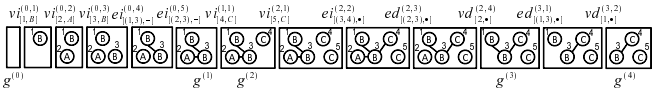
For the sake of simplicity, we simplify $tr^{(j,k)}_{[o_{jk},l_{jk}]}$ to $tr^{(j,k)}_{[o,l]}$ using the six TRs listed in Table 1. In summary, we define a transformation sequence as follows.

Definition 8 *A graph sequence $d^{(j)} = \langle g^{(j,1)}, \cdots, g^{(j,m_j)} \rangle$ is represented by $seq(d^{(j)}) = \langle tr^{(j,1)}_{[o,l]}, \cdots, tr^{(j,m_j-1)}_{[o,l]} \rangle$. Moreover, a graph sequence $d = \langle g^{(1)}, \cdots, g^{(z)} \rangle$ is represented by a transformation sequence $seq(d) = \langle seq(d^{(0)}), \cdots, seq(d^{(z-1)}) \rangle$.* ■

The notation for transformation sequences is far more compact than the original graph-based representation since only differences between two successive graphs in d are kept in the sequence. In addition, any graph sequence can be represented by the six TRs in Table 1.



(a) An example of a graph sequence d.



(b) Representation of the graph sequence d by using TRs.

Figure 7: Graph sequence and its TRs

Example 2 *The graph sequence d in Fig. 7(a) can be represented by a sequence of insertions and deletions of vertices and edges, as shown in Fig. 7(b). The transformation sequence is represented as* $\langle vi^{(0,1)}_{[1,B]} vi^{(0,2)}_{[2,A]} vi^{(0,3)}_{[3,B]} ei^{(0,4)}_{[(1,3),-]} ei^{(0,5)}_{[(2,3),-]} vi^{(1,1)}_{[4,C]} vi^{(2,1)}_{[5,C]} ei^{(2,2)}_{[(3,4),-]} ed^{(2,3)}_{[(2,3),\bullet]} vd^{(2,4)}_{[2,\bullet]} ed^{(3,1)}_{[(1,3),\bullet]} vd^{(3,2)}_{[1,\bullet]} \rangle$*, where "–" denotes an edge label.*

When transformation sequence s'_d is a subsequence of transformation sequence s_d, denoted as $s'_d \sqsubseteq s_d$, there is a mapping ϕ from vertex IDs in s'_d to those in s_d. We omit a detailed definition thereof owing to lack of space (see (Inokuchi and Washio, 2008) for the details). Given a set of graph sequences $DB = \{d \mid d = \langle g^{(1)}, \cdots, g^{(z)} \rangle\}$, we define a support $sup(s_p)$ of transformation sequence s_p as $sup(s_p) = |\{d \mid d \in DB, s_p \sqsubseteq seq(d)\}|/|DB|$. We call a transformation sequence whose support is no less than the minimum support sup', a frequent transformation subsequence (FTS). Given a set of graph sequences, GTRACE enumerates a set of all FTSs from the set according to the anti-monotonic property of the support. GTRACE-RS (Inokuchi et al., 2012) which is an extended version of GTRACE first mines FTSs each of which consists of a TR. It then mines FTSs by recursively adding one TR to the mined FTS.

4 Mining Rules for Rewriting States

As mentioned in Section 2, if the parser shown in Fig. 2 adds an incorrect dependency between words once, it never reaches the correct final state. Even if the parser keeps track of multiple candidate outputs using the beam search principle, sometimes all the multiple candidates reach incorrect final states. In this study, we set out to discover rules for rewriting states reaching incorrect final states to those reaching the correct final states from a corpus $D = \{(x, g)\}$ consisting of sentences $x = \langle w_0, w_1, \cdots, w_n \rangle$ and their dependency graphs g. The rewriting rules state that "if state c_g contains graph p as a subgraph, the state is transformed to another state using a certain TR". The rewriting rules contain knowledge about why the dependency parser outputs the incorrect final states and what should be done to fix these incorrect states. Since p and c_g can also be represented as TRs, each rewriting rule is represented as a sequences of TRs.

To mine these rewriting rules, it needs to be determined how to generate the input graph sequences for GTRACE from transition sequences of the dependency analysis. For the sake of simplicity, we assume that the beam width of the parser is 1. Let $C_{1,m}(x) = \langle c_g^{(1)}, c_g^{(2)}, \cdots, c_g^{(m)} \rangle$ be a transition sequence from the initial state, $c_g^{(1)}$, to the correct final state, $c_g^{(m)} = g$, for sentence $(x, g) \in D$. In addition, let $C'_{1,m'}(x) = \langle c_g^{(1)}, \cdots, c_g^{(k-1)}, c_g'^{(k)}, c_g'^{(k+1)}, \cdots, c_g'^{(m')} \rangle$ be another transition sequence for x, where the parser selects the incorrect transition between $c_g^{(k-1)}$ and $c_g'^{(k)}$ for some $k > 1$. One way of generating a graph sequence from transition sequence $C'_{1,m'}(x)$ is to append the correct final state g to the transition sequence after the parser outputs the incorrect final state; i.e., $d_A = \langle c_g^{(1)}, \cdots, c_g^{(k-1)}, c_g'^{(k)}, c_g'^{(k+1)}, \cdots, c_g'^{(m')}, g \rangle$.

We define rewriting rules R to be mined from the graph sequences in the form of d_A as FTSs, each of which contains a subsequence of $seq(C'_{1,m'}(x))$ and TRs to transform $c_g'^{(m')}$ to g; i.e.,

$$R = \{s_1 \Diamond s_2 \mid s_1 \sqsubseteq seq(C'_{1,m'}(x)),\ s_2 \sqsubseteq seq(\langle c_g'^{(m')}, g\rangle),\ (x,g) \in D,\ sup(s_1 \Diamond s_2) \geq sup'\}, \quad (1)$$

where sup' and $s_1 \Diamond s_2$ are the minimum support threshold and the concatenation of transformation sequences s_1 and s_2, respectively. We refer to s_1 of r in R as the precondition of rewriting rule r. Another way of generating a graph sequence from the transition sequence is to append the correct state $c_g^{(k)}$ to its transition subsequence immediately after the parser selects the incorrect transition; i.e., $d_B = \langle c_g^{(1)}, \cdots, c_g^{(k-1)}, c_g'^{(k)}, c_g^{(k)}\rangle$. Then, similar to the first approach, rewriting rules are mined from the graph sequences in the form of d_B. Since $f \sqsubseteq seq(d_B) \Rightarrow f \sqsubseteq seq(d_A)$, all FTSs mined from graph sequences generated in the second approach are also mined from those in the first approach. However, the converse does not hold, since d_A contains information about vertices and edges that is not included in d_B. Since this information is not used in feature vectors characterizing $c_g^{(k-1)}$ to select the next transition at state $c_g^{(k-1)}$, this may explain why incorrect dependency graphs are returned by transition-based dependency parsers. In addition, the first approach may contain "maximal" information gathered from the whole dependency graph that is not available during transitions of the conventional parser (Attardi and Ciaramita, 2008). Therefore, we use the first approach to generate graph sequences. In addition, to distinguish TRs in s_1 of Eq. (1) from those in s_2, we assign label l_2 to edges in g that are not in $c_g'^{(m')}$, and label l_1 to all other edges.

Example 3 *Figure 8 shows a graph sequence generated by appending the correct final state g to the transition sequence for the sentence in Example 1, where the parser selects an incorrect transition from $c_g^{(5)}$ to $c_g'^{(6)}$. Since edge $(2,4)$ is not in $c_g'^{(6)}$ but is in g, label l_2 is assigned to the edge. The transformation sequence of the graph sequence is given as* $\langle vi^{(0,1)}_{[0,\$]} vi^{(0,2)}_{[0,root]} vi^{(0,3)}_{[1,I]} vi^{(0,4)}_{[1,PRP]} vi^{(1,1)}_{[2,saw]} vi^{(1,2)}_{[2,VBD]} ei^{(2,1)}_{[(2,1),l_1]} vr^{(2,2)}_{[1,reduced]} ei^{(3,1)}_{[(0,2),l_1]} vi^{(3,2)}_{[3,him]} vi^{(3,3)}_{[3,PRP]} ei^{(4,1)}_{[(2,3),l_1]} vi^{(4,2)}_{[4,.]} vi^{(4,3)}_{[4,'.']} ed^{(5,1)}_{[(2,3),\bullet]} ei^{(5,2)}_{[(2,4),l_2]}\rangle$*, where ROOT, PRP, VBD, and '.' are the parts of speech (POSs) of the corresponding words*[1].

Let $r = \langle vi^{(0,1)}_{[0,root]} vi^{(1,1)}_{[2,VBD]} ei^{(3,1)}_{[(0,2),l_1]} ei^{(4,1)}_{[(2,3),l_1]} vi^{(4,2)}_{[4,.]} ei^{(5,1)}_{[(2,4),l_2]}\rangle$ be a rewriting rule. If the parser has the rewriting rule r and is in state $c_g'^{(6)}$ in Example 3, the method proposed in this paper deletes edge $(3,4)$ from $c_g'^{(6)}$, and adds edge $(2,4)$ to $c_g'^{(6)}$, by applying r to transit to another state g in Fig. 4 that can reach the correct final state, since the transformation sequence of transition sequence $\langle c_g^{(1)}, \cdots, c_g^{(5)}, c_g'^{(6)}\rangle$ contains the precondition of r as a subsequence. Therefore, the

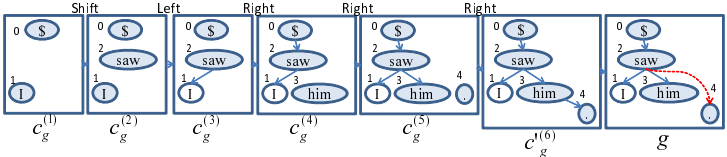


Figure 8: Graph sequence for a transition sequence

[1] We have *a priori* knowledge that each vertex in a state has at most one parent. Therefore, the fact that a TR t for inserting an edge labeled l_2 exists in transformation sequence s indicates that another TR for deleting an edge whose dependent is identical to t must exist in s. For this reason, in our implementation, we do not include TRs for deleting edges in s to reduce the computation time of GTRACE, which increases exponentially with the average length of the transformation sequences in its input.

rewriting rule that transforms from $c_g'^{(6)}$ to g corresponds to a bypass between states in the search space.

GTRACE mines a vast set of FTSs, R, in Eq. (1) from the graph sequences. Next, we discuss how to select certain FTSs from these. Desirable rewriting rules are those that rewrite states reaching incorrect final states to those reaching the correct final states. By rewriting states, the attachment score for a parser using rewriting rules should be better than that for a parser without rewriting rules. This is achieved by selecting the rewriting rule satisfying the following equation.

$$r = \arg\max_{r \in R} \left[\frac{1}{|D|} \sum_{x \in D} \#p(S_r, x) - \#p(S, x) \right], \tag{2}$$

where S_r and S are transition-based parsers with and without rewriting rule r, and $\#p$ is the number of words with correct parents in the dependency graph returned by the parser for sentence x. If $r = s_1 \Diamond s_2$ is a rule in R as given in Eq. (1), $|D| \times \sup(s_1 \Diamond s_2)$ and $|D| \times \big(\sup(s_1) - \sup(s_1 \Diamond s_2)\big)$ are the expected numbers of sentences in D, correctly and incorrectly rewritten by r, respectively. Thus, we obtain the following approximation.

$$\frac{1}{|D|} \sum_{x \in D} \#p(S_r, x) - \#p(S, x) \simeq \sup(s_1 \Diamond s_2) - \big(\sup(s_1) - \sup(s_1 \Diamond s_2)\big) = 2\sup(s_1 \Diamond s_2) - \sup(s_1). \tag{3}$$

We select certain FTSs that maximize the right-hand side of Eq. (3) from R. In addition, we limit the mined rewriting rules such that the number of TRs in s_2 is 1, which is denoted as $|s_2| = 1$, for the following reason. If there is a rewriting rule $r = s_1 \Diamond s_2$ that correctly rewrites a state c into c', where $s_2 = \langle tr_1 tr_2 \rangle$ consists of two TRs, we divide r into $r_1 = s_1 \Diamond tr_1$ and $r_2 = s_1' \Diamond tr_2$, where $s_1' = s_1 \Diamond tr_1$. If r_1 rewrites a state c into another state c'', the state c'' is rewritten into c' by r_2. Even if we limit the mined rewriting rules such that $|s_2| = 1$, we can mine r_1 and r_2, and the state c can be rewritten correctly by r_1 and r_2. In addition, by the limitation, we efficiently mine all rewriting rules because mining rewriting rules is a combinatorial problem of TRs.

We propose a method for mining rewriting rules from transition sequences traversed by a dependency parser. For the sake of simplicity of explanation, we first explain the basic algorithm for mining rewriting rules from transition sequences generated by a transition-based parser with beam width 1, and then expand it using a dependency parser incorporating the beam search principle. The left part of Fig. 9 gives the pseudo-code for mining the set of rewriting rules R from the transition sequences. Let D be a corpus $D = \{(x, g)\}$ consisting of sentences $x = \langle w_0, w_1, \cdots, w_n \rangle$ and their dependency graphs g. In line 6a, ParseWithRules returns a transition sequence d by parsing sentence x using the rewriting rules R. Next, in line 7a, after appending g to the tail of d, denoted by $\langle d \Diamond g \rangle$, $\langle d \Diamond g \rangle$ is added to DB. Subsequently, in line 8a, the attachment score is updated after comparing the final state $c_g^{(m)}$ with the correct dependency g of sentence x. In line 9a, if the attachment score for $R \cup \{r\}$ is not greater than that for R, R is returned. Otherwise, r is added to R. In line 13a, a rewriting rule r satisfying Eqs. (2) and (3) is mined from the FTSs enumerated by GTRACE from DB under the minimum support threshold sup'.

The right part of Fig. 9 gives the pseudo-code for parsing sentence x using the rewriting rules R to return a transition sequence for x. The procedures, except for those in lines b6 to b13, are similar to those in Fig. 2. In line b5, the last state in the transition sequence d is substituted

16b) return $C_{andidates}$

Figure 9: Algorithms for mining rewriting rules and parsing using the rules (beam width is 1)

into c_g by function $last$. All possible transition sequences for c_g are generated in line 14b, and the best of these is selected by function $best$ in line 14b. If there is a rewriting rule whose precondition is contained in $seq(d)$ and its mapping ϕ from vertex IDs in the precondition of r to vertex IDs in $seq(d)$, state $c_g = (N, A, N')$ is rewritten in line 10b or 12b and the parser transits to another state. In line 10b, edge (i, j) corresponding to (a, b), is added to A. In addition, if the j-th word has another parent i' different from i, edge (i', j) is deleted from A in line 12b.

In the case of a parser using a beam search with width b, ParseWithRules returns a set of transition sequences $=\{d_i \mid i = 1, \ldots, b\}$, instead of a single transition sequence. We assume that d_1 is the transition sequence whose final state has the best score of all $\{d_i\}$. If the final state of d_1 is isomorphic to g, we do not append g to d_i for any i, because we do not need any rewriting rules to transform states in transition sequences for sentences for which the parser returns correct final states. Otherwise, after appending g to the tail of each d_i, denoted by $\langle d_i \Diamond g \rangle$, $\langle d_i \Diamond g \rangle$ is added to DB similarly to the case in line a7. Therefore, DB consists of $|D| \times b$ graph sequences. On the other hand, the code for ParseWithRules incorporating the beam search principle is almost the same as the original. In line 15b, the b best transition sequences are selected from A_{genda} by function $best$.

5 Experiments

We evaluated the proposed method using English Penn Treebank data. We used Yamada's head rules to convert the phrase structure to a dependency structure (Yamada and Matsumoto, 2003). We also used the averaged perceptron algorithm with early-update strategy (Collins and Roark, 2004), where weights are updated whenever the gold-standard action-sequence falls off the beam, while the rest of the sequence is ignored. The idea behind this strategy is that later mistakes are often caused by earlier ones, and are irrelevant if the parser is already on the wrong track (Huang and Sagae, 2010).

We split the Wall Street Journal part of the corpus into sections 02-11 for training, sections

12-21 for mining rewriting rules, and section 22 for development. The set of feature templates in Zhang and Clark (2008) characterizing states in the parser was used. Figures 10, 13, and 14 show three of the few dozen rewriting rules mined using the proposed method under a minimum support threshold of 0.05% and beam width of 4, where h, i, j, k, and l are word IDs satisfying $h < i < j < k < l$, and the terms in each circle are words or their POS-tags. The minimum support threshold was set through trial and error using the development data. The supports $sup(s_1)$ and $sup(s_1 \Diamond s_2)$ of the rule shown in Fig. 10 are 1.22% and 0.95%, respectively. In addition, Fig. 11 shows some of the sentences in the corpus whose transition sequences are correctly rewritten by the rule. In Fig. 11, the annotations i, j, and h after words correspond to the respective word IDs in Fig. 10. Here, we explain the rule using concrete examples. The two sentences

- "$ Dozens of workers were injured." and
- "$ Dozens of workers were injured, authorities said."

and their correct dependency graphs, are shown on the left and right sides of Fig. 12, respectively. If the parser is in state $c_g^{(6)}$, where $\sigma = [0]$ and $\beta = [4, 5, \cdots, n]$, when parsing the first sentence, it usually selects Right to transit to the next state. Similarly, the parser incorrectly selects Right, instead of Shift, to transit to the next state from $c_g^{(6)}$ when parsing the second sentence. This is because when the parser is in state $c_g^{(6)}$, it does not know whether the phrase "authorities said." occurs at the end of the sentence. As mentioned in Section 2, if the parser shown in Fig. 2 adds an incorrect dependency between words once, it never reaches the correct final state. This rule rewrites the fifth state $g^{(5)}$ by deleting edge (i, j) and adding edge (h, j) without backtracking. Since we limit the mined rewriting rules to $r = s_1 \Diamond s_2$ where $|s_2| = 1$, this rule does not include deleting edge (h, i) and adding edge (j, i) in $g^{(5)}$ in the rewrite. However, we obtained another rewriting rule to do this.

The rewriting rule shown in Fig. 13 suggests that our parser incorrectly parses sentences containing "because of NN". The supports, $sup(s_1)$ and $sup(s_1 \Diamond s_2)$, of the rule are 0.71% and 0.54%, respectively. We assume that the parser is in state $(\sigma, \beta, A) = ([\cdots, h, i], [j, \cdots], A)$, where w_h ="because", w_i ="of", the POS-tag for w_j is NN (noun, singular or mass), and $(h, i) \in A$. Since the parser using the feature templates in Zhang and Clark (2008) does not know what the word for the parent of the stack top is, the parser incorrectly selects Right, instead of Reduce, to transit to the next state. This rule rewrites state $g^{(5)}$ by deleting edge (i, j) and adding edge (h, j), after the parser adds an incorrect edge.

The supports, $sup(s_1)$ and $sup(s_1 \Diamond s_2)$, of the rule shown in Fig. 14 are 0.053%. After mining the rewriting rule, we investigated words corresponding to vertices h, i, and j by scanning the corpus. The words, (w_h, w_i, w_j), were either (Procter, &, Gamble), (Peabody, &, Co.), (Ogilvy, &, Mather), (Young, &, Rubicam), (Shea, &, Gould), (Standard, &, Poor), (Bausch, &, Lomb), or (Dun, &, Bradstreet). The trigram of words comprising each triplet is a compound proper noun. The rule suggests incorrect parsing of words consisting of proper compound nouns. Since the parser does not know that the triplets are proper compound nouns, it cannot

$(h) Dozens of workers were(i) injured, authorities said(j).
$(h) But the Fed move was(i) a small gesture, traders said(j).
$(h) Mr. Agnos declined(i) the invitations, the White House said(j).
$(h) They continued(i) to represent that to the board," said(j) Mr. Lloyd.
$(h) Some laggard food issues attracted(i) bargain-hunters, traders said(j).

Figure 11: Sentences for which the rule in Fig. 10 correctly rewrites transition sequences

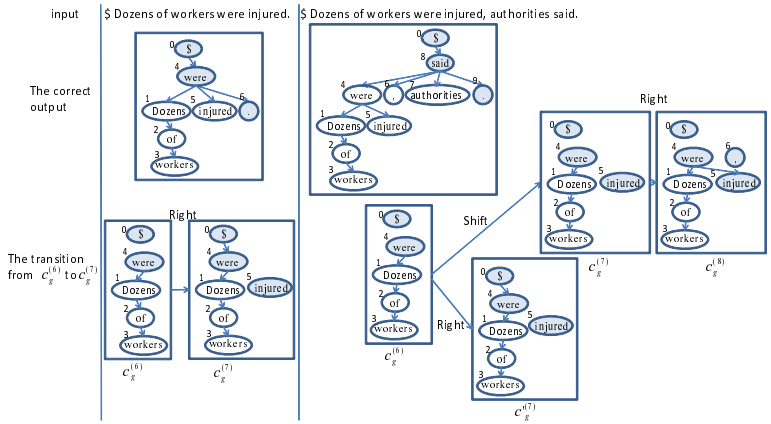

Figure 12: Transition of two similar sentences

correctly parse sentences containing "A & B's NN", where "A & B" is a proper compound noun. This rule rewrites state $g^{(9)}$ by deleting edge (l, j) and adding edge (i, j).

As shown above, the proposed method has the benefits that the rules mined by the method are human-readable and easily understandable. In addition, the rewriting rules contain context that is more complex and detailed than a set of features of the conventional parser, because of the use of the graph representation. Furthermore, if the mined rules are valid grammatically, and a dependency structure obtained by the proposed method, after being rewritten by the rules, is different from a dependency structure in the corpus made by humans, the latter dependency structure may contain incorrect dependencies. The proposed method is therefore also useful for rectifying human errors in the corpus.

According to the knowledge obtained from the mined rewriting rules, we designed three new types of feature templates characterizing states in the parser. First, according to the knowledge obtained from the first rewriting rule, we added feature templates N0w∘Flag and N0t∘Flag, where N0w and N0t denote the word at the top of the stack and its POS-tag in the parser, respectively, Flag is either true or false, and N0w∘Flag and N0t∘Flag are their concatenations. Flag is true, if one of the words "said", "say", or "says" appears after N0w in the sentence. Flag can be calculated in time linear to the length of the sentence during preprocessing. Since features of these templates provide the parser with information on whether a sentence contains "said", "say" or "says" at the end, the parser has a high probability of correctly parsing such sentences. Second, according to knowledge obtained from the second rewriting rule, we added feature templates SPTw∘STw∘N0t and SPTw∘STt∘N0t, where STw, STt, and STPw are the word at the top of the stack, its POS tag, and the word at the parent of the stack top, respectively. The

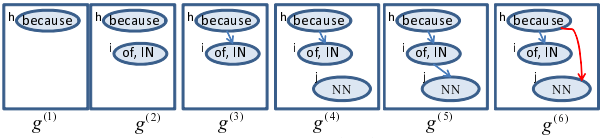

Figure 13: Mined rule #2

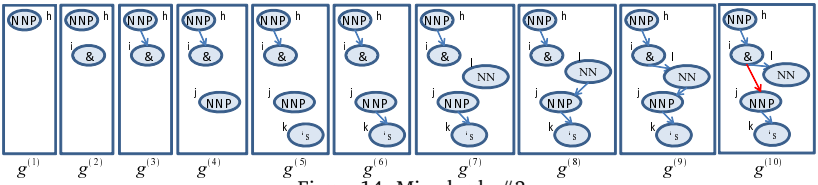

Figure 14: Mined rule #3

arc-eager shift -reduce parser using these feature templates has word information on the parent of the stack top, and is expected to parse sentences containing "because of NN" correctly. Third, according to knowledge obtained from the third rewriting rule, we added feature templates N-2w∘N-1w∘N0w, N-1w∘N0w∘N1w, and N0w∘N1w∘N2w, where N0w is the word at the buffer top, and N-2w, N-1w, N1w, and N2w are words before and after that word. Therefore, N-2w∘N-1w∘N0w, N-1w∘N0w∘N1w, and N0w∘N1w∘N2w are trigrams containing N0w in a sentence. The arc-eager shift-reduce parser using these feature templates is expected to parse sentences containing proper compound nouns correctly.

Figure 15 shows (1) the attachment scores for an arc-eager shift-reduce parser using only the conventional feature templates in Zhang and Clark (2008), (2) that using the feature templates given above as well as the conventional feature templates, and (3) that using the feature templates given above as well as the conventional feature templates and mined rewriting rules[2] for various beam widths. In these experiments, we split the WSJ part of the corpus into sections 02-21 for training, section 22 for development, and section 23 for testing. The figure shows that attachment scores are improved by adding the new feature templates to the conventional feature templates. In particular, the degree of improvement is large when the beam width is small. Although we used knowledge obtained from the three rewriting rules, greater improvement is expected by mining more rewriting rules and designing more feature templates based on the knowledge obtained from these rules. Table 2 reproduces the attachment scores for various dependency parsers given in Hayashi et al. (2012) including those of our proposed method. The table shows that our method is comparable to parsers of the latest studies with respect to the attachment score.

6 Conclusion

This paper proposed a method for mining rewriting rules from transition sequences of an arc-eager dependency parser incorporating the beam search principle for English sentences. The rewriting rules mined by the proposed method are human-readable, and it is possible for us to design new parsers and to generate feature templates for the machine learner of the parser to avoid producing incorrect dependency graphs. In this study, we used GTRACE to analyze transition sequences, although there are other data structures for representing graph sequences,

[2]Result using rewriting rules with beam with 64 was not obtainable due to memory overflow.

such as dynamic graphs (Borgwardt et al., 2006) and evolving graphs (Berlingerio et al., 2009), and algorithms for mining the graphs. Since insertions of vertices cannot be represented by dynamic graphs, and a vertex in an evolving graph always comes with an edge connected to the vertex, these data structures cannot be used to analyze transition sequences in transition-based parsers to mine rewriting rules. Compared with dynamic graphs and evolving graphs, the class of graph sequences is, therefore, general enough to apply to the analysis of transition sequences.

Revision rules proposed in Ahmed and Karypis (2011) transform only edges in dependency structures output by the dependency parser in post-processing. Since it is assumed that revision rules do not remove or add any vertices in the dependency structures, the revision rules cannot be applied to phrase structure analysis. On the other hand, rewriting rules transform states in the transition-based dependency parser. Since the method proposed in this paper can basically be applied to any transition systems whose internal states are represented by graphs, it can be applied to the phrase structure analysis. In addition, rewriting rules are more human-readable than revision rules. Kudo et al. (2005) proposed a method for extracting features represented by trees that are human-readable to obtain high attachment scores. Using the features, the transition-based parser selects a correct transition in each state. Compared with that method, using our method proposed in this paper, we obtain knowledge about why incorrect dependency graphs are returned by transition-based dependency parsers and knowledge about how we transform incorrect states into correct states.

ABSTRACT
This paper presents the first systematic study of the coreference resolution problem in a general inference-based discourse processing framework. Employing the mode of inference called weighted abduction, we propose a novel solution to the overmerging problem inherent to inference-based frameworks. The overmerging problem consists in erroneously assuming distinct entities to be identical. In discourse processing, overmerging causes establishing wrong coreference links. In order to approach this problem, we extend Hobbs et al. (1993)'s weighted abduction by introducing weighted unification and show how to learn the unification weights by applying machine learning techniques. For making large-scale processing and parameter learning in an abductive logic framework feasible, we employ a new efficient implementation of weighted abduction based on Integer Linear Programming. We then propose several linguistically motivated features for blocking incorrect unifications and employ different large-scale world knowledge resources for establishing unification via inference. We provide a large-scale evaluation on the CoNLL-2011 shared task dataset, showing that all features and almost all knowledge components improve the performance of our system.

KEYWORDS: weighted abduction, coreference resolution, Integer Linear Programming.

1 Introduction

In this paper, we explore coreference resolution in a discourse processing framework based on a mode of inference called *weighted abduction* (Hobbs et al., 1993). This framework is appealing because it is a realization of the observation that we understand new material by linking it with what we already know. It instantiates in natural language understanding the more general principle that we understand our environment by coming up with the best explanation for the observables in the environment. Hobbs et al. (1993) show that the lowest-cost abductive proof provides the solution to a whole range of natural language pragmatics problems, such as word sense disambiguation, anaphora and metonymy resolution, interpretation of noun compounds and prepositional phrases and detection of discourse relations. For examples of the application of weighted abduction to discourse processing see (Charniak and Goldman, 1991; Inoue and Inui, 2011; Ovchinnikova et al., 2011; Ovchinnikova, 2012).

If weighted abduction is applied to discourse processing, coreference links naturally follow as a by-product of constructing best explanations. In weighted abduction, coreference resolution is equal to unification of predications; see Sec. 3.1. Similarly, if deductive model building is applied to discourse interpretation, coreference links result from the model minimality. Both inference approaches are based on the idea that predications having the same predicates describe the same situation and therefore their arguments can be assumed to be equal if no logical contradictions follow. If the necessary knowledge is missing from the knowledge base, both the deductive and the abductive procedures are likely to miss relevant coreference links and establish wrong links (overmerge entities). The *overmerging* problem is a serious obstacle in applying reasoning to discourse processing, because it leads to a large number of incorrect inferences; see (Ovchinnikova, 2012) for examples. There have been attempts to employ semantic similarity for merging predications in a deductive framework (Dellert, 2011) and attempts to use linguistically motivated constraints in order to prohibit incorrect unification in an abductive framework (Ovchinnikova et al., 2011; Ovchinnikova, 2012). However, the issue of overmerging was never systematically studied and the proposed solutions were never evaluated. In this paper, we investigate whether adding linguistically motivated features can help to block incorrect links in an inference-based framework.

A lot of effort in NLP was put into coreference resolution systems ranging from rule-based (Lee et al., 2011, etc.) to machine learning-based resolvers (Soon et al., 2001; Ng and Cardie, 2002; Fernandes et al., 2012, etc.); see (Ng, 2010) for a detailed survey. Coreference resolution may require deep understanding of text, access to world knowledge, and inference ability. For example, (Levesque, 2011) considers twin sentences such as *Ed shouted at Tim because he crashed the car* and *Ed shouted at Tim because he was angry*. In order to resolve coreference in these sentences one requires world knowledge about people shouting when being angry and people shouting at someone who made a mistake, e.g., crashed a car. Surprisingly, most of the contemporary coreference resolution systems including the winners of the CoNLL-2011 and CoNLL-2012 shared tasks (Lee et al., 2011; Fernandes et al., 2012) do not exploit any world knowledge. There exist attempts to resolve coreference based on world knowledge resources such as WordNet hierarchy, Wikipedia, semantic similarity, narravite chains (Ponzetto and Strube, 2006; Ng, 2007; Irwin et al., 2011; Rahman and Ng, 2012). Unfortunately, the corresponding resolvers were either not evaluated in large-scale challenges or did not show convincing performance in the challenges. Thus, the question remains open whether employing world knowledge can improve coreference resolution in large unfiltered corpora. In this paper, we investigate whether adding world knowledge for establishing more coreference links can

improve coreference resolution. In the world knowledge employed, our work is most similar to the study on twin sentences presented in (Rahman and Ng, 2012). However, instead of using world knowledge for generating features in a machine learning framework, we explore inference-based discourse processing. Regarding inference, our method may seem related to the coreference resolution research based on Markov Logic Networks (MLNs) (Poon and Domingos, 2008; Song et al., 2012). However, previous MLN-based work on coreference resolution does not incorporate inference rules based on world knowledge.

The key contributions of our work are the following. First, we propose a novel solution to the overmerging problem in an inference-based framework. We extend (Hobbs et al., 1993)'s weighted abduction in order to accommodate unification weights and show how to learn the weights by applying machine learning techniques. For making large-scale processing and parameter learning in an abductive logic framework feasible, we employ a new efficient implementation of weighted abduction based on the Integer Linear Programming technique (Inoue and Inui, 2011).[1] Second, we propose several linguistically motivated features for blocking incorrect unifications and we employ different large-scale world knowledge resources for establishing unification via inference. Third, we report on a large-scale evaluation showing that all features and knowledge components improve the performance.

The structure of this paper is as follows. In Sec. 2, we introduce weighted abduction and its ILP-based implementation. Section 3 describes our discourse processing pipeline based on weighted abduction and discusses the overmerging problem, our solution to it, and types of knowledge we employ for generation of features and axioms. Section 4 presents the experiments on coreference resolution. The final section concludes the paper.

2 Abductive Inference

2.1 Weighted Abduction

Abduction is inference to the best explanation. Formally, logical abduction is defined as follows:

Given: Background knowledge B, observations O, where both B and O are sets of first-order logical formulas,

Find: A hypothesis H such that $H \cup B \models O, H \cup B \not\models \bot$, where H is a set of first-order logical formulas. We say that p is *hypothesized* if $H \models p$, and that p is *explained* if $(\exists q)\ q \rightarrow p \in B$ and q is hypothesized or explained.

Typically, there exist several hypotheses H explaining O. Each of them is called a *candidate hypothesis*. To rank candidate hypotheses according to plausibility, we use the framework of *weighted abduction* as defined by Hobbs et al. (1993). In this framework, observation O is a conjunction of propositions existentially quantified with the widest possible scope. Each proposition has a positive real-valued cost. We use the notation $P^{\$c}$ to indicate that proposition P has cost c and $cost(P)$ to represent the cost of P.

The background knowledge B is a set of first-order logic formulas of the form $P_1^{w_1} \wedge ... \wedge P_n^{w_n} \rightarrow Q_1 \wedge ... \wedge Q_m$. All variables occurring in the antecedent of such axioms are universally quantified with the widest possible scope. Other variables are existentially quantified within the scope of the universal quantifiers. Propositions in the antecedents are assigned positive real-valued *weights*. We use the notation P^w to indicate that proposition P has weight w.

[1] There has been work on applying ILP to coreference (Finkel and Manning, 2008; Denis and Baldridge, 2009), but with no relationship with logical inference.

The two main inference operations in weighted abduction are backward chaining and unification. *Backward chaining* is the introduction of new assumptions given an observation and background knowledge. For example, given $O = \exists x(q(x)^{\$10})$ and $B = \{\forall x(p(x)^{1.2} \rightarrow q(x))\}$, there are two candidate hypotheses: $H_1 = \exists x(q(x)^{\$10})$ and $H_2 = \exists x(p(x)^{\$12})$. In weighted abduction, a *cost function* f is used to calculate assumption costs. The function takes two arguments: costs of the propositions backchained on and weight of the assumption. Usually, a multiplication function is used, i.e. $f(c, w) = c \cdot w$, where c is the cost of the propositions backchained on and w is weight of the corresponding assumption. For example, if $q(x)$ costs \$10 and w of p is 1.2 in the example above, then assuming p in H_2 costs \$12.

Unification is the merging of propositions with the same predicate name by assuming that their arguments are same. For example, $O = \exists x, y(p(x)^{\$10} \wedge p(y)^{\$20} \wedge q(y)^{\$10})$. There is a candidate hypothesis $H = \exists x, y(p(x = y)^{\$10} \wedge x = y^{\$0} \wedge q(x = y)^{\$10})$, where $p(x)^{\$10}$ and $p(y)^{\$20}$ are merged by assuming $x = y$ (called *variable unification assumption*). Hobbs et al. (1993) assign the smallest cost to the result of the unification (i.e. \$10), and zero cost to the variable unification assumption. This principle often causes incompatible entities to be identified (e.g., a dog and a cat) on the basis of slender evidence, since unification always reduces the cost of hypothesis. In order to address this issue, we propose to assign a cost to the variable unification assumption. We use a weighted feature function to assign the cost, where the appropriate weights are learnable from the dataset (see Sec. 3 for further details).

Both operations (backchaining and unification) can be applied to an observation as many times as possible to generate a possibly infinite set of candidate hypotheses. Henceforth, we denote $\mathscr{H}_O$ to represent a set of all possible candidate hypotheses for O. Weighted abduction defines a *cost* of candidate hypothesis H as $cost(H) = \sum_{h \in H} cost(h)$, where h is an atomic conjunct in H also called an *elemental hypothesis* (e.g., $p(x)$ in the above H). In this framework, minimum-cost explanations are best explanations.

2.2 ILP-based Weighted Abduction

Recently, an implementation of weighted abduction based on Integer Linear Programming (ILP) was developed by Inoue and Inui (2011). In this approach the abductive reasoning problem is formulated as an ILP optimization problem. We adopt this solution since (i) the ILP-based reasoner is significantly more efficient than existing implementations of weighted abduction (Inoue and Inui, 2011), and (ii) its declarative nature makes it is highly extensible (Sec. 3).

Given B and O, the framework first enumerates set P of *potential elemental hypotheses* (atomic assumptions). Then it generates ILP variables and constraints based on this set to represent all possible *candidate hypotheses*. The four main ILP variables are $h_p \in \{0,1\}$, $r_p \in \{0,1\}$, $u_{p,q} \in \{0,1\}$, and $s_{x,y} \in \{0,1\}$, where p, q are potential elemental hypotheses and x, y are first-order logical variables or constants used in P. h_p is used to represent whether p is hypothesized ($h_p = 1$) or not ($h_p = 0$). r_p is used to represent whether p pays its cost ($r_p = 0$) or not (p is explained, $r_p = 1$). The ILP objective function is as follows.

$$\text{min. } cost(H) = \sum_{p \in \{p | p \in P, h_p = 1, r_p = 0\}} cost(p) \tag{1}$$

Thus, the cost of H is the sum of the costs of $p \in P$, such that p is included in the hypothesis ($h_p = 1$) and is *not* explained ($r_p = 0$). That is, the backchaining bottoms out in p.

The space of candidate hypotheses is restricted by several ILP constraints. For example, one of the constraints allows us to set $r_p = 1$ (p does not pay its cost) only if at least one proposition $q \in Q$, where Q is a set of propositions that explain p, is hypothesized ($h_q = 1$). The ILP formulation of this constraint is $r_p \leq \sum_{q \in Q} h_q$.

In order to represent unification of two propositions p and q we introduce variables u and s, such that $u_{p,q} = 1$ if p and q are unified and $u_{p,q} = 0$ otherwise; $s_{x,y} = 1$ if variables x and y are set to be equal and $s_{x,y} = 0$ otherwise. Additional constraints are defined on these variables. For example, $p(x_1, x_2, ..., x_n)$ and $p(y_1, y_2, ..., y_n)$ can be unified ($u_{p(x_1,x_2,...,x_n),p(y_1,y_2,...,y_n)} = 1$) only if their corresponding arguments are assumed to be equal (for all $i \in \{1, 2, ..., n\}$, $s_{x_i,y_i} = 1$). This is captured by the following ILP constraint: $n \cdot u_{p(x_1,x_2,...,x_n),p(y_1,y_2,...,y_n)} \leq \sum_{i=1}^{n} s_{x_i,y_i}$.

Formulation of the ILP constraints corresponding to variable inequality is rather straightforward.[2] For each pair of variables x and y such that $x \neq y \in P$, the following equality is introduced: $s_{x,y} = 0$.

3 Coreference Resolution in ILP-based Abductive Framework

3.1 Abduction for Discourse Processing

Abductive reasoning can be used to recover implicit information from natural language texts. The implicit information includes semantic relations between discourse entities, anaphoric relations, character's intentions, etc; see (Hobbs et al., 1993) for detailed examples.

A logical form (LF) of a text represents observations, which need to be explained by background knowledge. In our discourse processing pipeline, a text is first input to the English parser *Boxer* (Bos, 2008). For each segment, the parse produced by *Boxer* is a first-order fragment of the DRS language used in Discourse Representation Theory (Kamp and Reyle, 1993). An add-on to *Boxer* converts the DRS into a logical form in the style of (Hobbs, 1985).

The LF is a conjunction of propositions, which have generalized eventuality arguments that can be used for showing relationships among the propositions. According to (Hobbs, 1985), any predication in the logical notation has an extra argument, which refers to the "condition" of that predication being true. Thus, in the logical form $John(e_1, j) \wedge run(e_2, j)$ for the sentence *John runs*, e_2 is a running event by John and e_1 is a condition of j being named "John".

In the context of discourse processing, we call a hypothesis explaining a logical form *an interpretation* of this LF. The interpretation of the text is carried out by an abductive system. The system tries to prove the logical form of the text, allowing assumptions where necessary. Where the system is able to prove parts of the LF, it is anchoring it in what is already known from the overall discourse or from a knowledge base. Where assumptions are necessary, it is gaining new information.

Let us illustrate the procedure with an example implying coreference resolution. Suppose we need to interpret the text *John gave Bill a book; he was happy to have it*. A simplified logical form of this sentence is as follows:

$John(e_1, x_1) \wedge give(e_2, x_1, x_2, x_3) \wedge Bill(e_3, x_2) \wedge book(e_4, x_3) \wedge he(e_5, x_4) \wedge have(e_6, x_4, x_5) \wedge it(e_7, x_5)$

Suppose our knowledge base contains the following axioms

[2] See (Inoue and Inui, 2012) for the ILP representation of negated propositions.

(1) $give(e_1, x_1, x_2, x_3) \rightarrow get(e_2, x_2, x_3)$
(2) $get(e_1, x_1, x_2) \rightarrow have(e_2, x_1, x_2)$

Given these axioms, we can backchain on $have(e_6, x_4, x_5)$ to $give(e_0, u, x_5, x_4)$. After unifying this proposition with $give(e_2, x_1, x_2, x_3)$, we can infer the equality $x_2 = x_4$ and $x_3 = x_5$, which corresponds to linking *he* to *Bill* and *it* to *book* in the sentence.

3.2 Weighted Unification

Frequently, the lowest-cost interpretation results from identifying two entities with each other, so that their common properties only need to be proved or assumed once. This feature of the algorithm is called "unification", and is one of the principal methods by which coreference is resolved. A naive approach to coreference in an inference-based framework is to unify propositions having the same predicate names unless it implies logical contradictions (Hobbs et al., 1993; Bos, 2011). However, in situations when knowledge necessary for establishing contradictions is missing, the naive procedure results in *overmerging*. For example, given $O = animal(e_1, x) \wedge animal(e_2, y)$, weighted abduction incorrectly assumes x equals y even when $dog(e_3, x)$ and $cat(e_4, y)$ are observed. For *John runs and Bill runs*, with the observations $O = John(e_1, x) \wedge run(e_2, x) \wedge Bill(e_3, y) \wedge run(e_4, y)$, weighted abduction assumes John and Bill are the same individual just because they are both running. If we had complete knowledge about disjointness (*dog* and *cat* are disjoint, people have unique first names), the overmerging problem might not occur because of logical contradictions. However, it is not plausible to assume that we would have an exhaustive knowledge base.

In this study, we impose costs on variable unification assumptions in order to avoid the overmerging. If the unification weights are introduced, unification does not always reduce the overall cost of the hypothesis anymore, which loosens the assumption that all propositions with the same predicate names are coreferential.

How can we define unification weights? The cost of a variable unification assumption, say $x = y$, depends on the properties of x and y. For example, it depends on lexico-syntactic properties. If *x is different from y* or *x writes y* are observed in a text then its unlikely that x and y refer to the same entity. At the same time, observations like $dog(x) \wedge animal(y)$ serve as an evidence that x and y might be coreferential.

We extend the ILP-based weighted abduction framework developed by (Inoue and Inui, 2011) and use a feature-based linear function $\phi(x, y)$ to determine a cost of $x = y$. Features are based on various types of knowledge (see Sec. 3.3). In order to compute the weight of each feature, we parametrize the feature function by a n-dimensional real-valued weight vector $\mathbf{w} = \{w_1, w_2, ..., w_n\}$, and propose to tune $\mathbf{w}$ in a supervised manner.

In order to exploit the cost of variable unification assumptions in the reasoning process, we extend the ILP-based objective function for weighted abduction equation (1) as follows:

$$\text{min. } cost(H; \mathbf{w}) = \frac{1}{Z} \sum_{p \in \{p | p \in P, h_p = 1, r_p = 0\}} cost(p) + \frac{1}{|T_p|^2} \sum_{x,y \in T_p} \sum_{i}^{n} w_i \cdot f_{x,y,i}, \qquad (2)$$

where Z is a total cost of observations, and T_p is a set of logical atomic terms that appear in the set of potential elemental hypotheses, and $f_{x,y,i} \in \{0, 1\}$ is a newly introduced ILP variable that denotes the value of i-th feature for x, y. We normalize each term so that the size of observations and the number of logical terms does not affect to the strength of each term.

The features can be designed by a user. The value of each feature depends on the presence of certain propositions in the corresponding candidate hypothesis. For example, the value of feature $f_{x,y,i}$ can depend on the presence of $dog(x)$ and $cat(y)$. This dependence is represented by the following ILP constraint: $-m+1 \leq m \cdot f_{x,y,i} - \sum_{j=1}^{m} h_{p_m} \leq 0$, where h is an ILP variable (see Sec. 2.2) and $p_1, p_2, ..., p_m$ are propositions on which $f_{x,y,i}$ depends (i.e. $f_{x,y,i} = 1 \Leftrightarrow h_{p_1} = 1 \wedge h_{p_2} = 1 \wedge ... \wedge h_{p_m} = 1$).

Weight Learning

In order to train weight vector $\mathbf{w}$, we employ the modified version of the Passive-Aggressive (PA) algorithm (Crammer et al., 2006), which is a supervised large-margin online learning algorithm applicable to a wide range of linear classifiers ranging from binary classifiers to structured predictors. The original PA algorithm requires the complete set of gold standard labels to be present in the training set. In our case, however, the training set is annotated just with the coreference links (unification sets), but not with other assumptions supporting unification. For example, $dog(x) \wedge animal(y)$ will be annotated with $x = y$, but not with $dog(y)$. Therefore we modified the original algorithm for learning weights from a partial gold standard.

Algorithm 1 depicts our learning algorithm. Every time we receive a training instance (O, H_t) from a set $\mathbb{D}$ of training instances, where O is an observation and H_t is a set of gold standard variable unification assumptions for O, we first find the lowest-cost hypothesis $\hat{H}$ given the current weight vector (line 3). If variable unification assumptions made in $\hat{H}$ are inconsistent with H_t (e.g., *dog* and *animal* are unified in $\hat{H}$, but not in H_t), we train the weight vector (line 5–7). In order to train the vector, we find the lowest-cost hypothesis $\overline{H}$ among candidate hypotheses that *are consistent with* H_t (line 5). To get $\overline{H}$, we add ILP constraints for all $x = y$ in $H_t(s_{x,y} = 1)$ and for all $x \neq y$ in $H_t(s_{x,y} = 0)$ to the ILP optimization problem.

The new weight vector $\mathbf{w}$ should satisfy the following conditions: (i) $cost(\overline{H}; \mathbf{w})$ is less than $cost(\hat{H}; \mathbf{w})$ by at least a margin $\Delta(\hat{H}, \overline{H})$, and (ii) the difference between current weight vector $\mathbf{w}'$ and new weight vector $\mathbf{w}$ is minimal. In line 6, we calculate how much $\mathbf{w}$ should be corrected, where C is a parameter of the PA algorithm that is the aggressiveness of weight updates. $\phi(\hat{H})$ and $\phi(\overline{H})$ are the sums of feature vectors for variable unification assumptions in $\hat{H}$ and $\overline{H}$ respectively. $\Delta(\hat{H}, \overline{H})$ is a loss function that measures how different $\hat{H}$ and $\overline{H}$ are. The more different $\hat{H}$ and $\overline{H}$ are the larger an ensured margin is. In our experiments, we use the loss function $\Delta_P(\hat{H}, \overline{H}) = W_O / T_O$, where T_O is the total number of pairs of logical atomic terms in the observation and W_O is the total number of variable unification assumptions for observed logical terms in $\hat{H}$ that disagrees with $\overline{H}$. We implemented this training algorithm in a distributed learning framework (McDonald et al., 2010).

3.3 Features

Each feature we use is defined for pairs of unifiable variables (v_1, v_2). The features are summarized in Table 1.

Incompatible properties If two entities have incompatible properties, they are unlikely to be identical. We use WordNet antonymy (*black – white*) and sibling relation (*cat – dog*) to derive incompatible properties. Moreover, we assume that two proper names not belonging to the same WordNet synset are unlikely to refer to the same entity. Correspondingly, we generate three binary features *A*, *S*, and *P* (see Table 1).

Modality	$M(v_1, v_2) = \begin{cases} 1 \text{ if } \lvert MCPred(v_1) \cap MCPred(v_2) \rvert = \emptyset; \\ 0 \text{ otherwise} \end{cases}$
Common properties	$CP_1(v_1, v_2) = \lvert CPred(v_1, v_2) \rvert,$ $CP_2(v_1, v_2) = \sum_{p \in CPred(v_1, v_2)} Freq(p)$ $CP_3(v_1, v_2) = \sum_{p \in CPred(v_1, v_2)} WNAbst(p)$
Derivational relation	$DR(v_1, v_2) = \begin{cases} 1 \text{ if } \exists p_1(v_1, ..), p_2(v_2, ..): \\ p_1, p_2 \text{ are derivationally related;} \\ 0 \text{ otherwise} \end{cases}$

Table 1: Summary of the feature set.

Conditional unification If two entities have very frequent common properties, these properties usually do not represent a good evidence for the entities to be identical. For example, given *John goes* and *he goes*, it might be incorrect to assume that *John* and *he* are coreferential just

because they are both going. We want to allow unification of frequent predications (e.g., *go*) only if there is other evidence for their arguments to be unified. In order to capture this idea, we introduce binary feature CU and compute its value as follows: If v_1 and v_2 occur as first arguments of propositions $p_1(v_1, x_1, .., x_n), p_2(v_2, y_1, .., y_n)$, such that p_1, p_2 are frequent predicates, and $\forall i \in \{1, .., n\} : s_{x_i, y_i} = 1$ (where s is an ILP variable, see Sec. 2.2) then $CU(v_1, v_2) = 1$; otherwise $CU(v_1, v_2) = 0$.

Argument inequality We use two argument constraints to generate features. First, we assume that arguments of the same proposition usually cannot refer to the same entity. Reflexive verbs represent an exception (e.g., *John cut himself*), but we assume that these cases are resolved by the *Boxer* semantic parser (see Sec. 3.1) and do not require inference. We create binary feature SA and compute its value as follows: If v_1 and v_2 occur as arguments of the same proposition then $SA(v_1, v_2) = 1$; otherwise $SA(v_1, v_2) = 0$.

One more feature we introduce concerns event variables. For example, given the sentences *John said that Mary was reading* and *John said that he was tired* we do not want to unify both *say* propositions, because in each case something different has been said. Predicates like *say* usually have clauses as their arguments. Unifying clauses just because they are arguments of the same predicate is often incorrect. In our framework, a clause is represented by an event variable, i.e. a variable which is a first argument of the head of the clause. We make the following assumption: If two unifiable propositions $p(v_1, .., e_1, ..), p(v_2, .., e_2, ..)$ have event variables as their arguments, then they are unlikely to be unified if the event arguments have not been already unified. We create binary feature EA and compute its value as follows: if (i) there are two unifiable propositions $p(v_1, .., e_1, ..), p(v_2, .., e_2, ..)$ that have event variables e_1, e_2 as non-first arguments, (ii) $e_1 \neq e_2$, and (iii) $v_1 = v_2$, then $EA(v_1, v_2) = 1$; otherwise $EA(v_1, v_2) = 0$.

Explicit non-identity We manually collected a set of 33 predicates indicating explicit non-identity, e.g., *similar to*, *different from*. Presence of these predicates in a logical form indicates that their second and third arguments are unlikely to refer to the same entity. We create binary feature NI and compute its value as follows: If there is $p(e, v_1, v_2)$ and p is a predicate indicating explicit non-identity then $NI(v_1, v_2) = 1$; otherwise $NI(v_1, v_2) = 0$.

Functional relations A binary relation r is functional if $\forall x, y_1, y_2 : r(x, y_1) \wedge r(x, y_2) \rightarrow y_1 = y_2$. For example, a person can be a son of exactly one man. Lin et al. (2010) automatically learn functional relations from a corpus and assign a confidence score to each extracted relation. We use the set of functional relations generated by Lin et al. (2010) in order to generate feature FR. We extract 1,661 functional relations from the dataset. We create a binary feature FR and compute its value as follows: if (i) there are two predicates $p(e_1, v_1, x_1), p(e_2, v_2, x_2)$, where p indicates a functional relation, (ii) $x_1 \neq x_2$, and (iii) $v_1 = v_2$ then $FR(v_1, v_2) = 1$; otherwise $FR(v_1, v_2) = 0$.

Modality We assume that two predications having different modality are unlikely to refer to the same entity. For example, given *John runs* and *he does not/might run*, *John* and *he* are unlikely to be coreferential. Let $MPred(v)$ be a set of predicates that represent the modality of event v. In our experiments, we consider three modality-denoting predicates produced by the *Boxer* semantic parser (nec, pos, not), and verbal predicates (e.g., *think*) as modality-denoting predicates. We create binary feature M and compute its value as follows: if there are two unifiable verbal propositions $p(v_1, ...), p(v_2, ...)$ and $|MPred(v_1) \cap MPred(v_2)| = \emptyset$ then $M(v_1, v_2) = 1$; otherwise $M(v_1, v_2) = 0$.

Common properties We assume that the more properties two entities share the more likely it is that they are identical. For example, given *John was jogging, while Bill was sleeping. He jogs every day*, *John* and *he* are likely to be coreferential, because they are both arguments of *jog*. Let $CPred(v_1, v_2)$ be a set of pairs of predicates p_1, p_2, such that v_1, v_2 occur at the same argument positions of p_1 and p_2 while p_1 are p_2 equal or they occurs in the same WordNet synset. We generate three types of real-valued features: $CP_1(v_1, v_2) = |CPred(v_1, v_2)|$, $CP_2(v_1, v_2) = \sum_{p \in CPred(v_1, v_2)} Freq(p)$, and $CP_3(v_1, v_2) = \sum_{p \in CPred(v_1, v_2)} WNAbst(p)$, where $Freq(p)$ is a word-frequency of p from the Corpus of Contemporary American English[3], and $WNAbst(p)$ is a level of abstraction of p in the WordNet hierarchy (the number of steps to the root).

Derivational relations We use WordNet derivational relations between nouns and verbs in order to link nominalizations and verbs. For example, given *Sales of cars grew. The growth followed year-to-year increases*, *grew* and *growth* are coreferential. We generate binary feature *DR* to capture these links (see Table 1).

3.4 Knowledge for Inference

The abductive reasoning procedure is based on a knowledge base consisting of a set of axioms. In the experiment described in this paper we employed the following background knowledge.

WordNet The dataset we use for evaluation (see Sec. 4) is annotated with WordNet (Fellbaum, 1998) senses. Given this annotation, we mapped word senses to WordNet synsets. Given WordNet relations defined on synsets, we generate axioms of the following form:

Hyperonymy, instantiation: $synset_1(s_1, x) \rightarrow synset_2(s_2, x)$
Causation, entailment: $synset_1(s_1, e_1) \rightarrow synset_2(s_2, e_2)$
Meronymy, membership: $synset_1(s_1, x_1) \rightarrow synset_2(s_2, x_2) \wedge of(x_1, x_2)$

We extracted 22,815 axioms from WordNet.

FrameNet We generated axioms mapping predicates with their arguments into FrameNet (Ruppenhofer et al., 2010) frames and roles. For example, the following axiom maps the verb *give* to the GIVING frame.

$\text{GIVING}(e_1) \wedge \text{DONOR}(e_1, x_1) \wedge \text{RECIPIENT}(e_1, x_2) \wedge \text{THEME}(e_1, x_3) \rightarrow give(e_1, x_1, x_3) \wedge to(e_2, e_1, x_2)$

Weights of these axioms are based on frequencies of lexeme-frame mappings in the annotated corpora provided by the FrameNet project. Moreover, we used FrameNet frame relations to derive axioms. An example of an axiomatized relation is given below.

$\text{GIVING}(e_1) \wedge \text{DONOR}(e_1, x_1) \wedge \text{RECIPIENT}(e_1, x_2) \wedge \text{THEME}(e_1, x_3) \rightarrow$
$\text{GETTING}(e_2) \wedge \text{SOURCE}(e_2, x_1) \wedge \text{RECIPIENT}(e_1, x_2) \wedge \text{THEME}(e_1, x_3)$

In order to generate the FrameNet axioms, we used the previous work on axiomatizing FrameNet by Ovchinnikova (2012). We generated 12,060 axioms from the dataset. In addition, we used a resource assigning possible lexical fillers disambiguated into WordNet synsets to FrameNet roles (Bryl et al., 2012). For example, the role THEME of the GIVING frame is mapped to synsets `object#n#1` and *thing#n#1*. Given this information, the following axiom is generated.

$thing\#n\#1(s, x) \rightarrow \text{GIVING}(e_1) \wedge \text{THEME}(e_1, x)$

[3] http://www.wordfrequency.info/

Weights of these axioms are based on the scores provided by Bryl et al. (2012). We generated 24,571 axioms from the dataset.

Narrative chains Similar to (Rahman and Ng, 2012), we employ narrative chains learned by Chambers and Jurafsky (2009), which were shown to have impact on resolving complex coreference; see (Rahman and Ng, 2012) for details. Narrative chains are partially ordered sets of events centered around a common protagonist that are likely to happen in a sequence. Knowledge about such sequences can facilitate coreference resolution. For example, given *Max fell, because John pushed him* we know that *Max* and *him* are coreferential, because we know that an object of the pushing event can be a subject of the falling event. For example, we generate the following axioms.

$Script\#1(s, e_1, x_1, u) \rightarrow \text{arrest}(e_1, x_1, x_2, x_3) \wedge police(e_2, x_1)$
$Script\#1(s, e_1, x_1, u) \rightarrow \text{charge}(e_1, x_1, x_2, x_3) \wedge police(e_2, x_1)$

Weights of these axioms are based on the scores provided by (Chambers and Jurafsky, 2009). We extract 1,391,540 axioms from the dataset.

3.5 Disambiguation of Named Entities

In the experiment on coreference resolution, we extended *Boxer*'s output with the information inferred by the *AIDA* tool. The *AIDA* tool (Yosef et al., 2011) is a framework for entity detection and disambiguation. Given a natural language text, it maps mentions of ambiguous names onto canonical entities like people or places, registered in a knowledge base like DBpedia (Bizer et al., 2009) or YAGO (Suchanek et al., 2008). For example, mentions *A. Einstein* and *Einstein* will be both mapped to the YAGO node *Albert_Einstein*. An add-on to our pipeline assigns the same variables to each two named entities disambiguated by *AIDA* into the same YAGO node.

4 Evaluation

We evaluate coreference resolution in our weighted abduction framework using the CoNLL-2011 shared task dataset (Pradhan et al., 2011). The CoNLL-2011 dataset was based on the English portion of the OntoNotes 4.0 data (Hovy et al., 2006). OntoNotes is a corpus of large scale annotation of multiple levels of the shallow semantic structure in text. The OntoNotes coreference annotation captures general anaphoric coreference. Note that OntoNotes captures explicit coreference links only, while our procedure also discovers implicit semantic overlap.

The CoNLL-2011 shared task was to automatically identify mentions of entities and events in text and to link the corefering mentions together to form entity/event chains. In our experiment, we do not identify mentions, but only compute precision and recall of the inferred coreference links given the mentions identified in the gold standard annotation.

In the CoNLL-2011 shared task, four metrics were used for evaluating coreference performance: MUC, B^3, CEAF, and BLANC. The evaluation metrics are described in (Pradhan et al., 2011). Each of the metric tries to address the shortcomings of the earlier metrics. MUC is the oldest metric; it has been criticized for not penalizing overmerging (Recasens and Hovy, 2010). Since one of the goals of this study is to reduce overmerging in our inference-based framework, this metric does not seem to be representative for us. The B^3 and CEAF metrics were also considered to produce counterintuitive results (Luo, 2005; Recasens and Hovy, 2010). BLANC, as the most recent evaluation metric, overcomes the drawbacks of MUC, B^3, and CEAF. The definition formula of BLANC given in (Recasens and Hovy, 2010) is replicated in Table 2, where

rc, wc, rn, wn indicate the number of right coreference links, wrong coreference links, right non-coreference links, and wrong non-coreference links correspondingly.

Score	Coreference	Non-coreference	Metric
P	$P_c = \frac{rc}{rc+wc}$	$P_n = \frac{rn}{rn+wn}$	BLANC-P $= \frac{P_c+P_n}{2}$
R	$R_c = \frac{rc}{rc+wn}$	$R_n = \frac{rn}{rn+wc}$	BLANC-R $= \frac{R_c+R_n}{2}$
F	$F_c = \frac{2P_cR_c}{P_c+R_c}$	$F_n = \frac{2P_nR_n}{P_n+R_n}$	BLANC $= \frac{F_c+F_n}{2}$

Table 2: Definition formula for BLANC.

We rely on BLANC when drawing conclusions, but present values of the other three evaluation metrics as well.

4.1 Results and Discussions

We intend to evaluate whether the introduction of linguistically motivated features (Sec. 3.3) and world knowledge (Sec. 3.4) enables us to outperform the naive inference-based approach implying that predications with the same names refer to the same entities. In order to evaluate the impact of each feature and knowledge component separately, we run ablation tests.

Note that for 145 of 6,894 sentences in the test set, no logical forms were produces by the *Boxer* semantic parser. Moreover, in the run employing WordNet-based inference, inference results could not be produced for 101 of 303 test texts because of the computational complexity of reasoning. In order to keep the comparison fair, we use evaluate all features and knowledge components on the same set of 202 texts, for which inference results were produced in all runs.

Table 3 represents the results of the ablation tests. We test the features listed in Table 1 as well as axioms extracted from WordNet (WN), FrameNet (FN), narrative chains (NC) and knowledge provided by AIDA (AI). All features representing incompatible properties are tested together (IP in Table 3). Similarly, all argument inequality features (AI) and common property features (CP) are tested together.

The first row represents results for the run without employing any features and knowledge resources. In the second run, world knowledge is employed without linguistic features. These two runs correspond to the original weighted abduction approach to unification implying unification of all predications having the same predicate names. We see that adding knowledge results in lower values of BLANC. This happens because of the overmerging problem increased by additional coreference links inferred with the help of the employed knowledge resources.

Then we test linguistic features intended to block incorrect unification (IP, CU, AI, NI, FR, M) one by one. Each of the features improves the BLANC values; conditional unification CU has the most significant impact.[4] The common property feature (CP) and the derivational relations feature (M) introduce additional unifications. Therefore we test them together with the best combination of the unification blocking features (IP+CU+AI+NI+FR+M). Both features have a positive impact as compared to the run employing just the unification blocking features. Now we test each world knowledge component using the best combination of features

[4]It is interesting to note that MUC and B^3 evaluation metrics represent completely the opposite picture, which supports the criticism of these metrics for tolerating overmerging (Recasens and Hovy, 2010).

(IP+CU+AI+NI+FR+M+CP). Each knowledge component except for WordNet has a positive impact in terms of BLANC as compared to the run using the best combination of all features.

Table 3: Ablation tests of features and world knowledge.

The results of the ablation tests show significant improvement over the naive approach (by more than 20% F-measure), but can we claim that we solved the overmerging problem? We perform one more experiment in order to get a deeper understanding of the performance of our discourse processing pipeline in coreference resolution.

The best performance in the CoNLL-2011 shared task was achieved by the *Stanford NLP* system (Lee et al., 2011) that is a rule-based resolver encoding traditional linguistic constraints on coreference. We replicate the results of *Stanford NLP* as applied to the CoNLL-2011 dataset; see the first row in Table 4. We use the output of *Stanford NLP* only for those texts, which could be processed by our discourse processing pipeline, therefore the recall/precision values for *Stanford NLP* in Table 4 are lower than the original results published in (Lee et al., 2011).

We aim at checking whether enriching the output of the state-of-the-art coreference resolver with additional links inferred by our system using all features and all world knowledge will improve the performance. The evaluation of the "merged" output is presented in the second row of Table 4 (SNLP+WA). Unfortunately, the precision of SNLP+WA is lower than that of SNLP alone. This happens because adding world knowledge results in new coreference links, while the overmerging problem is not completely solved. SNLP discovers 2277 out of 7557 correct coreference links and 40247 out of 41527 correct non-coreference links. In the merged output, there are more correct coreference links (3065), but less correct non-coreference links (36959). Note that *Stanford NLP* performs noun phrase coreference resolution only, while our system is not restricted to noun phrases and can also discover implicit coreference links.

System	MUC			B^3			CEAFE			BLANC		
	R	P	F	R	P	F	R	P	F	R	P	F
SNLP	42.8	74.4	54.3	50.4	85.2	63.4	66.3	32.6	43.7	63.5	76.2	66.7
SNLP+WA	52.0	70.1	59.7	57.3	72.7	64.1	60.5	37.2	46.1	64.8	64.7	64.7

Table 4: Performance of the *Stanford NLP* system (SNLP) compared to performance of our weighted abduction engine enriched with *Stanford NLP* (SNLP+WA) output.

The main cause of overmerging is related incompatible properties. We anticipated the incom-

patible properties to have a more significant impact on precision than they actually had in the ablation tests. But in the current study, we consider only those properties to be incompatible which are expressed syntactically in the same way, e.g., *Japanese goods* vs. *German goods*. However, the same property can be expressed by a wide variety of syntactic constructions, e.g., *goods from Germany*, *goods produced in Germany*, *Germany produced goods* etc. In order to discover deeper contradictions, we have to work on normalization of the representation of properties, e.g., use *origin*:*Germany*:x instead of $German(e, x)$ and $from(e_1, x, y) \wedge Germany(e_2, y)$. FrameNet attempts to achieve such a normalization by using standardized frame and role names. Unfortunately, the limited coverage of the FrameNet resource (Shen and Lapata, 2007; Cao et al., 2008) does not allow us to solve the problem on a large scale.

Analyzing the results, we also found overmergings not implying any explicit contradictions. For example, in the sentence *He sat near him*, both *he* propositions are unlikely be coreferential, but our framework fails to capture that. Such overmergings might be blocked by explicit modeling of discourse salience. In the future, we plan to use existing discourse salience models (e.g., (Lappin and Leass, 1994)) to create real-valued salience features for weighted unification.

One more issue concerns the quality of the obtained interpretations. Our learning framework assumes that we can obtain optimal solutions, but we also exploit suboptimal solutions by imposing a timeout in this experiment. However, it has been reported that exploiting suboptimal solutions sometimes hurts performance (Finley and Joachims, 2008). In the future, we will address this problem using an approximate learning framework (e.g., (Huang et al., 2012)).

Conclusion and perspectives

In this paper, we investigated the overmerging problem in a general inference-based discourse processing pipeline using the mode of inference called weighted abduction. In our framework, resolving coreference is a by-product of constructing best interpretations of text. Coreference links naturally result from unifications of predications during the inference process. The naive approach to unification involves unifying predications with the same predicate names.

This paper presents the first systematic study of the overmerging problem resulting from naive unification. We proposed several linguistically motivated features for blocking incorrect unifications as well as employed different large-scale world knowledge resources for establishing unification via inference. We extended ILP-based weighted abduction in order to accommodate unification weights and showed how to learn the weights in a supervised manner. All features and almost all knowledge components proved to improve the performance of our system tested on a large state-of-the-art test dataset.

We cannot claim that the problem of overmerging has been solved, because we still discover overmerging of explicit anaphora produced by our system as compared to a state-of-the-art rule-based coreference resolver. However, the proposed framework presents a significant improvement over the naive approach (by over 20% of F-measure). Moreover, it is highly extensible for including more features and knowledge sources.

Acknowledgments

We would like to thank Johan Bos for helping us to set up the *Boxer* system for our experiments. We also thank the *Stanford NLP* team and the *AIDA* team for their cooperation. This work was partially supported by Grant-in-Aid for JSPS Fellows (22-9719) and Grant-in-Aid for Scientific Research (23240018).

ABSTRACT
Traditional general readability methods tend to underperform in domain-specific document retrieval because they fail to effectively differentiate the reading difficulty of the individual domain-specific terms and the semantic associations between the textual units in a document. On the other hand, recently proposed domain-specific readability methods have relied upon an external knowledge base which may be unavailable in some domains. We develop a novel unsupervised framework for computing domain-specific document readability. Our model does not require an ontology or a knowledge base to capture domain-specific terms in a document. The sequential flow of terms in a document is modeled as a connected sequence of n-gram fragments in the latent concept space. We investigate an automatic sequential n-gram determination scheme that aids in capturing appropriate n-gram fragments which are semantically associated with the document's theme and cohesive with the context. The domain-specific readability cost of a document is computed based on n-gram cohesion and n-gram specificity guided by the latent concepts. The cost can be employed to re-rank the search results generated from an information retrieval (IR) engine. The experimental results demonstrate that our framework achieves significant improvement in ranking documents against the state-of-the-art unsupervised comparative methods.

KEYWORDS: Term Sequence, LSI, IR, Domain-specific Readability, Ranking, Dynamic programming.

1 Introduction

Readability assessment is an important issue in NLP (Tanaka-Ishii et al., 2010). Traditional general readability methods (Dubay, 2004) have been applied to several problem tasks such as matching books with grade levels (Collins-Thompson and Callan, 2005; Fry, 1969). However, the problem of readability has not been well explored in Information Retrieval (IR) (Kim et al., 2012). Recently researchers have started looking at the problem in IR and several motivations for incorporating readability in an IR system have already been clearly laid out in (Kim et al., 2012; Tan et al., 2012; Nakatani et al., 2009; Yan et al., 2006; Collins-Thompson et al., 2011; Jameel et al., 2011; Zhao and Kan, 2010; Kumaran et al., 2005). What has lacked is a thorough investigation into the problem of reading difficulty in domain-specific IR because traditional unsupervised general readability formulae tend to underperform in domain-specific document retrieval (Yan et al., 2006; Jameel et al., 2011). Domain-specific IR is important because many people are searching for information outside their domain of expertise (Bhavnani, 2002; Yan et al., 2006).

The most affected group who regularly experience difficulties in retrieving documents based on readability are children (Collins-Thompson et al., 2011) and other users who are not domain experts (Yan et al., 2006). Hence, most of them will look for domain-specific documents which they can easily comprehend (Bhavnani, 2002). Domain experts employ complex search strategies such as usage of jargon and complex phrases to successfully retrieve documents based on their reading level (White et al., 2009). Moreover, domain experts know their target destinations such as the ACM Digital Library or Google Scholar using which they can successfully retrieve a document satisfying both relevance and their reading level (White et al., 2009). In contrast, non-domain experts face immense difficulties in formulating a query due to less exposure to the domain-specific terminologies (Vakkari et al., 2003; Paek and Chandrasekar, 2005).

Works which have looked into the problem of domain-specific readability (Yan et al., 2006; Zhao and Kan, 2010) have remained constrained to certain domains only, for instance, the Medical domain because of the required reliance on some knowledge bases to find domain-specific terms in a document. To circumvent this limitation, we propose a novel unsupervised framework for computing domain-specific document readability. The main factor that makes our work superior compared with the existing domain-specific readability methods is that our method does not require an external ontology or lexicon of domain-specific terms. We have previously proposed two terrain models (Jameel et al., 2011, 2012) in Latent Semantic Indexing (LSI) (Berry et al., 1995) to predict the technical difficulty of documents in domain-specific IR using heuristic methods based on conceptual hops between the unigrams and the evaluation is done on one domain only. In this paper, we present an n-gram sequence determination based method which captures appropriate n-gram fragments which are semantically linked with the document automatically while traversing forward following the term sequence in the document. We test the ranking effectiveness of our model on more than one domain. One application of our method is in domain-specific vertical search engines.

Our contributions are as follows: 1) We develop a novel framework to capture suitable n-gram fragments in a domain-specific document by optimizing n-gram fragment sequence connections and taking into account n-gram fragment specificity and cohesion. 2) Our method does not require a domain-specific knowledge base. 3) We conduct extensive experiments on domain-specific document collections in order to show the readability ranking performance.

2 Related Work

Unsupervised heuristic readability methods: Much research has been done in measuring the reading level of text (Qumsiyeh and Ng, 2011). A detailed description about important heuristic readability methods such as Dale-Chall (Dale and Chall, 1948), Automated Readability Index (ARI) (Senter and Smith, 1967), SMOG (McLaughlin, 1969), Coleman-Liau (Coleman and Liau, 1975) etc, can be found in (Dubay, 2004). These methods compute the vocabulary difficulty of a textual discourse. Their readability prediction is based on computing the number of syllables in a term, number of characters etc, which are the surface level features of text. Heuristic readability methods consist of two components linearly combined into a single formula. The components are - syntactic and semantic. These methods have long been in existence and still remain a dominant tool for computing the reading difficulty of traditional documents. In fact, many popular word processing packages use them today. However, readability methods tend to perform poorly on domain-specific texts (Yan et al., 2006) and web pages (Collins-Thompson and Callan, 2005). There are other shortcomings (Bruce et al., 1981) which undermine their importance. In (Nakatani et al., 2009) the authors described an unsupervised method to re-rank the search results of a web search engine in descending order of their comprehensibility using the Japanese Wikipedia but they failed to address the shortcomings in the readability formulae.

Why readability methods underperform on domain-specific documents? Consider a short sentence, "In its simplest form, a star network consists of one central switch, hub or computer, which acts as a conduit to transmit messages." The Flesch reading ease score for this sentence is 62.11, which according to the score is not a difficult sentence. However, the sentence carries a deep technical meaning which requires domain-specific knowledge for proper comprehension. Terms such as "star", "network", and "switch" are domain-specific terms in this example but the readability formula has detected them as easy due to the surface level features.

Domain-Specific Readability Methods: To address the shortcomings inherent in the heuristic readability methods, (Yan et al., 2006) proposed concept based readability ranking method where they have used a domain-specific ontology to capture the domain-specific terms in a document. Their method has a serious drawback in that it requires an ontology for every domain. The authors have only shown the application of their method in one domain. (Kim et al., 2012) described concept readability method in the medical domain. They have used average term and concept familiarity scores from the OAC CHV knowledge base to compute the difficulty of terms and concepts. (Zhao and Kan, 2010) presented domain-specific iterative readability method based on grade levels. Their method is influenced by two popular web link structure based algorithms which are HITS (Kleinberg, 1999) and SALSA (Lempel and Moran, 2001). A limitation of their approach is that they need some seed concepts to initialize their algorithm. This can sometimes be cumbersome as one has to search for a lexicon for every domain. In (Nakatani et al., 2010) the authors used Wikipedia to build a list of some technical terms. In contrast, our proposed framework in this paper does not require an ontology or seed concepts, which can be regarded as a major innovation. The two heuristic terrain models proposed in (Jameel et al., 2011, 2012) computed the technical difficulty of text documents and re-ranked the results obtained from a general purpose IR system. A limitation of the terrain models is that they cannot capture n-grams such as *random access memory* etc. Moreover, they lack a solid theoretical foundation. In this paper, we introduce a principled approach to n-gram fragment determination scheme where we first find the best n-gram sequence in a document automatically. Domain-specific readability cost model is then developed for a document based

Figure 1: A sentence with four n-gram fragments (s_1, s_2, s_3, s_4). This sample sentence has been taken from one of the Wikipedia documents in our Science test collection. The fragmented sentence has been obtained using Equation 5.

on a new formulation of cohesion and specificity.

Supervised Methods for Readability: Although our proposed framework is completely unsupervised, some supervised methods for computing the reading difficulty of text have been proposed as well (François and Miltsakaki, 2012). Supervised learning approach for readability can be considered as a classification problem. In (Liu et al., 2004), the authors have used Support Vector Machines (SVM) (Vapnik, 1995) for recognizing the reading levels of texts from user queries. They have used syntactic and vocabulary based features to train the classifier. Language modeling has been applied to readability (Collins-Thompson and Callan, 2005) where the authors described a smoothed unigram model for computing the readability of text documents such as web pages. In (Si and Callan, 2001), the authors also used unigram language model to predict readability. Topic familiarity is different from traditional general readability (Kumaran et al., 2005), where the authors studied re-ranking of a search engine result based on familiarity. They also studied the importance of stopwords in their familiarity classifier (FAMCLASS). In (Leroy et al., 2008), classification of health related documents into three levels, namely, Beginner, Intermediate and Advanced is discussed. The authors achieved high classification accuracy using their classifier. In (Schwarm and Ostendorf, 2005; Petersen and Ostendorf, 2009) the authors combined word level features with other textual features. They have used SVM together with several word level features to classify documents based on readability. In (Heilman et al., 2008) the authors introduced a k-Nearest Neighbor classifier based on grammatical features such as sentence length and the patterns of the parse tree. (Bendersky et al., 2011) used several features including readability to improve relevance ranking of the web search results.

Readability is a relative measure (Van Oosten and Hoste, 2011). In order to cater to the results on an individual user basis, recently, methods using query log analysis have been proposed. Search engine query log mining and building individual user profile classifier can also help to solve the problem to some extent as done in (Collins-Thompson et al., 2011; Tan et al., 2012; Kim et al., 2012). But this requires confidential and proprietary query log data with private user session details (Silverstein et al., 1999). Many users might not want their sessions to be recorded or used due to privacy concerns (Jones et al., 2007).

Readability has also been studied in computational linguistics (Leroy and Endicott, 2012). In (Kate et al., 2010) the authors used several linguistic and language model features to build a classifier to predict readability of texts. Language model features were found out to be important to their classifier. (Pitler and Nenkova, 2008) used several textual features in their classifier. Their result shows that word features and average sentence length are strong predictors but the strongest ones are the discourse features. One major limitation of the supervised methods is that one needs a large amount of expensive annotated data (Kanungo and Orr, 2009). Language modeling approaches cannot capture domain-specific concepts in a domain (Zhao and Kan, 2010). In contrast, our method does not need any annotated data.

3 Background and Overview

We tackle the problem of domain-specific readability of text documents. We take as input a document collection of related documents of a domain. We compute the domain-specific readability of each document in the collection. Given a query, a similarity-based IR system retrieves documents. We then re-rank the retrieved top-k results automatically based on readability.

3.1 Overview

We address the problem of domain-specific document readability based on an automatic scheme for finding appropriate n-grams in the Latent Semantic Indexing (LSI) (Berry et al., 1995) latent concept space. As in the previous domain-specific readability approaches, the task lies in an effective capturing of domain-specific terms in the document and their individual specificity scores or scopes (e.g. document scope in (Yan et al., 2006)). In the LSI latent space, n-gram fragments which are central to a document, mainly the domain-specific terms, come close to their document vectors because the semantic fabric of the n-gram fragments inclines best with the technical content of the document (Bellegarda, 2000; Jameel et al., 2011). Common n-grams will not be coherently linked with the document semantics. They can be considered as non-central in that technical storyline (Bellegarda, 2000). N-grams which are semantically similar in meaning will cluster close to each other in the latent space forming a word cloud of semantically related terms (Berry et al., 1995).

We denote the sequence of unigrams in a document d as $(t_1, t_2, \cdots, t_W)$. In Figure 1, an ordered sequence of terms $(t_1, t_2, \cdots, t_{10})$ is shown. Using our proposed methods, the sequence of unigrams can be formed into a sequence comprising of n-gram fragments such as "random access memory" or a connective such as "is a", which are examples of n-gram fragments of order 3 and 2 respectively. An example of a sequence of variable length n-gram fragments is also shown in Figure 1, which is composed of $S = (s_1, s_2, s_3, s_4)$. The sequential flow of terms in a document is modeled as a sequence of n-gram fragments. In this paper, we investigate an automatic sequential n-gram determination scheme that aids in capturing the appropriate n-grams which are semantically associated with the document's theme and cohesive with the context. Cost expended during n-gram formation step can be regarded as a reading difficulty cost of a document. Our proposed n-gram sequence cost optimization linearly combines the effect of both cohesion and specificity, which play a dominant role in determining the domain-specific readability of a document. Some domain-specific readability methods have similar consideration of cohesion and term's domain-specific importance such as (Jameel et al., 2011, 2012; Yan et al., 2006), but they have some serious limitations as mentioned in Section 2.

The first step of our framework is to generate all n-gram fragments (i.e. unigrams, bi-grams, tri-grams etc.) in a document with a predefined maximum value of n, and subsequently we construct a weighted n-gram fragment-document matrix using the product of normalized n-gram frequency and inverse n-gram document frequency (formulae given in (Salton and Buckley, 1988)), where rows are represented by n-gram fragments and columns by documents. Then we perform LSI and obtain a low-dimensional representation of the original vector space. The main computation in LSI is Singular Value Decomposition (SVD) (Golub and Reinsch, 1970). Computing the SVD of a matrix is generally computationally expensive both in space and time (Berry et al., 1995). But with the fast development of better algorithms to compute the SVD, such concerns have been addressed (Wang et al., 2011; Zha et al., 1998).

In (Yan et al., 2006) the authors introduced two components in determining the overall

domain-specific readability of a document which are "document scope" and "document cohesion". The hypothesis is that readability of a document will not only depend on the reading difficulty of the individual terms but also on how the terms in the document are related to one another in the document. Hence a document comprising of many domain-specific terms will be difficult to read and also if the terms are not related to each other (low cohesion) in the same document then the reader will face difficulties in relating different concepts of a domain (Yan et al., 2006). However, the computation of document scope and cohesion in (Yan et al., 2006) is accomplished using an ontology tree which requires an ontology for every domain. Our proposed computation of document scope is different as that in (Yan et al., 2006). We introduce "n-gram specificity" which is able to capture document scope more effectively. As stated earlier, an n-gram fragment which is coherently linked with the technical storyline of a document will be close (Bellegarda, 2000; Jameel et al., 2011, 2012) to the document in the LSI latent space and thus will be more *specific* to that technical storyline. We use the notion of closeness of an n-gram vector to the document vector in the LSI latent space to compute the n-gram specificity.

Psychologists have studied various aspects which lead a reader to comprehend particular piece of discourse (Graesser et al., 1997). An important aspect in text comprehension is cohesion between texts. Cohesion is the property of text in which the units are semantically related to each other and describe one theme. Cohesion is important because the interpretation of one element of text depends on that of another. Texts frequently exhibit varying degrees of cohesion in different sections and hence the start of the text will not be cohesive with the end of the same text (Halliday and Hasan, 1976). Our work is inspired by this observation and we maintain the term order in the document in order to compute cohesion between the n-gram fragments in sequence. Text cohesion has been discussed in (Yan et al., 2006; Ferstl and von Cramon, 2001; Morris and Hirst, 2006; Moe, 1979; Graesser et al., 2004) which establish relation between cohesion and comprehension. Accurate comprehension of technical texts requires accurate identification of the technical meaning of the terms and connections between the terms with the surrounding parts of the text (Freebody and Anderson, 1983). Describing too many difficult non-cohesive terms in sequence will make the reading path of the reader troublesome and thus will affect discourse comprehension (McNamara et al., 1996).

One may argue why we have used a conceptual model instead of the original high-dimensional vector space? An obvious bottleneck in the original vector space is the curse of dimensionality as one has to deal with the space which will be enormous. The high dimensionality would lead to huge computational cost. Moreover, obtaining the n-gram fragment and document semantic relationships directly from the vector space is not possible (Berry et al., 1995) unless additional techniques such as LSI (Deerwester et al., 1990) or the method described in (Yamamoto and Church, 2001) is applied. LSI also handles issues related to data sparsity.

4 Sequential N-gram Connection Model (SNCM)

We present our model that establishes sequential n-gram connections in the document and eventually a cost is expended in order to make such a connection of n-grams in sequence. The aggregated cost expended in the document can be regarded as a document's domain-specific readability cost. If the textual units are not cohesive, then the reader faces cognitive difficulties in comprehension. In addition, if the individual textual units are difficult, then the reader expends cognitive load in figuring out the inherent meaning of the textual unit while reading the text (Yan et al., 2006). This phenomenon can be captured in a cost computation

model described below.

Let s be an n-gram fragment. Let d be the document where this n-gram fragment occurs. Let this fragment be represented as a vector in the LSI latent space as $\vec{s}$ and the document vector as $\vec{d}$. We compute the n-gram specificity, $\vartheta(\vec{s},\vec{d})$, using the following formula:

$$\vartheta(\vec{s},\vec{d}) = \text{cosine\_sim}(\vec{s},\vec{d}) \tag{1}$$

where cosine_sim$(\vec{s},\vec{d})$ is the cosine similarity (formula given in (Bellegarda, 2000)) between the n-gram vector $\vec{s}$ and the document vector $\vec{d}$ in the latent space. An n-gram fragment will obtain a high cosine similarity if it is close to the document vector in the LSI latent space and a low cosine similarity value if it is not close. Therefore, what we expect is that domain-specific n-grams will obtain a high cosine similarity (Jameel et al., 2012) value compared with common/general n-gram fragments. In (Park et al., 2002), they named a domain-specific term extraction scheme as *Degree of Domain-specificity*. However, their method deals with a completely different problem task.

Suppose $T = (t_1, t_2, \cdots, t_W)$ is the term sequence and $S = (s_1, s_2, \cdots, s_K)$ is one particular n-gram fragmented sequence of T, W is the total number of terms in the document d, K is the number of n-grams in S. We denote n-gram cohesion, $\eta(\vec{s_i}, \vec{s_{i+1}})$, between the two n-grams s_i and s_{i+1} at positions i and $i+1$ in sequence whose vectors are represented as $\vec{s_i}$ and $\vec{s_{i+1}}$ respectively for a particular document as:

$$\eta(\vec{s_i}, \vec{s_{i+1}}) = \text{cosine\_sim}(\vec{s_i}, \vec{s_{i+1}}) \tag{2}$$

When the cosine similarity between the two consecutive n-grams is high, the n-gram fragments are cohesive. The reason is that in the latent concept space n-gram fragments which appear under similar storylines and similar semantic meaning will cluster close to each other (Berry et al., 1995; Jameel et al., 2011, 2012). Hence the closer they are, the more semantically related they tend to become. A reader will be able to semantically relate those n-gram fragments (which are cohesive) easily (Halliday and Hasan, 1976) and will comprehend a piece of textual discourse well. A document tends to be semantically readable if the constituent terms are simple (i.e. low specificity values) with reference to the document vector in the LSI latent space. Therefore, we hypothesize that specificity values will be directly proportional to the document's overall domain-specific reading difficulty. In fact, in order to compute document generality and readability, (Yan et al., 2006, 2011) have made a similar hypothesis and have evaluated their hypothesis through experiments. We also hypothesize that cohesion is inversely related to the document domain-specific readability. Again, this assumption is in line with the assumptions made in (Yan et al., 2006, 2011).

4.1 Our First Model (SNCM1)

Our framework works towards determining a least cost n-gram connected sequence in the document where at each forward transition sequential n-gram cohesion is minimized. The sequence of terms consisting of variable n-gram fragments is considered while traversing forward. For a particular document, suppose the term sequence T and its n-gram fragmented sequence S are defined in a similar manner as above. The cost of the n-gram fragment sequence S, $C_1^{(d)}(S)$, can be written as:

$$C_1^{(d)}(S) = \sum_{k=1}^{K} \left(\frac{1}{\eta(\vec{s_{k-1}}, \vec{s_k}) + 1} \right) \tag{3}$$

1 is added in the denominator to handle the cases where the n-gram vectors are orthogonal to each other. Our goal is to minimize this cost, $C_1^{(d)}(S)$. The rationale for such minimization

formulation is to fit the most cohesive n-gram fragment in sequence which matches with the sequential storyline of the document. We achieve this using the following optimization scheme given in Equation 4.

$$\min_{S} C_1^{(d)}(S) \tag{4}$$

This scheme ensures that an n-gram will be the least cost match at that position if it cohesively fits in that sequential discourse. We now describe a dynamic programming method to find the optimal cost. We define $C_1^{(d)}(T_i)$ as the optimal cost from the beginning until the term t_i in the document. Since the accumulated cost is the sum of the local costs, it can be decomposed in the same way as its predecessors and the local cost accumulated with the n-gram itself. To obtain the optimal path cost, we have to select the predecessor with the minimum total cost. Another issue is that we need to set a maximum bound for the number of terms in an n-gram. In principle, this bound could be set to any number m. Let $\vec{S_X}$ be a unigram composed of t_i, $\vec{S_Y}$ be a bigram composed of (t_{i-1}, t_i) and $\vec{S_Z}$ be an m-gram composed of $(t_{i-m+1}, \cdots, t_i)$. $\vec{S_{X-1}}$, $\vec{S_{Y-1}}$ and $\vec{S_{Z-1}}$ represent the particular n-gram (where n may be from 1 to m) in the optimal sequential path that appears just before $\vec{S_X}$, $\vec{S_Y}$ and $\vec{S_Z}$ respectively. The optimal cost for all the terms from t_1 until position t_i, (denoted as $C_1^{(d)}(T_i)$) can be written as:

$$\begin{aligned} C_1^{(d)}(T_i) = \text{minimum}\Big(& C_1^{(d)}(T_{i-1}) + \frac{1}{\eta(\vec{S_{X-1}}, \vec{S_X}) + 1}, \\ & C_1^{(d)}(T_{i-2}) + \frac{1}{\eta(\vec{S_{Y-1}}, \vec{S_Y}) + 1}, \\ & \cdots, \\ & \cdots, \\ & C_1^{(d)}(T_{i-m}) + \frac{1}{\eta(\vec{S_{Z-1}}, \vec{S_Z}) + 1}\Big) \end{aligned} \tag{5}$$

The final reading difficulty of a document will not only depend on cohesion but also specificity. Therefore, to compute the final readability cost of a text document, we linearly combine specificity values of the n-grams formed during sequential linear n-gram determination scheme using Equation 5. The overall document domain-specific readability cost, $E_1^{(d)}$, is given in Equation 6 where α ($0 \leq \alpha \leq 1$) is a parameter controlling the relative contribution of cohesion and specificity. A higher cost indicates that the document is difficult to read and a low cost is indicative of the ease in reading the document. We shall use the cost values to re-rank the search results obtained from a general purpose IR system.

$$E_1^{(d)} = \frac{\alpha C_1^{(d)}(T_W) + (1-\alpha)\sum_{i=1}^{K} \vartheta(\vec{s_i}, \vec{d})}{W} \tag{6}$$

where W is the total number of terms in the document and it removes the document length bias. Note that W in the denominator is more suitable than K because the reading difficulty of a document is not dependent on the number of n-gram fragments formed.

4.2 An Extended Model: SNCM2

We now modify our previous model in Equation 3 further and extend to the case where we combine the effect of both cohesion and specificity. In this model, we linearly combine the effect of specificity along with cohesion during n-gram fragment determination phase. We design the cost, $C_2^{(d)}(S)$, of an n-gram fragment sequence formation S as:

$$C_2^{(d)}(S) = \sum_{k=1}^{K} \left(\beta\, \vartheta(\vec{s_k}, \vec{d}) + (1-\beta) \frac{1}{\eta(\vec{s_{k-1}}, \vec{s_k}) + 1} \right) \tag{7}$$

β $(0 \leq \beta \leq 1)$ is a parameter controlling the relative weights of the two components. Our goal is to minimize the total cost $C_2^{(d)}(S)$ as follows:

$$\min_{S} C_2^{(d)}(S) \tag{8}$$

We can apply similar dynamic programming methodology. Let the optimal cost for all the terms from t_1 until position t_i be $C_2^{(d)}(T_i)$.

$$\begin{aligned} C_2^{(d)}(T_i) = \text{minimum} \\ \Bigg(& C_2^{(d)}(T_{i-1}) + \beta\, \vartheta(\vec{S_X}, \vec{d}) + (1-\beta) \frac{1}{\eta(\vec{S_{X-1}}, \vec{S_X} + 1)}, \\ & C_2^{(d)}(T_{i-2}) + \beta\, \vartheta(\vec{S_Y}, \vec{d}) + (1-\beta) \frac{1}{\eta(\vec{S_{Y-1}}, \vec{S_Y} + 1)}, \\ & \cdots, \\ & \cdots, \\ & C_2^{(d)}(T_{i-m}) + \beta\, \vartheta(\vec{S_Z}, \vec{d}) + (1-\beta) \frac{1}{\eta(\vec{S_{Z-1}}, \vec{S_Z} + 1)} \Bigg) \end{aligned} \tag{9}$$

The overall document domain-specific readability cost $E_2^{(d)}$ is given in Equation 10. We rank the documents based on an optimal cost obtained at the end of the n-gram sequence formation.

$$E_2^{(d)} = \frac{C_2^{(d)}(T_W)}{W} \tag{10}$$

Intuitive Justification: Specificity helps us in finding an n-gram fragment which matches with the technical storyline of the entire document. Cohesion on the other hand helps in finding the best linked n-gram fragments in the sequential discourse based on the context. In Equation 9 our objective is to find a least cost n-gram fragment that is a best match in the n-gram sequence which considers both components, namely, cohesion and specificity simultaneously in the document. The intuition behind adopting this strategy is to find n-gram fragments in a document which are semantically linked with the document's thematic structure and are cohesive with the context. However, in Equation 5 we are minimizing only cohesion between the n-gram fragments in sequence. This strategy may help us find cohesive n-grams with the context but the n-grams may not be thematically linked with the technical storyline of the document because of the absence of specificity during n-gram sequence determination phase. A closer look at the two variants of our model paints some interesting pictures. When $\beta = 0$ and $\alpha = 1$ the two variants (`SNCM1` and `SNCM2`) behave equivalently. Note that the cost expended to fit a specific n-gram fragment will be more in comparison to an n-gram fragment which is common/general. The longer the contextual history m, the better n-gram fragment prediction will be. However, longer contextual histories shall bring about additional computational burden especially for large datasets as ours.

5 Empirical Evaluation

5.0.1 Experimental Setup

Testbed Data: Current IR evaluation test sets such as TREC, and CLEF cannot be used in our experiments due to lack of readability annotations. Currently, they only contain relevance

judgments. So we chose two popular domains 1) Psychology, and 2) Science and subsequently we crawled a large number of web pages in these domains. We enlist some of the important resources from where we crawled the majority of the web pages as enlisting every crawled resource would be too long. Psychology web pages were crawled from: 1) Wikipedia, 2) Psychology.com, 3) Psychology Today 4) Simple English Wikipedia. Science web pages were crawled from: 1) ScienceDaily, 2) ScienceForKids, 4) Simple English Wikipedia 5) Wikipedia, 6) About.com and some more related web resources. We also included Computer Science documents in the Science domain. The reason for choosing these online resources was mainly due to their popularity and high quality content. By crawling web pages from different resources available online we are able to collect domain-specific documents which match diverse genres and audience. In all, our test collection includes 170,000 documents in Psychology with 154,512 n-grams in the vocabulary, and 300,000 documents in Science consisting of 490,770 n-grams in the vocabulary. No term stemming was performed as we wish to keep the original words. In fact, traditional unsupervised readability methods do not consider stemmed terms. We prepared two sets of document collection, one with stopwords[1] kept and another with stopwords removed. The objective is to study the role of stopwords in domain-specific readability (Refer Section 2). Note that we conduct experiments in each domain separately.

We used Zettair[2] to conduct document retrieval and obtained a ranked list using Okapi BM25 (Robertson et al., 1996) ranking function. BM25 retrieves documents based on relevance and the retrieved list contained a mix of easy readable and difficult to read documents. We then selected top-k documents retrieved from the ranked list where $k = 10$ for evaluation purpose. Selecting a higher value of k would lead to a huge cognitive load on the human subjects (which we describe later in the text) during annotation. Therefore, we keep this number as low as possible. Also, a previous study has found that users generally look at the first page of the search results containing the top ten documents (Silverstein et al., 1999).

Domain-specific information needs: Topics are queries posed to an IR system. We strictly followed topic development guidelines laid out in "INEX 2009 Topic Development Guidelines"[3]. We had asked two undergraduate students possessing beginner level knowledge in both Science and Psychology to generate domain-specific topics which represent real information needs. They generated 110 topics in Psychology and 150 topics in Science. We enlist some sample information needs in two domains here: Science: 1) "x-ray machine", 2) "acid and alkali" 3) "why the sky is blue", Psychology: 1) "depression", 2) "bad dreams", 3) "school of Psychology".

Annotations and metrics: To obtain the ground truth of domain-specific readability of the documents for evaluation purpose, two human annotators who were undergraduate students having varied background were invited. They had basic knowledge about Science and Psychology. They were asked to rate the documents based on relative domain-specific readability judgment of the documents. For the judgment, the selection was among "very low domain-specific readability" (i.e. difficult to read), "reasonably low domain-specific readability", "average domain-specific readability", "reasonably high domain-specific readability" and "very high domain-specific readability". These options were further translated to integer gains ranging from 4 to 0. A simple readable document obtained a score of 4 whereas the most difficult obtained a score of 0. In the beginning we acquainted them with the main aim of the study

[1] http://jmlr.csail.mit.edu/papers/volume5/lewis04a/a11-smart-stop-list/english.stop
[2] http://www.seg.rmit.edu.au/zettair/
[3] http://www.inex.otago.ac.nz/tracks/adhoc/gtd.asp

and showed them some sample documents from our test collection so that they could get an idea about the relative difficulty levels of the documents in the collection. Overall, the annotators annotated 983 documents in Psychology and 1442 documents in Science. In order to ascertain whether the manual annotation that we collected was feasible and reproducible, we assessed the inter-annotator agreement by computing the Cohen's Kappa coefficient. We found that there was an acceptable agreement between the annotators (approximately 0.8) in both Psychology and Science domains.

The evaluation metric is NDCG (same formula as in (Cai et al., 2011)) which is widely used for IR ranking effectiveness measurement. We computed the NDCG@i for each annotator and aggregated the final NDCG by taking the average. NDCG is well suited for our task because it is defined by an explicit position discount factor and it can leverage the judgments in terms of multiple ordered categories. NDCG@i scores will directly correlate with the readability annotation of the documents given by humans. Such scores can measure the quality of difficulty ranking of documents based on readability judgments provided by humans. If NDCG is high, it means the ranking function correlates better with the human judgments.

Result re-ranking scheme: We automatically re-rank the search results obtained from an IR system from *simple* to *difficult* readable documents using our proposed model as well as comparative methods. The reason is that domain experts normally employ complex search strategies to successfully retrieve documents based on their reading level (refer Section 2). They can find their material of interest easily but non-experts face difficulty in locating their content as they have to sift through the ranked list carefully to locate a document which can match their domain-specific reading level. In addition, previous related approaches have also followed similar re-ranking scheme (i.e. re-ranking from simple to advanced without integrating the readability scores in the initial retrieval score) such as (Yan et al., 2006; Nakatani et al., 2009; Kumaran et al., 2005) and in (Yan et al., 2011), the authors re-rank the top-k documents obtained from a baseline IR system based on decreasing specificity.

Comparative methods: We chose popular unsupervised general readability methods as our comparative models. They are ARI: Automated Readability Index, Coleman-Liau (denoted as C-L in the tables in our results), Flesch Reading Ease formula, Fog, LIX and SMOG. More details about these readability methods can be found in (Dubay, 2004). Our model does not have a syntactic component. Hence, it would be more appropriate to compare with the semantic components of the general readability methods (similar scheme also adopted in (Yan et al., 2006; Collins-Thompson and Callan, 2005). More details about the semantic components can be found in (Yan et al., 2006; Collins-Thompson and Callan, 2005; Dubay, 2004). For each readability formula; it computes a readability score for every document. Then the documents are re-ranked in descending order of the readability score. In addition, we also chose some recent unsupervised comparative methods described in (Collins-Thompson and Callan, 2005) such as Mean Log Frequency (denoted as `MLF`) and %UNK. We also compare our method with `CHM` described in Jameel et al., (Jameel et al., 2011). We denote their method as `CHM`.

In addition, we compare our method by manually collecting an extensive list of domain-specific concepts from online resources. The collection process was indeed cumbersome and time consuming but it will help us evaluate our method by mimicking the working principle of the recently proposed domain-specific readability methods which rely on some external knowledge-bases. Overall we collected about 900 domain-specific concepts in Science and about 600 in Psychology. In this method, we count how many times domain-specific terms occur in the

document with respect to the list contained in the lexicon and then divide by the number of words in the document to remove document length bias. We name this comparative method as Counts.

We had set the value for m in Equations 5 and 9 to 3 in our experiments. This could help capture tri-gram fragments which we believe is a suitable number for large datasets. We used MATLAB to compute SVD of the matrix using the "svds" function. The number of latent concepts in LSI were 200 as previous studies have found that 150-200 dimensions give optimal performance (Dumais, 1995). Our term weighting scheme was the product of normalized n-gram count and inverse n-gram document frequency (formulae given in (Salton and Buckley, 1988)). Our main models are SNCM1 and SNCM2 with stopwords kept intact. Our objective is to study the performance of our proposed variants by keeping the entire documents sequence intact without removal of any of the features as term order plays an important role in our model. Moreover, general traditional readability methods also work on original texts. We had set the value of $\alpha = \beta = 0.5$ in our experiments, which means that both the components have equal weights in determining the final readability ranking order.

5.0.2 Results and Analysis

To enlighten the reader more about the specificity values, we show some specificity values obtained from our experimental dataset in Table 2. The technical storyline of $Doc1$ revolves around *Earth Science* and $Doc2$ deals with *Lung Cancer*. Domain-specific terms which we indicate in bold text have obtained higher specificity values compared to common n-gram fragments. We can also observe that the domain-specific terms appear simple in terms of the number of syllables (denoted as Syl). Such n-grams will appear common to any readability formula which relies on the number of syllables for text readability prediction. Note that for a readability formula, if the number of syllables is more, the word is difficult.

Table 6: Varying α for SNCM1 in Science with stopwords.

The main result of the document ranking performance is given in Table 1. In the Psychology domain, SNCM2 has performed better than other comparative methods whereas in the Science domain we notice that SNCM1 has fared better than all other models. We performed a paired t-test between the SNCM variants and the comparative methods. We have obtained statistically significant improvement with ($p < 0.05$) for all comparisons. Counts did not perform well in both domains. An obvious reason is that this method demands a longer list of technical terms, which is extremely time consuming to obtain. Readability methods have failed to give optimal ranking performance. It is because they fail to capture the inherent semantics of text which our method can effectively capture. CHM performed rather poorly in both the domains. One reason could be due to the weak model and incorporation of non-linearity using a heuristic approach. %UNK has shown some good performance. One reason is due to the use of an elaborate list of words (over 3000). In Table 3 we present results based on the improvement we have obtained on query basis. Results show that our models have obtained tangible improvement against the comparative methods.

Some interesting conclusions can be derived from the results in Tables 4,5,6,7,8,9,10 and 11. These results highlight the role of the two components, namely, cohesion and specificity in influencing the overall ranking of the results. Tables 4,5,8 and 9 show the effect of varying α and β in the Psychology domain. Our discussion will mainly focus on the results when $\alpha = 0$, $\alpha = 1$ and $\beta = 0$, $\beta = 1$ because these values portray the contribution that the two components, namely, cohesion and specificity individually make in the overall ranking of the search results. We notice in the Psychology domain that ranking of the search results is significantly dominated by cohesion (note the values close to $\alpha = 1$ and $\beta = 0$). This observation can be reasoned out from the usage of terms across the documents in the collection. We noticed in the Psychology corpus that the documents are more general than the Science documents. Science documents contain relatively more domain-specific terms than Psychology documents. Thus the contribution of specificity will be more uniform across documents in Psychology than in Science. Hence usage of terminologies will be almost at the same level.

We obtained some interesting results in the Science domain as well. In Tables 6 and 7, we note

that the gap in the results when $\alpha = 0$ and $\alpha = 1$ is not very wide. This means that both the components have approximately equal role in affecting the final ranking of the search results. However an interesting conclusion is that cohesion has a slightly more dominant effect than specificity but the importance of specificity cannot be completely disregarded (we conclude this when $\alpha = \beta = 0.5$). Even for SNCM2 in Tables 10 and 11 the observations remain the same where we note that both components have almost equal role in affecting the overall ranking of the results.

@10	0.693	0.695	0.697	0.694	0.717

Table 11: Varying β for SNCM2 in Science without stopwords.

We can now infer that cohesion has a more deep seated role compared to specificity in the two domains but specificity cannot be completely disregarded. We also studied the behavior of SNCM variants along with the role of stopwords in the two domains. From the results we note the stopwords have an important role to play in influencing ranking. This stands consistent with the prior findings discussed in Section 2.

6 Conclusions and Future Work

We have presented our SNCM models where we form a fragmented n-gram sequence in a document. We find a least cost path in the n-gram sequence. The cost reflects the domain-specific readability of a text document. We have shown that general readability methods and other state-of-the-art unsupervised methods are not effective to determine the readability of a text document. Experiments in two domains show the superiority of our proposed models. Our proposed approach is more scalable than recently proposed domain-specific readability methods because we do not use any external domain-specific ontology to capture domain-specific terms.

In the future, we would study how the hyperlink structure of the web can aid in determining the reading difficulty of text documents. The hypothesis is that a general web page would link with other general web pages (Akamatsu et al., 2011) as well. We would also explore other features which could help improve readability ranking performance such as a web page layout and content such as fonts, title fields, line and paragraph breaks, etc.

Abstract

Coreference resolution is the problem of clustering mentions into entities and is very critical for natural language understanding. *This paper studies the problem of coreference resolution in the context of the newly emerging domain of Electronic Health Records (EHRs).* The commonly used "best-link" model for coreference resolution considers only the scores from a pairwise classifier in selecting the best antecedent. In this paper, we extend this model to include several constraints derived from surface-form of the mentions and the context in which they appear. Another major contribution of this paper is to show the use of domain-specific knowledge sources, mention parsing and clinical descriptors in deriving features which contribute to improved coreference resolution performance. We present experiments on 4 different clinical datasets illustrating that our approach outperforms a strong baseline and a state-of-the-art system by a wide margin.

Keywords: Natural Language Processing, Information Extraction, Coreference Resolution, Electronic Health Records, Knowledge Based Systems.

Proceedings of COLING 2012: Technical Papers, pages 1327–1342,
COLING 2012, Mumbai, December 2012.

1 Introduction

The HITECH (Health Information Technology for Economic and Clinical Health) Act, part of the 2009 economic stimulus package (American Recovery and Reinvestment Act) passed by the US Congress, aims at inducing more physicians to adopt *Electronic Health Records (EHRs)*. An EHR is an evolving concept defined as a systematic collection of electronic health information about individual patient. Ability to automatically extract information from EHRs lies at the heart of several applications.

This paper addresses the task of coreference resolution for EHRs. *Coreference resolution is the task of finding referring expressions in a text that refer to the same entity, i.e., finding expressions that corefer*. The set of coreferring expressions is called as a coreference chain. Consider the following text sampled from one of the EHRs in the corpus used by us:

> *This 63-year-old man had **[malignant fibrous histiocytoma of duodenum]**, discovered in 02/95. Other than **[a mass in the duodenum]**, the patient was also diagnosed with anemia. A **[leiomyosarcoma]** was resected after embolization of the splenic artery. However, **[it]** could not be completely excised; moreover **[the tumor]** metastasized to the liver as was discovered on follow up scan in 06/95.*

In the above text, all the phrases which are shown in brackets refer to the same entity and hence form a coreference chain. It is clear that identifying such coreference chains requires a lot of medical knowledge. For example, we need to know that "mass" can refer to a "malignant histiocytoma".

Most of the work on coreference resolution has focussed on the news text. Several different architectures have been proposed for coreference resolution. Recently, entity-based models for coreference resolution have been proposed. Such approaches try to directly model the entities in the text and usually involve some kind of global inference and tend to be quite complex. However, most of the best results on coreference resolution were achieved with simpler architectures which use a pairwise classifier between mentions and a decoding strategy like "closest-first" or "best-link" to first find the best antecedent for every mention. This step is then followed up by an inference procedure in which coreference chains are formed (Chang et al., 2011; Pradhan et al., 2011).

In this paper, we extend the "best-link" model to include several constraints derived from surface-form of the mentions and the context in which they appear. Another contribution of this paper is to show the use of domain-specific knowledge sources (like UMLS[1], MetaMap), mention parsing and clinical descriptors (obtained from medical ontologies) in deriving the features which are helpful for coreference resolution. In clinical Information Extraction (IE), researchers often map clinical text to UMLS concepts (Zheng et al., 2012; Rink et al., 2012). But such mapping alone doesn't allow an IE system to exploit the useful information contained in the parent trees of the concepts. Clinical descriptors designed by us overcome this limitation. We use two medical ontologies, MeSH[2] and SNOMED CT[3] to design our descriptors.

We conducted experiments on four different clinical datasets. Our results show that knowledge sources help in improving the recall and constraints help to increase the precision of the system. Knowledge and constraints used by us helped us to achieve significant performance improvements over a strong baseline derived from existing state-of-the-art approaches.

[2] http://www.nlm.nih.gov/mesh/meshhome.html
[3] http://www.ihtsdo.org/snomed-ct/

To summarize, the key contributions of our paper are as follows:

- This paper studies coreference resolution on the new and important domain of EHRs.
- This paper presents different knowledge sources which would be useful for Information Extraction in medical and clinical domains. We use medical ontologies (MeSH, SNOMED CT) to get clinical descriptors which encode useful information contained in the parent trees of the concepts.
- We propose a rich local model to find the best antecedent.
- We use *mention parsing* to obtain a semantic representation of the mentions. Similar technique can also be used for other domains.
- Our system outperforms a strong baseline on four different clinical datasets.

2 Task Description

Coreference resolution aims at clustering together textual mentions within a single document based on underlying referent entities. For our experiments, we used the datasets provided by i2b2 team as part of coreference challenge. *We use the same problem definition as was specified in the i2b2 coreference challenge.* Mentions have already been identified and classified into 4 types : test (TEST), treatment (TRE), problem (PROB) and pronoun (PRON). Coreference relation can exist only within the mentions of same type. However, PRON mentions can corefer with any other mention. Given the entity mentions along with the types, the aim is to build coreference chains for the first 3 types: TEST, TRE and PROB. Since PRON mentions can corefer with the mentions of other types, there are no separate pronoun (PRON) chains.

3 Coreference Model

In this paper, we view coreference resolution as a graph problem: Given a set of mentions and their context as nodes, generate a set of edges such that any two mentions that belong in the same equivalence class are connected by some path in the graph. We construct this entity-mention graph by finding out the best antecedent of each given mention (anaphor) such that the antecedent belongs to the same equivalence class as the anaphor. The "Best-Link" strategy (Ng and Cardie, 2002; Bengtson and Roth, 2008; Chang et al., 2011) for selecting the antecedent of a mention chooses as the antecedent that candidate which gets the maximum score according to a pairwise coreference function pc. We extend the "Best-Link" strategy by including several constraints in its objective function as shown below.

3.1 Decision Model: Constrained Best-Link

Given a document d and a pairwise coreference scoring function pc that maps an ordered pair of mentions to a value indicating the probability that they are coreferential, we generate a coreference graph G_d according to the following decision model:

For each mention m_i in document d, let B_{m_i} be the set of mentions appearing before m_i in d. Thus, $B_{m_i} = \{m_1, m_2, ..., m_{i-1}\}$. Let a be the highest scoring antecedent. Then, we have:

$$
\begin{aligned}
a &= \underset{m_j \in B_{m_i}}{\arg\max} \quad score_i(m_j) \\
&= \underset{m_j \in B_{m_i}}{\arg\max} \quad k_1 \cdot pc(m_j, m_i) - d(m_j, m_i) + \sum_{l=1}^{L} C_l(m_j, m_i)
\end{aligned} \tag{1}
$$

In the above equation, $d(m_j, m_i)$ refers to the normalized distance between m_j and m_i which takes values between 0 and 1. In equation (1), C_l refers to l^{th} constraint and is defined as follows (for all values of l):

$$C_l(m_j, m_i) = \begin{cases} 0 & \text{if } l^{th} \text{ constraint is satisfied} \\ -p_l & \text{otherwise} \end{cases} \quad (2)$$

If $score_i(a)$ is greater than a threshold δ, then we add the edge (a, m_i) to the coreference graph G_d. Threshold parameter δ is chosen to be $\frac{k_1}{2}$. Value of $pc(m_j, m_i)$ lies between 0 and 1. The value of k_1 is chosen to be sufficiently greater than 1 so that the pairwise classifier is given preference over the distance term in choosing the best antecedent. But if the pc values of any two candidates are almost similar, then the antecedent which is closer to the anaphor gets the higher score because of the distance term in Equation (1). Thus, our decision model combines the advantages of both "best-link" and "closest-first" models which are generally used for coreference resolution. Setting $k_1 = \infty$ and $L = 0$ reduces our model to the standard "best-link" decision model.

p_l is the penalty associated with the l^{th} constraint. Thus, different constraints can have different penalties. Higher the penalty associated with the constraint, the stronger it is enforced. If $0 < p_l < \frac{k_1}{2}$, then the constraint is soft because violation of such constraint by a mention pair doesn't necessarily rule it out. But if $p_l > \frac{k_1}{2}$, then the constraint becomes hard.

The resulting graph produced by the decoding technique mentioned above contains connected components, each representing one equivalence class, with all the mentions in the component referring to the same entity. Equivalence classes are determined by taking the transitive closure of all the links.

3.2 Pairwise Coreference Function

We train 4 classifiers, one each for TEST, TRE, PROB and PRON classes. Each of these classifiers takes as input an ordered pair of mentions (a, m) such that a precedes m in the document, and produces as output a value that is interpreted as the conditional probability that a and m belong in the same equivalence class. For any mention-pair (a, m), the classifier is chosen based on the type of mention m.

For each mention m we select from m's equivalence class the closest preceding mention a and present the pair (a, m) as a positive training example to the classifier which corresponds to the type of mention m. For each m, we generate negative examples (a, m) for all mentions a that precede m and are not in the same equivalence class.

We learn the pairwise classifiers using LIBSVM package (Chang and Lin, 2011).

4 Baseline

In this section, we describe the baseline system used by us. We designed the baseline system based on the existing state-of-the-art coreference systems which use pairwise models (Bengtson and Roth 2008; Haghighi and Klein 2009). Baseline system uses the coreference model as described in the previous section. However, there are no constraints in the baseline system. The features used for training the pairwise classifier have been described below. All the features used by us take only two values: 1 (if the feature is active) or 0 (if the feature is not active).

4.1 Lexical Features

Lexical features indicate whether two strings share some property. These features are listed below:

- Both the mentions have identical surface forms (i.e. $extent_{m_i} == extent_{m_j}$).
- Surface form of one of the mentions is a proper substring of that of another.
- Both the mentions share the same head word.

4.2 Syntactic Features

We check for the presence of several syntactic constructs among the mentions and generate the following features which tell whether or not the given mention pair satisfies the constructs:

- *Apposition*: Two noun phrases (NPs) are appositive when they are placed side-by-side with one element serving to define or modify the other e.g. *In a recent examination, the patient was diagnosed with **[medulloblastoma]**, **[a malignant brain tumor]**.*
- *Predicate Nominative*: The predicate nominative is the noun following a linking verb that restates or stands for the subject e.g. ***[Coronary Arteriosclerosis]** is a **[heart disease]** which happens when the coronary arteries become narrowed.*
- *Relative Pronoun*: It is a pronoun that modifies the head of the antecedent NP e.g. *After discussion , an **[abdominal CT scan]** was obtained **[which]** revealed diffuse metastatic lesions of the ribs .*

4.3 Semantic Features

Some of the coreferential mention pairs have similar but not identical heads. To find out whether any two words are similar or not requires semantic knowledge. Wordnet has been extensively used as a source of semantic knowledge for general English text. We generate the following two features from Wordnet:

- *Wordnet-head-match*: We get the synsets of heads of both the mentions and see whether the heads share any common synset. For example, the words *hemorrhage* and *bleeding* share the same synset which refers to the *flow of blood from a ruptured blood vessel*.
- *Wordnet-head-hypernyms-match*: Some closely related words (like *epistaxis* and *hemorrhage*) do not share any common synset. However, if we consider the parents (or hypernyms) of the synsets of such words in the Wordnet hierarchy, we can see that the two words are similar. We take only the immediate hypernyms of the synsets. Inclusion of hypernyms which are more than 1 level above the synsets of the words leads to over-generalization. For example, we may get that *nausea* and *anemia* are coreferent which is actually not true.

4.4 Distance-Based Features

We used the following distance-based features:

- *Adjacent-Mentions*: This feature is active if there is no intervening mention between the given mentions which has the same type as the mentions under consideration.
- *Distant-Mentions*: This feature is active if the two mentions are separated by more than 2 sentences.

5 Using Domain-Specific Knowledge

One of the major limitations of the baseline system is that it lacks domain-specific knowledge. In medical terminology, same concept can be represented in several different ways. For example, “headache”, “cranial pain” and “cephalgia” all refer to the same concept. Similarly, “Atrial Fibrillation”, “AF” and “AFib” also refer to the same concept. The baseline system is not sufficient to

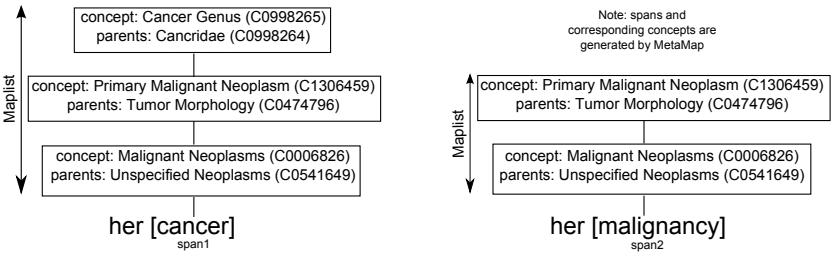

Figure 1: This figure shows the UMLS mappings for two mentions "her cancer" and "her malignancy". The terms "cancer" and "malignancy" have at least one common concept. Our matching procedure based on UMLS correctly predicts the given mentions to be coreferent.

address the ambiguity and variability that exists in medical terminology. To improve the performance of coreference resolution, we extended the baseline system by incorporating domain-specific knowledge into it.

5.1 UMLS and MetaMap

The UMLS (UMLS, 2012), or Unified Medical Language System, is a set of files and software that brings together many health and biomedical vocabularies. MetaMap (Aronson and Lang, 2010) is a configurable program which maps biomedical text to the UMLS Metathesaurus. We use the mapping provided by MetaMap to represent the mentions in a standard way which allows for effective matching of the mentions. We find the parents of concepts using the Web Service provided by UTS (UTS, 2012) (UMLS Technology Services).

Matching Mentions Using UMLS: We would refer to the surface forms of the two mentions by $s1$ and $s2$. First, we remove the stopwords from the given strings and then process the resulting strings using MetaMap and thus, get the mappings of the mentions to UMLS concepts. Next, we check whether any two spans (given by MetaMap) of $s1$ and $s2$ are equivalent. Two spans are considered equivalent if they share the same UMLS concepts (or parents of UMLS concepts). Whenever we find two equivalent spans, we remove them from $s1$ and $s2$. Finally, we check whether the resulting strings $s1$ and $s2$ match trivially. Two strings match trivially if they are identical or one of them is a substring of the other.

Consider Figure 1 for an example. This figure shows the UMLS mappings for two mentions "her cancer" and "her malignancy". "her" is considered as a stopword and is first removed from both the strings. Since the two spans "cancer" and "malignancy" share same UMLS concepts, they are equivalent. So, we remove "cancer" and "malignancy" from the two strings. The resulting strings are both empty and are considered to be matching.

Features Derived: Based on the matching procedure described above, we derive the following two features:

- *UMLS-Match*: In this feature, we do not consider the parents of the concepts during the matching
- *UMLS-Match-Parents*: In this feature, parents of the concepts are also considered during the matching

5.2 Mention Parsing

We parsed the mentions to extract the components like Modifiers, Body Parts and Anatomical Terms of location (ATs). We did not require exact match for these extracted components. We just specified that these components should not be incompatible with each other. The remaining portions of the surface forms of mentions were canonicalized and matching procedure described in Section 5.1 was used to determine whether they matched. Figure 2 shows an example where the structures obtained by parsing the two mentions are matching to one another.

Canonicalization referred to above involves the following two steps:

- *Expanding the abbreviations*: Clinical narratives use a lot of abbreviations. A few examples are: mri (magnetic resonance imaging), copd (chronic obstructive pulmonary disease) etc. Abbreviations were expanded to their full forms as a normalization step. We collected abbreviations from several sources like training data, Wikipedia[4], Medilexicon[5] etc. For ambiguous abbreviations, we considered all possible expansions. If a match was found using any of the expansions, then coreference pair was considered valid.
- *Converting Hyponyms to Hypernyms*: During preprocessing, we converted some of the common hyponyms to the corresponding hypernyms. Examples of such conversions are: chemotherapy → therapy, hemicolectomy → colectomy. Such conversions were found to be very helpful because it is a common practice in clinical documents to refer to some of the problems and treatments introduced earlier in the document with their more general names later on. These hyponym-hypernym pairs were collected from the unannotated training data in an unsupervised setting.

Features Derived: Following feature was derived from mention parsing:

- *Mention-Parsing*: This feature is true for the mention pairs which match according to the mention parsing procedure described above.

5.3 Clinical Descriptors

MeSH[6] (Medical Subject Headings) is the National Library of Medicine's controlled vocabulary thesaurus. It consists of sets of terms in a hierarchical structure that permits searching at various levels of specificity. We obtain MeSH descriptor for a concept in the following way:

1. First of all, we get all the paths from the concept to the root of MeSH hierarchy. In general, there can be more than 1 paths.
2. Then we construct one list which consists of the top 4 parents of all the paths obtained in Step 1.
3. The list obtained in step 2 is pruned where more preference is given to those parents which appear more frequently.
4. The final list obtained in step 3 is the MeSH descriptor of the concept.

Similar procedure is used to obtain the SNOMED CT[7] descriptor of a concept. SNOMED CT (SNOMED Clinical Terms) is yet another medical ontology which consists of the most comprehensive, multilingual clinical healthcare terminology in the world. SNOMED CT is owned,

[7] http://www.ihtsdo.org/snomed-ct/

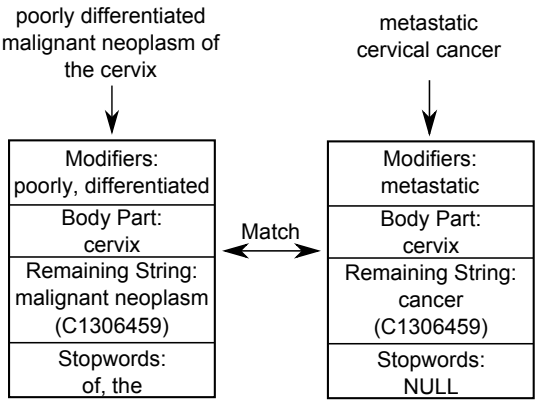

Figure 2: This figure shows the structures obtained by the mention parsing of two mentions shown on the top of the figure. Since the two structures match one another, we predict the two mentions to be coreferent.

maintained and distributed by the International Health Terminology Standard Development Organisation (IHTSDO). Figure 3 and Figure 4 show two different paths in MeSH and SNOMED CT parent trees for the same concept "Myocardial Infarction". We found that, in general, SNOMED CT gives much more paths (from concept to root of hierarchy) than MeSH. Some concepts in SNOMED CT have more than 300 possible paths to the root of hierarchy.

Features Derived: Based on the clinical descriptors described above, we derive the following two features:

- *MeSH-Match*: This feature is active if the Mesh descriptors of two concepts are the same
- *SNOMEDCT-Match*: This feature is active if the SNOMED CT descriptors of two concepts are the same

6 Description of Constraints

Constraints are used to model domain knowledge and they refer to those conditions which, if not satisfied, strongly indicate that the given mention pair is not coreferential. Features, on the other hand, can be more vague and don't necessarily provide such a strong clue. Constraints are applied only during the inference phase and not the learning phase. So, constraints can be added or removed without having to retrain the classifiers. Even if a particular constraint is not seen very often in the training data, it can still be very useful at the test time if the testing data contains cases where the constraint is applicable. This is a clear advantage of modeling constraints separately from the features. We divide the constraints in two categories depending on whether the constraint is derived from the surface form of the mentions or from the context in which the mentions occur. Constraints used by us are described in the following subsections. These constraints were obtained by the manual examination of small portion of training data.

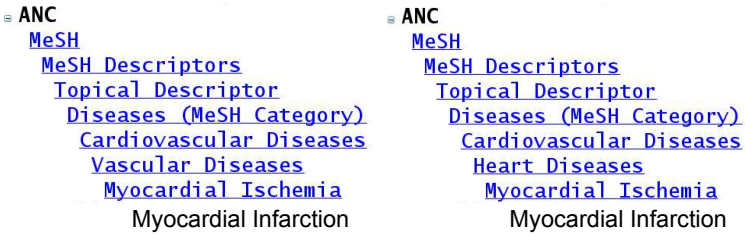

Figure 3: Figure showing two different paths in MeSH parent tree for the concept "Myocardial Infarction"

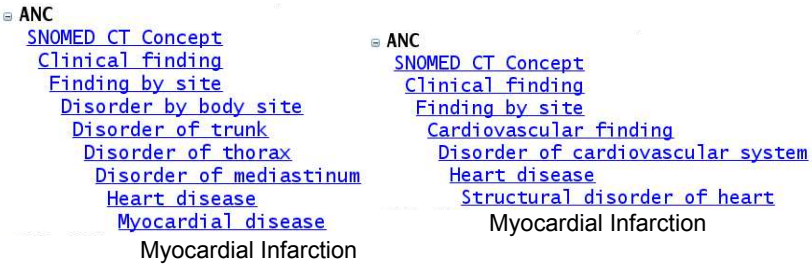

Figure 4: Figure showing two different paths in SNOMED CT parent tree for the concept "Myocardial Infarction"

6.1 Surface Form Constraints

Following surface form constraints were used by us:

- *Length Constraint*: Surface form of both the mentions must be at least 2 characters long.
- *Modifier Constraint*: Mentions should not have incompatible modifiers e.g. "small/large"
- *Body Parts Constraint*: If body parts (like chest, arm, head) are specified, they should not be incompatible.
- *Anatomical Terms Constraint*: If anatomical terms[8] (like proximal, anterior, dorsal) are specified, they should not be incompatible.
- *Popular Head Constraint*: Certain head words like "disease" occur very commonly in the dataset. Mentions which have same popular head are considered coreferential only if the classifier predicts the mentions to be coreferential even after removing the heads from the mentions.
- *Number Constraint*: Two mentions must agree in number.
- *Temporal Constraint*: If only one of the mentions contains the word "follow-up" or "repeat", then the mention pair is not considered coreferential because the two mentions refer to tests or treatments which have been done at different times.

[8] http://en.wikipedia.org/wiki/Anatomical_terms_of_location

6.2 Contextual Constraints

Following contextual constraints were used by us:

- *Family History*: If the left context of any mention (in a window of size 4) contains the phrase "family history", then the mention pair is not considered coreferential because one of the mentions refers to some family member of the patient and not the patient himself. Window size was determined using cross-validation on the training set.
- *Negation Constraint*: None of the mentions should be present in a negated form.
- *PRN Constraint*: Problem mentions which have "p.r.n." as the prefix can't participate in coreference relation because such mentions refer to hypothetical problems and not the real problems. For example, "p.r.n. headache" means "if the headache arises ...".
- *TEST Constraint*: We observed from the documents in the training data that the TEST mentions which appear under the heading "LABORATORY DATA" generally don't participate in coreference.

Other than the above mentioned constraints, following additional constraint was used to disallow coreference chains beginning with pronouns.

- In Equation (1), if m_j is a pronoun, then there must exist some mention m_k with $k < j$ such that m_k is a valid antecedent of m_j.

7 Experimental Setup

Datasets: For our experiments, we used the coreference datasets made available by i2b2 team as part of 2011 i2b2 challenge. The datasets consist of EHRs from three different organizations: Partners HealthCare (Part), Beth Israel Deaconess Medical Center (Beth) and University of Pittsburgh (Pit). The data from University of Pittsburgh is divided into 2 parts, namely Discharge and Progress records. All records have been fully de-identified and manually annotated for coreference. This gave us a total of 4 datasets. We would refer to these datasets as *Part*, *Beth*, *PitD* and *PitP* in the following discussion.

The total number of documents in the training set of *Part*, *Beth*, *PitD* and *PitP* are 136, 115, 119 and 122 respectively. Test set of *Part*, *Beth*, *PitD* and *PitP* contains 94, 79, 77 and 72 documents respectively. For more information about the datasets, please refer to Uzuner et al. (Uzuner et al., 2012). We used B-cubed (Bagga and Baldwin, 1998), MUC (Vilain et al., 1995) and CEAF (Luo, 2005) as the evaluation metrics in our experiments.

Choice of Parameters: We use cross-validation on the training data to determine the system parameters. In Equation (1), we set $k_1 = 100$. With this choice of k_1, distance term becomes significant only if the scores given by pairwise classifier for different mention pairs differ by less than 0.01. Since all our constraints are important to be enforced, we chose $p_l = 100$ in Equation (2) for all values of l. This choice of penalty parameters makes all the constraints hard.

8 Results

Table 1 compares the performance of four systems (1) Baseline (B), (2) Baseline + Knowledge (BK), (3) Baseline + Knowledge + Constraints (BKC) and (4) Baseline + Constraints (BC). We compare the performance of these systems for *Test*, *Treatment* and *Problem* categories on 4 different datasets, namely, *Part*, *Beth*, *PitD* and *PitP*. Table 1 reports precision (P), recall (R) and F1 scores for MUC evaluation metric. For B-cubed and CEAF Evaluation metrics, we only show the F1 scores because of space limitation. Please note that there are no separate scores for PRON category because there

are no separate PRON chains. PRON mentions are included within the TEST, TRE and PROB chains. Results shown in Table 1 are quite interesting and are explained below.

It is interesting to note that adding knowledge to the system always leads to higher recall values. On the other hand, addition of constraints always leads to higher precision values. Next, we note that different metrics behave differently in evaluating the performance of the systems. B-cubed metric gives higher F1 scores that CEAF metric which in turn gives higher F1 scores than MUC metric. This is because of the presence of large number of singletons in the corpora. B-cubed metric highly awards the correct prediction of singletons. MUC, on the other hand, is totally insensitive to singletons. CEAF is intermediate between B-cubed and MUC as far as singletons are concerned.

Next, we note the following major points about each category of mentions. For statistical significance tests, Bootstrap Resampling Test (Koehn, 2004) was used at $p = 0.05$.

1. ***Test***: For *Test* mentions, the best configuration is Baseline+Constraints (BC). For MUC metric, both BKC and BC performed the best for 2 corpora each. However, for B-cubed and CEAF evaluation metrics, BC performed the best for all the corpora. Hence, overall, we can say that BC is the best configuration for *Test* mentions. This is because of the fact that coreference for *Test* mentions (like "his ct scan", "a mammogram" etc.) can generally be easily predicted simply by looking at the surface forms. Also, many of the *Test* coreference chains are quite short with only 2-3 mentions which occur close to one another. So, knowledge is not so helpful for *Test* mentions.
2. ***Treatment***: For *Treatment* mentions, the best configuration is Baseline+Knowledge (BK). This is clearly evident from MUC metric. Only for *Beth* corpus, BKC performed better than BK but the difference is not statistically significant (67.8 vs 67.9). For B-cubed and CEAF evaluation metrics, the maximum F1 scores for *Treatment* category are quite close to Baseline scores and hence, the results are not statistically significant. Thus, B-cubed and CEAF metrics do not help much in predicting which system is better for *Treatment* mentions.
3. ***Problem***: For *Problem* mentions, the best system is Baseline+Knowledge+Constraints (BKC). This is clearly evident from B-cubed and CEAF Evaluation metrics. For MUC evaluation metric, BK performed better than BKC for 2 corpora. However, the difference in such cases is not statistically significant (69.1 vs 69.3 and 58.3 vs 58.4). Thus, we see that both, knowledge and constraints, benefit *Problem* mentions. This is due to the fact that *Problem* mentions, in general are quite long and complicated. *Problem* mentions generally occur with modifiers and have variegated surface forms. For example, "the patient's low potassium level" is coreferrent with "postoperatively hypokalemia".

Finally, in Table 2, we show the comparison of our system with a state-of-the-art system, Ware et al. (Ware et al., 2012), which used same test settings as ours. The numbers reported in Table 2 refer to the unweighted average of Bcubed, MUC and CEAF F1 scores computed across all the 4 corpora. We chose unweighted average for comparison because it was the official metric of i2b2 2011 shared task on coreference. We see from this table that our system consistently outperformed Ware et al.'s system for all categories of mentions.

9 Error Analysis

Table 3 shows the number of pairwise errors produced by our system on a portion of the test dataset. Rows indicate types of antecedent; columns are mention types. Each cell shows the number of precision/recall errors for that configuration. The total number of gold links is 2,252. We see that our system makes more precision errors than the recall errors. This is also confirmed by the results

Ware et al.	68.4	79.4	80.8
This Paper	**69.1**	**80.7**	**81.6**

Table 2: This table shows the comparison of system presented in this paper with a state-of-the-art system, Ware et al. The numbers refer to the unweighted average of Bcubed, MUC and CEAF F1 scores computed across all the 4 corpora.

	TEST	TRE	PROB	PRON
TEST	92/60	-	-	22/12
TRE	-	187/186	-	57/14
PROB	-	-	320/293	70/21
PRON	32/10	47/13	97/37	20/7
Total	124/70	234/199	417/330	169/54

Table 3: This table shows the number of pairwise errors produced by our system on a portion of the test dataset. Rows indicate types of antecedent; columns are mention types. Each cell shows the number of precision/recall errors for that configuration. The total number of gold links is 2,252.

in Table 1. Error analysis of our system reveals that its precision can be improved by analyzing the context of the mentions more deeply. For example, it would be helpful to know the time (if mentioned) at which a particular test was conducted. It would be also beneficial to know whether a particular problem is mentioned in relation to the patient or one of his/her family members. On inspection, we found that our system made recall errors only on very difficult mention pairs. Predicting coreference relation among such mention pairs requires a lot of reasoning.

10 Related Work

For news text, several different architectures have been proposed for coreference resolution. Systems have been developed which allow for entity-level features or features over sets of noun phrases (Culotta et al., 2007). Such methods generally involve some kind of global inference which is difficult to implement and may also be intractable. Research (Finkel and Manning, 2008; Haghighi and Klein, 2007; Poon and Domingos, 2008) has also been carried out to explore how to reconcile pairwise decisions to form coherent clusters.

However, pairwise models with rich knowledge base have been shown to be very successful in both supervised and unsupervised setups (Bengtson and Roth, 2008; Haghighi and Klein, 2009). An important step in such models is to find the antecedent for each mention. For selecting the antecedent, "best-link" decoding strategy has been shown to give better results than "closest-first". In this paper, we extended the "best-link" strategy used by researchers by incorporating other factors like distance between mentions, several constraints etc. during the inference step.

There has been an increasing interest in knowledge-rich coreference resolution (Uryupina et al., 2011; Rahman and Ng, 2011; Bryl et al., 2010; Ng, 2010; Ponzetto and Strube, 2006; Bean and Riloff, 2004). Wikipedia is one of the most common knowledge resources that have been used by researchers. However, Wikipedia is not very good for clinical text because it doesn't have sufficient coverage of medical terms and also lacks precision. *In this paper, we used domain-specific knowledge sources like UMLS, MeSH and SNOMED CT to improve coreference resolution in clinical*

domain.

One of the earliest works in coreference resolution in clinical domain is that of Zheng et al. (Zheng et al., 2011). In this work, authors review recent advances in general purpose coreference resolution to lay the foundation for methodologies in the clinical domain. Later, Zheng et al. (Zheng et al., 2012) describe a simple pairwise classification technique for coreference resolution in clinical domain and got an overall B-cubed score of 0.69 and MUC score of 0.35. Bodnari et al. (Bodnari et al., 2012) and Jindal et al. (Jindal and Roth, 2012) also use a pairwise classification technique for clinical coreference resolution and use UMLS to get some of their semantic features. However, they don't use the concepts' parents information available in UMLS. Uzuner et al. (Uzuner et al., 2012) give a brief overview of several systems which participated in 2012 i2b2 coreference challenge. Most of the systems submitted in the challenge were rule-based. Rink et al. (Rink et al., 2012) used a multi-pass sieve architecture which is similar to the one developed by Raghunathan et al. (Raghunathan et al., 2010). Xu et al. (Xu et al., 2012) developed an effective strategy for pronoun resolution where they first determined the type of the pronoun and then chose the closest preceding concept of the same type as the antecedent. All these works assumed mentions' boundaries (along with their types) to be given just like ours.

Conclusion

Electronic Health Records are becoming increasingly important and their automatic analysis lies at the heart of several applications. This paper presented a system for coreference resolution for EHRs. In this paper, we proposed a rich model for selecting the best antecedent which involves inference using pairwise classifier scores and several constraints derived from surface-form of the mentions and the context in which they appear. We also showed the importance of domain-specific knowledge sources and clinical descriptors for achieving good performance in coreference resolution. While the knowledge sources used by us helped to improve the recall, constraints were helpful to increase the precision of system. Our experimental results show that different mention types benefit to different extent from knowledge and constraints. Our system consistently outperformed a strong baseline and a state-of-the-art system on four different datasets.

Towards a Generic and Flexible Citation Classifier Based on a Faceted Classification Scheme

ABSTRACT
Citations are a valuable resource for characterizing scientific publications that has already been used in applications such as summarization and information retrieval. These applications could be even better served by expanding citation information. We aim to achieve this by extracting and classifying citation information from the text, so that subsequent applications may make use of it. We make three contributions to the advancement of fine-grained citation classification. First, our work uses a standard classification scheme for citations that was developed independently of automatic classification and therefore is not bound to any particular citation application. Second, to address the lack of available annotated corpora and reproducible results for citation classification, we are making available a manually-annotated corpus as a benchmark for further citation classification research. Third, we introduce new features designed for citation classification and compare them experimentally with previously proposed citation features, showing that these new features improve classification accuracy.

KEYWORDS: citation classification, feature extraction.

Proceedings of COLING 2012: Technical Papers, pages 1343–1358,
COLING 2012, Mumbai, December 2012.

1 Introduction

Citations are a valuable resource for characterizing scientific publications and their links to each other. They have been exploited for a number of natural language processing (NLP) and information retrieval (IR) applications, including summarization (Qazvinian and Radev, 2008; Qazvinian et al., 2010)[CJPF][1], improved indexing and retrieval (Ritchie et al., 2006)[CJPF]; and building integrated research databases (Nanba et al., 2004)[CJPF]. Bibliometric measures that quantify the impact of publications (e.g., Moed, 2005)[CJPF] are also based on citations.

Most of this work does not differentiate between uses of citations, e.g., whether a citation is more or less important to the paper or whether the paper's authors support or refute the claims made in the cited work. However, recently a number of research groups have attempted to classify citations with respect to dimensions like importance and relation to cited work (Teufel et al., 2006b; Dong and Schäfer, 2011; Sugiyama et al., 2010; Abu-Jbara and Radev, 2012)[CEPF]. By adding such fine-grained information to individual citations, the various applications of citation analysis can be better served; e.g., citations that are foundational to a paper may constitute better summary sentences for the cited paper.

Thus, there are clear potential benefits to fine-grained citation analysis; and a number of case studies have been published that demonstrate this potential (Nanba et al., 2004; Teufel et al., 2006b)[CEPF]. However, fine-grained citation analysis is currently not widely used in applications that access and analyze the scientific literature. In this paper, we identify a number of potential reasons for this state of affairs and propose solutions.

The first problem with current fine-grained citation analysis is that prior work has tended to develop custom classification schemes for a particular application. This means that the development cycle for a citation classifier must be started from scratch for each new application. In contrast to this prior work, we base our work on a standard classification scheme for citations from information science, the classification scheme of Moravcsik and Murugesan (1975)[CERF] (henceforth MM). We believe it is important to use an annotation scheme that is not bound to automatic citation classification for one particular task such as IR or bibliographic measures. Instead, it should be expressive enough to handle citations across many tasks. The MM scheme comprises four different dimensions or *facets*, which allows us to annotate the quality of the cited work along with its relation to the citing work. This gives the classification flexibility, so that it can be used in different application scenarios; e.g., some facets of the citation are more relevant for IR in digital libraries, while others are more useful in automatic summarization.

The second reason that fine-grained citation analysis has not seen widespread adoption is that it remains a challenge to accurately and automatically classify citations according to a predefined classification scheme (Teufel et al., 2006b)[CEPF]. We address this problem by introducing several novel features designed specifically for use in citation classification. Some of these new features are needed to support the more flexible and generic MM facet classification scheme. In particular, we extract novel features that capture the relationship between the citing paper and the cited paper. Identifying this relationship helps in understanding what motivated an author to reference the cited work. We also investigate how different features perform across the four facets, and how other variables, like the size of the context from which we extract features, affect the classification. We go on to compare different feature sets used for citation

[1]The citation annotation, described later in Sections 2 and 3, has likewise been applied to the citations in this paper. The following abbreviations apply: **C**=*conceptual*; **O**=*operational*; **E**=*evolutionary*; **J**=*juxtapositional*; **R**=*organic*; **P**=*perfunctory*; **F**=*confirmative*; **N**=*negational*.

classification. In particular we compare different lexical, syntactic, and positional features. To our knowledge this is the most extensive investigation of the comparative utility of features for citation analysis to date.

The final barrier to widespread adoption of fine-grained citation analysis is the fact that progress in the field has been hampered by the lack of a standard annotated corpus. Although all of the previous work we cover has used corpora of NLP articles for citation analysis experiments, none has tried reusing an existing corpus or annotation scheme. This makes accurately comparing results impossible, which in turn makes it difficult to gauge the advancement of the state of the art. Authors have focused on developing new annotation schemes, but no work has gone into building resources that allow the research community to evaluate and compare different citation classification methods.

As we will show below, results are also difficult or impossible to reproduce because existing citation approaches have not been described in sufficient detail and resources created or used for the approach have not been published. To address the lack of reproducible experiments in citation classification, we are making available, in conjunction with this paper, the manually-annotated corpus and feature vectors that produce the results reported here.[2] We hope that this corpus can provide a benchmark for further advances in citation classification.

The rest of the paper is structured as follows. Sections 2 and 3 cover the details of our annotation scheme and corpus, followed by a detailed description of the features used for classification in Section 4. Section 5 presents the different classification experiments we conduct with a discussion of the results in Section 6. Section 7 discusses related work. Finally, we close with a summary and an outline of future work.

2 Annotation scheme

In selecting our fine-grained classification scheme, we focused on two criteria. The first criterion is that we should consult the field of research that has the most expertise and the longest research record in developing classification schemes for citations. This field is information science. We have chosen the scheme proposed by Moravcsik and Murugesan (MM) because it adequately represents scientific literature for a broad range of citation classification scenarios. Furthermore, it is a well-established annotation scheme that is widely cited and used inside and outside of the information science community.

The second criterion for selecting the scheme was that it should be flexible and adaptable for different citation use cases. The MM scheme achieves this in that it is composed of four *independent* or *orthogonal* facets. For each facet, it assigns a label from a set of two labels. The scheme can be summarized with the four questions they posed: (i) Is the reference conceptual or operational? (ii) Is the reference organic or perfunctory? (iii) Is the reference evolutionary or juxtapositional? (iv) Is the reference confirmative or negational?

The *conceptual* vs *operational* facet – **CONC-OP** – asks: "Is this an idea or a tool?," where examples of tools are MRI in brain imaging and part-of-speech (POS) taggers in NLP. The *organic* vs *perfunctory* facet – **ORG-PERF** – distinguishes those citations that form the underpinnings of the citing work from more cursory citations. The *evolutionary* vs *juxtapositional* facet – **EVOL-JUX** – highlights the relationship between the citing and cited papers. If the citing paper builds on the cited work, it is EVOL while it is JUX if it presents an alternative to the cited

[2] `http://www.ims.uni-stuttgart.de/~jochimcs/citation-classification`.

work. Finally, **CONF-NEG**, the *confirmative* vs *negational* facet, captures the completeness and correctness of the cited work. A NEG citation usually is not derogatory, it may simply say that the cited work is weaker than the citing work or is otherwise missing some critical point. These distinctions are covered in more detail in the annotation guidelines.[2]

These four facets can be thought of as orthogonal dimensions along which citations can vary. This is the basis for flexible and adaptable citation analysis; e.g., a facet that is not relevant for a particular application can simply be omitted. If interactions between two facets are important for another application, they are made available by the citation classifier without complicating the model or its training.

Although there are now four facets to annotate for each citation instead of a single label, the annotation task is not more difficult. Making a binary decision is easier than trying to pick a label from ten possibilities with subtle differences between some of them. Yet, with the combination of different facets we still can achieve a finer-grained label.

It is also important to note that this classification has no undefined class. Several previous annotation schemes have a default label, *neutral* or *other*, that is assigned to a citation when no other classes can be. In the work we have seen that uses such annotation schemes, more than half of the citation instances are assigned this undefined label. In these cases, summarization or IR systems that want to make use of citation information obtain no useful information from the citation classifier for more than half of citations.

3 Corpus

Our corpus, like corpora from some previous studies (Athar, 2011; Dong and Schäfer, 2011)[CEPF], is taken from NLP literature. Specifically, we have taken the 2004 ACL proceedings from the ACL Anthology Reference Corpus (ARC) (Bird et al., 2008)[OEPF]. NLP literature was chosen because our annotators (NLP students) are more familiar with this data and can make more informed decisions when annotating the citations.

Some statistics on the number of documents and citations in the corpus can be found in Table 1. Each citation in the corpus has been independently annotated by at least two of six annotators. Gold labels are chosen by a simple majority vote and in the case of ties the votes of more experienced annotators are weighted higher. The annotators were given guidelines to help ensure consistent annotation. We built a browser-based annotation tool that displays the full text of the paper, so that the annotators can look at the wider context of the citation when necessary. In many cases the context necessary for annotation is only one sentence, but it will often span sentences or fill a paragraph.

section	docs	citations
main ACL	57	1668
student	6	101
poster/demo	21	239
total	84	2008

CONC	OP	EVOL	JUX
1792	216	1804	204
ORG	**PERF**	**CONF**	**NEG**
203	1805	1836	172

Table 1: ACL 2004 corpus (left) and summary of annotated citations (right).

As mentioned in Section 2, no facets were left undefined. This reduces the classification to only two classes and avoids a neutral class. For our purposes it is reasonable to avoid having a neutral class; e.g., a citation that is not explicitly CONF should still be implicitly considered CONF because including the citation is still an endorsement of the cited work.

Fleiss's κ values of the annotation are .42 (CONC-OP), .45 (EVOL-JUX), .18 (ORG-PERF) and .41 (CONF-NEG). These numbers indicate that the difficulty of the annotation task varies for the different facets, with ORG-PERF being most difficult.[3] Due to the highly skewed distribution, κ suffers from *prevalence* (Eugenio and Glass, 2004)[CEPF]; yet three of the facets still have *moderate* agreement (according to Landis and Koch (1977)[CEPF]), and ORG-PERF has *slight* agreement. We feel that the observed agreement[4] is high enough that we can rely on the gold labels for evaluation.

We are releasing the corpus along with this paper.[2] To the best of our knowledge this corpus is the first to be annotated by individuals other than the study's authors. It is important to have independent annotators to limit any bias in the gold-standard annotation. One consequence of this is that our inter-annotator agreement scores are lower than those previously published as the previous annotation came from the developers of the respective annotation schemes and from the authors reporting on the classification experiments using them.

4 Description of features

Our goal is to accurately classify citations according to MM, the annotation scheme described in Section 2. We make the assumption that the necessary clues for correctly labeling citations, both manually and automatically, can be found in the context of the citation, i.e., the running text surrounding the citation. If we are able to extract the right clues from the citation context we can accurately label the citation's use.

Because there is not yet a standard corpus for the task of automatic citation classification, the results from previous work are difficult to compare. Previous studies have used different corpora, different annotation schemes, different feature sets, and different classifiers. In an effort to borrow from – and eventually compare ourselves to – previous work, we investigate some of the features used previously and introduce our own. The reader may want to refer to the overview of features in Table 2 as we describe the features in what follows.

Lexical features. Much of the earlier work on automatic citation classification (Dong and Schäfer, 2011; Nanba and Okumura, 1999; Teufel et al., 2006b)[CEPF] relied on cue words and phrases ($\texttt{cues}_k$). These were often implemented as follows. For a class (e.g., Dong and Schäfer's *idea* class), a list of of cues (e.g., the word "following") are defined that indicate that class. Finally, a Boolean feature (e.g., $\texttt{cues}_{idea}$) is set to true if any word from the list is in the citing context. This results in k Boolean features where k is often the number of classification labels (although it can be greater, see Dong and Schäfer (2011)[CEPF]).

Different length n-grams were later used by Athar (2011)[CJPF] with results indicating that combined unigram, bigram, and trigram features (`1+2+3-gram`) performed better than unigrams (`1-gram`) and unigrams plus bigrams (`1+2-gram`).

We use only unigrams because they perform at least as well as using unigrams, bigrams and trigrams in our experiments, without introducing a much larger, sparsely-populated feature set. Unigrams should also be quite robust and perform reasonably well across the four facets.

Word-level linguistic features. Part-of-speech (POS) tags of the words in the citation sentence were used as features by Athar (2011)[CJPF] (`POS` and `1-gram+POS`). Select linguistic features

[3] MM's definition was "is the reference truly needed for the understanding of the referring paper," so the annotation hinges on the understanding of the individual annotator, resulting in higher disagreement.

[4] Agreements were: .86 (CONC-OP), .88 (EVOL-JUX), .72 (ORG-PERF), .91 (CONF-NEG)

feature class	name	source	type or *example value*	description
lexical feats.	cues$_k$	NO99, TST06, DS11	Boolean	k Boolean features: one for each group of cue words/phrases
	1-gram	Ath11, own	*hard*	unigrams
	1+2-gram	Ath11	*hard language*	unigrams & bigrams
	1+2+3-gram	Ath11	*hard language like*	unigrams, bigrams, & trigrams
word-level linguistic feats.	POS	Ath11	*NN, JJ, IN*	POS tags
	1-gram+POS	Ath11	*quality+NN, new+JJ*	POS tag-word conjunctions
	tense	TST06	*present, past*	verbal tense
	voice	TST06	*active, passive*	verbal voice
	modal	TST06	*can, may*	modal verb (if any)
	has-modal	own	Boolean	sentence has modal verb
	root	own	*have, present*	dependency root node
	main-verb	own	*present, use*	main verb
	has-1stPRP	own	Boolean	first person POS
	has-3rdPRP	own	Boolean	third person POS
	comp/sup	own	*more, better*	comparative/superlative POS
	but	own	Boolean	has "but"
	has-cf	own	Boolean	has "cf."
ling. structure feats.	dep-rel	Ath11	*pobj:to:information*	Stanford typed dependencies (de Marneffe et al., 2006)
	POS-pattern$_k$	DS11	Boolean	k Boolean features: one for each POS tag pattern
	is-constituent	own	Boolean	citation is a constituent
	self-comp	own	Boolean	author linked to comparative
	other-comp	own	Boolean	citation linked to comparative
	other-contrast	own	Boolean	citation is in contrastive clause
	self-good	own	Boolean	author linked to positive sentiment
location feats.	section	DS11	*Introduction, Method*	1 of 6 possible section headings
	paper-loc	TST06	unknown	citation position in paper
	paragraph-loc	TST06	unknown	citation position in paragraph
	section-loc	TST06	unknown	citation position in section
	sentence-loc	own	*beginning, middle, end*	location in the first quarter, middle half (25%-75%), and last quarter
frequency feats.	popularity	DS11	Integer	citations in the same sentence
	density	DS11	Integer	citations in the same context (sentence and its neighbors)
	avgDensity	DS11	Real	average density of neighboring sentences
sent. feats.	scilex	Ath11	unknown	scientific polarity lexicon
	cpol	Ath11	unknown	general polarity lexicon
	positive-words	own	*best, advantage*	general positive lexicon
	negative-words	own	*problem, against*	general negative lexicon
other feats.	self-cite	TST06	Boolean	citation to own work
	has-resource	own	Boolean	resource entity found with NER
	has-tool	own	Boolean	tool entity found with NER

Table 2: Feature list (grouped by feature class). NO99=Nanba and Okumura (1999); TST06=Teufel et al. (2006b); Ath11=Athar (2011); DS11=Dong and Schäfer (2011). "unknown" = exact definition of the feature (e.g., Boolean or Real) is unknown. Examples of possible feature values are given in italics where appropriate.

related only to the main verb were shown to be effective by Teufel et al. (2006b)[CEPF]; e.g., tense (`tense`), voice (`voice`), and modality (`modal`).

We also include modality in our feature set (`has-modal`) along with separate features for the main verb (`main-verb`) and the root (`root`) as determined by the MATE dependency parser (Bohnet, 2010)[OEPF]! We do not include POS as features per se, but some features are triggered by the occurrence of selected POS: 1st and 3rd person pronouns (`has-1stPRP`, `has-3rdPRP`); and comparatives and superlatives (`comp/sup`). Comparatives and superlatives can help distinguish CONF from NEG. Pronouns on the other hand may be useful in classifying EVOL-JUX, e.g., first person pronouns are used when clarifying the differences between proposed and cited approaches. We add two other features for the contrastive conjunction "but" (`but`) and the abbreviation "cf." (`has-cf`). In our analysis of citations we looked at the role of contrastive conjunctions in citation sentences and found these simple features to be useful.

Linguistic structure features. Dependency relations (`dep-rel`) were used as features and showed a marked improvement over the baseline by Athar (2011)[CEPN]! Dong and Schäfer (2011)[CEPF] used seven regular expression patterns of POS tags ($\texttt{POS-pattern}_k$) to capture syntactic information (e.g., ".*(VHP|VHZ) VV.*"); then $k = 7$ Boolean features marked the presence (or absence) of these patterns.

We add other new features related to the linguistic structure of the citation sentence. For `is-constituent`, the citation is labeled as a constituent if the authors appear outside of the parentheses with only the date in parentheses, e.g., "Gusfield (1997) showed that . . . ", or if the citation acts as a placeholder for the cited work following a preposition, e.g., ". . . following the experiments in (Kaplan et al., 2004)". These cases are distinguished from citations like: ". . . are two popular examples of kernel methods (Fukunaga, 1990; Cortes and Vapnik, 1995)". We are relying here on a certain style of writing and citation format, like that found in ACL proceedings. We expect this feature to help for ORG-PERF as organic citations are more likely to show up as constituents in citation sentences.

The personal pronoun and comparative features mentioned above (`has-1stPRP`, `has-3rdPRP`, and `comp/sup`) are useful features, but we would like to extract a more specific feature that links them. We want features that indicate that the citing work is better than the cited work. To obtain these features we parse the sentence and extract relations from the parse tree. For the author/comparative relation, we first find the comparative in the sentence and traverse the tree to find the subject of the phrase that contains that comparative. If the subject refers to the author of the paper (e.g., with a first person pronoun), we set the `self-comp` feature to true.

We also found that JUX citations are often set apart using contrastive conjunctions, e.g., *while* or *despite*. We again traverse the parse tree to extract the relationship between contrastive conjunctions and the citation (`other-contrast`), where the citation or cited authors show up in the dependent clause governed by the contrastive conjunction. The feature is set to true if the citation is found among the descendants of the contrastive conjunction.

Location features. The section of the paper in which the citation is located (`section`) was used as a feature by Dong and Schäfer (2011)[CEPF]! Teufel et al. (2006b)[CEPF] also included location features at different granularities: within the paper (`paper-loc`), within the paragraph (`paragraph-loc`), and within the section (`section-loc`).

We include a different location feature approximating where the citation is found in the sentence (`sentence-loc`): beginning, middle, or end. This feature is motivated by the fact that citations

at the end of the sentence are predominantly PERF.

Frequency features. Dong and Schäfer (2011)[CEPF] used the number of citations in a single sentence (`popularity`) and in the citation sentence plus its neighboring sentences (`density`) as features. They also included a third feature for the average density of neighboring sentences (`avgDensity`).

Sentiment features. Athar (2011)[CEPF] included two different polarity lexicons. One is hand-crafted and specific to the scientific domain (`scilex`). The other is the large general purpose polarity lexicon from Wilson et al. (2005)[OEPF] (`cpol`). He also tried features (`neg`) that account for negation. This was done by appending "_neg" to the end of the 15 lexical items that follow any negation term.

We were not able to obtain the scientific polarity lexicon, but use the polarity lexicon from Wilson et al. (2005)[OEPF] to extract sentiment features. Our polarity features are represented as a bag of words (BOW) where the citation context words present in the polarity lexicon are added to the BOW features `positive-words` or `negative-words` according to their polarity. Although CONF-NEG is not strictly a matter of sentiment, we still apply this feature hoping for improvements on this facet.

Self-reference feature. Teufel et al. (2006b)[CEPF] used a feature, `self-cite`, that indicates if one of the citing authors also (co-)authored the cited work. This feature is unique in that it is the only feature based on the reference and not the individual citation and therefore not taken from the context in which it is found.
