Introduction from the Program Chairs

The members of the International Committee on Computational Linguistics were immensely privileged to be able to accept the invitation to hold our 24th COLING Conference here in India, a country which can justly be thought of as the center of the linguistic world. This is where Panini wrote the first formal grammar in the 6th century BC and where a linguistic diversity flourishes today that is nothing short of astounding to the rest of us. This conference has received twice as many submissions as any of its predecessors and, in many ways, is twice as rich because of the high proportion of contributions by teachers, researchers and, above all, students. Many are from India and other countries, such as Iran, with long and diverse linguistic traditions. There are challenges here for linguists of all varieties, most especially for those who put their faith in n-grams and machine learning.

The 195 full-length technical papers in 5 parallel tracks, 138 posters, and 66 demonstrations that will be presented still constitute no more than a quarter of the total number of submissions. The chairs of some of the 26 program subcommittees were overwhelmed with both their number and their quality. The International Committee is always greatly indebted to the area chairs and reviewers for the invaluable work that they do. Never so much as on this occasion.

Our greatest debt is clearly to our colleagues here in Mumbai, as will become clear to all as the week proceeds. They were even less well equipped than we on the permanent committee to predict what they were getting into, but they have risen to the occasion in every way and you will find them to be immensely warm, helpful, and resourceful hosts.

COLING's founding fathers wanted these conferences to be more than learned presentations. They wanted them to be opportunities to meet, and talk and delight in the company of other who share our fascination with language and the processes that make it work. Some call this the COLING spirit. There is nowhere that could nurture this spirit more effectively than here in India.

Martin Kay
Christian Boitet
(Program chairs)
December 2012, Mumbai

Introduction from the Organizing Chairs

It is a matter of great pride that the 24^{th} International Conference on Computational Linguistics (COLING 2012) is taking place in India, the land of multilinguality and multiculure. The organization of an event of COLING's scale takes enormous energy, planning and time. Two years back, in Beijing, when COLING was awarded to India, we knew that the task will be demanding, and happily for us, the NLP team at IIT Bombay, the organzing institute, has risen to the occasion.

At the time of going to press, the total number of registrants in COLING has exceeded 700. With delegates coming from 60 countries, COLING 2012 will witness a colourful diversity of language and culture, and fittingly so. Conforming to current practices of international conferences, there are two days of workshops and tutorials before the main conference and one day of workshop immediately after. 15 focussed and topical workshops will be attended by about 300 delegates, as will be 6 high quality tutorials of contemporary interest.

Social events include a reception in the evening of 10^{th} Dec, a banquet in a nearby 7 star hotel on 11^{th} Dec, an excursion to the famed Bhaja caves on 12^{th} Dec and a cultural evening of Indian classical music on 13^{th} Dec. Bhaja Caves, built in the period 3^{rd} century BC to 2^{nd} century CE, is a set of Buddhist monastery-caves near the hill station of Lonavala, nestled in the Sahayadri mountain ranges, about 90 km to the south-east of Mumbai. There will be cultural evening on the fourth day of the conference, featuring a solo performance on "tabla", the representative of Indian percussion instruments, and another solo on Sitar, an instrument that drew world's attention Indian classical music tradition.

Indian Institute of Technology Bombay is fittingly the host of COLING 2012. IITs have, over the years, emerged as the premier institutes of technology in India. The Computer Science and Engineering Department at IIT Bombay is one of the largest and oldest Departments of CSE in the country. Each and every member of the 40 strong NLP group at IIT Bombay is toiling hard to make COLING 2012 a resounding success.

The Government and industries have been our generous sponsors. All their names and logos are to be found in printed and USB proceedings. We thank them wholeheartedly.

Technology Development in Indian Languages (TDIL) project of Department of IT, Ministry of Communication and Information Technology, has been the harbinger of growth of NLP in India. COLING happening in India is a result of this long history of active patronage.

Logistics wise, the “large events” – inauguration, invited speeches, reception and the cultural program – are in the convocation hall of IIT Bombay. Oral presentations are all in the newly constructed Victor Menezes Convention Center (VMCC) about 200 mtrs from the convocation hall. Poster presentations are in the convocation hall, except on the first day, when it is VMCC.

A very competent team of volunteers will be available for any assistance. We hope COLING participants will have a memorable time in India.

Pushpak Bhattacharyya
Rajeev Sangal
(Organizing chairs)
December 2012, Mumbai

Program Committee:

Program Chair: Martin Kay (Stanford University)
Program Co-chair: Christian Boitet (University of Grenoble)
Workshop Chair: Prof. Laurent Besacier
Tutorial Chair: Prof. Sadao Kuroshashi

Area Chairs:

Indian language technology: Dipti Sharma (IIIT Hyderabad)
Underresourced languages: Vincent Berment (C&S, Paris & LIG, GETALP, Grenoble)
Morphology & POS Tagging: Gábor Prószéky (MorphoLogic & Pázmány Péter Catholic University, Budapest)
Grammar and formalisms: Hans Uszkoreit (DFKI, Saarbrücken)
Parsing: Mark Johnson (Macquirie Univ., Sydney)
Semantics: Igor Boguslavsky (RAS, IPPI/IITP, Moscow & UPM, Madrid)
Discourse and pragmatics: Eva Hajičova (Charles Univ., Prague)
Coreference analysis resolution: Alexander Gelbukh (Instituto Politécnico Nacional, Mexico-city)
Ontologies and terminology: Christophe Roche (Univ. de Savoie, Chambéry)
Textual Entailment: Lauri Karttunen (Stanford University)
Resources and annotation: Nicoletta Calzolari (CNR – ILC, Pisa)
Psychological and neurological modelling: Véronique Aubergé CNRS – LIG lab Grenoble) & Rohit Manchanda (IITB, Mumbai)
Empirical Machine Translation: Philipp Koehn (University of Edinburgh)
Expert or Hybrid Machine Translation: Mandel Shi (Xiamen University)
Hybrid man+machine architectures & human factors: Hervé Blanchon (Université de Grenoble (LIG, GETALP))
Information Retrieval: Jian-Yun Nie (Univ. de Montréal (RALI))
Summarization: Horacio Saggion (Universitat Pompeu Fabra) & Sivaji Bandyopadhyaya (Jadavpur University)
Named Entity recognition: Sergei Nirenburg (Univ. of Maryland, Baltimore)
Word Sense Disambiguation: Mathieu Lafourcade (Univ. de Montpellier II (LIRMM))
Sentiment and text classification: Yorick Wilks (Univ. of Sheffield)
Information & content extraction, text mining: Junichi Tsujii (MSRA, Beijing)
Question Answering: Constantin Orasan (University of Wolverhampton)
Speech recognition and synthesis: Roland Kuhn (National Research Council of Canada, Ottawa)
Software internationalization & localization: Andy Way (Univ. of Dublin and Applied Language)
Deployment of NLP-based applications, software integration & quality: Rajeev Sangal (IIIT Hyderabad) & Christian Boitet (Université de Grenoble (UJF, LIG, GETALP))
Natural Language Generation: Donia Scott (Univ. of Sussex)

Invited Speakers:

Prof. Paul Kiparsky (Stanford University)
Prof. Makoto Nagao (Kyoto University)
Prof. Dipti Misra (Sharma IIIT-Hyderabad)
Prof. Barbara Moser-Mercer (University of Geneva)

Organizing Committee:

Organizing Chair: Pushpak Bhattacharrya
Organizing Co-Chair: Rajeev Sangal
Vasant Zende
Rupash Modak
Ganesh Ramakrishnan
Balamurali A R
N. Vasudevan
Rahul Sharnagat
Raj dabre
Jaya Sarswati
Rajita Shukla
Gajanan Rane
Samir Soni
Ritesh Shah (CDAC Mumbai)
Deepak Jagtap
Anup Kunchukuttan
Abhijeet Mishra
Brijesh Bhatt
Swapnil Choudhary
Laxmi Kashyap
Kahsyap Popat
Manish Shrivastava

Publication committee:

Publication chair: Roger Evans (University of Brighton)
Ms. Sudha (IIT Bombay)
Mrs. Rajita Shukla (IIT Bombay)
Mr. Rahul Sharnagat (IIT Bombay)
Mr. Kashyap Popat (IIT Bombay)

List of the 723 reviewers for COLING-2012, Mumbai

Eneko Agirre, University of the Basque Country, Spain.
Lupe Aguado, Universidad Politécnica de Madrid, Spain.
Khurshid Ahmad, Trinity College, University of Dublin, Ireland.
Rania Al-Sabbagh, University of Illinois at Urbana-Champaign, United States.
Vicente Alabau, Universitat Politècnica de València, Spain.
Inaki Alegria, University of the Basque Country, Spain.
Laura Alonso Alemany, Universidad Nacional de Córdoba, Argentina.
Le An Ha, Univ. Wolverhampton, United Kingdom.
Sophia Ananiadou, University of Manchester, United Kingdom.
R Ananthakrishnan, IBM Research - India, India.
Ion Androutsopoulos, Athens University of Economics and Business, Greece.
Gabor Angeli, Stanford, United States.
Marianna Apidianaki, LIMSI-CNRS, France.
Eiji Aramaki, The university of Tokyo, Japan.
Karunesh Arora, CDAC, India.
Nicholas Asher, CNRS, IRIT, Université Paul Sabatier, Toulouse, France.

Minimum Description Length as the basis of Panini's grammar

Prof. Paul Kiparsky
Robert M. and Anne T. Bass Professor in the School of Humanities and Sciences
Department of Linguistics, Stanford University

Abstract
Panini attempted, and to a considerable extent succeeded, in constructing the shortest possible complete grammar of Sanskrit that contains a description of its own metalanguage. Minimizing the total length of the grammar required introducing a rule or convention just in case it achieves overall economies in the grammar which outweigh the cost of stating it.

The grammar presupposes nothing beyond certain elementary relations (such as "before" and "after") and operations (such as "replace"). Based on them, it defines a rich descriptive formalism. Simplicity dictates the inclusion of rules of grammar that encode all generalizations about Sanskrit phonology, morphology, and syntax, as well as of rules that define its grammatical categories, and of metarules that stipulate how rules of grammar apply and interact with each other. The grammar uses a fixed rule format, phonological and morphosyntactic features, rule ordering, cyclicity, blocking, the equivalent of Theta roles, inheritance hierarchies, and several hundred technical terms denoting classes of lexemes and morphemes. Four levels of representation (approximately corresponding to semantics, syntax, morphology, and phonology) emerge from the analysis.

Completeness of empirical coverage requires, among other things, the exhaustive treatment of derivational morphology, clausal syntax, variation (three degrees of optionality), and even of certain dialectal and sociolinguistic facts. Some of the abovementioned devices could be dispensed with in a less exhaustive description, as I will illustrate with the karaka system.

The grammar appears to be very nearly optimal. Although this has not be proved (except for certain subsystems), it appears likely, for no-one has been able to shorten the grammar in non-trivial ways (without losing content), either by modifying the rules without changing the metalanguage, or by modifying the metalanguage with additional devices and conventions, or removing some of the existing ones.

It would be anachronistic to construe the formal apparatus used by Panini as embodying a "theory": from his perspective it merely serves to compress the grammar. But the fact that many of the same conventions and principles that modern generative grammar posits as universals of language emerge just from the attempt to construct the maximally compact description of a single language is quite remarkable. It could

be taken as a challenge to the widespread assumption that learners are innately equipped with a format for grammatical description. For if a generative grammar can be arrived at purely by minimizing description length, without relying on any further prior assumptions, might not language acquisition by humans proceed in the same way? I will argue that this is not the case, because there is no effective procedure for constructing the maximally compact representation without prior analytic bias. In fact, the near-perfection of Panini's grammar and its metalanguage required hand-crafting by many generations of grammarians. In contrast, the rapidity of normal language acquisition, and the existence of robust cross-linguistic generalizations, remains a persuasive argument for UG.

The adaptive brain: acquiring a complex cognitive skill in complex contexts

Prof. Barbara Moser-Mercer
Director, Department of Interpretation
Faculty of Translation and Interpretation, University of Geneva

Abstract
Real-time human communication across language barriers relies on consecutive and simultaneous interpretation, a complex cognitive skill that can be acquired only over a certain period of time. Interpreting novices differ from interpreting experts in terms of their knowledge and knowledge organization, their analytical strategies, their use of memory processes, and the smoothness and speed with which they execute the interpreting task. In order to be able to move from comprehending a speech in one language and simultaneously interpreting that speech into another, the learner needs to make considerable adaptations to component processes of tasks already mastered, for the most part, before even being admitted to an interpreter training program. These adaptations concern mostly language comprehension and knowledge organization, component skills non-interpreters need in order to communicate. One must thus assume that significant changes occur in brain activity (functional changes or plasticity) and brain structure (structural plasticity) during the acquisition of interpreting skills that are the result of learning, knowledge re-organization, strategy acquisition, and task monitoring.

In investigating this hypothesis we have recently found evidence for brain structural plasticity in individuals training to become simultaneous interpreters as they develop expertise in this skill. We found that in interpreting students, but not in matched multilingual controls, there is an increase in gray matter volume over the course of a 15-month training program in brain regions known to be involved not only in semantic processing but also in aspects of executive function and error monitoring. Tasks involving the conversion of content from one language to another (i.e., translation and interpretation) mainly engage a left-lateralized cortico-subcortical circuit, including the basal ganglia, inferior frontal gyrus, and DLPFC. There is strong anatomical support for functional links between these regions. We propose that the evidence suggests the presence of two distinct networks contributing to the executive control of language. Although perturbing either may have superficially similar behavioral consequences, they are likely to have differing roles.

The plasticity of the brain allows for reshaping and reorganization, acquiring expertise in a task involves the generation of new neuronal connections whose survival is dependent on stimulation through extended electrical pulses that reverberate in the neural net to establish associations and connections between areas of specialized

information. The interpreter is constantly establishing logical connections on-line between what has already been comprehended and what is being heard, relying on multiple associations that have been formed while preparing for a specific assignment. The interpreter's ability to link new to existing information is thus one of the prime skills to be developed during skill acquisition: being able to associate multiple facets of data in neural networks with only a single sensory trigger firing up the entire network of associated facts emerges as one of the most important factors for successful skill acquisition. Fluency and speeded expert performance develop in a learning environment that is highly contextualized and provides multiple exposures to information so that the task can be executed efficiently as the multilingual brain adapts to complex demands.

Our understanding of skill acquisition in interpreting then informs our pedagogical approach and allows us to design learning environments for even the most extreme contexts, with socio-cultural environments characterized by political instability and conflict, where skills need to be acquired swiftly and reliably.

Digital Book, Digital Library, and Natural Language Processing

Prof. Makoto Nagao
Professor Emeritus, Kyoto University
Former President, National Diet (Congress) Library, Japan

Abstract
The following topics will be discussed with the author's experience with natural language processing and its applications to digital library.

1. Features of forth-coming digital books compared to the present-day paper books
2. Features of digital library which organizes digital books and offers highly sophisticated utilization of knowledge accumulated in digital library. This includes problems in digitization, structuring of a book according to the table of contents, varieties of retrieval methods which extract sections of a book, linking related parts of books as a hypertext structure, etc.
3. Construction of an ideal digital library based on these features
4. Natural language processing technologies which are required for the construction of future digital libraries.

NLP from Paninian Perspective

Prof. Dipti Misra Sharma
Prof. Dipti Misra Sharma

Abstract
Akshar Bharati, for several years now, has been pursuing NLP basing its linguistic models on Paninian grammatical framework. The talk will re-look at how the concepts from Panini's Grammar help in selecting and modelling linguistically informed NLP (both building resources and systems). (Akshar Bharati et al, 1995) proposed Computational Paninian Grammar models for various levels of linguistic analysis. It is noticed that it works well for relatively free word order languages. Not only, the insights from Panini's grammar help in exploiting morphological properties in computationally efficient parsing but also help in the selection of appropriate features for better machine learning.

Panini's grammar focusses on how language is used for comunication. Thus, language is viewed as a system which encodes information. There are three major schools of thought in the Indian grammatical tradition, the grammarians, the logicians and the text analysts. All of these schools lay emphasis on interpretation of meaning (Shaabdabodha)from what is given in a sentence. The grammar provides ways of identification of various linguistic units, their generation processes, relations across units and the syntactic realization of these relations. The talk will look at how a principled application of the concepts and the methods given in this tradition help in developing efficient computational models.

Most parsing approaches in NLP adopt either a constituency based grammar model or a dependency based one. Conversion from one to the other, combining constituency and dependency representation and producing a hyprid tree are some of the areas that the scholars in NLP have been looking at in the direction of bringing the two approaches together. However, Paninian approach suggests that languages encode information both ways. Thus, the talk will also explore whether both consituency and dependency can be incorporated in a single model and whether this would lead to better parsing.

Multi-dimensional feature merger for Question Answering

Apoorv Agarwal[1] *J. William Murdock*[2]
Jennifer Chu-Carroll[2] *Adam Lally*[2] *Aditya Kalyanpur*[2]
(1) Department of Computer Science, Columbia University, New York, NY, U.S.A.
(2) IBM T.J. Watson Research Center, Yorktown Heights, NY, U.S.A.
apoorv@cs.columbia.edu, {murdockj, jencc, alally,
adityakal}@us.ibm.com

Abstract

In this paper, we introduce new features for question-answering systems. These features are inspired by the fact that justification of the correct answer (out of many candidate answers) may be present in multiple passages. Our features attempt to combine evidence from multiple passages retrieved for a candidate answer. We present results on two data-sets: Jeopardy! and Doctor's Dilemma. In both data-sets, our features are ranked highest in correlation with gold class (in the training data) and significantly improve the performance of our existing QA system, Watson.

Keywords: Question Answering, multi-dimensional feature merger, Watson.

Proceedings of COLING 2012: Technical Papers, pages 1–16,
COLING 2012, Mumbai, December 2012.

1 Introduction

Most existing factoid question answering systems adopt search strategies and scoring algorithms with the assumption that a short passage exists in the reference corpus which contains sufficient information to answer each question. This assumption largely holds true for short and focused factoid questions such as those found in the TREC QA track (Voorhees and Tice, 2000). Examples of TREC QA questions include "*When did Hawaii become a state?*" and "*What strait separates North America from Asia?*" However, some more complex factoid questions contain facts encompassing multiple facets of the answer, which often cannot be found together in a short text passage. Consider the following examples, selected from collections of Jeopardy![1] and Doctor's Dilemma[2] questions, respectively:

> (1) WHO'S WHO IN SPORTS: Born in 1956, this Swedish tennis player won 6 French Opens & 5 straight Wimbledons (A: Björn Borg)
>
> (2) CARDIOLOGY: Murmur associated with this condition is harsh, systolic, diamond-shaped, and increases in intensity with Valsalva (A: Hypertrophic cardiomyopathy)

In both examples, information presented in the question can reasonably be expected to be in documents that describe the respective answer entities. However, it is quite unlikely that all the information will be present in one or two adjacent sentences in the document. More specifically, in example (1), we find birth year and nationality information in the basic biographic section of documents about Björn Borg, while statistics about his tennis record can generally be found in a section about Borg's career. Similarly, for example (2), the descriptions of typical murmurs associated with hypertrophic cardiomyopathy (harsh, systolic, and diamond-shaped) may not fall under the same section as the impact of Valsalva maneuver on the murmur (which is a factor used to distinguish hypertrophic cardiomyopathy from aortic stenosis). As a result, a typical passage retrieved from most reference corpus would cover only a portion of the facts given in the question.

These multi-faceted factoid questions present a challenge for existing question answering systems which make the aforementioned assumption. Consider the following short passages relevant to the question in example (2):

> (2.1 a) Hypertrophic cardiomyopathy generates a harsh late-systolic murmur, ending at S2.
>
> (2.1 b) The straining phase of the Valsalva maneuver induces an increase in the intensity of the systolic ejection murmur of hypertrophic cardiomyopathy.
>
> (2.2 a) A harsh, late-peaking, basal murmur radiating to the carotid arteries suggests aortic stenosis.
>
> (2.2 b) A classic physical finding of aortic stenosis is a harsh, crescendo-decrescendo systolic murmur that is loudest over the second right intercostal space and radiates to the carotid arteries.

Existing systems which evaluate each passage separately against the question would view each passage as having a similar degree of support for either hypertrophic cardiomyopathy or aortic

[1] http://www.jeopardy.com; Jeopardy! is a registered trademark of Jeopardy! Productions, Inc.
[2] http://www.acponline.org/residents_fellows/competitions/doctors_dilemma

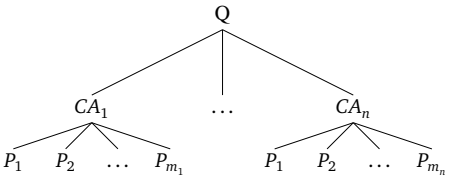

Figure 1: Typical question answering scenario. *Q* refers to question. *CA* are candidate answers for question *Q*, and *p* refers to passages supporting candidate answers.

stenosis as the answer to the question. However, these systems lose sight of a crucial fact, namely, that even though each passage covers half of the facts in the question, (2.1 a) and (2.1 b) cover disjoint subsets of the facts, while (2.2 a) and (2.2 b) address the same set of facts.

In this paper, we introduce the notion of *multi-dimensional feature merger* or *MDM* features, which allow for passage scoring results to be combined across different dimensions, such as question segments and different passage scoring algorithms. In this motivating example, MDM features that combine results across question segments would capture the broader coverage of passages (2.1 a) and (2.2 b), and thus enable the system to recognize hypertophic cardiomyopathy as a better answer for the question than aortic stenosis. We describe a general-purpose MDM feature merging framework that can be adopted in question answering systems that evaluate candidate answers by matching candidate-bearing passages against the question. We discuss our implementation of this MDM feature merging framework on top of our own question answering system, Watson. Finally, we demonstrate how passage scoring results can be merged across various dimensions in our system, resulting in 1) new features that are more highly correlated with correct answers than the base features from which they were derived, and 2) significant component level performance improvement and 3) end-to-end performance improvement. We present a comprehensive set of experiments for our current domain of interest – the medical domain and a less comprehensive set of experiments for Jeopardy! data.

The rest of the paper is organized as follows. In section 2, we describe our feature set. Since we build on existing state-of-the-art QA system, in section 3, we briefly describe the current system, focusing on the component of the system that we enhance in this paper. In section 4, we describe passage scorers in the current system, with specific examples of features that leverage scores assigned to passages by these scorers. In section 5, we presents a detailed description of the data we use for training and testing. Additionally, we present experiments and results to show the impact of our features. Section 6 presents a survey of current work in question answering. Finally, we conclude and present future direction of research in the last section.

2 Multi-dimensional feature merger (MDM)

Given a question, *Q*, each of its candidate answer, *CA*, has a set of supporting passages (Figure 1). In a typical question-answering system, support of each passage for a candidate answer is quantified. Then a merging strategy is used to combine the support of all passages for a particular candidate answer. In this paper, we introduce a general framework for merging support from supporting passages.

The methodology of calculating the support of a passage for a candidate answer is called *passage scoring* (Murdock et al., 2012a). At an abstract level, a passage scorer is responsible for quantifying how well a passage *matches* a question. We represent a question and a passage as an ordered set of

sum($\vec{s}$)	avg($\vec{s}$)	std($\vec{s}$)	max($\vec{s}$)	min($\vec{s}$)	non-zero($\vec{s}$)
$\sum_{j=1}^{cols} s_j$	$\frac{sum(\vec{s})}{cols}$	$\sqrt{\frac{\sum_{j=1}^{cols}(s_j - avg(\vec{s}))^2}{cols-1}}$	$\arg\max_{j\in[1,cols]} s_j$	$\arg\min_{j\in[1,cols]} s_j$	$\lvert\{s_j \lvert s_j \neq 0 \forall j \in [1, cols]\}\rvert$

Table 1: Standard formulae that constitute $g(M)$

Question	large	land	animal	has	large	ears	
P1.1	x_1	x_2	x_3	x_4	x_5	x_6	$\vec{f_{1,1}}$
P1.2	x_7	x_8	x_9	x_{10}	x_{11}	x_{12}	$\vec{f_{1.2}}$
P2.1	x_{13}	x_{14}	x_{15}	x_{16}	x_{17}	x_{18}	$\vec{f_{2,1}}$
P2.2	x_{19}	x_{20}	x_{21}	x_{22}	x_{23}	x_{24}	$\vec{f_{2.2}}$

Table 2: Passage match scores for question and passages in Figure 2.

terms ($Q = \{q_1, q_2, \ldots, q_n\}$), and ($P = \{p_1, p_2, \ldots, p_m\}$) respectively, Passage scorers align question terms to passage terms and assign a *score* based on how well the terms align. For example, a passage scorer will take as input Q and P and output a vector of scores that represents how well the passage matches the question. We denote this vector for P as $\vec{f}$ such that f_i is the score of how well one of the passage terms matches the i^{th} term in the question. Note the length of this vector is fixed per question but may vary across questions.

We collect all these vectors per question, per candidate answer into a matrix, M. For example, CA_1 may be represented as a matrix where row i corresponds to the passage scoring vector for passage P_i. An element of this matrix, $f_{i,j}$ is the score assigned by one of the passage scorers of how well passage P_i aligns with the term j in the question Q.

This matrix is of variable dimensions for different candidate answers per question. Number of rows could be different because the number of supporting passages could be different for each candidate answer for the same question. Since different questions have different number of question terms, the number of columns could be different for candidate answers across questions. Therefore, we cannot capture the distribution of this matrix simply by linearizing the matrix.

In this paper, we define a function $f : M \rightarrow \mathbf{R}^N$, that maps each matrix into feature vector of fixed length, N. This function is defined as follows:

$$f(M) =< g(M), g(M') >$$

where M' is the transpose of matrix M and g is a function $g : M \rightarrow \mathbf{R}^{N/2}$ that maps a matrix into feature vector of fixed length, defined as follows:

$$g(M) =<\text{sum}(\vec{s}), \text{avg}(\vec{s}), \text{std}(\vec{s}), \max(\vec{s}), \min(\vec{s}), \dim(\vec{s}), \text{non-zero}(\vec{s})>$$

where $\vec{s}$ is a vector of dimensionality $\dim(\vec{s})$, such that $s_j = \sum_{i=1}^{rows} f_{i,j}$ and the remaining standard formulae are given in Table 1.

Consider an example Jeopardy! question:[3] *This large land animal also has large ears.* Consider two candidate answers and their supporting passages:

[3] modified for readability.

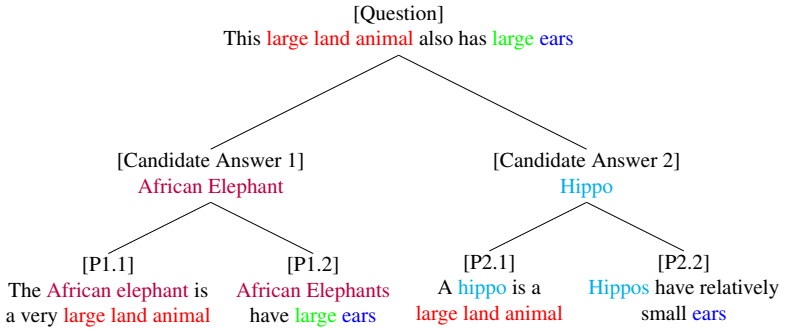

Figure 2: A specific example showing candidate answers and supporting passages for a modified Jeopardy! question. P1.1 means first justifying passage for the first candidate answer.

1. Candidate answer 1: African Elephant
   (a) P1.1: The African Elephant is a very large land animal.
   (b) P1.2: African elephants have large ears.
2. Candidate answer 2: Hippo
   (a) P2.1: A hippo is a large land animal.
   (b) P2.2: Hippos have relatively small ears.

This example is shown pictorially in Figure 2

Table 2 abstractly shows how passage scorers assign values to specific question terms for specific passages. For example, consider the P1.1 row, which represents how well the passage *The African elephant is a very large land animal* supports the answer *elephant* for the question *This large land animal also has large ears*. If the passage scorer is effective, it will give a high score to x_1, x_2 and x_3 (because the passage does, indeed, provide strong justification for "elephant" satisfying the requirements of being large land animal). It will give a very small score (typically 0) to x_4, x_5, and x_6, because the passage says nothing about elephants having large ears. However, some passage scorers may be mislead by the fact that the term "large" appears twice question and either one could align to the one occurrence in the passage. Often some passage scorers match too many terms and thus assign credit to terms that don't deserve it while others match too few and miss important content; this is why we have a diverse collection of scorers and let the classifier sort out how much to trust each of them.

Using one of the existing merging strategy, say MAX, candidate answer 1, African Elephant, will get assigned a feature value equal to $MAX\{(x_1+x_2+x_3+x_4+x_5+x_6),(x_7+x_8+x_9+x_{10}+x_{11}+x_{12})\}$. So either passage P1.1 or passage P1.2 will be selected as an optimal passage. As is apparent from this merger strategy, it does not attempt to leverage the complementary information in the two passages. Our merging strategy will attempt to capture the distribution of alignment across passages. For the matrix for African Elephant, M, $f(M) =< g(M), g(M') >$. First dimension of vectors

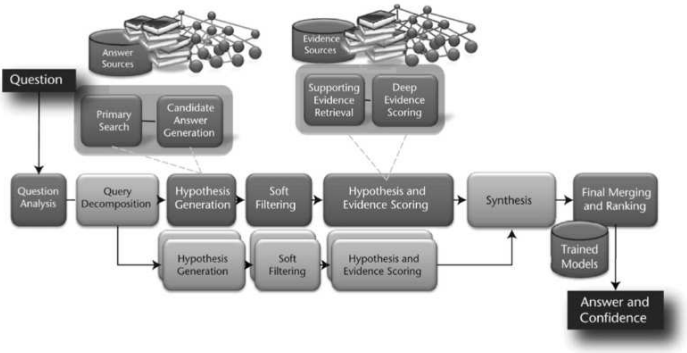

Figure 3: Architecture of Watson, state-of-the-art DeepQA system (taken from (Ferrucci et al., 2010)).

$g(M)$ and $g(M')$ will be the same, because $sum(\vec{s}) = sum(\vec{s'}) = \sum_{i=1}^{12} x_i$. But others will be different. For example, $mean(\vec{s}) = \frac{1}{6} * sum(\vec{s})$, whereas, $mean(\vec{s'}) = \frac{1}{2} * sum(\vec{s})$.

Note, the $sum(\vec{s})$ feature is aggregating the information across passages. In a passage scorer, which assigns 1 for a match and 0 otherwise, it is clear why this feature will have a higher value for African Elephant, the correct answer, than Hippo (because Hippo's don't have *large* ears).

Our framework is general in three ways: 1) It is independent on the type of passage scorer, 2) More matrix operations (like *rank(M)*), may be easily added to the definition of function $g(M)$, and 3) Our framework is easily extensible to beyond two dimensions, which can be used to capture additional orthogonal feature dimensions (see future work section for an example).

In the following sections, we first describe a specific, and state-of-the-art QA system, Watson. We present where our features fit in the larger architecture. Then we give an overview of specific passage scorers and merging strategies in the current system, followed by experiments and results showing that the new features we introduce add value to the current system.

3 Overview of Watson

IBM undertook the challenge to build a question-answering system named *Watson* that is able to answer open domain questions, such as those posed in a U.S. quiz show Jeopardy!. An overview of the architecture of Watson is illustrated in Figure 3. We refer the reader to (Ferrucci et al., 2010) for a detailed description of the architecture. In this section, we present a high level overview of the system pointing out where our features fit in.

The DeepQA system analyzes a question, *Question Analysis* (Lally et al., 2012), and generates multiple possible candidate answers, *Hypothesis Generation* (Chu-Carroll et al., 2012).It then applies many different answer scoring algorithms, each of which produces features that are used to evaluate whether the answer is correct. One way in which DeepQA evaluates candidate answers is to first retrieve passages of text that contain the candidate answer, via a technique called Supporting Evidence Retrieval; each passage is then scored using a variety of algorithms called passage scorers

$$< Q_1, CA_1, -1 >, < Q_1, CA_2, -1 >, \ldots, < Q_1, CA_i, 1 >, \ldots, < Q_1, CA_{n_1}, -1 >$$
$$< Q_2, CA_1, -1 >, < Q_2, CA_2, -1 >, \ldots, < Q_2, CA_j, 1 >, \ldots, < Q_2, CA_{n_2}, -1 >$$
$$\ldots$$
$$< Q_m, CA_1, -1 >, < Q_m, CA_2, -1 >, \ldots, < Q_m, CA_k, 1 >, \ldots, < Q_m, CA_{n_m}, -1 >$$

Figure 4: Training and test data for a question-answering system. Each question Q has multiple candidate answers, CA, where few, if any, are correct (class = 1).

in the *Hypothesis and Evidence Scoring* phase (Murdock et al., 2012a). All of the features are sent to a *Final Merging and Ranking* (Gondek et al., 2012) component, which uses machine learning techniques to weigh and combine features to produce a single confidence value estimating the probability that the candidate answer is correct. The features we introduce are extracted and made available to the machine learning model in the Final Merging and Ranking component, where the scores assigned by different passage scorers are available. In the next section 4, we give details of existing passage scorers and their feature merging strategies used prior to the framework introduced in this paper.

4 Passage scoring

Our question-answering system works by finding candidate answers, employing a variety of algorithms to compute feature values relating to those answers, and then using a statistical classifier to determine which candidate answer is correct. A question-answering scenario is shown in Figure 1. For a given question Q, search components find a set of candidate answers $\{CA_1, CA_2, \ldots, CA_n\}$. The task of the classifier is to decide which of the candidate answers is the correct answer. Hence the training and test data for that classifier looks as in Figure 4.

Each candidate answer is associated with one or more passages that contain the candidate answer. A subset of the algorithms that compute feature values in our system are the passage scoring components. These components evaluate the evidence that a single passage provides relating to how well the candidate answer satisfies the requirements of the question. Thus among the feature values associated with a candidate answer, some will be passage scoring features.

Our passage scorers are described in detail elsewhere (Murdock et al., 2012a). Here we provide only a brief introduction to provide context for later sections of this paper. We have a variety of passage scoring algorithms that use different strategies for determining which parts of a question to attempt to match to each part of a passage and for determining whether two parts of a passage match. Some attempt to align question terms to passage terms using syntactic structure and/or semantic relations, while others use word order or ignore the relationship among terms completely (e.g., simply counting how many question terms appear in the passage, regardless of whether those terms are similarly arranged).

Watson's passage scorers leverage available annotation components developed for the DeepQA framework, such as dependency parsing, Named Entity (NE) recognition, coreference resolution and relation detection. The question and the passage are decomposed into sets of terms, where a term can either be a single token or a multiword token. All of these scorers try to determine the amount of overlap between the passage and the question by looking at which terms match. The individual scorers put different restrictions on when a term is considered to *match*.

Currently, there are four scorers being used in the system:

1. **Passage Term Match**: Assigns a score based on which question terms are included in the passage, regardless of word order or grammatical relationship.

2. **Skip Bigram**: Assigns a score based on whether pairs of terms that are connected or nearly connected in the syntactic-semantic structure of the question match corresponding pairs of terms in the passage.

3. **Textual Alignment**: Assigns a score based on how well the word order of the passage aligns with that of the question, when the focus is replaced with the candidate answer.

4. **Logical Form Answer Candidate Scorer** (LFACS): Targets high-precision matching between the syntactic structures of passages and questions, and is therefore quite restrictive concerning structural overlap of the question and the passage. Like Skip Bigram, it operates on syntactic-semantic structural graphs, which contain one node for each lexical item.

Each passage scoring component produces a fixed number of feature value pairs for each candidate answer within each passage. Some of these values range from 0 to 1, where a high score indicates that the passage matches the question well based on that passage scorer's evaluation criteria; other passage scorers have other ranges. Watson's final answer merging and ranking component considers a pre-defined set of features and applies a machine learned model to score each candidate answer. However, since each candidate has multiple, and generally a varying number of supporting passages, we use a merger to combine passage scores for $<$ candidate answer, passage $>$ pairs into a fixed set of features. For example, if a candidate answer has three passages and a passage scorer assigns a value of 0.5, 0.6, and 0.7 to each passage, these scores may be merged using a merger strategy like MAX. Using this merger strategy, the feature added to the learning model for the candidate answer under consideration will be $MAX(0.5, 0.6, 0.7) = 0.7$.

We have the following three distinct algorithms that we use to merge features across passages (Gondek et al., 2012).

1. Maximum: The final score for the candidate answer is the maximum score for that answer in any passages found for that answer.

2. Sum: The final score for the candidate answer is the sum of the scores for that answer in each of the passages found for that answer.

3. Decaying sum: The final score for the candidate answer is computed to be $\sum_{i=0}^{m} \frac{p_i}{2^i}$, where $p_0, p_1, \ldots, p_m$ are the scores of the passages that contain the answers, sorted in descending order.

A key limitation of our earlier work is that the passage scorers capture limited complementary information that the passages have to offer. For example, in Figure 2, a passage scoring component may assign scores $s_{1.1}, s_{1.2}$ to passages P1.1 and P1.2 respectively. A merger strategy that takes maximum across passages will choose $MAX(s_{1.1}, s_{1.2})$ as the optimal supporting passage. However, since these passages have complementary information to offer, it would be better to somehow aggregate this information. This is exactly where our multi-dimensional merging features come into the picture.

As described in earlier publications (Gondek et al., 2012), for each of our features, we have two other derived features: a feature for whether that feature is missing and a standardized version of the

Feature name	Explanation	In terms of Table 2
MDM-TextualAlignment-sum-then-mean	For each question term, compute the sum of the Textual Alignment scores across all passages, and then compute the mean of the sums	$f(M) = [(x_1 + x_7) + (x_2 + x_8) + (x_3 + x_9) + (x_4 + x_{10}) + (x_5 + x_{11}) + (x_6 + x_12)]/6$
MDM-SkipBigram-transpose-sum-then-mean	For each passage, compute the sum of the Skip-Bigram scores across all question terms, and then compute the mean of the sums	$f(M) = [(x_1 + x_2 + \ldots + x_6) + (x_7 + x_8 + \ldots + x_{12})]/2$
MDM-LFACS-max-then-sum	For each question term, compute the maximum of the LFACS scores across all passages, and then compute the mean of the maxima	$f(M) = max(x_1, x_2, \ldots, x_6) + max(x_7, x_8, \ldots, x_{12})$
MDM-SkipBigramScore-transpose-sum-then-nonZeroColumns	For each passage, compute the sum of the Skip-Bigram scores across all question terms, and then compute the number of sums that are non-zero	Set $cnt = 0$. If $(x_1 + x_2 + \ldots + x_6) > 0, cnt = cnt + 1$. If $(x_7 + x_8 + \ldots + x_{12}) > 0, cnt = cnt + 1$. $F(M) = cnt$.

Table 3: Examples of MDM features. First column is the feature name, column 2 a natural language description of the feature and the third column is the exact mathematical formula in reference to Table 2 for passages P1.1 and P1.2 belonging to the candidate answer 1.

feature. When the value of a feature is missing, we assert a value of 0 for the feature and a value of 1 for the corresponding derived missing feature; this allows the learner to distinguish between cases where the feature actually has 0 value versus cases where it simply did not apply at all. The standardized version of a feature is computed by subtracting the mean value of that feature and dividing by the standard deviation for that feature. Both mean and standard deviation are computed across all answers to a single question, *not* across all answers to all questions in the test set. The purpose of the standardized feature is to encode how much the base feature differs from a typical value of that feature for a single question.

In Table 3, we present examples of some top scoring (in terms of correlation with the gold class) MDM features. For a passage scoring feature X, we produce the following MDM features: MDM-X-sum-then-mean ($avg(\vec{s})$), MDM-X-transpose-sum-then-mean ($avg(\vec{s'})$), MDM-X-sum-then-max ($max(\vec{s})$) etc.

5 Experiments and Results

To demonstrate the generality of our approach, we experimented with two data sets, an open-domain question set and one focused on the medical domain. We briefly describe these data sets in this section. Our first open-domain test set is a randomly selected set of 3,505 Jeopardy! questions. Jeopardy! questions span a large number of domains, including arts and entertainment, history, geography, and science. These questions are also generally more complex, incorporating multiple loosely related facts about the correct answers, particularly as compared with typical questions from the TREC QA track. The last characteristic makes Jeopardy! questions an excellent test set for our MDM feature merging framework.

Our second test set is a collection of 905 Doctor's Dilemma questions. Doctor's Dilemma, also

	#Questions	#Positive	#Negative	#Average cand. per Q
Jeopardy!	11,520	12,173	2,555,396	222.87
Doctor's Dilemma	1,322	2,338	543,963	413.23

Table 4: Data distribution for our data-sets. #Question refers to number of questions. #Positive refers to number of positive instances i.e. correct answers to questions, #Negative refers to number of negative instances and #Average cand. per Q refers to the average number of candidates considered for a particular question. Note, this is simply total number of positive and negative examples divided by the number of questions in the data-set.

known as Medical Jeopardy, is a competition organized by the American College of Physicians for medical interns and residents and held each year at the Internal Medicine meeting. The format of these questions is modeled after Jeopardy!, while their content is focused solely on topics related to medicine. Although not as linguistically complex as Jeopardy! questions, Doctor's Dilemma questions generally also consists of multiple facts about the correct answer, making it suitable as a test set for MDM features. Following are some examples from the Doctor's Dilemma domain:

1. The syndrome characterized by joint pain, abdominal pain, palpable purpura, and a nephritic sediment. Answer: Henoch-Schonlein Purpura.

2. Familial adenomatous polyposis is caused by mutations of this gene. Answer: APC Gene.

3. The syndrome characterized by narrowing of the extra-hepatic bile duct from mechanical compression by a gallstone impacted in the cystic duct. Answer: Mirizzi's Syndrome.

We use a supervised learning paradigm, with features extracted as described in previous sections. We use logistic regression classifier for training and testing. We report results on a held-out test set for both data-sets. The distribution of training set for the two data-sets are in Table 4. We test on 3,505 Jeopardy! questions and 905 DD questions.

We present three types of analyses to show the usefulness of our features. First, we present the correlation of our features with the gold class (for the training set only) i.e. correctness of a candidate answer. Second, we present a *component level analysis*, where we add our features to a baseline QA system and show improvement. Third, we present results on the end-to-end Watson system.

5.1 Correlation

A standard way to judge the goodness of features is to look at the features' Pearson's r correlation with the gold class (Hall, 2000). The Pearson's r correlation coefficient between feature X and gold standard Y is given by:

$$r = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2}\sqrt{\sum_{i=1}^{n}(Y_i - \bar{Y})^2}}$$

where $\bar{X}$ and $\bar{Y}$ are the arithmetic mean of feature values and gold class values respectively. We refer to the degree of correlation between the feature and the gold class as the "informativeness" of the feature. Naturally, we would like to keep features that have high informativeness.

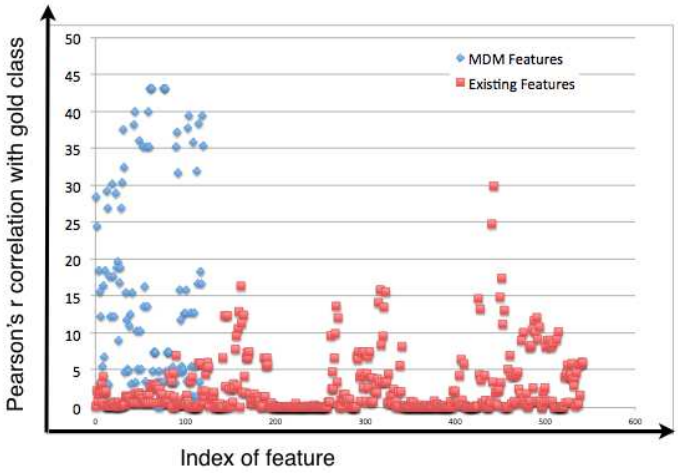

Figure 5: Inform analysis comparison of MDM features with the existing features in the system trained on **Jeopardy!** data. X-axis is the feature index (in no specific order) and Y-axis is the % correlation of features with the gold class.

Figure 5 presents the informativeness of existing features (red squared dots) and MDM features (blue diamond dots) for the Jeopardy! data-set. In figure 5, the x-axis is the feature index (existing features indexed from 1 to 535 and new features indexed from 1 to 110) and the y-axis is the informativeness of the features. For example, the highest informativeness of existing features (square red dot) is 30% ($100 \cdot r$), while the highest informativeness of MDM features is 43.2%. Many of the MDM features have higher informativeness than the most correlated feature in the existing system.

Similar is the case with the medical domain data. Figure 6 presents the informativeness of existing features (red squared dots) and MDM features (blue diamond dots) for the Doctor's Dilemma data-set. The highest informativeness of MDM features is 21.5%, which is comparable to the three existing features with highest informativeness (between 20% to 21%). However, as the graph shows, the vast majority of MDM features have substantially higher informativeness than the original features. the Jeopardy! domain, many of the MDM features are more correlated with answer correctness than most of the original features.

5.2 Component level analysis

As described in section 3, we add new features in the final merger stage of the system. Our features are calculated for each of the four passage scorers described in section 4. In this section, we evaluate the impact of these MDM features when only a single passage scoring component is employed in the system. To do so, we create a *component level baseline* for each of our four passage scorers as follows: on top of the Watson answer-scoring baseline configuration(Ferrucci et al., 2010), which includes all of the standard question analysis, search, and candidate generation, but only one answer scorer (which checks answer types using a named entity detector (Murdock et al., 2012b)) and a simplified configuration for merging and ranking answers. We add each of our existing Passage

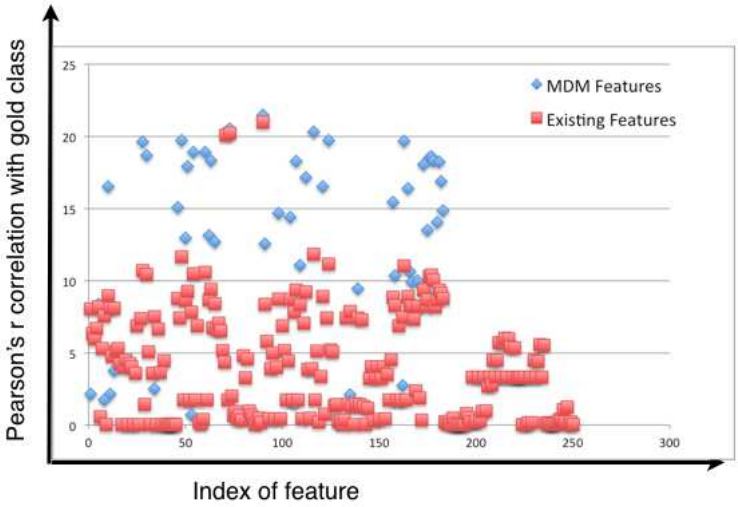

Figure 6: Inform analysis comparison of MDM features with the existing features in the system trained on **Doctor's Dilemma** data. X-axis is the feature index (in no specific order) and Y-axis is the % correlation of features with the gold class.

Term Match, Skip Bigram, Textual Alignment, and LFACS passage scoring, to create four baseline systems. We then compare each baseline to the system with our MDM features for the corresponding passage scorer and show a significant gain in Precision@70% and accuracy.

We often consider Precision@70% as a numerical measure that combines the ability to correctly answer questions and the ability to measure confidence; this metric corresponds to the precision when the system answers 70% of the questions of which it is most confident.

Table 5 present results for our component level analysis for Doctor's Dilemma questions. A component level baseline for each passage scorer was computed as described above. System performance improves across the board after adding MDM features for a passage scorer. Using

	Component Level Baseline		With MDM features	
Passage Scorer	Precision@70%	%Accuracy	Precision@70%	%Accuracy
Passage Term Match	24.9	20.2	29.2	23.4
Skip Bigram	26.8	21.5	28.7	23.3
Textual Alignment	22.9	18.8	25.7	21.1
LFACS	25.7	20.3	28.5	22.4

Table 5: Component level comparison for Doctor's Dilemma data-set for each of the four passage scorers. Each component level baseline is the answer-scoring baseline plus features for one of the passage scorers. All the numbers after adding MDM features for a passage scorer are significantly better than the baseline by $p < 0.05$, using McNemar's significance testing.

	Baseline		With MDM features	
Data-set	Precision@70%	%Accuracy	Precision@70%	%Accuracy
Doctor's Dilemma	37.2	29.2	40.2	31.3

Table 6: End-to-End comparison for medical domain data, Doctor's Dilemma. Baseline refers to the configuration with all the current features in the system. With MDM features refers to the configuration when we add all our MDM features to the existing feature set. This difference in performance is statistically significant with $p < 0.05$, using McNemar's significance testing.

McNemar's significance test, these are statistically significant improvements over the baseline at $p < 0.05$. As is clear from the results, for each of the four passage scorers, adding MDM features that capture the distribution of the passage scores across multiple passages improves the performance, in terms of both Precision@70% and % accuracy, by a significant amount.

For the Jeopardy! data-set, for the LFACS passage scorer, Precision@70% improves from 64.9% to 71.3% and % Accuracy improves from 52.2% to 57.3%. Both these improvements are statistically significant at $p < 0.05$, using McNemar's significance testing.

Based on these experimental results, we conclude that addition of MDM features for passage scorers significantly improves the performance of our QA system.

5.3 End-to-End Analysis

In this section, we present results for running the full Watson system with and without MDM features. Table 6 shows the Precision@70% and % accuracy performance on the Doctor's Dilemma test set. The results show that by adding MDM features to existing system, we are able to get a statistically significantly better performance than the baseline system: Precision@70% improves from 37.2 to 40.2 and % accuracy improves from 29.2% to 31.3%.

6 Literature Survey

Question answering has had a long history (Simmons, 1970) and has seen considerable advancement over the past decade (Maybury, 2004; Strzalkowski and Harabagiu, 2006). However, to the best of our knowledge, there is no general purpose framework integrated into a QA system that is capable of aggregating information across multiple pieces of evidence, each analyzed using different analytics (features), and comparing this with coverage of terms/facts in the input question.

A technique that is complementary to ours is corpus expansion (Schlaefer et al., 2011), in which corpus documents are expanded to include topically related facts from an external resource (e.g. Web). Sometimes in this process, pseudo documents are created which contain aggregate information about a particular entity. This approach helps standard document search by providing better document-level evidence/scores for the input search terms. The system is more likely to find a single document that addresses all of the parts of the question in a corpus after it has been expanded. However, passage scoring still encounters the same underlying problem even with an expanded corpus: in some cases, there will not be any single passage that addresses all of the requirements of the question.

The second related approach is question decomposition (Kalyanpur et al., 2012; Felshin, 2005), which aims at decomposing the question into different facts that need to be independently or sequentially solved in order to arrive at the correct answer. However, question decomposition does not deal with the issue of combining multiple pieces of evidence (possibly assessed using different

analytics) for the same fact within a decomposed question (which our approach does). In addition, the process of decomposing a question into multiple subquestions is an extremely challenging linguistic one, and is very sensitive to how questions are phrased; a set of rules that are effective at formulating subquestions from Jeopardy! clues may not be as effective for other types of questions. Multi-dimensional merging also requires that the question be divided up, but it does not require that the parts of the question form coherent subquestions, since it is performed *after* all of the linguistic analysis and comparison to evidence. In our implementation of multi-dimensional merging, we simply divide up the question into single terms.

We consider both corpus expansion and question decomposition as complementary to our approach. Both approaches are included in our baseline Jeopardy! system, and corpus expansion is included in our baseline medical system. The fact that our results show postive impact on effective question answering shows that multi-dimensional merging can add value to a system that already uses both corpus expansion and question decomposition techniques.

Conclusion and perspectives

We introduced a general framework for aggregating evidence from different passages retrieved for a candidate answer. Moreover, we introduced a novel set of features, multi-dimensional feature merger or MDM features, that fit this framework and significantly improve the performance of the current state-of-the-art QA system, Watson. However, our framework is general and not restricted to Watson. It may be employed in any QA system that captures how well retrieved passages match the question under consideration.

In this paper, we only considered merging evidence across passages and question terms. However, this may be easily extended to merging evidence across passage scorers. There might be value in considering how different passage scorers match supporting passages with candidate answers. Using our framework, all that is required is adding a new dimension: depth to the two-dimensional matrix M, thus giving rise to a $3-D$ matrix, say $M3D$. Each two dimensional matrix, M in $M3D$ belongs one passage scorer. Therefore, depth of $M3D$ is the number of passage scorers used to match supporting passages with the question. In the future, we will explore decomposing and thus deriving features from this $3-D$ matrix, possibly using Tensor algebra (Kolda and Bader, 2008).

ABSTRACT
Unsupervised Relation Extraction (URE) is the task of extracting relations of *a priori* unknown semantic types using clustering methods on a vector space model of entity pairs and patterns. In this paper, we show that an informed feature generation technique based on dependency trees significantly improves clustering quality, as measured by the F-score, and therefore the ability of the URE method to discover relations in text. Furthermore, we extend URE to produce a set of weighted patterns for each identified relation that can be used by an information extraction system to find further instances of this relation. Each pattern is assigned to one or multiple relations with different confidence strengths, indicating how reliably a pattern evokes a relation, using the theory of Discriminative Category Matching. We evaluate our findings in two tasks against strong baselines and show significant improvements both in relation discovery and information extraction.

1 Introduction

Recently, there has been great interest in broadening information extraction methods to allow for unsupervised discovery of relational information in large document collections of unknown content. Contrary to classic information extraction in which relationship types (such as BORNIN or MARRIEDTO) are specified in advance, such methods automatically identify *a priori* unknown relationship types in a given corpus. For these identified semantic relations[1], they subsequently or simultaneously perform an information extraction step, thereby transforming the corpus into structured, relational data without any supervision or previous knowledge about its content.

One such approach, Unsupervised Relation Extraction (URE), addresses this challenge by building on the *latent relation hypothesis* which states that pairs of words that co-occur in similar patterns tend to have similar relations (Turney, 2008; Rosenfeld and Feldman, 2007). Current techniques capture this in a vector space model by computing a *pair-pattern matrix* in which each row represents an entity pair and each column a distinct pattern, with co-occurrence counts as cell values. This representation allows us to compute the similarity of two entity pairs by comparing the distribution over observed patterns. Using such a similarity metric, clustering methods can find clusters of entity pairs that share similar patterns and can therefore be assumed to represent a relation. Ideally, a clustering method returns three kinds of structured information, each of which is highly relevant to information discovery and extraction in unknown corpora: Firstly, a set of clusters, each of which represents one distinct *relation*. Secondly, for each cluster a set of *entity pairs* between which this relation holds. Thirdly, for each cluster a set of discriminative *patterns* that extensionally describe the relation and may be used by an information extraction system to find further *relation instances* of this relation.

The choice of patterns as well as their significance within a cluster assignment is crucial to the success of this endeavor. Each pattern may be underspecified or ambiguous and give different amounts of explicit or implicit evidence to different relations. Worse, as the complexity of language permits for one relation to be expressed in a multitude of ways, we may expect the distribution of patterns observed for each relation to be heavy-tailed, with a few patterns observed in high numbers and a large number of very rare patterns.

Take, for instance, the relation MARRIEDTO: Patterns that indicate this relation range from explicit and discriminative expressions, such as "*X married Y*" and "*X married to Y*", over entailment, such as "*X divorced from Y*" and "*X ex-wife of Y*", to mere implicit evidence, such as "*X fell in love with Y*". Here, *X* and *Y* are placeholders for an entity each. At the same time, these patterns may also express other relations at varying degrees; the pattern "*X divorced from Y*", for example, explicitly expresses the DIVORCEDFROM relation, while also entailing the MARRIEDTO relation. The desired result should reflect this and allow one-to-many assignments of patterns to relations, in which each pattern-relation assignment is weighted according to a *distinctiveness* value: High distinctiveness indicates a pattern that explicitly and unambiguously evokes a relation, low distinctiveness more implicit or ambiguous patterns.

In this paper, we examine more closely the task of discovering and ranking discriminative patterns for each relation and the impact of the choice of pattern generation scheme on overall URE results. By focusing on patterns, URE benefits in two ways: On the one hand we show that an informed feature generation strategy can markedly reduce the amount of underspecified and ambiguous patterns in the pair-pattern matrix, thereby significantly improving clustering

[1] In this paper, we refer to relationship types as *relations* and to instances of relationship types as *relation instances*.

approaches. On the other hand, this allows us to extend URE to not only identify relations, but also to find and rank a list of patterns for each relation that can be used in subsequent information extraction.

Contributions. We propose an unsupervised approach that identifies relations in a corpus of unknown content by clustering entity pairs and characterizes each relation by finding a list of patterns ordered according to the amount of explicit evidence they give to the presence of the identified relation. The contributions of this paper can be summarized as follows:

Algorithm for feature selection in a dependency graph. We propose an algorithm that selects possible patterns for a given entity pair in a dependency path, as an extension of the *shortest path* method. The approach is capable of capturing a wider range of phenomena than previous part-of-speech based feature generation and filtering approaches by incorporating syntactic elements for long range dependencies, complements for light or support verbs, appositions and context for arguments in direct conjunction. We show that the proposed feature selection technique increases the clustering quality F-measure by 65% over baseline approaches and that identified patterns are better suited to be used in an information extraction task.

Method for computing weighted pattern-relation assignments. We propose an approach that uses clustering results to compile a set of pattern-relation assignments, weighted according to the amount of discriminative evidence each pattern gives to an assigned relation. The method is based on the theory of Discriminative Category Matching (Fung et al., 2002). We experimentally show that these assignments produce patterns suitable for the task of information extraction.

We evaluate the proposed method in two different tasks: A *clustering task* in which we evaluate our clustering approach on three ground truth datasets of different composition against three baseline approaches [2]. We investigate the impact of our proposed feature selection algorithm on overall clustering quality and its ability to find the optimal amount of relationships in different datasets. Secondly, an *information extraction task* in which we evaluate the ranked patterns on two gold standard corpora and compare precision and recall with a baseline approach.

The remainder of the paper is organized as follows: Section 2 reviews previous work in the area of clustering for unsupervised relation discovery. We outline several approaches used as baselines in our evaluation. Section 3 outlines our clustering approach. In Section 3.1 we illustrate our proposed algorithm for pattern extraction in dependency trees, and in Section 3.3 our proposed method for identifying and ranking discriminative patterns. Section 4 describes evaluation methods, experimental setup and datasets, and reports the results on the two evaluation tasks. Finally, Section 5 concludes this paper.

2 Related Work

Most previous work utilizes the pair-pattern matrix to either measure the similarity of pairs of words, or to measure the similarity between patterns for a number of different purposes. In this section we review this work with respect to our pattern extraction and clustering approach and identify evaluation baselines.

[2] The datasets used in our experiments are available on request for research purposes.

Relation discovery. (Rosenfeld and Feldman, 2007) cluster entity pairs in the pair-pattern matrix to identify semantic relations. The resulting clusters are interpreted as each representing one relation that holds between all entity pairs in the cluster. They use the text between two entities in a sentence as patterns, but also allow arbitrary word skips, meaning that for each sentence containing an entity pair a large number of features are generated. They cluster the matrix using *k*-means and hierarchical agglomerative approaches and find that better results are reached with a complex feature space. (Bollegala et al., 2010) propose a co-clustering approach that simultaneously clusters both entity pairs and patterns for identifying relations, using not only lexical, but also shallow syntactic patterns. They expand the feature set to also include prefix and postfix spans. More recently, (Wang et al., 2011) analyzed the impact of filtering techniques and found that overall clustering quality F-measure significantly increases by using a set of filters to eliminate patterns that are unlikely to represent a relation. They filter out a total of 80% of all observed patterns. They use the text between entities as patterns, without word skips, and include named entity class information into the feature set.

Contrary to previous approaches in relation discovery, we employ a feature generation technique that utilizes information from a dependency parser. Our observation is that current dependency parsers are becoming orders of magnitudes faster while retaining a sufficiently high precision and recall, see (Rush and Petrov, 2012) and (Zhang and Nivre, 2011). We comparatively evaluate our feature generation technique against baselines modeled after the three approaches mentioned above.

Similarity of patterns or words. Instead of using clustering to identify relations, much work has focused on measuring the pairwise similarity of patterns or words. (Turney, 2006) computes the pairwise similarity of lexical patterns to solve the problem of finding analogies between word pairs. (Turney, 2011) compares pairs of words using the distribution over patterns to find proportional analogies and evaluate this on corpora of word comprehension tests, such as analogy questions in SAT or TOEFL tests. By contrast, (Lin and Pantel, 2001) directly measure the pairwise similarity between patterns in dependency trees using the distribution over word pairs to find inference rules from text. (Sun and Grishman, 2010) extend this with a clustering approach to group patterns into clusters, which they use to guide semi-supervised relation extraction methods. While this approach returns clusters of patterns for each discovered relation, the clustering is "hard", meaning that each pattern is assigned to exactly one cluster. This is contrary to our intuition that each pattern may give different amounts of evidence to different semantic relations. Nevertheless, we use a reimplementation of this approach as baseline for the evaluation of our proposed pattern ranking method.

3 Relation Discovery and Pattern Ranking

We propose a method that takes as input a document collection, identifies relations by clustering entity pairs with a similar pattern distribution, and outputs a ranked list of patterns for each relation. This is done in three steps: First, we generate the pair-pattern matrix using a feature generation approach based on deep syntactic analysis as explained in Section 3.1. Second, we run a clustering algorithm to group entity pairs into clusters representing relations (see Section 3.2). Finally, we compute the distinctiveness for each pattern in each cluster based on the distribution of patterns both within and across generated clusters as detailed in Section 3.3.

3.1 Feature Generation Using Dependency Trees

The proposed feature generation algorithm takes as input a set of dependency parsed sentences and entity pairs[3]. For each sentence and entity pair it generates a list of patterns that are used as features for the entity pair. The method determines a set of *core tokens* by collecting all tokens on the shortest path between the two entities. It then finds a set of *optional tokens* by collecting all tokens linked to a core token with certain typed dependency. It generates one feature for each combination of the core tokens and the power set (the set of all possible subsets) of the optional tokens.

Typed dependencies that indicate possibly important information even if not on the shortest path were determined through experimentation. Simple examples of cases in which important information is not on the shortest path are negation and particles, which are directly connected to a verb (with the dependencies "*neg*" and "*prt*" respectively) but never function as a link on the path between two arguments bound by this verb. Other examples are appositions, which may be connected to an entity but are not themselves part of the shortest path (indicated by "*nn*" or "*appos*"), and light verb constructions in which only the verb, but not the typically more important noun is part of the shortest path. Another example - discussed in detail below - are two entities in conjunction that function as an argument for a verb.

The method consists of four steps:

Step 1: Compute the shortest path between subject and object. The shortest path between two entities in a dependency path serves as basis for our extraction method. Recent research shows that lexical tokens along the shortest path represent particularly discriminative patterns for extraction of binary and even higher-order relations (Etzioni et al., 2011; Akbik and Broß, 2009). By focusing on the tokens that syntactically link both entities, we can skip over tokens that are less likely to be relevant to the relationship. This step yields a list of core tokens likely to be relevant to the relation expressed between the two entities.

Step 2: Collect of a set optional tokens on the path. We collect all tokens that *may* be relevant to identifying a relation by iterating over each token on the shortest path and examining all typed dependencies of each token to non-path tokens. If the dependency is one of {*nn*, *neg*, *prt*, *poss*, *possessive*, *nsubj*, *nsubjpass*} we collect the target token into a list of optional tokens. This step yields a list of tokens to be added to the core list to produce a good extraction pattern.

Step 3: Generate features. We build the power set over all optional tokens and generate one feature for each combination of the shortest path and optional set. This power set includes the empty set as well, so the shortest path without any optional tokens is included in the features.

Step 4: Remove uninformative features. We filter out all features that consist only of closed-world word classes. Examples are features like "*X and Y*" or "*X of Y*". The intuition for this step is that such patterns are semantically too weak to be used as patterns and not suitable for clustering approaches.

The following example sentence illustrates the feature generation process: *"James Joyce and his longtime lover Nora Barnacle got married in 1931"*. Figure 1 depicts the sentence's dependency parse. Here, the shortest path is a "*conj*"-link, directly connecting the two entities "*James Joyce*"

[3]We use the Stanford dependency parser (Klein and Manning, 2003) and Stanford typed dependencies (De Marneffe et al., 2006) in our experiments.

and "*Nora Barnacle*". The resulting pattern "*X and Y*"[4] is highly ambiguous and therefore of limited use. We collect the tokens "*and*", "*his*", "*lover*" and "*married*" into a set of optional tokens and build its power set. By taking each combination of the power set and the shortest path (and after filtering non-informative features) we arrive at a total of five features. Table 1 lists them and compares them to shallow patterns as generated by (Turney, 2011) and (Wang et al., 2011).

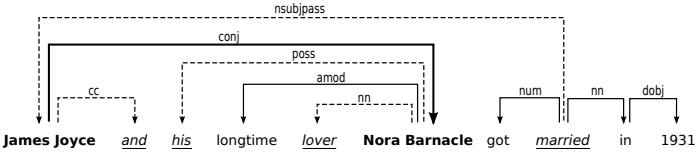

Figure 1: Dependency parse of the example sentence. The entity pair and shortest path are marked in bold. "*James Joyce*" and "*Nora Barnacle*" are directly connected with a "*conj*" link. Links to optional tokens are illustrated as dotted lines; optional tokens are underlined.

(Turney, 2011)	**X** and his longtime lover **Y**, **X** and his longtime * **Y**, **X** and his * lover **Y**, **X** and * longtime lover **Y**, **X** * his longtime lover **Y**, [..]
(Wang et al., 2011)	**PERSON** and his longtime lover **PERSON**
PROPOSED	**X** and lover **Y**, **X** and **Y** married, **X** and lover **Y** married, **X** and his lover **Y**, **X** and his lover **Y** married

Table 1: Features from different generation methods for the sentence in Figure 1. We observe that the features generated by the proposed approach all indicate the MARRIEDTO relation either explicitly or implicitly. By contrast, the shallow feature generation technique used by (Turney, 2011) produces a total of 24 patterns, many of which are highly underspecified. (Wang et al., 2011) generate only one overspecified feature.

3.2 Relation Discovery by Clustering Entity Pairs

From the features as generated according to Section 3.1 we build a pair-pattern matrix for all entity pairs observed at least 20 times in the corpus. This is accomplished by counting co-occurrences between patterns (features) and entity pairs. We cluster this vector space model using the k-means algorithm which partitions entity pairs into k clusters of similar variance[5]. Following (Bullinaria and Levy, 2007), we use the Cosine similarity to measure distances between feature vectors – a measure useful for highly sparse vectors like the ones at hand.

[4] In this case, the pattern "X and Y" is a verbalization of the entities X and Y being linked by the typed dependency "*conj*" for readability reasons.

[5] We use Apache Mahout (*http://mahout.apache.org/*) in our experiments.

The k-means algorithm requires us to manually specify the number of output clusters which in turn allows us to control the granularity of discovered relations. For instance, the cluster representing the relation ChildOf for low values of k is split into two clusters representing the relations SonOf and DaughterOf given higher values of k. Following (Rosenfeld and Feldman, 2007) we interpret each cluster within a clustering as a distinct, unlabeled relation and all entity pairs as relation instances.

3.3 Ranking Patterns by Distinctiveness

Clustering assigns each entity pair to a cluster and thereby implicitly produces a set of patterns per cluster, namely all non-zero features of the entity pairs in that cluster. The approach proposed here for ranking these patterns is based on two intuitions. The first being that clusters are representative of relations, meaning that the distribution of patterns in a cluster dominantly contains a single relation. This implies that patterns that are shared by a majority of entity pairs in a cluster are common ways of expressing a relation, while patterns that are shared only by few entity pairs are either less commonly used or provide only implicit evidence of a relation. To capture this intuition we compute pattern weights by adding up the counts per pattern over all entity pairs within a cluster. We normalize the value to compute the *significance* of a pattern:

$$Significance_{i,R} = \frac{\log_2(f_{i,R}+1)}{\log_2(P_R+1)} \tag{1}$$

As the equation shows, the significance of a pattern i within a cluster R is denoted as the logarithmic ratio of its weight $f_{i,R}$ normalized by the sum over all pattern weights P_R in the cluster.

The second intuition is that patterns that occur in more than one cluster may be ambiguous and lend different amounts of evidence to different relations. Such patterns therefore have low *clarity*. We collect the distributed evidence of these patterns across clusters and relate it to a pattern's highest significance over all clusters. The following equation measures this clarity for each pattern, with $0 \leq Clarity_i \leq 1$.

$$Clarity_i = \begin{cases} \log_2 \frac{n \cdot \max\limits_{j \in \{1..n\}} \left\{ Significance_{i,R_j} \right\}}{\sum\limits_{j=1}^{n} Significance_{i,R_j}} \cdot \frac{1}{\log_2 n}, & n > 1 \\ 1, & n = 1 \end{cases} \tag{2}$$

Thereby, a pattern i has a high $Clarity_i$ if it is significant in one cluster and insignificant in the others. (Note that $1/\log_2 n$ is a normalization factor.) If we observe a pattern only once and in one cluster its $Clarity$ is 1.

Following the theory of Discriminative Category Matching (DCM) (Fung et al., 2002), the overall *distinctiveness* of a pattern given a cluster is a combination of *Significance* and *Clarity* accordingly; with a normalization factor of $\sqrt{2}$:

$$Distinctiveness_{i,R} = \frac{Significance_{i,R}^2 \cdot Clarity_i^2}{\sqrt{Significance_{i,R}^2 + Clarity_i^2}} \cdot \sqrt{2} \tag{3}$$

We use this $Distinctiveness$ measure to re-weigh the pattern-cluster assignments and produce a ranked list of patterns for each cluster.

4 Evaluation

We quantify the proposed approach in two tasks: a *clustering task* to measure the impact of our feature generation method on overall clustering performance and evaluate the ability to discover relations. And an *information extraction task* to examine clustered patterns with respect to their usefulness to information extraction. Since ground truth is not usually readily available for large amounts of text, assessing the quality of large scale clustering results has proven to be difficult. We therefore use distant supervision based on the YAGO knowledge base to automatically construct various ground truth data sets. Details of the set-up, advantages and drawbacks of such an evaluation approach as well as measures used to analyze clustering quality against such ground truth are discussed in Section 4.1. Details on clustering evaluation and the information extraction task are discussed in Sections 4.2 and 4.3 respectively.

4.1 Experimental Setup

4.1.1 Datasets

The extrinsic evaluation of URE is problematic as it requires a document collection with exact knowledge regarding its content in the form of labeled relation triples. Several projects have constructed such a ground truth manually, which has a number of drawbacks: Firstly, there is a high cost involved in manually annotating sentences with relations, limiting the size of the ground truth as well as the ability to quickly generate new evaluation sets. Secondly, much care must be taken to ensure that no URE-specific assumptions are modeled into the ground truth, i.e. "overfitting" the ground truth to the capabilities of the algorithm that is to be evaluated. The inherent risk in manual annotation is the creation of a ground truth that does not realistically reflect the application scenario the URE approach is intended for.

We therefore choose a *distant supervision*-based approach to automatically generate a number of labeled training, test and evaluation sets. In distant supervision, an existing knowledge base of facts (triples consisting of two entities and a relation that holds between the entities) is used as support tool (Mintz et al., 2009). We use YAGO, a semantic knowledge base derived from Wikipedia, WordNet and GeoNames with knowledge of more than 10 million entities and around 447 million facts (Hoffart et al., 2011). The relations in YAGO are semantic labels, such as WasBornIn, ActedIn and DiedIn and are therefore different from a textual representation of these relations in a sentence.

The approach randomly selects a number of entity pairs from the knowledge base and retrieves from the Web[6] a set of sentences containing each entity pair. The assumption is that a sentence that contains an entity pair for which the knowledge base specifies a relation is likely to express it, either explicitly or implicitly. Accordingly, this allows the method to automatically label all retrieved sentences with relations, enabling the generation of a ground truth of arbitrary size. In order to assess the quality of the ground truth we manually examine 200 sentences with a total of 209 relations and 29 distinct relations[7]. We find that in 159 cases the relation is either explicitly or implicitly represented in the sentence, whereas in 50 cases the entity pair is present in the sentence but the YAGO relation between them could not be inferred from the text.

Examples for explicit, implicit and false sentences are given in Table 2. While imperfect, the

[6] We use the Bing API (*http://www.bing.com/developers/*) to retrieve sentences.

[7] In 9 cases, one entity pair has more than one relation in YAGO. Some persons, for example, both ActedIn and Produced a movie.

assumption therefore holds for approximately 76% of the generated ground truth. For our evaluation purposes we find this satisfactory, as this realistically simulates noise while reliably indicating the relational content of generated evaluation sets.

sentence retrieved	relation expressed
***Mystery Men** (1999) stars **Ben Stiller** as Mr. Furious.*	explicit
***Mystery Men** brought on board a talented cast from William H. Macy to **Ben Stiller**.*	explicit
*What was **Ben Stiller**'s character's super quality in **Mystery Men**?*	implicit
***Ben Stiller** does not think **Mystery Men** should be remade.*	false

Table 2: Sentences retrieved for the entity pair "*Ben Stiller*" and "*Mystery Men*", labeled in YAGO with relation ACTEDIN and the degree of explicitness: explicit, implicit or not at all.

We use this approach to generate 5 different ground truth datasets for the two evaluation tasks. For the clustering task, we generate 3 datasets of approximately 200.000 sentences, each with a different number of distinct relations. For the information extraction task, we generate two small gold standard corpora that are manually checked for correctness, with all falsely labeled sentences filtered out: **GOLD**, a corpus of 300 sentences that explicitly express the labeled relation, and **SILVER**, a corpus of 400 sentences that either explicitly or implicitly express the labeled relation. Refer to Table 3 for a list of all datasets.

dataset	# sentences	# relations	# entity pairs	manually cleansed
R10	200.000	10	12.000	false
R20	200.000	20	9.000	false
R30	200.000	30	6.000	false
GOLD	300	20	300	true
SILVER	400	20	400	true

Table 3: Datasets created using YAGO and distant supervision. The three large datasets differ in number of distinct relations and contained entity pairs. **GOLD** and **SILVER** are smaller, manually cleaned datasets.

4.1.2 Measures

We use **BCubed** for extrinsic clustering evaluation (Amigó et al., 2009), an effective measure extendable to overlapping clustering, which satisfies the following essential criteria for measuring cluster quality [8]:

- *Cluster homogeneity*, which rewards clusterings with pure clusters.
- *Cluster completeness*, which promotes "same label, same cluster" policy.
- *Rag bag*, which rewards introducing a garbage cluster over polluting pure clusters.
- *Small cluster preservation*, which penalizes spreading data points of a rare label across various clusters.

General BCubed precision and recall are computed based on *Multiplicity*, a measure of the minimum intersection between two data points o_i and o_j regarding their labels and cluster assignments. In our case this intersection contains 1 element at most, since we performed

[8] Cf. (Han et al., 2011, Ch. 1, p. 6) for a more verbose elaboration on these quality criteria and BCubed in general.

non-overlapping clustering. Depending on whether precision or recall is computed, Multiplicity is normalized with the amount of shared cluster assignments or shared labels respectively:

$$Multiplicity_{precision}(o_i, o_j) = \frac{min(|C(o_i) \cap C(o_j)|, |L(o_i) \cap L(o_j)|)}{|C(o_i) \cap C(o_j)|} \tag{4}$$

$$Multiplicity_{recall}(o_i, o_j) = \frac{min(|C(o_i) \cap C(o_j)|, |L(o_i) \cap L(o_j)|)}{|L(o_i) \cap L(o_j)|} \tag{5}$$

Here $C(o_i)$ denotes the set of cluster assignments of a data point o_i given a clustering and $L(o_i)$ the set of labels for a given data point o_i according to ground truth. Precision and recall are then calculated by averaging Multiplicity over all data points [9]:

$$Precision_{BCubed} = \frac{\sum_{i=1}^{n} \frac{\sum_{o_j : C(o_i) \cap C(o_j) \neq \emptyset} Multiplicity_{precision}(o_i, o_j)}{\| \{ o_j | C(o_i) \cap C(o_j) \neq \emptyset \} \|}}{n} \tag{6}$$

$$Recall_{BCubed} = \frac{\sum_{i=1}^{n} \frac{\sum_{o_j : L(o_i) \cap L(o_j) \neq \emptyset} Multiplicity_{recall}(o_i, o_j)}{\| \{ o_j | L(o_i) \cap L(o_j) \neq \emptyset \} \|}}{n} \tag{7}$$

In a final step $Precision_{BCubed}$ and $Recall_{BCubed}$ are combined to give the F_1-score.

4.2 Clustering Task

We evaluate our method's ability to identify relations by comparing it on ground truth datasets of different composition with several baselines. We use BCubed F-measure to judge overall clustering performance.

4.2.1 Baselines

We compare our feature generation method (referred to as **PROP**) to the three baseline approaches using shallow analysis that were introduced in Section 2: The first is based on (Turney, 2011) and (Rosenfeld and Feldman, 2007) and uses a lexical feature generation technique with arbitrary word skips. We refer to this approach as **TUR**. A second baseline is modeled after (Bollegala et al., 2010), uses shallow lexico-syntactic patterns including pre- and postfix spans, and is referred to as **BOL**. The third baseline, after (Wang et al., 2011), uses lexical patterns without word skips and incorporates named entity class information. Patterns containing the verbs *to say* or *to tell* are filtered. This method is referred to as **WAN**.

[9] Note that self-relation is not excluded. And that Multiplicity is defined only when the two data points share at least 1 cluster assignment or label respectively.

4.2.2 Results

The results of the comparative evaluation are visualized in Figure 2. It clearly shows the impact of using an informed feature generation method. On the R30 dataset, we note overall increases in F-measure of 65% over the next best approach. Overall F-measure is highest around a k of 30 at **0.445**. The next best approach is WAN at $k = 12$ with **0.288**. This shows that our feature generation algorithm is capable of finding patterns for many expressions that shallow feature generation methods miss. Also, as F-measure peaks around $k = 30$, the results indicate that the clustering mechanism can effectively model the relations contained in the corpus.

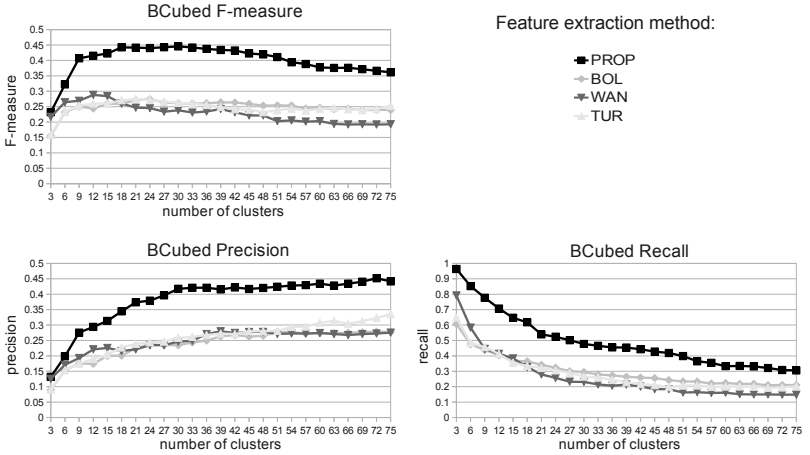

Figure 2: Clustering quality in terms of precision, recall and F_1-measure on the R30 dataset. The proposed feature generation approach (black line, square data points) outperforms all baseline approaches.

In order to examine this observation more closely, we use our approach on the R20 and R10 datasets, which contain 20 and 10 distinct relations respectively in the same amount of sentences as R30. The results are shown in Figure 3. Compared to results on the R30 dataset, we measure strong increases in F-measure on the R10 dataset which may be due to a much larger amount of examples per relation. However, we note that the results on the R20 and R30 are roughly similar, even though they are of different relational composition.

To gain more insight into these results, we inspect the data manually by randomly selecting clusters at different k. We make a number of observations. Firstly, when increasing k, the resulting clusters represent finer granularities of relations. The YAGO relation ChildOf, for example, is split into two clusters at higher k one representing the relation SonOf, the other DaugherOf. Similarly, the relation Created is split into multiple clusters, representing CreatedFilm, CreatedMusic and CreatedNovel respectively. The YAGO relation LocatedIn is split at various k into clusters of finer granularities, first into CityLocatedIn and VillageLocatedIn, then at an even higher k also into RiverLocatedIn. The YAGO relation IsAffiliatedTo is split at higher k into AffiliatedToSportsTeam and AffiliatedToPoliticalParty. These observations

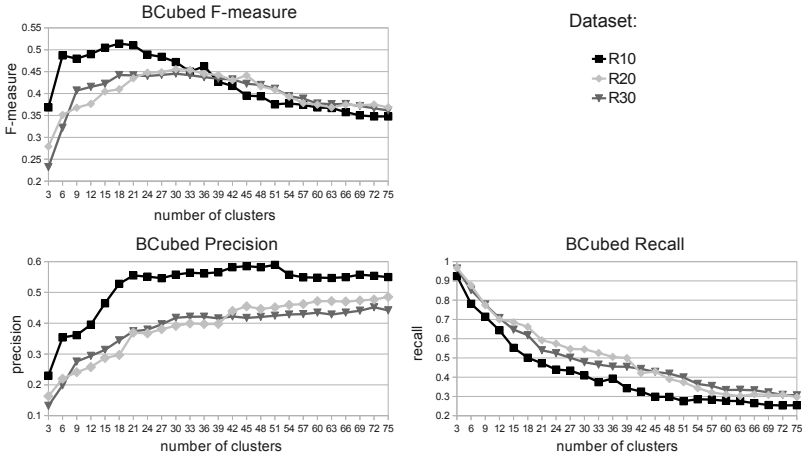

Figure 3: Clustering quality for the proposed approach on different datasets. Performance is best on dataset R10 which consists of relations typically expressed explicitly. R20 and R30 datasets each contain various more implicit or difficult to detect relations, causing lower F-measure.

indicate that the approach can be directed through parameterization to discover relations of varying granularity. However, we also note that some clusters split for difficult to interpret reasons, such as MARRIEDTO which splits into two clusters at higher k.

Generally, we observe that some relations are easier to identify by URE than others; relations like HASWONPRIZE or MARRIEDTO are often explicitly expressed and therefore easier to cluster. Other relations, like LIVESIN are often, if at all, very implicitly expressed causing difficulties to the algorithm. Other relations, such as DEALSWITH, which signifies trade relations between two countries, are almost impossible to find as very few sentences express this relation. Again other relations, such as KNOWNFOR are semantically very broad as there are any number of accomplishments (expressed in any number of ways) a person may be known for. This causes problems for a clustering approach. However, our approach is capable of finding a subset of all KNOWNFOR relations in a cluster that resembles the INVENTORINVENTED relation. This indicates that not only the amount of distinct relations in a corpus is important, but also how explicitly they are expressed and whether one relation dominates a given entity pair. We also find that the most highly ranked patterns usually characterize clusters very well. Example clustering results are shown in Table 4. Here, we find examples of explicit patterns, entailment and implicit patterns. We examine the patterns more closely in the information extraction task.

4.3 Information Extraction Task

We evaluate the ranked patterns on the GOLD and SILVER datasets using the generated patterns as classifiers. If the classifier finds a known pattern in a sentence it extracts and labels a relation, but only if the distinctiveness of the pattern is above the classifier's *threshold* setting. We compute a precision-recall curve for our proposed approach over a range of threshold values

ID	example entity pairs	example patterns	YAGO label
(1)	- Media General; WJAR - CBS Radio; WPHT - News Corporation; Fox	*1.* **Y** owned by **X** *3.* **X** operate **Y** *5.* **X** acquire **Y** *6.* **X** parent company of **Y** *32.* **X** gain for buying **Y**	[OWNS]
(2)	- Ronny Yu; Fearless - John Madden; Proof - Dana Brown; Highwater	*1.* **Y** film directed by **X** *2.* **Y** directed by **X** *7.* **X** 's film **Y** *14.* find trailer info for **Y** by **X**	[DIRECTED]
(3)	- Alan Turing; Turing test - Carlos Chagas; Chagas disease - Hans Geiger; Geiger counter	*1.* **Y** invented by **X** *2.* **X** creator of **Y** *3.* **Y** discovered by **X** *7.* **Y** named after **X** *19.* **X** inventor known for invention of **Y**	[KNOWNFOR]

Table 4: Example of clustering output. Each cluster contains a set of entity pairs and is defined via a ranked list of patterns. The rank is given in italics before each pattern. The YAGO relation labels are not part of the clustering output and added for evaluation purposes only.

from 0 to 1, see Figure 4. The results show that the threshold can be used to control the tradeoff between precision and recall. If the threshold is set high, the extractor only uses patterns with high distinctiveness and finds relations at high precision and lower recall. At lower threshold settings, recall gradually increases while precision decreases. This indicates that the proposed method computes a valid ranking of patterns. The ability to use such a threshold setting to influence the precision-recall tradeoff is a valuable feature for information extraction.

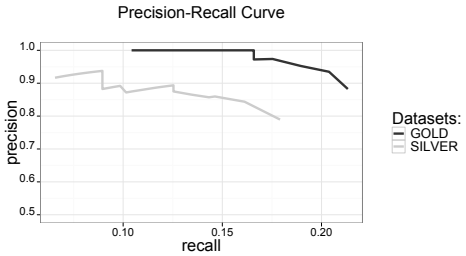

Figure 4: Precision-recall curves on the GOLD and SILVER gold standards for a range of threshold values. By lowering the confidence threshold, we trade high precision for an increase in recall.

We compare the approach against a reimplementation of (Lin and Pantel, 2001) in which patterns are directly clustered according to the distribution of entity pairs as introduced in (Sun and Grishman, 2010). This baseline (referred to as **PAN**) produces a hard clustering of patterns, without a distinctiveness value that can be used as threshold. We therefore compare the proposed approach against this baseline at two threshold levels: A threshold of 0 (PROP-0)

and 1 (PROP-1). For completeness, we also compare the proposed approach using **TUR** and **WAN** instead of our proposed feature generation method. This is denoted as **PROP-TUR** and **PROP-WAN** respectively, again at threshold settings of 0 and 1.

	GOLD			SILVER		
approach	**precision**	**recall**	**F_1-measure**	**precision**	**recall**	**F_1-measure**
PROP-0	0.88	**0.21**	**0.34**	0.79	**0.18**	**0.29**
PROP-1	**1**	0.1	0.18	**0.92**	0.07	0.13
PAN	0.58	0.15	0.24	0.51	0.1	0.17
PROP-WAN-0	0.6	0.03	0.06	0.56	0.05	0.09
PROP-WAN-1	0.19	0.1	0.13	0.21	0.11	0.14
PROP-TUR-0	0.28	0.14	0.19	0.26	0.14	0.18
PROP-TUR-1	0.31	0.18	0.23	0.29	0.17	0.21

Table 5: Results of the information extraction task on the GOLD and SILVER ground truths. The proposed approach outperforms the baseline in precision, recall and F_1-measure.

The results in Table 5 show that the proposed method outperforms the baseline. Shallow patterns, as used in **TUR** and **WAN**, are hardly usable for information extraction. Especially on the GOLD dataset, in which all relations are explicitly expressed, we note very high precision of the proposed approach. As expected, precision is lower on the SILVER dataset, which also includes implicit expressions of relations, but still higher than the baseline. Overall, the results show that the pattern-relation assignment of the proposed approach yields valuable results for the task of information extraction.

5 Conclusion

In this paper we have presented a method for Unsupervised Relation Extraction that discovers relations from unstructured text as well as finding a list of discriminative patterns for each discovered relation. We introduced a feature generation algorithm that utilizes dependency parse information and demonstrated that using an informed feature generation technique significantly improves overall clustering F-measure. We interpreted clustering results to produce a set of pattern-relation assignments weighted according to the distinctiveness of each assignment using the theory of Discriminative Category Matching. We demonstrated that the strength of an assignment indicates how reliably a pattern evokes a relation by using the patterns for information extraction at different confidence thresholds. We presented a thorough evaluation of both relation discovery and pattern ranking on 5 datasets of different composition. We believe our approach to be a promising step towards achieving the goals of URE.

Future work will focus on further evaluation on a range of different clustering algorithms in order to find an optimal approach. Specifically, we believe that using overlapping or fuzzy clustering algorithms may counterbalance problems of entity pair ambiguities. Furthermore, since using more samples positively affected clustering quality, we aim to scale up the method to large corpora and more broadly inspect the results at different levels of granularity.

ABSTRACT
We investigate differences in point of view (POV) between two objective documents, where one is describing the subject matter in a more positive/negative way than the other, and present an automatic method for detecting such POV differences. We use Amazon Mechanical Turk (AMT) to annotate sentences as positive, negative or neutral based on their POV towards a given target. A statistical classifier is trained to predict the *POV score* of a document, which reflects how positive/negative the document's POV towards its target is. The results of our experiments on a set of articles in the Arabic and English Wikipedias from the *people* category show that our method successfully detects POV differences.

KEYWORDS: sentiment analysis, content analysis, natural language processing.

COLING 2012, Mumbai, December 2012.

1 Introduction

In many areas of public discourse, content creators strive for objectivity. Reporters try to report the facts without bias; judges are expected to write opinions that are not influenced by personal views; encyclopedias are committed to what Wikipedia calls a "neutral point of view" (NPOV), defined as "... representing fairly, proportionately, and as far as possible without bias, all significant views that have been published by reliable sources".[1]

Even though objectivity is an important ideal, content creators cannot avoid being influenced by their background and context. There are two main reasons for this (Scheufele, 1999; Habermas, 2006; Littlejohn and Foss, 2010; D'Alessio and Allen, 2000). First, there are always many different non-equivalent ways of conveying a given piece of information. By choosing one vs. the other, the content creator introduces part of his/her point of view (POV) into the discourse. For example, "his wars caused the death of more than a million civilians" (a translation of a sentence in the French Wikipedia) puts Napoleon in a more negative light than "more than a million civilians died in his wars", which in turn is more negative than "more than a million civilians died in the wars fought between him and his enemies". This is so because the chain of causality between Napoleon and people being killed is more explicit in the first sentence than in the third. None of these sentences is a violation of Wikipedia's neutral point of view policy.

The second reason for different objective points of view is that the selection of what information to present is also influenced by background and context. If for space reasons only one of two equally relevant facts about a politician – one positive, one negative – can be added to a newspaper article, then this choice impacts how positive/negative the article is. This is an unavoidable dilemma journalists face on a daily basis. It is usually impossible to include all available information.

We call the difference between two objective documents, where one describes the subject in a more positive/negative way than the other, a *point of view difference* or *POV difference*. This paper develops a method that detects POV differences and quantifies their magnitude.

The automatic identification of POV and POV differences is of high potential for content analysis in the social sciences – which we take to include the humanities in this paper. Early content analysis was motivated by concerns about the declining quality of public debate in modern mass societies and tried to answer empirically questions such as: Do the media live up to their own quality standards of factually accurate and ideologically unbiased reporting? Are no relevant facts omitted? Are all relevant POVs equally represented? (Krippendorff, 2004, 55ff.)

There are also systematic reasons for the widespread empirical investigation of the evaluative positions taken by various speakers in the media. Our social world is permanently produced and reproduced, interpreted and criticized in social interactions of actors with their – often conflicting – intentions, values and reasons for actions (Berger and Luckmann, 1966; Habermas, 1984). This activity leaves traces – interpretable symbols, text and images. Evaluative aspects are almost always of central importance for the social science research question that motivates a content analysis. Typical questions that scholars, readers, the public and practitioners ask are: How favorably are the objects (e.g., social groups, politicians, policies, countries, corporations) perceived? Do different groups of people (e.g., migrants, citizens of different countries) view a certain object differently in a systematic fashion? How can this be explained? Which effect will this have?

[1] `http://en.wikipedia.org/wiki/Wikipedia:Neutral_point_of_view`

In most content analysis today, positive and negative presentation of subject are annotated – or coded – *manually*, an expensive and time-consuming method. To maximize intercoder agreement, the coding usually is restricted to explicit evaluative claims although some authors have also looked at stylistic means – such as irony and emotional language – for weakening or strengthening evaluations (Früh, 2011, 241–260). The result of this type of manual analysis is usually an aggregate value of the variable of interest that can then be used to compare groups (e.g., French vs. U.S. newspapers) or to analyze changes over time.

These efforts have not resulted in a widely shared research methodology. This may be due to the problem that there will never be an "objective" standard of what would constitute a pure, neutral way of reporting (Krippendorff, 2004, 55–57). Moreover, the subtle differences in evaluative tone and connotation that are of so much interest to social scientists are difficult to operationalize in a reliable way.

The approach presented in this paper overcomes these two problems of current content analysis. First, we develop a fully automatic method that is suitable for the analysis of large amounts of text and thereby reduces the obstacles that manual analysis and reliance on human coders present.

Second, while we acknowledge that the *absolute* assessment of POV is an important problem, we do not pretend to define an objective neutral standard in this paper. Instead, we cast the problem of assessing POVs as a *relative* problem and thereby avoid the difficulties inherent in attempting to define objective standards.

POV differences are also related to work on sentiment analysis in natural language processing (NLP). In contrast to most prior work in sentiment analysis, we are concerned only with *objective language* in this paper. For example, we do not address the analysis of editorials (which are intentionally opinionated) or of badly written Wikipedia articles (which violate the NPOV principle). The question as to how to automatically assess whether a piece of text written in objective language represents a positive or negative POV of the subject matter and to what extent has not been addressed before.

In addition to defining the problem of POV difference detection and proposing a method for solving it, we also provide an *evaluation gold standard*. It consists of articles and sentences from the Arabic and English Wikipedias that were annotated for POV and for POV differences using a combination of Amazon Mechanical Turk and student annotators. We chose the Arabic and English Wikipedias as the basis for our data set because we found that it contains many POV differences.

This paper is organized as follows. Section 2 introduces and motivates the concept of POV difference. Section 3 presents data acquisition and preparation. We describe our approach to the detection of POV differences in Section 4. Section 5 presents experiments and evaluates results. In Section 6, we discuss our results. Section 7 covers related work. Finally, conclusions and a brief summary of planned future work are given in Section 8.

2 Point of view (POV) differences

As a concrete example for a POV difference consider the French and Spanish Wikipedia articles about Napoleon.[2] Both articles are objective and meet the neutral POV criteria of Wikipedia. However, there is a POV difference between them: the French article is more positive than

[2]Based on the versions available online on 2012-04-01.

the Spanish article. We can find instances of the two types of reasons for POV differences that we discussed above: (i) different ways of describing a certain fact and (ii) different ways of selecting subsets of facts.

An example of different descriptions of the same facts is the phrase "sus agresivas guerras de conquista" 'his aggressive wars of conquest' in the Spanish Wikipedia. This amounts to a negative evaluation of Napoleon. Nowhere in the French article are Napoleon's wars called aggressive. Instead, his readiness to attack and the speed of his campaigns are referred to in more positive words: "offensive immédiate" 'immediate offensive', "marche forcée" 'forced march', "impressionante de rapidité" 'impressive for its rapidity'.

An example of a different selection of facts is the number of casualties during the Peninsular war. Only the Spanish article gives an estimate (300,000), which potentially casts a negative light on Napoleon as someone who is responsible for the loss of many lives.

Our goal in this paper is to develop a method that detects and quantifies such POV differences. Our approach is to first train a classifier that detects absolute POV. We then calculate POV difference between two articles as the difference of the absolute POV scores.

3 Data acquisition and preparation

Our approach to estimating POV differences for a pair of documents is to *estimate the absolute POV score* for each of the two articles of the pair and then *calculate the difference*. This approach will be described in detail in Section 4. To build a POV difference detector and evaluate it, we need a gold standard. Our gold standard consists of two parts, one for absolute POV and one for POV differences. While we could limit ourselves to only evaluating our main task, the estimation of POV differences, we decided instead to also evalute the quality of absolute POV scores. In this section, we describe the two gold standards we need for executing this plan: the gold standard for absolute POV scores and the gold standard for POV differences.

Gold standard for absolute POV. We first must decide which unit of text to create the gold standard for. Even though we are interested in the evaluation of entire documents, we do not annotate documents for two reasons. First, most documents will contain a mix of different POVs, so that a single label gives a statistical classifier noisy information. Second, reading and evaluating an entire document takes a long time for an annotator and would make gold standard creation expensive.

On the other hand, our units cannot be too small – e.g., words or phrases – because POV is a complex phenomenon that cannot be judged reliably at such a low level; the sentences about Napoleon in the introduction are examples for this.

Based on this reasoning we choose *the sentence* as our annotation unit. We annotate two sets of 1200 sentences, one for Arabic and one for English. The Arabic (resp. English) set consists of the first 20 sentences of 60 Arabic (resp. English) Wikipedia articles from the category *people*. We selected articles about people that are well known in both Western culture and Arabic culture because they are more likely to have been written by experienced authors and therefore to have a high quality.

The second major decision concerns the classification scheme for POV. We define three *POV classes*: positive, neutral and negative. These classes cover the potential cases of POV. We need a neutral class since many sentences do not contain any information that implies positive or negative POV.

Target: Mel Gibson

Paragraph: ... some audio recordings alleged to be of Gibson were posted on the internet. The same day Gibson was dropped by his agency , William Morris Endeavor. Civil rights activists alleged that Gibson had shown patterns of racism ... and called for a boycott of Gibson's movies.

Answer: Positive _____, Negative _____, Neutral _____

Figure 1: Interface of the AMT task.

The final decision concerns the annotators. We use Amazon Mechanical Turk (AMT). AMT has become a standard method for gold standard creation in NLP because annotations are of reasonable quality and comparatively low in cost (cf. (Alonso and Lease, 2011)).

For many objective statements, it is clear which POV class – positive, neutral or negative – applies to them. However, there is a certain subset of statements for which the decision is difficult. The different degrees of explicitness in describing a causal chain from Napoleon's actions to people dying in the introduction are a good example. As the statements become more explicit about the causal relation, at some point the sentence acquires a negative POV, but people differ as to when that point is reached.

Figure 1 shows the interface of the AMT task.[3] We ask non-expert workers to provide annotations for POV, a difficult decision for a subset of sentences. Thus, the design of the HIT (Human Intelligence Task) in AMT is crucial: in order to get acceptable agreement, the AMT task must be simple and easy to understand; definitions must be clear and the annotation interface well-structured.

Definitions of the three POV classes are provided in the instructions: the sentence has a positive (resp. negative, neutral) POV toward the target if it states that the target did something positive (resp. negative, neutral) or is described in a positive (resp. negative, neutral) way. No direct information about the target is also rated as neutral. Four examples from Wikipedia articles are given to help workers understand the task: one for positive, one for negative, and two for the neutral POV class. One neutral example shows a sentence that is directly relevant to the target, but is neither positive nor negative. The other neutral example is a negative sentence that is not relevant to assessing the POV of the article towards the target – e.g., because it talks about historical background that the target is not involved in. Because we found almost no sentences that had a mix of positive/negative elements, we did not explicitly include this case in the instructions.

The instructions are appropriately adapted for Arabic and English. They state that the Arabic (resp. English) task is only for Arabic (resp. English) native speakers. Even though the workers of the Arabic task have to be Arabic native speakers, the language of the instructions is English. All AMT workers know English since the AMT platform has only an English interface; so English as instruction language does not impose any additional restrictions on eligibility.

Each task includes one of the 1200 selected sentences (in blue color), the target that the article the sentence is extracted from is about (top line in Figure 1: "Mel Gibson"), and the surrounding paragraph (in black). To ensure sufficient context, we show to workers the entire paragraph

[3] We have reformatted the output that annotators see for space reasons and better legibility. E.g., we have omitted some text (marked "..."). Annotators see the entire paragraph without omissions.

	Arabic	English
agreement – all workers	.30	.48
agreement – majority of workers	.90	.95
Fleiss' κ	.215	.419

	Arabic	English
positive	.435	.47
neutral	.42	.34
negative	.145	.19

Table 1: Absolute POV gold standard: agreement (left); sentence label distribution (right).

containing the sentence to be annotated. Even though reading only the sentence is sufficient for the annotation task in most cases, sometimes it is difficult to determine the correct POV without reading some preceding or following sentences. For example, if the target sentence contains a pronoun, the annotator needs the context of the paragraph to resolve the reference.

We select one word from the sentence to be annotated randomly and render it in green. In the figure, the word is *agency*. The worker has to type this word in the corresponding answer field instead of using radio buttons or check boxes. We have found that this simple copying operation improves AMT annotation quality (Laws et al., 2011).

Workers are asked to label the sentence with one of three labels: positive, neutral and negative, based on the POV of the sentence toward the target. In Figure 1, the sentence to be annotated shows a negative POV towards the target (Mel Gibson), so we would expect the worker to annotate it as negative.

Incomplete assignments where the worker submits the task without giving all the required information and suspicious assignments where the worker spends only a few seconds on the task are rejected and republished to a different worker.

We use Fleiss' κ (Fleiss, 1971) (instead of Cohen's κ) to compute intercoder agreement because it can be applied when there are more than two raters and different items are rated by different raters (which is the case when using AMT). κ is .215 for Arabic, which is considered *fair* agreement; and .419 for English, which is considered *moderate* agreement (Landis and Koch, 1977).

We assign a sentence to the class chosen by at least two of the three annotators if there is such a class. If the three annotators assign three different labels (positive, neutral and negative), we assign the sentence to the neutral class. The proportion of sentences that have agreement between two or more workers is .90 for Arabic and .95 for English. Table 1 (left) summarizes agreement statistics for the absolute POV gold standard.

The difference between the agreement among the three workers and the agreement of the majority of workers (two workers) indicates problems with the quality of the AMT results. A number of workers did not follow the instructions very carefully. For example, some workers labeled sentences that are not directly relevant to the target as positive/negative, in violation of the instructions. Our impression is that one cause of such incorrect annotations is inexperience with AMT; in general, Arabic workers seem to have less experience than English workers.

Also, as we discussed above while there are many sentences that clearly belong to a particular POV class, other sentences are in the grey area between the two. One of the authors[4] assigned labels to a subset of Arabic sentences and compared them with the labels that were assigned to the sentences based on the majority-based gold standard label. We found that gold standard labels generally agree with our own judgments.

[4]Khalid Al Khatib, a native speaker of Arabic.

Table 1 (right) shows the distribution of labels. The positive class is more frequent than the negative class in both Arabic and English. The reason seems to be that the majority of people deemed worthy of a Wikipedia article are people like inventors, poets and athletes who are generally described in a positive way.

Gold standard for POV differences. As for the gold standard for absolute POV, we have to make decisions about three aspects for the gold standard for POV differences: unit of annotation, classification scheme and type of annotator.

For POV differences, our unit of annotation is a *pair of Wikipedia articles*. We need a pair of articles because a difference can only be annotated if the two things that we want to compare are represented. We have to go up to the level of documents because Wikipedias of different languages are not aligned on the sentence/paragraph level. We use Interwiki links to establish which articles in Arabic and English correspond to each other.

We use JWPL[5] to download articles that are in the *people* category and present in both the 20120114 Arabic and the 20111115 English Wikipedia. There are 16,000 such pairs.

We selected four categories that we sampled pairs of articles from. These categories are: Arab nationalists (5 pairs), Israeli nationalists (5 pairs), hand picked (5 pairs), and random (15 pairs). The motivation for the first two categories is that we expect strong POV differences for Arab and Israeli nationalists based on our personal knowledge of the two Wikipedias. Including these ten pairs ensures that a wide spectrum of POV differences is represented in the evaluation set. For the hand picked category, we selected people who are internationally well known both in the West and the Arab world. The motivation for this category is that we want to be able to present some results to the reader that are easy to interpret – without having to look up obscure personalities in Wikipedia. The random subset (15 pairs) is a standard random sample.

The length range of downloaded articles is 1–1128 sentences for English and 1–1050 sentences for Arabic. Short articles have many problems concerning quality and completeness and are often marked as stubs that require further work. We therefore impose the constraint that both articles must contain at least 50 sentences. We also exclude very long articles because they would make the annotation task too time-consuming and expensive.

The second design decision concerns the classification scheme. Here we propose a scheme with five different classes: much more positive, more positive, equal, more negative and much more negative. This scheme is more fine-grained than for absolute POV because a document pair is a rich source of information compared to a single sentence. There is sufficient information available to make more subtle distinctions such as between “more positive” and “much more positive”.

The final design decision concerns the annotators. Here we decided against AMT because reading, understanding and evaluating a pair of documents is a complex and time-consuming task that does not correspond to the typical HIT on AMT. More importantly, we need annotators for the task that are highly proficient in both Arabic and English. This type of annotator is difficult to find on AMT; and it is difficult to verify a high level of proficiency in a language on AMT.

For these reasons, we decided to hire engineering master students at our university for the annotation task. They are all students in an information technology master’s program, native

[5] `http://www.ukp.tu-darmstadt.de/software/jwpl/`

Target: Michael Faraday

Q1. The attitude of the English article toward the target compared to the Arabic article is:

1. Much more positive
2. More positive
3. Equal
4. More negative **X**
5. Much more negative

Q2. Briefly justify your answer to question 1.
Both Articles have a very positive attitude towards Faraday but I sensed it more in the Arabic one. For example in the marriage section of the Arabic article compared with the English one ,the attitude was much more positive and it mentioned that he was a loved , devoted, humble person which isn't mentioned in the English article. Also the controversy with Davy was only mentioned in the English article not the Arabic one. The Arabic article didn't mention anything negative towards Faraday.

Figure 2: Annotation setup and example of a completed annotation for POV differences. The annotator chose "More negative" ("**X**") and wrote an explanation (in italics).

speakers of Arabic and have an excellent command of English.

The annotation setup is shown in Figure 2. The annotator reads the Arabic and English Wikipedia articles and compares the two articles based on the articles' POV toward the target. The annotation guidelines state that information that is not directly related to the target must be ignored in the annotation decision and that the decision must be based solely on the contents of the two articles. Annotators are also instructed to not be influenced by their personal opinion, emotion or POV toward the target. The annotators have to justify their answers. In our experience, this helps the annotators to provide consistent and objective annotations.

Each pair of articles is annotated by three different annotators. We map the five point rating scale to $[-2,-1,0,1,2]$; e.g., "much more positive" is mapped to 2. The gold standard score Δ^{g}_{POV} for a pair of articles is then the average of the three scores given by the annotators (where the superscript g indicates "gold standard").

Intercoder agreement is $\alpha = .585$ (Krippendorff, 2004). This agreement is not as good as we would like it to be, but it is sufficient to evaluate our method; several other studies have published evaluation results based on gold standards with similar agreement (Bhardwaj et al., 2010; Brusk et al., 2010; Becker et al., 2012; Chen et al., 2012).[6]

4 Method

Absolute POV classification. For the task of determining the absolute POV – positive, neutral, negative – of a sentence, we adopt a statistical classification approach and use the Stanford MaxEnt classifier (Manning and Klein, 2003) with default parameters.

We refer to the probability of the positive (resp. negative) class for a sentence s as PosScore (resp. NegScore):

$$\text{PosScore}(s) = P(\text{positive}|s) \qquad \text{NegScore}(s) = P(\text{negative}|s)$$

Our features are bag of words (BOW) and letter k-grams (n-grams) where $2 \leq k \leq 6$.

[6]The two gold standards are available at `ifnlp.org/~schuetze/pov`.

For English, BOW and n-gram features are directly computed from text (as tokenized by the Stanford classifier) without any further linguistic preprocessing like lemmatization.

For Arabic, we investigate a number of different options for linguistic preprocessing. Arabic is a clitic language and highly inflectional. Normalization and lemmatization of Arabic text are beneficial preprocessing steps in many NLP applications. Lemmatization has been used widely in classification problems due to its ability to generate one form that matches many other related forms (Al Ameed et al., 2005). Therefore, in addition to the non-lemmatized surface forms, we used two lemmatization types: stem and root. We use *light stemming* to extract the stem: only frequent suffixes/prefixes are removed. In contrast, a word is reduced to its corresponding root by removing *all* affixes, not just frequent affixes (Al Ameed et al., 2005). We use the Arabic Text Mining tool for computing stems and roots.[7]

We use the term "bag of words" to refer to all word-level features, including "bag of stems" and "bag of roots".

Estimation of POV differences. To estimate POV differences we first need an aggregate measure of absolute POV on the document level. For this purpose, we define a document's POVScore as follows:

$$\text{POVScore}(d) = 1/|d|[\textstyle\sum_{s \in d}(\text{PosScore}(s) - \text{NegScore}(s))]$$

where $|d|$ is the number of sentences in the document. The POVScore is simply the difference of the averages of the PosScores and NegScores of the sentences of the article. This scoring method takes into consideration how positive or negative each sentence in the article is while ignoring any neutral meaning components. The higher POVScore(d), the more positive the article is. POVScore ranges from -1 to 1.

Our assumption is that most sentences of a Wikipedia article describe the target directly. This assumption can result in errors as we will discuss in Section 6.

We can now define the POV difference Δ_{POV} of a pair of articles as the difference of the POVScore of the English article and the POVScore of the Arabic article:

$$\Delta_{\text{POV}}(\{d_e, d_a\}) = \text{POVScore}(d_e) - \text{POVScore}(d_a)$$

where d_e is the English article of the pair and d_a is the Arabic article of the pair.

5 Experiments and results

Absolute POV classification. We train MaxEnt in tenfold cross validation on the gold standard described in Section 3 using the BOW and letter n-gram representations described in Section 4. Folds were constructed in a way that ensures that all sentences from a particular Wikipedia article are in same fold. The baseline in our experiment is to assign all sentences to the positive class, the most frequent class in both Arabic and English.

Table 2 gives evaluation results. The best result in each column is in bold. For Arabic, the classifier is better than the baseline for all six representations, both in accuracy and F_1. The overall best results are achieved using the stem representation with letter n-grams: accuracy is .584, F_1 is .474. The problem of root-based lemmatization is that many words with the same root have different meanings (Al Ameed et al., 2005). BOW without lemmatization ("BOW, tokens") performs less well because Arabic is highly inflected.

For English, accuracy is .608 and F_1 .533 using n-grams. Using BOW, accuracy is .587 and F_1

[7] `http://sourceforge.net/projects/ar-text-mining`

		Arabic		English	
		acc	F_1	acc	F_1
	baseline	.437	.206	.478	.214
BOW	tokens	.569†	.447†	.587†	.506†
BOW	roots	.555†	.464†		
BOW	stems	.561†	.460†		
n-grams	tokens	.574†	.453†	**.608**†	**.533**†
n-grams	roots	.580†	.470†		
n-grams	stems	**.584**†	**.474**†		

Table 2: Accuracy (acc) and F_1 of absolute POV classification. BOW = bag of words. †: significantly better than the baseline ($p < .01$).

	POVScore		
personality	English	Arabic	Δ_{POV}
Baruch Goldstein	.244	-.199	.443
Tzipi Livni	.549	.009	.540
Ariel Sharon	.259	-.113	.372
Wael Ghonim	.398	.528	-.130
Gamal Abdel Nasser	.296	.389	-.093
Saladin	.201	.320	-.119
Michael Jackson	.475	.617	-.142
Maria Sharapova	.579	.683	-.104
Steven Spielberg	.570	.744	-.174

Table 3: POV differences: Israeli, Islamic/Arabic and international personalities.

.506. The classifier outperforms the baseline by a fair margin in this case too. The best results are achieved using n-gram features.

All differences in accuracy and F_1 between the classifier and the baseline are statistically significant at $p < .01$.[8] However, the differences in accuracy and F_1 between using BOW and n-grams features are not significant.

Estimation of POV differences. We use the classifiers that achieved the best results in the previous section for computing POV differences: n-grams on tokens for the English absolute POV classifier and n-grams on stems for the Arabic absolute POV classifier.

For each of the 30 gold standard pairs (Section 3), we run the Arabic (resp. English) classifier on all sentences of the Arabic (resp. English) article. We then compute the two document scores and the difference $\Delta_{POV}(\{d_e, d_a\})$ (Section 4).

Table 3, shows examples for three Israeli, three Islamic/Arabic and three international personalities. Israeli personalities generally have more negative articles in Arabic than English. Islamic and Arabic personalities generally have more positive articles in Arabic than in English. International personalities also have more positive articles in Arabic than in English; we attribute this to our impression that Arabic Wikipedia authors tend to be more enthusiastic about the achievements of artists and athletes even if they are held in high regard in both the Arabic-speaking and the English-speaking world.

[8] Approximate randomization test (Noreen, 1989)

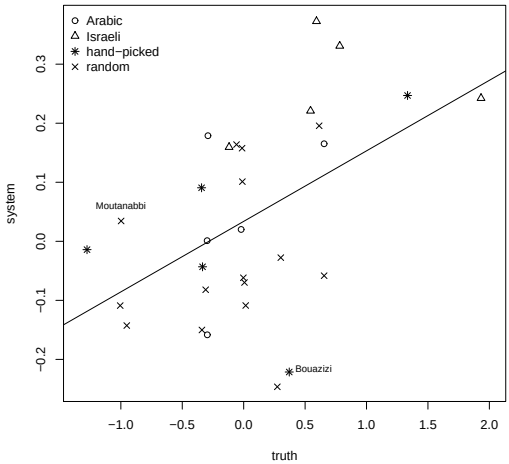

Figure 3: Estimated POV difference Δ_{POV} as a function of true POV difference $\Delta^{\text{g}}_{\text{POV}}$. The different symbols are used to show the category of each gold standard pair.

Figure 3 plots estimated POV difference Δ_{POV} as a function of true POV difference $\Delta^{\text{g}}_{\text{POV}}$ for the 30 pairs in the evaluation set. The correlation between human annotations and system scores is statistically significant for Spearman's ρ and Kendall's τ (both at $p < .005$).

We performed an error analysis for large divergences between true and predicted POV difference. The reason for divergences mostly seems to be that we use a simple BOW representation. We will illustrate this problem with two pairs of articles – Bouazizi and Moutanabbi (see marked points in Figure 3) – in the analysis we present in the next section.

6 Discussion

In our analysis of the errors we found that most of the cases with large divergences between automatically calculated POV difference and gold standard POV difference were due to the simple BOW representation we use – where we will use *BOW* in this section as a short hand for both bag of words and n-gram representations. This type of classifier is often not capable of detecting the subtle semantic nuances that are necessary to accurately assess absolute POV and POV differences. There are two main subcases of this general problem.

First, our assumption that all sentences in the Wikipedia article are describing the target is incorrect. (As in the rest of the paper we refer to the subject of the Wikipedia article as the target in this section.) There are sentences that describe people or events that have an impact on the life of the target, but are not directly about the target. These sentences can affect the system POVScore even though they are not communicating information relevant to the absolute

POV of the article towards the target. Identifying the subject of a sentence (target vs. something else) is not possible using BOW.

A special case of this are passages in Wikipedia about artists that contain titles and descriptions of movies, novels and other works of art. Again, this information can affect the system POVScore even though the fact that – for example – an actor played a murderer does not contribute to a negative POV about him.

The second subcase concerns parts of articles that *are* directly about the target, but not relevant for POV. The article may describe negative events that happened to the target, e.g., "Roosevelt contracted ... polio which resulted in permanent paralysis." Again, this will decrease the POVScore of the article even though the information reports something negative about the circumstances of the person's life that will not affect a reader's POV towards the person in a negative way.

An even subtler problem occurs if positive or negative words occur in a sentence that is directly relevant for POV towards the target, but these positive or negative words are in the scope of another word that reverses their meaning (cf. (Kessler and Schütze, 2012)). For example, the statement: *John started a war on violence against women* supports a positive POV towards John even though most of the words in the statement are negative words.

The immediate effect of the shortcomings of a BOW-based feature representation is an incorrect estimation of absolute POV. However, since these effects are somewhat random and will in most cases not affect Arabic and English to the same extent, the BOW problem can also give rise to incorrect POV differences.

In our data set, this is the reason that our system does not correctly predict the POV difference for Mohamed Bouazizi, the Tunisian who is credited with starting the Arab Spring (see data point marked "Bouazizi" in Figure 3). The system prediction is -.217 whereas the true score is .333. The problem with this pair of articles is that Bouazizi is described as a mostly positive person in both languages, but the circumstances of his life are described as tragic. Since our system does not distinguish between sentences that are directly relevant about the target vs. those that are not, this causes an incorrectly estimated POV difference.

A second example is Moutanabbi, a famous Arabic poet (system score: .034, truth: −1.00, data point marked "Moutanabbi" in Figure 3). His English article is positive, but his Arabic article is even more positive, hence the truth score of -1.00. The Arabic article is not handled well by a BOW representation for similar reasons as for Bouazizi. In particular, it contains poems about negative phenomena like mudslinging and sadness; and it describes the negative behavior of fellow poets towards Moutanabbi – this is negative, but will not create a negative impression of Moutanabbi in the mind of the reader.

There is one positive aspect of simplistic BOW representations. A potential concern is that the annotation of POV could be affected by annotator bias. Annotators have their own POV and even though we explicitly ask them to base their annotations solely on the content provided, there is a danger that they will be influenced by their personal views. However, in a BOW model this is not a problem: potentially incorrect annotations may contribute noise, but no systematic biases will be introduced. For example, even if an annotator is sympathetic with a murderer and the resulting annotation could mislead a classifier into believing that "murderer" is a positive word, there will be other annotations containing "murderer" that will counterbalance the incorrect annotation.

Note that for POV *differences*, personal annotator POV is less of a problem. We can expect a good annotator to provide a high-quality assessement of POV differences because a relative judgment about two articles is not in conflict with one's own personal views.

7 Related Work

Sentiment analysis (Pang and Lee, 2008) is mostly concerned with subjective language. However, the classification of objective language into positive vs. negative might also be considered sentiment analysis since the two tasks have a similar structure and face similar challenges.

Many papers have studied sentiment analysis in the news domain. Although this domain mainly contains objective content, subjectivity is also found to some extent, e.g., in editorials. Most previous work on sentiment analysis of news has ignored objective content. For example, Wiebe et al. (2005) released the Multi-Perspective Question Answering (MPQA) corpus. This corpus has detailed manual annotations of a set of 535 news articles. The corpus separates subjective and objective expressions. It has some information about objective content (such as the source and the target of the objective speech), but only has sentiment information about the subjective content. Our annotated corpus is different because it is concerned with objective language. Our task requires different annotation guidelines and, in general, a different setup for the annotation process compared to work on sentiment analysis.

Balahur et al. (2010), Abdul-Mageed and Diab (2011) and Balahur and Steinberger (2009) try to distinguish between positive and negative sentiment vs. good and bad news. Good and bad news are considered objective information and excluded from the classification process. In contrast, our method deals with good and bad objective information in the classification step.

Some prior work has classified financial news according to polarity. Some papers limit their classification to the subjective content of the news (e.g., (Agic et al., 2010)); other papers have classified objective content as well (Ahmad, 2006; Devitt and Ahmad, 2007; Shtrimberg, 2004). For example, Shtrimberg (2004) proposed an approach to classify news stories about companies as positive or negative. His classifier learned from a corpus where every news story about a company is labeled based on its impact on the future price of its stock. However, impact on price is different from positive/negative. For example, bad economic news can have a positive impact on stock prices if investors think it will make the Federal Reserve more likely to launch another round of quantitative easing. Our approach generates a score that indicates the POV of the article toward the subject matter and that is not directly related to the impact such information might have on the financial markets.

Another topic related to POV is media bias (Gentzkow and Shapiro, 2005, 2006). Some studies on this topic investigate bias in Wikipedia. Herzig et al. (2011) propose a novel annotation scheme as a basic step towards an automatic machine learning system to detect biased language in English Wikipedia. The scheme has multiple levels of bias tagging: the intra-sentential level, which includes polar-phrase, weasel, repetition, and personal-tone, and the sentence and entry level. The proposed scheme was applied to a set of articles from the service providers category in Wikipedia. Annotation categories distinguished between biased language and unbiased language. The authors conducted their annotation scheme based on the articles which explicitly *violate* the NPOV principle. Our approach studies POV differences under the assumption that Wikipedia articles mostly *adhere* to the NPOV principle and do not use biased linguistic expressions.

A line of research related to POV is work on perspectives and viewpoints (Lin et al., 2006; Paul et al., 2010). Most of this work uses Bitterlemons, a corpus of 594 articles each of which is written either from an Israeli or from a Palestinian perspective. Perspective classification (Lin and Hauptmann, 2006; Greene and Resnik, 2009; Klebanov et al., 2010) and modeling (Ahmed and Xing, 2010; Hardisty et al., 2010) then attempts to automatically detect the perspective of an article. Perspective and positive/negative POV are related, but different concepts; e.g., the sentences "political prisoners are released in Hamas deal" and "parties discuss new construction in Judea and Samaria" are both neutral or positive, but indicate different – Palestinian vs. Israeli – perspectives. In addition, much of the content of the Bitterlemons corpus is subjective – 66% of sentences according to Lin et al. (2006). In contrast, we address the problem of identifying positive/negative POV in objective language. Finally, the computational work on Bitterlemons is mostly on the document level whereas the measures we propose are based on sentences.

Massa and Scrinzi (2011) describe Manypedia, a web tool that supports comparing articles on the same subject in Wikipedia versions of different languages. They define the linguistic point of view as the potential difference in POV between Wikipedia articles from different languages due to the isolation of editor communities of these language versions. The tool provides users with multiple options such as translating the articles using Google Translate, extracting the most frequent words and showing information about editing of the article (e.g., total number of edits and editors). In contrast to our approach, Manypedia does not aim to provide automatic NLP analysis functionalities.

8 Conclusion and Future Work

The comparative analysis of differences – be they subtle or conspicuous – in the evaluation of particular subject matters is of great importance in the social sciences. The method we propose in this paper has two advantages. By choosing a relative instead of an absolute approach we avoid the old and still unsettled problem of defining an objective, neutral standard; and by taking a statistical classification approach, we provide an automatic method suitable for the analysis of large amounts of text.

Future work. We would like to address two problems in future work. First, our error analysis showed that most errors in predicting POV difference were due to our simple representation of sentences: bag of words. We would like to use more sophisticated representations that take into account the scope of positive and negative words; and also language understanding methods that can detect what a statement is about – the target itself or something not directly related to the target.

Second, we pointed out that there seem to be cultural differences in the magnitude of absolute POV. In particular, we found that international personalities are viewed in more positive light in the Arabic Wikipedia than in English. This means that there are at least two possible reasons for a POV difference: it can be due to a generally lower or higher level of absolute POV in one language; or it can be due to a genuinely different evaluation of a personality in two Wikipedias. We plan to distinguish these two different kinds of POV difference in future work.

Acknowledgments. We thank Deutsche Forschungsgemeinschaft for funding this research (DFG, SFB 732, D7); the anonymous reviewers, Christian Scheible, Wiltrud Kessler, Charles Jochim and Andrea Glaser for their valuable comments; and Amr Yassin, Ghada Dessouky, Mariam Hassib and Mirna Bouchra for performing the annotation.

{ralrfou, skiena}@cs.stonybrook.edu

ABSTRACT
Online content analysis employs algorithmic methods to identify entities in unstructured text. Both machine learning and knowledge-base approaches lie at the foundation of contemporary named entities extraction systems. However, the progress in deploying these approaches on web-scale has been been hampered by the computational cost of NLP over massive text corpora. We present SpeedRead (SR), a named entity recognition pipeline that runs at least 10 times faster than Stanford NLP pipeline. This pipeline consists of a high performance Penn Treebank-compliant tokenizer, close to state-of-art part-of-speech (POS) tagger and knowledge-based named entity recognizer.

KEYWORDS: Tokenization, Part Of Speech, Named Entity Recognition, NLP pipelines.

Proceedings of COLING 2012: Technical Papers, pages 51–66,

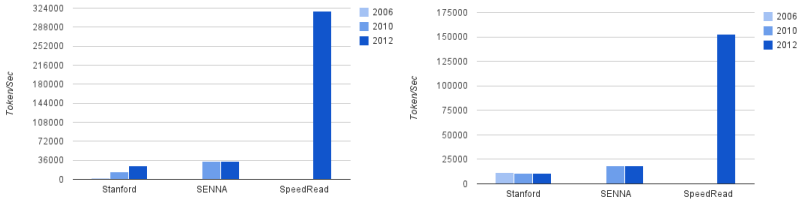
1 Introduction

Information retrieval (IR) systems rely on text as a main source of data, which is processed using natural language processing (NLP) techniques to extract information and relations. Named entity recognition is essential in information and event-extraction tasks. Since NLP algorithms require computationally expensive operations, the NLP stages of an IR system become the bottleneck with regards to scalability (Pauls and Klein, 2011). Most of the relevant work, conducted by researchers, was limited to small corpora of news and blogs because of the limitation of the available algorithms in terms of speed. Most of the NLP pipelines use previously computed features that are generated by other NLP tasks, which adds computational cost to the overall NLP pipeline. For example, named entity recognition and parsing need POS tags; co-reference resolution requires named entities. In effect, we anticipate lower speed for future tasks.

A conservative estimate of a sample of the web news and articles can add up to terabytes of text. On such scale, speed makes a huge difference. For example, considering the task of annotating 10 TiBs of text with POS tags and named entities using a 20 CPU cores computer cluster would take at least 4 months using the fastest NLP pipeline available for researchers, our calculations show. Using our proposed NLP pipeline the time is reduced to a week.

Several projects have tried to improve the speed by using code optimization. Figure 1a shows that Stanford POS tagger has improved throughout the years, increasing its speed by more than 10 times between 2006 and 2012. However, the current speed is twice slower than the SENNA POS tagger.



(a) POS taggers performance.

(b) NER taggers performance.

Figure 1: Performance of NLP pipelines through the years over POS and NER tagging. Stanford POS tagger uses L3W model, its speed in 2006 is slow to be apparent in the graph. Stanford tagger uses CONLL 4 classes model. SENNA pipeline was first released in 2008

In this paper, we present a new NLP pipeline, SpeedRead, where we integrate global knowledge extracted from large corpora with machine learning algorithms to achieve high performance. Figures 1a and 1b show that our pipeline is 10 times faster than Stanford pipeline in both tasks: POS tagging and NER tagging. Our design is built on two principles: (1) majority of the words have unique annotations and tagging them is an easy task; (2) the features extracted for the frequent words should be cached for later use by the classifier. Both principles are simple and they show how to bridge the large gap in performance between current systems and what can be achieved.

Our work makes the following contributions:

Phase	SpeedRead Relative Speed
Tokenization	11.8
POS	11.1
NER	13.9
TOK+POS+NER	18.0

Table 1: SpeedRead relative speed to Stanford pipeline.

- *Exposing the performance limitations of the current NLP systems:* We show that there is an algorithmic room for improving performance, rather than relying solely on optimizing the code.
- *High performance NLP pipeline that supports English tokenization, POS tagging and named entity recognition:* Novel design decisions that are not taken by most of the available tools to explore new area of the accuracy-performance space. SpeedRead is available under an open-source license. The code's organization is simple and it is written in Python for its readability benefits. This makes it easier for others to contribute and hack.
- *Techniques to reduce computation needed for sequence tagging tasks:* We distinguish between ambiguous and non-ambiguous words. We use the larger copora to calculate the frequent words and their frequent tags. We cache the extracted features of the most frequent words to avoid unnecessary calculations and boost performance.

Figure 2 shows the design of the SpeedRead pipeline. The first stage is tokenization followed by POS tagging that is used as an essential feature to decide the boundaries of the named entities' phrases. Once the phrases are detected, a classifier decides to which category these named entities belong to.

This paper is structured as follows. In Section 2, we discuss the current NLP pipelines, available to researchers. Section 3 discusses SpeedRead tokenizer's architecture, speed and accuracy. In Section 4, we discuss the status of the current state-of-art POS taggers and describe SpeedRead new POS tagger. Section 5 describes the architecture SpeedRead's named entity recognition phase. Finally, in Section 5.2, we discuss the status of the pipeline and the future improvements.

1.1 Experimental Setup

All the experiments presented in this paper were conducted on a single machine that has i7 intel 920 processor running on 2.67GHz, the operating system used is Ubuntu 11.10. The time of execution is the sum of *{sys, user}* periods calculated by the Linux command `time`. The speeds that are reported are calculated by averaging the execution time of five runs without considering any initialization times.

2 Related Work

There are many available natural language processing packages available for researchers under open source licenses or non-commercial ones. However, this section is not meant to review the literature of named entity recognition research as this is already available in (Nadeau and Sekine, 2007). We are trying to discuss the most popular solutions and the ones we think are interesting to present.

Stanford NLP pipeline (Toutanova and Manning, 2000; Toutanova et al., 2003; Klein et al., 2003; Finkel et al., 2005; Lee et al., 2011) is one of the most popular and used NLP packages.

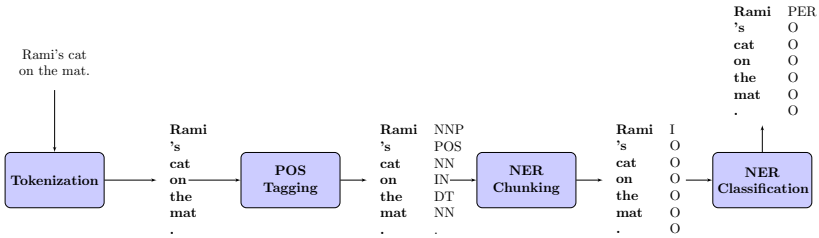


Figure 2: SpeadRead named entity recognition pipeline. First, tokenization split the words into basic units to be processed in the later phases. POS tagging identifies to which speech categories words belong to. There are 45 part of speech category, we are mainly interested in nouns. Chunking identifies the borders of phrases that make up the named entities. In the above sentence, the named entity, Rami, is one word phrase. The last stage classifies each phrase to one of four categories; Person, Location, Organization or Miscellaneous.

The pipeline is rich in features, flexible for tweaking and supports many natural languages. Despite being written in Java, there are many other programming language bindings that are maintained by the community. The pipeline offers a tokenization, POS tagging, named entity recognition, parsing and co-referencing resolution. The pipeline requirements of memory and computation are non-trivial. To accommodate the various computational resources, the pipeline offers several models for each task that vary in speed, memory consumption and accuracy. In general, to achieve good performance in terms of speed, the user has to increase the memory available to the pipeline to 1-3 GiBs and choose the faster but less accurate models.

More recent efforts include SENNA pipeline. Even though it lacks a proper tokenizer, it offers POS tagging, named entity recognition, chunking, semantic role labeling(Collobert and Weston, 2008) and parsing (Collobert, 2011). The pipeline has simple interface, high speed and small memory footprint (less than 190MiB).

SENNA builds on the idea of deep learning of extracting useful features from unlabeled text. This unsupervised learning phase is done using auto-encoders and neural networks language models. It allows the pipeline to map words into another space of representation that has lower dimensionality. SENNA maps every word available in its 130 thousand word dictionary to a vector of 50 floating numbers. These vectors are then merged into a sentence structure using convolutional networks. The same architecture is then trained on different tasks using annotated text to generate different classifiers. The big advantage of taking this approach is the lesser amount of engineering that it requires to solve multiple problems.

NLTK (Bird et al., 2009) is a set of tools and interfaces to other NLP packages. Its simple APIs and good documentation makes it a favorable option for students and researchers. Written in Python, NLTK does not offer great speed or close to state-of-art accuracy with its tools. On the other hand, it is well maintained and has great community support.

WikipediaMiner (Milne and Witten, 2008) detects conceptual words and named entities; it also disambiguates the word senses. This approach can be modified to detect only the words that represent entities, then using the disambiguated sense, it can decide which class the entity belongs to. Its use of the Wikipedia interlinking information is a good example of the power

of using knowledge-based systems. Our basic investigation shows that the current system needs large chunks of memory to load all the interlinking graph of Wikipedia and it would be hard to optimize for speed. TAGME (Ferragina and Scaiella, 2010) is extending the work of WikipediaMiner to annotate short snippets of text. They are presenting a new disambiguation system that is faster and more accurate. Their system is much simpler and takes into account the sparseness of the senses and the possible lack of unambiguous senses in short texts.

Stanford and SENNA performed the best in terms of speed and quality in our early investigation. Therefore, we will focus on both of them from now on as good representatives of a wide range of NLP packages.

3 Tokenizer

The first task that an NLP pipeline has to deal with is tokenization and sentence segmentation (Webster and Kit, 1992). Tokenization target is to identify tokens in the text. Tokens are the basic units which need not to be processed in the subsequent stages. Part of the complexity of tokenization comes from the fact that the definition of what a token is, depends on the application that is being developed. Punctuation brings another level of ambiguity; commas and periods can play different roles in the text. For example, we do not need to split a number like $1,000.54$ into more units whereas we need to split a comma-separated list of words. On the other hand, tokenization is important as it reduces the size of the vocabulary and improves the accuracy of the taggers by producing similar vocabulary to the one used for training.

As many NLP tasks' gold standards are dependent on Penn Treebank(PTB), a corpus of annotated text and parsed sentences taken from Wall Street Journal (WSJ), we opted for their tokenization scheme.

Searching for good tokenizers, we limited our options to the ones that support Unicode. We believe that Unicode support is essential to any applications that depends on the pipeline. Stanford tokenizer and Ucto (Gompel, 2012) projects offer almost Penn Treebank (PTB) compliant tokenizers plus other variations that are richer in terms of features.

Table 2 shows that there is a substantial gap in performance between basic white space tokenizer (words are delimited by spaces or tabs and sentences are split by new line characters) and more sophisticated tokenizers as Stanford tokenizer and Ucto. We observed that the Stanford tokenizer is 50 times slower than the baseline (WhiteSpace tokenizer), which motivated us to look at the problem again.

The Stanford tokenizer is implemented using JFlex, a Java alternative to Flex. The tokenizer matured over the years by adding more features and modes of operation which makes it harder for us to modify. Ucto uses C++ to compile a list of regular expressions that passes over the text multiple times.

SpeedRead, like the Stanford tokenizer, uses a lexical analyzer to construct the tokenizer. However, we use different generating engine than the (F)lex family. SpeedRead depends on Quex (Schafer, 2012), a lexical analyzer generator, to generate our tokenizer. Quex makes different trade-off decisions than the usual lex tools when it comes to the tokenizer's generation time. Quex spends more time optimizing its internal NFA to produce a faster engine. While generating a tokenizer from a normal lex file can take few minutes, Quex takes hours for the same task. However, Quex supports Unicode in multiple ways and has similar description language to lex, but is cleaner and more powerful. The extensive multiple mode support makes

Tokenizer	Word/Second	Relative Speed
Ucto	185,500	0.8
PTB Sed Script	214220	0.96
Stanford	222,176	1.0
SpeedRead	2,626,183	**11.8**
WhiteSpace	11,130,048	50.0

Table 2: Speed of different tokenizers measured as word/second; Every tokenizer generates different number of tokens. For consistency, the original words count before tokenization used to calculate the speed. Words count is calculated using linux command *wc*. Execution time includes both tokenization and sentence segmentation times with the exception that the original PTB Sed Script does not do sentence segmentation. Ucto's default configuration is used. Stanford tokenizer runs with strict PTB flag turned on.

it easy to write the lexical rules in understandable and organized way. All of that results in a fast C implementation of a Penn Treebank compliant tokenizer as Table 2 shows.

As a design decision, we did not support some features which we believe will not affect the accuracy of the tokenizer. Table 3 shows the features which are not implemented. While some of the features are easy to add as supporting contractions, others, involving abbreviations especially *U.S.*, prove to be complex (Gillick, 2009).

Feature	Text	PTB	SpeedRead
Reordering	Japan. ...	Japan	Japan . ...
Punctuation addition	U.S."	U.S. . "	U.S. "
Contractions	gimme	gim me	gimme

Table 3: Some features that are not implemented in SpeedRead Tokenizer. Contractions that involves apstrophes are implemented in SpeedRead. For instance, *can't* will be tokenized to *ca n't*.

Table 4 shows that the accuracy of our tokenizer is Penn Treebank compliant, despite the missing features. Moreover, running SpeedRead and Stanford tokenizers over Reuters RCV1 corpus results in approximately 214, 215 million tokens consecutively.

3.1 Sentence Segmentation

While PTB offers a set of rules for tokenization, their tokenizer assumes that the sentences are already segmented, which is done manually. SpeedRead's sentence segmentation uses the same rules that Stanford tokenizer uses. For instance, a period is an end of a sentence unless it is part of an acronym or abbreviation. The list of rules to detect those acronyms and abbreviations are taken from the Stanford tokenizer. Any quotations or brackets, that follow the end of the sentence, will be part of that sentence. Running SpeedRead's sentence segmentation on Reuters RCV1 generated 7.8 million sentences, while Stanford tokenizer generated 8.2 million sentences.

Tokenizer	Accuracy
PTB Sed Script	100.0%
Stanford tokenizer	99.7%
SpeedRead	**99.0**%
White Space	0.0%

Table 4: Accuracy of the tokenizers over the first 1000 sentence in the Penn Treebank. The gold standard was created by getting the tokenized text from the parse trees and manually segment the original text into sentences according to the parse trees. Errors in differentiating between starting and ending quotations are not considered. Not supporting MXPOST convention, replacing brackets with special tokens, is not considered necessary.

4 Part of Speech Tagger (POS)

Earlier work to solve the POS tagging problem relied on lexical and local features using maximum entropy models (Toutanova and Manning, 2000). Later, more advanced models took advantage of the context words and their predicted tags (Toutanova et al., 2003) to achieve higher accuracy. As POS tagging is a sequence tagging problem, modeling the sequence into a Maximum Entropy Markov Model (MEMM) or Conditional Random Fields (CRF) model (to infer the probability of the tags' sequences) seems to be the preferred option. The probability of each tag is computed using log-linear model with features that include large enough context words and their already-computed tags. This transforms every instance of the problem into a large vector of features that is expensive to compute. Then the sequence of vectors are fed to graphical model to compute the probability of each class, using the inference rules. The size of features' vector and the inference computation are the same regardless of the complexity of the problem.

Although the previous algorithms are sufficient to achieve satisfying accuracy, their computation requirements are overkill for most of the cases faced by the algorithm. For example, *the* has a unique POS tag that never changes depending on its position in the sentence. Moreover, *more* and *that* are frequent enough in the English text that there is a need to cache their extracted features.

4.1 Algorithm

SpeedRead takes advantage of the previous observations and tries to distinguish between ambiguous and certain words. To understand such influences, we ran a Stanford POS tagger (left 3 words Model (L3W); trained on Wall Street Journal(WSJ), Sections 1-18) over a 1 GiB of news text to calculate the following dictionaries:

- The most frequent POS tag of each token (Uni).
- The most frequent POS tag of each token, given the previous POS tag (Bi).
- The most frequent POS tag of each token, given the previous and next POS tags (Tri).

Using the above dictionaries to calculate the POS tag of a word, leads to various precision/recall scores. (Lee et al., 2011) shows that using sieves is the solution to combine several rules/dictionaries. In a sieve algorithm, there is a set of rules that are cascaded after each other. The algorithm runs the rules from the highest in precision to the lowest. The first rule, matching the problem instance, returns its computed tag immediately. SpeedRead

implements few sieves in the following order:

1. **Certain tokens**: Given a sentence, if the percentage frequency of the most frequent tag of a token is more than a threshold (in our work, 95%) then return that tag.
2. **Left and Right tags** (Tri): For each token with unknown tag, return the most frequent tag, given the left and right POS tags if they are known.
3. **Left tags** (Bi): For each token with unknown tag, return the most frequent tag, given the left POS tag if it is known from the previous stages.
4. **Token tag** (Uni) : For each token with unknown tag up to this stage, return the most frequent tag.
5. **Backoff tag**: If the token is unknown, use regular expression tagger to deduce the tag; the regular expression tagger relies heavily on matching suffixes.

4.2 Results

Table 5 shows the performance of different algorithms running on different sections of PTB. Stanford and SENNA models use sections 1-18, 19-21, 22-24 for training, development and testing datasets, respectively. Despite the simplicity of our algorithm, it achieves relatively high accuracy on the various datasets available.

Applying more context-aware rules, SpeedRead with sieves 1-5 (SR[Tri/Bi/Uni]) implemented, shows improvement in accuracy by around 2.85% compared to just using unigrams, SpeedRead with sieves 1,4-5 (SR[Uni]). To be sure that our algorithm is robust enough and not overfitting the dataset, we calculated the dictionaries again by running SENNA POS tagger(Collobert et al., 2011) over Reuters RCV1 corpus and the results were similar.

POS Tagger \ Sections	19-21	22-24	1-24
Stanford Bidirectional	97.27	97.32	98.16
Stanford L3W	96.97	96.89	97.90
SENNA	97.81	96.99	97.68
SR[Tri/Bi/Uni]	96.73	**96.39**	96.66
SR[Bi/Uni]	96.06	95.82	96.03
SR[Uni]	93.73	93.56	93.70

Table 5: Accuracy of different taggers on different sections of Penn Treebank. The first column corresponds to the development set and the second to the testing set.

Tables 5 and 6 show the tradeoff between accuracy and speed. Stanford pipeline offers two models with different speeds and accuracies. Since Left 3 Words model (L3W) is the preferred tagger to use in practice, we chose it to be our reference in terms of speed. L3W model runs 18 times faster than the state-of-art Bidirectional model and is only 0.4% less accurate. SpeedRead pushes the speed by another factor of 11 with only 0.5% drop in accuracy. Since the speed of some algorithms vary with the memory used, every algorithm was given enough memory that adding more memory will not affect its speed. The memory footprint is reported in the fourth column of Table 6.

POS Tagger	Speed Token/Sec	Relative Speed	Memory in MiB
Stanford Bi	1389	0.04	900
Stanford L3W	28,646	1.00	450
SENNA	34,385	1.20	150
SR [Tri/Bi/Uni]	318,368	**11.11**	600
SR [Bi/Uni]	397,501	13.87	250
SR [Uni]	564,977	19.72	120

Table 6: Speed of different POS taggers. The first two taggers are Stanford taggers. The first tagger runs the Bidirectional(Bi) model and the second runs the Left 3 Words (L3w) model. SpeedRead has three variations

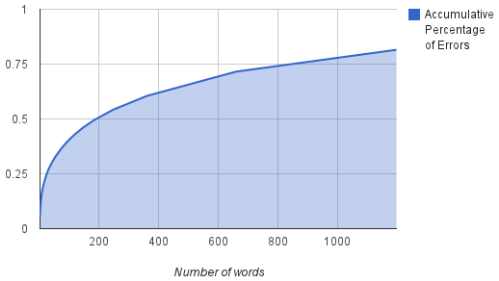

Figure 3: Accumulative percentage of errors made by the most frequent mistagged words. The total number of words is around 2000, the graph lists only the most frequent 1000.

4.3 Error Analysis

The most common errors are functional words, such as *that, more, ..* which have multiple roles in speech. This confirms some of the conclusions reported by (Manning, 2011). Figure 3 shows that less than 10% of mistagged words are responsible for slightly more than 50% of the errors. Regarding unknown words, the only part of the tagger that generalizes over unseen tokens is the regular expression tagger. Regular expressions are not extensive enough to achieve high accuracy. Therefore, we are planning to implement another backoff phase for the frequent unseen words where we accumulate the sentences, containing these words, after sufficient amount of text is processed and then run Stanford/SENNA tagger over those sentences to calculate the most common tag.

Table 7 shows the confusion matrix of the most ambiguous tags; the less ambiguous tags are clustered into one category, `0`. One of the biggest sources of confusion in tagging is between adjectives (JJ) and nouns (NN). Proper nouns are the second source of errors as most of the capitalized words will be mistakenly tagged as proper nouns while they are either adjectives or nouns. Such errors are the result of the weak logic implemented in the backoff tagger in SpeedRead, where regular expressions are applied in sequence returning the first match. Other types of errors are adverbs (RB) and propositions (IN). These errors are mainly because of the

Ref \ Test	DT	IN	JJ	NN	NNP	NNPS	NNS	RB	VBD
DT	11094	62	3	7	3	0	0	1	0
IN	15	13329	9	1	0	0	0	88	0
JJ	1	11	7461	**257**	130	2	10	65	38
NN	1	5	**288**	17196	111	0	18	11	2
NNP	8	13	118	109	12585	264	31	8	0
NNPS	0	0	0	0	70	81	16	0	0
NNS	0	0	1	23	20	42	7922	0	0
RB	17	**281**	103	23	8	0	0	3892	0
VBD	0	0	8	5	4	0	0	0	4311
VBG	0	0	25	104	5	0	0	0	0
O	26	163	154	172	47	4	107	67	174

Table 7: Confusion Matrix of the POS tags assigned by SpeedRead over the words of sections 22-24 of PTB. O represents all the other not mentioned tags.

ambiguity of the functional words. Functional words need deeper understanding of discourse, semantic and syntactic nature of the text. Taking into consideration the contexts around the words improves the accuracy of tagging. However, trigrams are still small to be considered sufficient context for resolving all the ambiguities.

5 Named Entity Recognition (NER)

Named entity recognition is essential to understand and extract information from text. Many efforts and several shared tasks, aiming to improve named entity recognition and classification, had been made; CONLL 2000/2003 (Tjong Kim Sang and De Meulder, 2003) are some of the shared tasks that addressed the named entity recognition task. We use CONLL 2003's definition of named entity recognition and classification task. CONLL 2003 defines the chunk borders of an entity by using IOB tags, where `I-TYPE` means that the word is inside an entity, `B-TYPE` means a beginning of a new entity if the previous token is part of an entity of the same type and `O` for anything that is not part of an entity. For classification, the task defines four different types: Person(PER), Organization(ORG), Location(LOC) and Miscellaneous(MISC) (See Figure 4).

We split the task into two phases. The first is to detect the borders of the entity phrase. After the entity chunk is detected, the second phase will classify each entity phrase to either a Person, Location, Organization or Miscellaneous.

Columbia/ORG *is an* **American**/Misc *university located in* **New**/LOC **York**/LOC.

Figure 4: Annotated text after NER.

5.1 Chunking

We rely on the POS tags of the phrase words to detect the phrase that constitute an entity. A word is considered to be a part of an entity: (1) if it is a demonym (our compiled list contains 320 nationalities), (2) if one of the following conjunction words {`&`, `de`, `of`} appearing in middle of an entity phrase or, (3) if its POS tag is `NNP(S)` except if it belongs to one of these sets:

- Week days and months and their abbreviations.
- Sports (our compiled list contains 182 names).
- Job and profession titles (our compiled list contains 314 title).
- Single Capital letters.

These sets are compiled using freebase.

CONLL dataset shows a strong correlation between POS tags `NNP(S)` and the words that are part of entities' phrases; 86% of the words that appear in entities' phrases have `NNP(S)` POS tags. The remaining words are distributed among different POS tags; 6.3% are demonyms. Adding the demonyms and proper nouns guarantee 92.3% coverage of the entities' words that appear in the dataset.

Using POS tags as main criteria to detect the entity phrases is expected, given the importance of the POS tags for the NER task. 14 out of 16 submitted paper to CONLL 2003 used POS tags as part of their feature set.

The behavior of the chunking algorithm is greedy as it tries to concatenate as many consecutive words as possible into one entity phrase. A technical issue appears in detecting the borders of phrases when multiple entities appear after each other without non-entity separator. This situation can be divided into two cases. Firstly, if the two consecutive entities are of the same type. In this case, the chunking tag should be `B-TYPE`. Looking at the dataset, such tag appears less than 0.2% out of all the entities' tags. For example, in the original Stanford MEMM implementation, the classifier (Klein et al., 2003) generates `IOB` chunking tags while in the later CRF models (Finkel et al., 2005) only `IO` chunking tags are generated. The second case is when the phrases are of different types. In the dataset, this case appears 248 times over 34834 entities. Since both cases are not frequent enough to harm the performance of the classifiers, SpeedRead does not recognize them.

5.1.1 Results

Table 8 shows F1 score of the chunking phase using different taggers to generate the POS tags. This score is calculated over the chunking tags of the words. `I` and `B` tags are considered as one class while `O` is left as it is. It is clear from Table 8 that using better POS taggers does not necessarily produce better results. The quality of SpeedRead POS tagging is sufficient for the chunking stage. SENNA and SpeedRead POS taggers work better for the detection phase because they are more aggressive, assigning the `NNP` tag to any capitalized word. On the other hand, Stanford tagger prefers to assign the tag of the lowered case shape of the word, if it is a common word.

Phase \ Dataset	Train	Dev	Test
SR+SR POS	94.24	94.49	**93.12**
SR+Stanford POS L3W	92.98	93.37	92.05
SR+CONLL POS	90.88	90.82	89.43
SR+SENNA POS	94.73	95.07	**93.80**

Table 8: F1 scores of the chunking phase using different POS tags. F1 score is calculated over tokens and not entities.

5.1.2 Error Analysis

Table 9 shows the error cases that appears in the chunking phase. The most common class of errors in the chunking phase is titles, such as *{RESULTS, DIVISION, CONFERENCE, PTS, PCT}*. These words seem to confuse the POS tagger. Another source of confusion for the POS tagger is the words *{Women, Men}*; such words appear in the name of sports so they get assigned `NNP` tag. As expected, all numbers that are part of entities are not detected. Conjunction words are the second important class of errors. (Pawel and Robert, 2007) shows that conjunction words that appear in middle of entities' phrases are hard to detect and need special classification task. As most of *of* occurrences are part of entities and the converse is true for *and*, we decided to include the former and exclude the later.

Word	Percentage	Type of error
Titles	22.7%	Detected
Titles	4.9%	Missed
of	2.6%	Detected
96, 95, 1000 ...	2.6%	Missed
Men	1.3%	Detected
Women	1.3%	Detected
and	1.1%	Missed
central	1.1%	Detected

Table 9: Most frequent errors in the chunking stage.

5.2 Classification

Classification is a harder problem than just detecting an entity. For example, "West Bank" can belong to two classes, location and organization. Disambiguating the sense of an entity depends on the context. For instance, "Mr. Green" indicates that "Green" is a person, while "around Green" points to a location. To classify an entity, we used a logistic regression classifier, sklearn (Scikit, 2011). The features we feed to the classifier are two factors per type: $\phi_{ij}(Type_i, phrase_j)$ and $\psi_{ij}(Type_i, context_j)$. Context consists of two words that precede and follow an entity phrase. To calculate these factors:

$$\phi_{ij}(Type_i, phrase) = \prod_{k}^{n} P(Type_i|w_k) \tag{1}$$

$$\psi_{ij}(Type_i, context = \{w_{before}, w_{after}\}) = P(Type_i|w_{before}) \times P(Type_i|w_{after}) \tag{2}$$

The conditional probabilities of the types, given a specific word, are calculated using the distribution of tags frequencies over words, retrieved from the annotated Reuters RCV1 corpus. SENNA NER tagger has been used to annotate the corpus.

Table 10 indicates the importance of the classification phase. First row shows that, given chunked input, the classification phase is able to achieve close scores to the state-of- art classifiers. However, given the chunks generated by SpeedRead, the scores drop around 9.5% in F1 scores.

Phase \ Dataset	Training	Dev	Test
SR+Gold Chunks	90.80	91.98	87.87
SpeeRead	82.05	83.35	78.28
Stanford	99.28	92.98	89.03
SENNA	96.75	97.24	89.58

Table 10: F1 scores calculated using conlleval.pl script for NER taggers. The table shows that SpeedRead F1 score is 10% below the sate-of-art achieved by SENNA.

To analyze the scores of the classification phase further, Table 11 shows a confusion matrix over the tags generated by SpeedRead. The errors that involve `O` are signs of chunking errors; there are 1158 chunking errors which exceed the total number of classification errors, 849.

Ref \ Test	LOC	MISC	ORG	PER	O
LOC	1737	34	95	36	23
MISC	36	660	57	52	113
ORG	**323**	73	1954	37	109
PER	26	8	72	2632	35
O	66	248	**412**	152	37445

Table 11: Confusion matrix of the SpeadRead NER tags over the CONLL test dataset tokens.

The chunking errors contain more false positives than false negatives. The chunking algorithm is aggressive in considering every `NNP(S)` as part of an entity. That would be fine if we had a perfect POS tagger. The reality that the POS tagger has hard time classifying uppercased words in titles and camel cased words that appear at the beginning of the sentence.

Once non-entity is considered part of an entity phrase, the classifier has higher chance of classifying it as an *ORG* than any other tag. The names of the organizations contain a mix of locations and persons' names, forcing the classifier to consider any long or mix of words as an organization entity. That appears more clearly in the second most frequent category of errors. 323 words in organizations entities' names were classified as locations. This could be explained by the fact that many companies and banks name themselves after country names and their locations. For example, "Bank of England" could be classified as a location because of the strong association between England and the tag location.

Table 12 shows that Stanford pipeline has a high cost for the accuracy achieved by the classifier. SENNA achieves close accuracy with twice the speed and less memory usage. SpeedRead takes another approach by focusing on speed. We are able to speed up the pipeline to the factor of 13. SpeedRead's memory footprint is half the memory consumed by the Stanford pipeline. Even though SpeedRead's accuracy is not close to the state-of-art, it still achieves 18% increase over the CONLL 2003 baseline. Moreover, adapting the pipeline to new domains could be easily done by integrating other knowledge base sources as freebase or Wikipedia. SENNA and SpeedRead are able to calculate POS tags at the end of the NER phase without extra computation while that is not true of Stanford pipeline standalone NER application. Using Stanford corenlp pipeline does not guarantee better execution time.

NER Tagger	Token/Sec	Relative Speed	Memory MiB
Stanford	11,612	1.00	1900
SENNA	18,579	2.13	150
SpeedRead	153,194	**13.9**	950

Table 12: Speed of different NER taggers. SpeedRead is faster by 13.9 times using half the memory consumed by Stanford.

Conclusion and Future Work

Our success in implementing a high performance tokenizer and POS tagger shows that it is possible to use simple algorithms and conditional probabilities, accumulated from a large corpora, to achieve good classification and chunking accuracies.

This could lead to a general technique of approximating any sequence tagging problem using sufficiently large dictionaries of conditional probabilities of contexts and inputs. This approximation has the advantage of speeding up the calculations and opens the horizon for new applications where scalability matters.

Expanding this approach to other languages depends on the availability of other high accurate taggers in these languages. We are looking to infer these conditional probabilities from a global knowledge base as freebase or the interlinking graph of Wikipedia.

SpeedRead is available under GPLv3 license and it is available to download from `www.textmap.org/speedread`. We anticipate that it will be useful to large spectrum of named entity recognition applications.

Abstract

In this article we investigate the translation of financial terms from English into German in the isolation of an ontology vocabulary. For this study we automatically built new domain-specific resources from the translation search engine Linguee and from the online encyclopaedia Wikipedia. Due to the fact that we performed the translation approach on a monolingual ontology, we ran several sub-experiments to find the most appropriate model to translate the financial vocabulary. The findings from these experiments lead to the conclusion that a hybrid translation system, a combination of bilingual terminological resources and statistical machine translation, can help to improve translation of domain-specific terms. Finally we undertook a manual cross-lingual evaluation on the monolingual ontology to get a better understanding on this specific short text translation task.

Keywords: Ontologies and terminology, Empirical machine translation.

Proceedings of COLING 2012: Technical Papers, pages 67–82,
COLING 2012, Mumbai, December 2012.

1 Introduction

Our research on the translation of ontology vocabularies is motivated by the challenge of translating domain-specific terms with restricted or no additional textual context that in other cases may be used to improve the translation. For our experiment we started by translating financial terms with the baseline systems trained on the JRC-Acquis (Steinberger et al., 2006) corpus and the European Central Bank Corpus (Tiedemann, 2009). Although both resources contain a large amount of parallel data, the translations were not satisfactory. To improve the translations of the financial ontology vocabulary we built a new parallel resource, which was generated using Linguee, an online translation query service. With this data, we could train a small model, which produced better translations than the baseline model using only general resources.

Since the manual development of terminological resources is a time intensive and expensive task, we used Wikipedia as a background knowledge base and examined the articles tagged with domain-specific categories. With this extracted domain-specific data we built a specialised English-German lexicon to store translations of domain-specific terms. These terms were then used in a pre-processing method in the decoding approach. This approach incorporates the work by (Aggarwal et al., 2011), where the authors use the ontology structure to calculate the similarity between the labels. They combine the semantic, terminological and linguistic information for monolingual ontology matching, which can be extended to the multilingual scenario. We split the financial terms into n-grams and queried for financial sub-terms in Wikipedia, which we used to query Wikipedia.

The remainder of the paper is organised as follows: In Section 2 we give an overview on the related work. In Section 3 we describe the ontology and the existing parallel resources, which were used for generating the translation and language model. Section 4 presents the new resources which were used for improving the term translation. Furthermore we discuss the results of exploiting the different resources. We conclude with a summary and give an outlook on future work.

2 Related Work

The related research focusses on different aspects relevant to our work: domain-specific term translation. Firstly we have to understand the structure of these specific terms and the variations which come when dealing with these terms. Kerremans (2010) discusses in detail the issue of terminological variation in the context of specialised translation on a parallel corpus of biodiversity texts. He shows that a term often cannot be aligned to any term in the target language. As a result, he proposes that specialised translation dictionaries should store different translation possibilities or term variants. In addition to that, Weller et al. (2011) describe methods for terminology extraction and bilingual term alignment from comparable corpora. In their compound translation task, they use a dictionary to avoid out-of-domain translation. In contrast, to address this problem, which frequently arises in domain-specific translation we decided to generate our own customised lexicon; which we constructed from the multilingual Wikipedia and its dense inter-article link structure.

Erdmann et al. (2008) also extracted terms from Wikipedia articles; however, they assumed that two articles connected by an Interlanguage link are likely to have the same content and thus an equivalent title. We likewise build a lexicon from Wikipedia, but instead of collecting all of the titles from Wikipedia, we target only the domain-specific titles and their translated equivalents. Vivaldi and Rodriguez (2010) proposed a methodology for term extraction in the biomedical domain with the help of Wikipedia. As a starting point, they manually selected a set of seed words for a domain, which were then used to find the corresponding nodes in this resource. For cleaning their collected data, they used thresholds to avoid storing undesirable categories. Müller and Gurevych (2008) used

Wikipedia and Wiktionary as knowledge bases to integrate semantic knowledge into Information Retrieval. Their models, text semantic relatedness (for Wikipedia) and word semantic relatedness (for Wiktionary), are compared to a statistical model implemented in Lucene. In their approach to bilingual retrieval, they use the cross-language links in Wikipedia, which improved the retrieval performance in their experiment, especially when the machine translation system generated incorrect translations. Zesch et al. (2008) address the issues in accessing the largest collaborative resources: Wikipedia and Wiktionary. They describe several modules and APIs for converting a Wikipedia XML Dump into a more suitable format. Instead of parsing the large Wikipedia XML Dump, they suggest to store the Dump into a database, which significantly increases the performance in retrieval time of queries.

3 Experimental Data

We are investigating the problem of translating a domain-specific vocabulary, therefore our experiments started with an analysis of the financial terms stored in the investigated ontology. With these extracted terms we built different multilingual resources, which were used for financial term translation. Firstly, we used the encyclopaedia Wikipedia, where we extracted the titles from domain-specific Wikipedia articles. Secondly, we used the same financial labels to build a parallel resource for the financial domain. For this approach we used the Linguee Web service.

In this section, we present several types of data. Section 3.1 gives an overview of the data that was used in translation. In Sections 3.2 and 3.3 we describe existing multilingual resources, which were used to train the translation and language model. For our current research we used JRC-Acquis and the European Central Bank (ECB) corpus, respectively. In the end we describe the procedure to obtain domains-specific resources by Linguee 3.4 and Wikipedia 3.5.

3.1 The Financial Ontology

For our study we used the UK GAAP[1] financial ontology, prepared by the XBRL[2] European Business Registers (xEBR) Working Group. This financial ontology is a framework for describing financial accounting and profile information of business entities across Europe; see also Declerck et al. (2010). The ontology holds 142 concepts and is partially aligned into German, Dutch, Spanish, French and Italian. We identified only 16 English financial terms and their German equivalents, which were used as reference translations for automatic evaluation.

The financial terms are not really terms from a linguistic point of view, but they are used in financial or accounting reports as unique financial expressions or tags to organize and retrieve automatically reported information. Therefore it is important to translate these financial terms exactly. Table 1 illustrates the structure of xEBR terms.

It is obvious that they are not comparable to general language, but instead are more like headlines in newspapers, which are often short, very informative, and written in a telegraphic style. xEBR terms are often only noun phrases without any determiner. The length of the financial terms varies, e.g. the longest financial term considered for translation has a length of 11 tokens, while others may consist of 1 or 2 (Figure 1).

[1] GAAP - Generally Accepted Accounting Practice
[2] XBRL - eXtensible Business Reporting Language, `http://www.xbrl.org/`

Term Length	Term Examples
11	Taxes Remuneration And Social Security Payable After More Than One Year
10	Amounts Owed To Credit Institutions After More Than One Year ...
	...
2	Net Turnover, Liquid Assets, Income Taxes, Financial Charges ...
1	Assets, Capital, Equity, Securities, Charges, Balance, Capital, Reserves ...

Table 1: Examples for financial labels in the UK GAAP

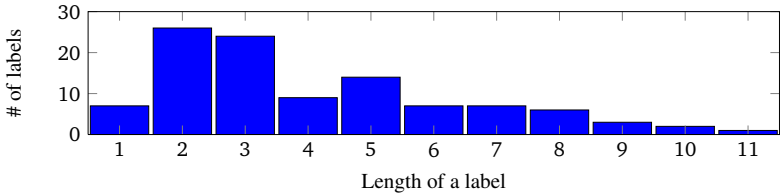

Figure 1: Label length of the UK GAAP ontology

3.2 JRC-Acquis

The general parallel corpus JRC-Acquis[3] was used as baseline training data. This corpus is available in almost every EU official language (except Irish), and is a collection of legislative texts written between 1950 and now.

Although previous research showed, that a training model built by using a general resource cannot be used to translate domain-specific terms (Wu et al., 2008), we decided to evaluate the translations on these resources to illustrate any improvement steps from a general resource to specialised domain resources.

3.3 European Central Bank Corpus

For comparison with JRC-Acquis, we also did experiments using the European Central Bank Corpus[4], which contains a financial vocabulary. The multilingual corpus is generated by extracting the website and documentation from the European Central Bank and is aligned among 19 European languages. For our research we used the English-German language pair, which consists of 113,171 sentence pairs or 2.8 million English and 2.5 million German tokens.

3.4 Linguee - Dictionary and Translation Search Engine

Alongside these existing resources, we built a new parallel resource based on the ontology vocabulary that we want to translate. Therefore we used Linguee,[5] a combination of a dictionary and a search engine, which indexes around 100 million bilingual texts on words and expressions. The search results show example sentences that depict how the searched expression has been translated in context. The bilingual dataset was gathered from the web, particularly from multilingual websites of companies, organisations or universities. Other sources include EU documents and patent

[3] http://langtech.jrc.it/JRC-Acquis.html
[4] http://opus.lingfil.uu.se/ECB.php
[5] http://www.linguee.com/

specifications. Since Linguee includes EU documents, they also use parallel sentences from JRC-Acquis, whereby the proportion of sentences returned by Linguee is very low, only 131 sentences or 0.54% overlap with the corpus.

In contrast to translation engines like Google Translate and Bing Translator, which give you the most probable translation of a source text, every entry in the Linguee database was translated manually.

Domain-specific parallel corpus generation

To build a new training model that is specialised for our xEBR ontology, we used the Linguee search engine. This resource can be queried on single words and on word expressions with or without quotation marks. We stored the HTML output of the Linguee queries of our financial terms and parsed these files to extract plain parallel text. From this, we built a financial parallel corpus with 24,247 translation pairs, including single words, multi-word expressions and sentences (Table 2). The English part of the parallel resource contained 1,032,676 tokens and the German part 865,460.

Single terms	Enterprise, share, reserve, debtor, expenses, ...
Multi-words	at a specific amount, credit institute, in the amount of, doubled over the last year
Sentences	Finally, the European Parliament called for social and cultural aspects of immigration to receive equal treatment than economic and security aspects of the issue.

Table 2: Examples of extracted text from the translation search engine Linguee

3.5 Wikipedia

Wikipedia[6] is a multilingual, freely available encyclopaedia that was built by a collaborative effort of voluntary contributors. All combined Wikipedias hold approximately 19 million articles or more than 8 billion words in more than 270 languages, making it the largest collection of freely available knowledge.[7]

With the heavily interlinked information base, Wikipedia forms a rich lexical and semantic resource. Besides a large number of articles, it also holds a hierarchy of categories that Wikipedia articles are tagged with. It includes knowledge about named entities, domain-specific terms and word senses. Furthermore, the redirect system of Wikipedia articles can be used as a dictionary for synonyms, spelling variations and abbreviations.

Domain-specific lexicon generation

To improve translations, based on the domain-specific parallel corpus, we built a cross-lingual terminological lexicon. From the Wikipedia articles we used different information units: the title, the category (or categories) of the title and the internal Interwiki\Interlanguage links of the title. The concept of Interwiki links can be used to make links to other Wikipedia articles in the same language or to another Wikipedia language i.e. Interlanguage links. The domain-specific lexicon was generated by two approaches:

a) domain detection of the ontology (bottom-up approach);

b) extraction of cross-lingual terminology (top-down approach).

[6] http://www.wikipedia.org

[7] http://en.wikipedia.org/wiki/Wikipedia:Size_comparison

In our first approach, we used Wikipedia to determine the domain (or several domains) of the ontology. The bottom-up approach (a) is to represent this domain by the most frequent categories associated with the vocabulary we want to translate. For this approach, the financial terms, which were extracted from the ontology, were used to query the Wikipedia knowledge base.[8] Initially a Wikipedia article was considered for further examination if its title is equivalent to our financial terms. In this first step, 7 terms from our ontology were identified in the Wikipedia knowledge base, i.e.:

Income tax, Earnings before interest and taxes, Asset, Stocks, Debtor, Gross profit, Income

We then collected the categories of the articles associated with these titles. Since a category can appear with different financial term, we also stored the frequency of these categories.[9] In a second round, we split our financial terms into all possible n-grams and repeated the query again to find additional categories based on the split n-grams. Table 3 shows the collected categories of the first approach and how often they appeared with respect to the extracted financial terms.

Collected Wikipedia Categories	
Frequency	Name
8	Generally Accepted Accounting Principles
4	Debt
	...
1	Political science terms
1	Physical punishments

Table 3: Collected Wikipedia Categories based on the extracted financial terms

After storing all categories, the only categories considered were the ones that had a frequency value more than the calculated arithmetic mean of all the frequencies (> 3.15). For the calculation of the arithmetic mean only the categories that had a frequency larger than 1 were considered, since 2,262 of 3,615 collected categories (62.6%) had a frequency of 1. Using this threshold we avoided the extraction of a vocabulary that is not related to the ontology. Without this threshold, out-of-domain categories would be stored, which would extend the lexicon with vocabulary that would not benefit the ontology translation, e.g. *Physical punishments*, which was a category associated with the financial term *Stocks*.

In the next step, we further extended the list of the previous collected categories with the use of full and split terms. This was done by storing new categories based on the Wikipedia Interwiki links of each article which was tagged with a category from Table 3. For example, we collected all categories of the Wikipedia article *Balance sheet*.[10] In addition to that, we examined all Interwiki links of the article *Balance sheet* and also stored the categories of articles which have an incoming link from this article.[11] For example, we stored all categories of the 106 articles which are linked with the article *Balance sheet*. The frequencies of these categories were summed up again to re-calculate the geometric mean. Finally a new category was added to the final category list, if the new category frequency exceeds the arithmetic mean threshold (> 18.40).

[8] For the Wikipedia Query we used the Wikipedia XML dump; `enwiki-20120702-pages-articles`

[9] The Wikipedia titles *Operating Income*, *Income*, *Gross profit*, *Income statement*, *Debtor* ... are tagged with the category *Generally Accepted Accounting Principles*

[10] *Financial statements*, *Accounting terminology*

[11] *Balance sheet*

Final Category List	
Frequency	Name
95	Economics terminology
62	Generally Accepted Accounting Principles
61	Macroeconomics
	...

Table 4: Most frequent Categories based on the xEBR terms and their Interwiki links

The final category list contained 33 financial Wikipedia categories (Table 4), which were used to extract the financial terms and their translations.

With the final list of categories, we started an investigation of all Wikipedia articles tagged with these financial categories. Each Wikipedia title was considered as a useful domain-specific term and was stored in our lexicon if a German title in the Wikipedia knowledge base also existed. As an example, we examined the category *Accounting terminology* and stored the English Wikipedia title *Balance sheet* with the German equivalent Wikipedia title *Bilanz*.

At the end of the lexicon generation we examined 5,228 Wikipedia articles that were tagged with one or more financial categories. From this set of articles we were able to generate a terminological lexicon with 3,228 English-German entities. The difference between the number of examined titles and the lexicon items is attributed to the fact that not all English Wikipedia titles are linked to a German one. These translation pairs were used to suggest the SMT system to choose the extracted translations by annotating the decoder input using the XML input markup scheme.

4 Experiments and Evaluation

Since the UK GAAP is a monolingual ontology, it holds no reference translation needed for automatic evaluation. Therefore we performed several experiments to find the best approach to translate this financial ontology. For decoding, we used the Moses Toolkit, with its standard settings (Section 4.1). If reference translations were available, we undertook an automatic evaluation using the BLEU (Papineni et al., 2002), NIST (Doddington, 2002), TER (Snover et al., 2006), and Meteor[12] (Denkowski and Lavie, 2011) algorithms.

With the first evaluation experiment we translated 16 aligned English-German labels with different translation models (Section 4.2). Furthermore, we translated the bilingual German GAAP to see which translation model performs best regarding the 2794 financial labels that are stored in this ontology (Section 4.3). We also compared the perplexity between several language models and the vocabulary stored in the UK GAAP ontology (Section 4.4). Finally we applied the best translation model to the monolingual ontology and undertook a manual, cross-lingual evaluation with six annotators (Section 4.5).

4.1 Translation System: Moses Toolkit

For generating the translations from English into German, we used the statistical translation toolkit Moses (Koehn et al., 2007). Furthermore, we aimed to improve the translations only on the surface level, and therefore no part-of-speech information was taken into account. Word and phrase alignments were built with the GIZA++ toolkit (Och and Ney, 2003), where the 5-gram language

[12]Meteor configuration: exact, stem, paraphrase

model was built by SRILM with Kneser-Ney smoothing (Stolcke, 2002).

4.2 Translating aligned UK – German GAAP labels

The UK GAAP is a monolingual ontology which holds 142 financial labels. With the help of the German equivalent, i.e. German GAAP, we aligned 16 German labels with the English ones, stored in the UK GAAP. This allowed us to do a small automatic evaluation, regardless of the low number of labels to be translated.

		Scoring Metric				
Source	# correct	BLEU-2	BLEU-4	NIST	TER	Meteor
JRC-Acquis	3	0.2629	0.2747	1.8112	0.6969	0.1579
ECB	3	0.2572	0.2725	1.5282	0.7878	0.1707
Linguee+Wikipedia	5	0.3623	0.2922	2.3259	0.6363	0.4085

Table 5: Evaluation scores for aligned UK–German GAAP translations

Despite the small amount of translations Table 5 shows the Linguee + Wikipedia resource produces the best BLEU score.

#	Source Label	Linguee+Wikipedia Model	Reference Translation
1	Fixed assets	Anlagevermögen	Anlagevermögen
2	Tangible fixed assets	Sachanlagen	Sachanlagen
3	Other tangible fixed assets	sonstige Sachanlagen	sonstige Sachanlagen
4	Equity	Eigenkapital	Eigenkapital
5	Income statement	Gewinn- und Verlustrechnung	Gewinn- und Verlustrechnung
6	Intangible fixed assets	immaterielle Vermögenswerte	Immaterielle Vermögensgegenstände
7	Other intangible fixed	sonstige immaterielle Vermögenswerte	sonstige immaterielle Vermögensgegenstände
8	Social security cost	Sozialbeiträge	soziale Abgaben
9	Other provisions	die sonstigen Rückstellungen	sonstige Rückstellungen
10	Other operating income	die sonstigen betrieblichen Erträge	sonstige betriebliche Erträge
11	Wages and salaries	die Löhne und Gehälter	Löhne und Gehälter
12	Current assets	kurzfristige Vermögenswerte	Umlaufvermögen
13	Work in progress	angefangene Arbeiten	unfertige Erzeugnisse
14	Work in progress	angefangene Arbeiten	unfertige Leistungen
15	Extraordinary income	das außerordentliche Ergebnis	außerordentliche Erträge
16	Equity and Liabilities	Eigenkapital und Zur	Bilanzsumme, Summe Passiva

Table 6: Results of financial translations generated by Linguee+Wikipedia translation model

Table 6 shows the translations of the 16 financial labels which were aligned between the UK and the German GAAP. The first part of the table, examples 1 to 5, represents the correct translations, which match exactly with the reference provided by the xEBR Working Group.

The next block represents translations which do not match completely with the reference translations. Examples 6 and 7 illustrate the problem of translating the label *fixed assets*[13] that can be translated into near synonyms *Vermögenswerte* or *Vermögensgegenstände*. Example 8 shows where the translation model generated a compound, but the reference translation consists of two separate tokens. If we de-compound the translation *Sozialbeträge* into *soziale Beträge*, we get a synonym to

[13] *Fixed assets* and *Other fixed assets*

the reference translation. Examples 9 to 11 represent translations with over-specification, since the ontology labels do not require the German article[14] at the beginning of a label.

The last part of the table illustrates incorrect translations. Examples 12 to 14 are translated into idiomatic expressions, whereby example 15 shows a wrong lexical choice. The word *Income* was translated into*Ergebnis*, whereas it should have been translated into *Erträge*. In example 16 a part of the source label, i.e. *Liabilities* is missed in the target translation.

4.3 Translating the German GAAP with different models

Since we built a financial parallel resource (see Section 3.4 and 3.5) and generated a translation model based on this financial vocabulary, we tested how well the model performs on a similar ontology. Therefore we translated the aforementioned German GAAP ontology, which holds 2,794 labels[15].

		Scoring Metric				
Source	# correct	BLEU-2	BLEU-4	NIST	TER	Meteor
JRC-Acquis	47	0.2276	0.1122	2.7022	0.9337	0.1761
ECB	24	0.1715	0.0596	2.1921	0.9834	0.1321
Linguee+Wikipedia	79	0.3397	0.2292	3.9383	0.8291	0.2917

Table 7: Evaluation scores for German GAAP term translations

Table 7 illustrates the automatic metrics used to evaluate the translation of the German GAAP, where the best BLEU results are generated by the Linguee+Wikipedia translation model. We can deduce from this experiment that even though JRC-Acquis has a larger number of tokens than the Linguee+Wikipedia corpus, it does not generate better translations of financial labels. The ECB corpus also does not generate better translations, although it is considered a domain-specific corpus.

4.4 Perplexity of different language models

The automatic evaluation with the small amount of translation and their references cannot demonstrate the quality of the translation model with regard to the whole UK GAAP ontology. Therefore we compared the perplexity[16] of different language models and the vocabulary of the UK GAAP ontology. Since a better language model should assign a higher probability to its test set, we tested which generated language model gives the highest probability on the UK GAAP vocabulary.

The perplexity (1) is a reformulation of cross-entropy (2).

$$PP = 2^{H(p_{LM})} \tag{1}$$

$$H(p_{LM}) = -\frac{1}{n}\sum_{i=1}^{n} log p_{LM}(w_i|, \ldots, w_{i-1}) \tag{2}$$

Table 8 illustrates that the ECB language model generates the worst perplexity on the UK GAAP vocabulary. On the other hand, the best probability is calculated by the Linguee+Wikipedia language

[14]German articles: die, der, das

[15]For comparison, the monolingual UK GAAP holds only 142 financial labels

[16]The perplexity was calculated with the SRILM ngram tool

model, which is not a surprise, since the resource is generated from the same vocabulary. Besides that, the best perplexity is generated by the German GAAP language model, which indicates that the vocabulary is most similar to the UK GAAP in comparison to other languages models.

	logprob	Perplexity
JRC-Acquis LM	-1,656.39	243.625
ECB LM	-1,871.33	497.098
German GAAP LM	-1,528.92	159.608
Linguee + Wikipedia LM	-1,277.15	69.226

Table 8: Perplexity of the language models

4.5 Manual Evaluation of Translation Quality - UK GAAP

We have undertaken a manual evaluation campaign to assess the translation quality of our terminology translation system, which was performed with the Appraise Toolkit.(Federmann, 2012)

In this section, we will a) describe the annotation setup and task presented to the human annotators, b) report on the translation quality achieved by the Linguee+Wikipedia approach, and c) present inter-annotator agreement scores that allow us to judge the reliability of the human rankings.

4.5.1 Annotation Setup

In order to manually assess the translation quality of the different systems under investigation, we designed a simple classification scheme consisting of three distinct classes:

1. *Acceptable (A)*: terms classified as acceptable are either fully identical to the reference term or semantically equivalent;
2. *Can easily be fixed (C)*: terms in this class require some minor correction (such as fixing of typos, removal of punctuation, etc.) but are nearly acceptable. The general semantics of the reference term are correctly conveyed to the reader.
3. *None of both (N)*: the translation of the term does not match the intended semantics or it is plain wrong. Items in this class are considered severe errors which cannot easily be fixed and hence should be avoided wherever possible.

4.5.2 Annotation Data

We set up an evaluation task containing 142 term translations and the corresponding source term. The set was then given to a total of six human annotators who classified the observed translation output according to the classification scheme described above. The human annotators were lay users without in-depth knowledge of the terms' domain.

In total, we collected 852 classification items from six annotators. Table 9 shows the results from the manual evaluation for term translations into German. We report the distribution of classes per evaluation task which are displayed in *best-to-worst* order.

	Classes		
System	A	C	N
Linguee+Wikipedia Model	59.15%	29.34%	11.50%

Table 9: Results from the manual evaluation for German

In order to better be able to interpret these rankings, we computed the inter-annotator agreement between human annotators. We report the scores generated with the following agreement metrics:

- S (Bennett et al., 1954);
- π (Scott, 1955);
- κ (Fleiss, 1971);
- α (Krippendorff, 2004).

Table 10 presents the aforementioned metrics' scores for German term translations.

	Agreement Metric			
System	S	π	κ	α
Linguee+Wikipedia Model	0.467	0.355	0.357	0.355

Table 10: Annotator agreement scores for German

Overall, we achieve an average κ score of 0.357, which can be interpreted as *fair agreement* following (Landis and Koch, 1977). Given the observed inter-annotator agreement, we expect the reported ranking results to be meaningful. The inclusion of domain experts into the manual evaluation campaign will be an interesting extension of the work presented.

4.6 Manual error analysis of UK GAAP

In addition to the manual evaluation we performed with six annotators on the UK GAAP ontology monolingual (Section 4.5), we also performed a closer analysis of each label.

In the first step, we extracted 36 labels from the manual evaluation campaign, where all evaluators annotated the translation as "Acceptable". Examples 1 to 7 (Table 11) depict a small set of the acceptable translations.

#	Source label	Target label
1	Equity	Eigenkapital
2	Stocks	Wertpapiere
3	Key Balance Sheet Figures	Bilanzkennzahlen
4	Revaluation Reserve	Neubewertungsrücklage
5	Interest And Similar Charges	Zinsen und ähnliche Aufwendungen
6	Debenture Loans After More Than One Year	Schuldscheindarlehen nach mehr als einem Jahr
7	Profit Or Loss On Ordinary Activities Before Taxes	Gewinn oder Verlust aus der gewöhnlichen Geschäftstätigkeit vor Steuern
8	Net Operating Income	Ergebnis aus der
9	Equity And Liabilities	Und Passiva
10	Profit Loss For The Period	Ergebnis der

Table 11: Translations which all annotators considered as "Acceptable" (1-7) and "None of both" (8-10)

We also extracted financial labels where all evaluators annotated the translations of the labels as "None of both", which indicates a low quality of the translations. These labels are shown in the

last part of Table 11, examples 8 to 10. The reason for the low quality of the translations is that the target label omits part of the source label. In example 8 we miss the translation for the segment *Net operating*, in 9 *Equity* is not translated and in example 10 *Loss for the period* is missing.

4.7 Interpretation of the evaluation time and the quality of translations

In addition to the evaluation of the quality of financial label translation, we also measured the evaluation time regarding different criteria, i.e. regarding the length of the label, the quality of the translation and the evaluation time for all labels.

Evaluation time regarding the length of the source labels

Figure 2 illustrates the evaluation time regarding the length of a source label. We learned that, on average, the evaluation time increased with the length of the source label, e.g. the evaluators spent more than 9 seconds to evaluate unigram label.[17] On the other hand, it took more than 26 seconds to evaluate the longest financial label.[18]

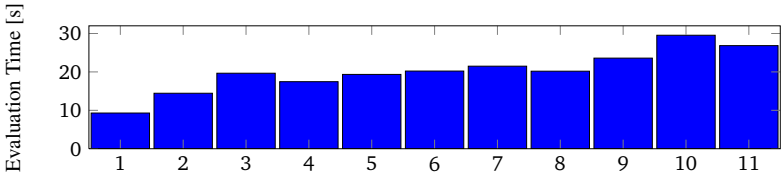

Figure 2: Evaluation time per length of the source labels

Evaluation time with respect to the quality of the translations

The evaluation task asked the evaluators to evaluate the translation quality based on three classes, "Acceptable", "Can easily be fixed" and "None of both" (cf. Section 4.5). To get a more fine-grained classification with a broader span of data, we gave each label a numeric value regarding the translation quality set by the six evaluators, e.g. the financial label *Charges* and its translation *Kosten* was annotated by all evaluators as "Acceptable"; analogously, the financial label *Financial Charges* and its translation *finanziellen Belastungen* was annotated by four evaluators with "Acceptable", whereas two evaluators annotated it as "Can easily be fixed". Since we know how each evaluator annotated a translation, we interpret the three evaluation classes into a numerical value evaluation score, i.e. if an translation was annotated with "Acceptable" we add the value 3 to the evaluation score, if it was annotated with "Can easily be fixed" we add 2, and if it was annotated with "None of both", we do not add any value to the score. With this reformulation, the financial label *Charges-Kosten* gets an evaluation score of 18,[19] and the *Financial Charges-finanziellen Belastungen* gets an evaluation score of 16.[20] With this additional classification we get a broader variety with 18 different quality classes, compared to the three classes set by the evaluators.

Figure 3 depicts the evaluation time regarding the translation quality of the financial labels. For

[17] *Assets*, *Reserves*, *Equity*, *Stocks* ...
[18] *Taxes Remuneration And Social Security Payable After More Than One Year*
[19] 3+3+3+3+3+3 = 18
[20] 3+3+3+3+2+2 = 16

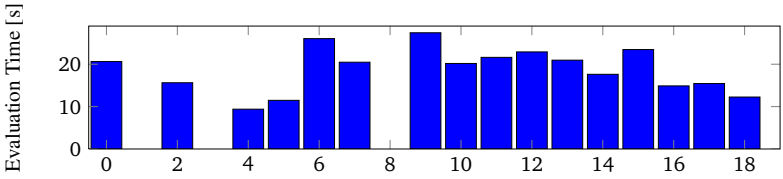

Figure 3: Evaluation time per quality of the translation

labels, which have an evaluation score of zero[21] the evaluation time is more than 20 seconds. The evaluation time decreases for labels with an evaluation score between two and five, but starts to increase when the evaluation score is equal six or more. For labels that have an evaluation score between six and thirteen, the evaluation time is higher than for labels with a lower or higher score. At the end the evaluation time decreases again. We can deduce from this experiment that it is easier to evaluate good and weak translations, but on the other hand it is harder to evaluate translations that do not belong to these two evaluation classes.

Evaluation time for the financial 142 labels

Figure 4 shows the evaluation time for all 142 labels stored in the UK GAAP ontology. We can see that the longest evaluation time to evaluate one term was more than 62 seconds, namely for the label *Operating Bach Ratios*. On the other hand, the fastest time to evaluate a label was less than 3 second for the label *Staff Costs* which was translated into *Personalkosten*.

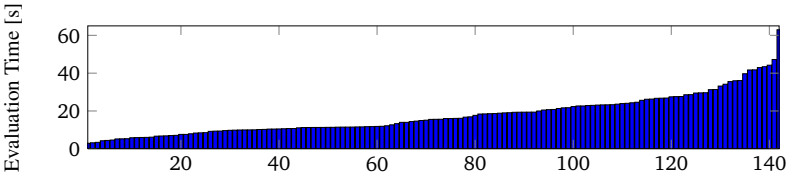

Figure 4: Evaluation time for the financial 142 labels

#	Source label	Time [s]
1	Staff Costs	2.946
2	Capital	3.177
3	Extraordinary Charges	3.421
⋮	⋮	⋮
140	Deferred Charges And Accrued Income	44.213
141	Depreciation On Intangible And Tangible Fixed Assets	47.211
142	Operating Bach Ratios	62.943

Table 12: Financial labels with the fastest (above) and the slowest (below) evaluation time

Table 12 shows the five fastest and slowest evaluation for the financial labels.

[21] *Net Operating Income*, *Equity And Liabilities*, *Profit Loss For The Period*

Conclusion and Future Work

We presented our work on the translation of a monolingual financial ontology. We performed smaller sub-experiments to determine the most appropriate translation model to translate financial labels in isolation. Hence we evaluated the translations on a small subset of aligned labels between different financial ontologies. Furthermore, we evaluated different translation models on a comparable ontology from the financial domain and compared the perplexity of the ontology to be translated with different resources. All these sub-experiments proved that the approach of building new, specific resources showed a large impact on the translation quality. Therefore, generating specialised resources for different specific domains will be the focus of our future work. On the one hand, building appropriate translation models is important, but our experiment also highlighted the importance of additional non-parallel resources, like Wikipedia, Wiktionary,[22] and DBpedia.[23] In addition to extracting Wikipedia articles with their multilingual equivalents, Wikipedia holds much more information in the articles themselves. Therefore, exploiting these non-parallel resources, as shown by (Fišer et al., 2011), would clearly help to improve the performance of the translation system. Future work needs to include the Wikipedia redirect system, which would allow a better understanding of the synonymy and spelling variations of specific terms.

In addition to exploiting new resources for statistical machine translation, the manual evaluation for monolingual resources needs to become the focus of our future work. The manual evaluation campaign was time consuming, but provided a closer look into the translation errors. It indicates that the evaluation classes for manual evaluation have to be reformulated into more fine-grained decisions. We learned that we may distinguish between translations with "one grammatical error" or "several grammatical errors". It might also be interesting to classify the types of grammatical error, e.g. number, gender or case, e.g. *Betriebsstoffen* vs. *Betriebsstoffe*. During the evaluation we also observed over-specification, where the translation into German *Die Forderungen ...*,[24] does not require the German article *die* at the beginning. Specifically to the German language we further observed some compound errors, e.g. *Ergebnis Verlust* should be merged into a compound expression. Another major issue were errors of omissions, where we miss some information from the source side, e.g. the translation *Und Passiva* omits the source part *Equity*. Further to the linguistic error classification, the type of the translation mismatch might be interesting to investigate, i.e. cultural, linguistic or domain-specific. Also it is important to know if a translation is too broad or too narrow. Especially for GAAP national differences are important as financial concepts largely depend on the legal system of the country.

In summary, the work presented in this paper outlines an initial approach to domain-specific ontology translation. It provides an indication that external resources are useful for overcoming the sparsity of data, as well as a wealth of challenges to fuel future work on this task.

Acknowledgments

This work has been funded under the Seventh Framework Programme for Research and Technological Development of the European Commission through the T4ME contract (grant agreement no.: 249119) and in part by the European Union under Grant No. 248458 for the Monnet project as well as by the Science Foundation Ireland under Grant No. SFI/08/CE/I1380 (Lion-2). The authors would like to thank Noëmi Aepli, Tobias Wunner and Thierry Declerck for their help with the manual evaluation. We are grateful to the anonymous reviewers for their valuable feedback.

ABSTRACT

Unknown words, or out of vocabulary words (OOV), cause a significant problem to morphological analysers, syntactic parses, MT systems and other NLP applications. Unknown words make up 29 % of the word types in in a large Arabic corpus used in this study. With today's corpus sizes exceeding 10^9 words, it becomes impossible to manually check corpora for new words to be included in a lexicon. We develop a finite-state morphological guesser and integrate it with a machine-learning-based pre-annotation tool in a pipeline architecture for extracting unknown words, lemmatizing them, and giving them a priority weight for inclusion in a lexical database. The processing is performed on a corpus of contemporary Arabic of 1,089,111,204 words. Our method is tested on a manually-annotated gold standard and yields encouraging results despite the complexity of the task. Our work shows the usability of a highly non-deterministic morphological guesser in a practical and complex application.

TITLE IN ARABIC

القاموس العائم للغة العربية: طريقة آلية لتحديث قاعدة البيانات المعجمية من خلال اكتشاف الكلمات الغير معروفة وردها إلى أصلها

ABSTRACT IN ARABIC

تسبب الكلمات الغير معروفة أو الكلمات الغير مدونة في القواميس مشكلة كبيرة في التحليل الصرفي والإعراب الآلي والترجمة الآلية وغيرها من تطبيقات المعالجة الآلية للغات الطبيعية. فتشكل الكلمات الغير معروفة نسبة 29 % من الكلمات الموجودة في ذخيرة النصوص المستخدمة في هذا البحث. ومع الزيادة الهائلة في حجم ذخائر النصوص التي تتجاوز اليوم مليار كلمة يصبح من المستحيل إجراء أي بحث يدوي عن الكلمات الجديدة لإدراجها في المعاجم الحديثة. ولذلك قمنا بتطوير أداة للتخمين الصرفي قائمة على تقنية آلات الحالة المحدودة وتم دمجها مع أداة قائمة على التعلم الآلي واستخدمناهما معا في عملية تشبه خط الأنابيب تكون مخرجات بعض أجزائه مدخلات لأجزائه الأخرى بحيث نتمكن من استخراج الكلمات الغير معروفة وردها إلى أصلها وإعطائها وزنا يعبر عن الأولوية في الإدراج في قاعدة البيانات المعجمية. ويعتمد هذا البحث على ذخيرة نصوص حجمها 1,089,111,204 كلمة. وقد قمنا باختبار الطريقة التي طورناها باستخدام معيار تم بناؤه يدويا ويقدم نتائج مرضية بالرغم من تعقيد المهمة. وتبين الطريقة التي استخدمناها فائدة أداة التخمين الصرفي الذي يعطي نتائج بها درجة كبيرة من الغموض في تطبيقات عملية ومعقدة.

1 Introduction

Due to the complexity and semi-algorithmic nature of Arabic morphology (that employs numerous rules and constraints on inflection, derivation and cliticization), it has been a challenge for computational processing and analysis (Kiraz, 2001; Beesley 2003). A lexicon is an indispensable part of a morphological analyser (Dichy and Farghaly, 2003; Attia, 2006; Buckwalter, 2004; Beesley, 2001), and the coverage of the lexical database is a key factor in the coverage of the morphological analyser, and limitations in the lexicon will cascade through to higher levels of processing. Moreover, out of vocabulary words (or OOVs) have impact negatively on the performance of parsers (Attia et al., 2010) and MT applications (Huang et al. 2010). This is why an automatic method for updating a lexical database and dealing with unknown words is crucially important.

We present the first attempt, to the best of our knowledge, to address the lemmatization (rather than stemming) of Arabic unknown words. The problem with lemmatizing unknown words is that they cannot be matched against a morphological lexicon. Furthermore, the specific problem with lemmatizing Arabic words is the richness and complexity of Arabic morphological derivational and inflectional processes. For the purposes of this paper, unknown words are words not found by the SAMA morphological analyser (Maamouri et al., 2010) but accepted by the Microsoft Spell Checker. We develop a rule-based finite-state morphological guesser and use a machine learning based disambiguator, MADA (Roth et al., 2008), in a pipeline-based approach to lemmatization.

We test our method against a manually created gold standard of 1,310 types (unique words) and show a significant improvement over the baseline. Furthermore, we devise a novel algorithm for weighting and prioritizing new words for inclusion in a lexicon depending on three factors: number of form variations of the lemmas, cumulative frequency of the forms, and the type of POS (part of speech) tag.

This paper is structured as follows. The remainder of the introduction provides more details on the complexity of the lemmatization process in Arabic, why dealing with unknown words is important, previous work on the topic, and the data used in our experiments. Section 2 presents the methodology we follow in extracting and analysing unknown words. Section 3 provides details on the morphological guesser we develop to help deal with the problem. Section 4 presents and discusses the evaluation results, and Section 5 concludes.

1.1 Complexity of Lemmatization in Arabic

Arabic is an inflectionally rich language with nouns specified for number, gender and case; and verbs specified for tense, number, gender, person, voice and mood. These inflectional processes entail complex alterations on base forms. Arabic is also a clitic language. Clitics are morphemes that have the syntactic characteristics of a word but are morphologically bound to other words (Crystal, 1980). In Arabic, many coordinating conjunctions, the definite article, many prepositions and particles, and a class of pronouns are all clitics that attach themselves either to the start or end of words, and subsequently change the base form according to alteration rules which include assimilation and deletion. These facts complicate the process of lemmatization, or returning the base form given the inflected form.

For English, one can reasonably assume that new words appear very often in their base forms, or the lexical look-up forms. Lindén (2008) indicates that about 86 % of the new words in English appear in their base form. However, in Arabic, which is highly inflectional in nature, only 45 % of new token types in our test set appear in their base form. Moreover, 36 % of the unknown types do not appear in their base form at all in the entire corpus.

1.2 Why Deal with Unknown Words?

Sinclair (1987) introduced the term "Floating Dictionary", a self-updating dictionary that is able to automatically monitor language change. "It would, so to speak, float on top of a corpus, rather like a jelly-fish, its tendrils constantly sensing the state of the language." We think that an electronic 'floating dictionary' should be able to perform at least three major tasks. It should be able to tell which words are not is use anymore, which words have newly appeared in a language, and which word usages or senses have changed based on contemporary data. In this paper we explain our methodology for automatically detecting new words in Arabic, lemmatizing such new words in order to relate multiple surface forms to their base underlying representations, deciding on the word POS tag, collecting statistics on the frequency of use, and modelling human decisions on whether to include the new words in a lexicon or not.

New words are constantly finding their way into any living human language. These new words are either coined or borrowed, or they can be transliterations of proper nouns from other languages. The inclusion of new words in a lexicon is a non-trivial task as it needs to address two important problems. First, there is the problem of detection, or how do we know that a new word has appeared? Second, there is the problem of reaching a decision on the new word, or how do we judge whether the new word is worth adding to the lexicon or not? This is usually done by looking at whether the word is frequent enough, whether it appears in various forms and inflections, and whether it is well-distributed in a corpus. This enables us to determine whether the word constitutes a core lexical item or the usage of the word is just accidental or idiosyncratic.

We address this issue by developing an automatic technique to recognize unknown words and reduce them to their lemmas, predict their POS, and rank them in their order of importance.

1.3 Previous Work

Lemmatization of unknown words has been addressed for Slovene in (Erjavec and Džerosk, 2004), for Hebrew in (Adler at al., 2008) and for English, Finnish, Swedish and Swahili in (Lindén, 2008). Apart from the language involved, our work is different in that we incorporate a finite state guesser in the process. Lemmatization of Arabic words has been addressed in (Roth et al., 2008; Dichy, 2001). The idea of finding and stemming unknown Arabic words has been utilized by Diab et al, (2004). While Diab et al. do not mention unknown words specifically, the fact that they use a character-based classification model and tokenization indicates that they can handle unknown words and perform stemming on them. However, they do not present any evaluation on unknown words specifically. Mohamed and Kübler (2010) handle unknown words explicitly and provide results for known and unknown words in both word segmentation (stemming) and part of speech tagging. They reach a stemming accuracy of 81.39 % on unknown words and over 99 % on known words.

Diab et al.'s and Mohammed and Kübler's work focuses on stemming rather than lemmatization, which are quite distinct albeit frequently confused. The difference between stemming and lemmatization is that stemming strips off prefixes and suffixes and leaves the bare stem, while lemmatization returns the canonical base form. To illustrate this with an example, take the Arabic verb form يقولون 'yqwlwn' "they say". Stemming will remove the present prefix 'y' and the plural suffix 'wn' and leave قول 'qwl' which is a non-word in Arabic. By contrast, full lemmatization will reveal that the word has gone through an alteration process and return the canonical قال 'qAl' "to say" as the base form.

Lemmatization reduces surface forms to their canonical base representations (or dictionary look-up form), i.e, words before undergoing any inflection, which, in Arabic, means verbs in their perfective, indicative, 3rd person, masculine, singular forms, such as شَكَرَ $akara "to thank"; and nominals (the term used for both nouns and adjectives) in their nominative, singular, masculine forms, such as طالِب TAlib "student"; and nominative plural for *pluralia tantum* nouns (or nouns that appear only in the plural form and are not derived from a singular form) , such as ناس nAs "people".

1.4 Data Used

In our work we use a large-scale corpus of 1,089,111,204 words, consisting of the Arabic Gigaword Fourth Edition (Parker et al., 2009) with 925,461,707 words, in addition to 163,649,497 words from news articles crawled from the Al-Jazeera web site. In this corpus, unknown words appear at a rate between 2 % of word tokens (when we ignore possible spelling variants) and 9 % of word tokens (when possible spelling variants are included). In this context spelling variants refer to alternative (sub-standard) spellings recognized by SAMA which are mostly related to the possible overlap between orthographically similar letters, such as the various shapes of *hamzahs* (أ إ ا آ), *taa' marboutah* and *haa'* (ة ه), and *yaa'* and *alif maqsoura* (ي ى).

2 Methodology

To deal with unknown (or out-of-vocabulary) words, we use a pipeline approach which predicts part-of-speech tags and morpho-syntactic features before lemmatization. In the first stage of the pipeline, we use MADA (Roth et al., 2008), an SVM-based tool that relies on the word context to assign POS tags and morpho-syntactic features. MADA internally uses the SAMA morphological analyser (Maamouri et al., 2010), an updated version of Buckalter morphology (Buckwalter, 2004). Second, we develop a finite-state morphological guesser that can provide all the possible interpretations of a given word. The morphological guesser first takes an Arabic surface form as a whole and then strips all possible affixes and clitics off one by one until all possible analyses are exhausted. The morphological guesser is highly non-deterministic as it outputs a large number of solutions. To counteract this non-determinism, all the solutions are matched against the POS and morpho-syntactic tag output for the full surface token by MADA and the analysis with the closest resemblance (i.e. the analysis with the largest number of matching morphological features) is selected.

Beside the complexity of lemmatization described in Section 1.1, the problem is further compounded when dealing with unknown words that cannot be matched by existing lexicons. This requires the development of a finite-state guesser to list all the possible interpretations of an unknown string of letters (explained in detail in Section 3).

To identify, extract and lemmatize unknown Arabic words we use the following sequence of processing steps (Figure 1):

- A corpus of 1,089,111,204 tokens (7,348,173 types) is analysed with MADA.
- The number of types for which MADA could not find an analysis in the Buckwalter morphological analyser is 2,116,180 (about 29 % of the types).

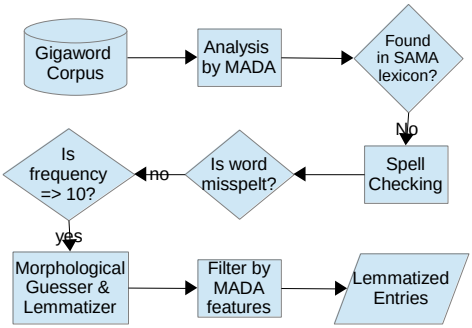

FIGURE 1 – Lemmatization process

- These unknown types were spell checked by the Microsoft Arabic spell checker using MS Office 2010. Among the unknown types of 2,116,180, the number of types accepted as correct is 208,188. The advantage of using spell checking at this stage is that it provides significant filtration of the forms (almost 90 % reduction) and retains a more compact, more manageable, and better quality list of entries to deal with in further processing. The disadvantage is that there is no guarantee that all word forms not accepted by the MS speller are actually spelling mistakes (or that all the ones accepted are correct).
- We select types with frequency of 10 or more of the types accepted by the MS spell checker. This results in a total of 40,277 types.
- We use the full POS tags and morpho-syntactic features produced by MADA.
- We use the finite-state morphological guesser to produce all possible morphological interpretations and relevant lemmatizations.
- We compare the POS tags and morphosyntactic features in MADA output with the output of the morphological guesser and choose the one with the highest matching score.

For testing and evaluation we gold annotate 1,310 words randomly selected from the 40,277 types, providing the gold lemma, the gold POS and lexicographic preference for inclusion in a dictionary. It is to be noted that working with the 2,116,180 types before filtering out possible spelling errors will require annotating a much larger gold standard.

3 Morphological Guesser

Arabic morphotactics allows words to be concatenated with a comparatively large number of clitics (Attia, 2006). Clitics themselves can be concatenated one after the other. Furthermore, clitics undergo assimilation with word stems and with each other, which makes them even harder to handle using surface features only. A verb can comprise up to four tokens (a conjunction, complementizer, verb stem and object pronoun) as illustrated in Table 1. Moreover the verb stem can be prefixed and suffixed with bound morphemes that mark the morpho-syntactic features of tense, number, gender, person, voice and mood. The lemma resides as a nucleus inside layers of proclitics, prefixes, suffixes and enclitics. A verb lemma like شكر '$akara' "to thank" can generate up to 2,552 different valid forms.

Proclitics		**Prefix**	**Lemma**	**Suffix**	**Enclitic**
Conjunction/ question article	*Comp*	*Tense/mood – number/gender*	*Verb*	*Tense/mood – number/gender*	*Object pronoun*
Conjunctions و wa 'and' or ف fa 'then'	ل li 'to'	Imperfective tense (5)	lemma	Imperfective tense (10)	First person (2)
Question word أ > 'is it true that'	س sa 'will'	Perfective tense (1)		Perfective tense (12)	Second person (5)
	ل la 'then'	Imperative (2)		Imperative (5)	Third person (5)

TABLE 1 – Proclitics, enclitics, prefixes and suffixes with Arabic verbs

Proclitics			**lemma**	**Suffix**	**Enclitic**
Conjunction/ question article	*Preposition*	*Definite article*	*Noun*	*Gender/Number*	*Genitive pronoun*
Conjunctions و wa 'and' or ف fa 'then'	ب bi 'with', ك ka 'as' or ل li 'to'	ال Al 'the'	Stem	Masculine Dual (4)	First person (2)
				Feminine Dual (4)	
Question word أ > 'is it true that'				Masculine regular plural (4)	Second person (5)
				Feminine regular plural (1)	Third person (5)
				Feminine Mark (1)	

TABLE 2 – Proclitics, enclitics, prefixes and suffixes with Arabic nouns

Similarly a noun stem can be attached to up to three clitics as shown in Table 2. Although Table 2 shows four clitics, we note that the definite article and the genitive (or possessive) pronoun are mutually exclusive. Nominal stems can also be suffixed with bound morphemes that mark the morpho-syntactic features of number, gender and case. a typical noun like معلم 'muEal~im' 'teacher', generates 519 valid forms.

We develop a finite state (Beesley and Karttunen, 2003; Hulden, 2009) morphological guesser for Arabic that can analyse unknown words with all possible clitics, morpho-syntactic affixes and all relevant alteration operations that include insertion, assimilation, and deletion. Beesley and Karttunen (2003) give some advice on how to create a basic guesser. The core idea of a guesser is to assume that a stem is composed of any arbitrary sequence of non-numeric characters, and this stem can be prefixed and/or suffixed with a predefined set of prefixes, suffixes or clitics. The guesser marks clitic boundaries and tries to return the stem to its default unmarked form, the lemma. Due to the nondeterministic nature of the guesser, there will be a multitude of possible lemmas for each form. The Arabic FST guesser consists of three parts: a lexc file, alteration rules and an XFST compilation file. First, there is the lexc file (Figure 2) with lexicons and continuation classes for the Arabic guesser. The lexc file specifies that there is an optional conjunction, followed by an optional preposition, followed by an optional definite article before the Arabic noun.

```

```

FIGURE 2 – Snapshot of the Arabic lexc file

Second, there are the alteration rules which handle the morphological processes of assimilation and deletion. In our system there are about 130 replace rules to handle alterations that affect verbs, nouns, adjectives and function words when they undergo inflections or are attached to affixes and clitics. They take the form of XFST replace rules:

```
A -> w || "+pres" Alphabet _ Alphabet
```

The example rule indicates that ‘A’ changes to ‘w’ under the condition of having the left context ‘+pres’ and a single alphabetical character and the right context of another alphabetical character. Following this rule the verb قال qAl “to say” will change to يقول yaqwl in the present tense form.

Third, there are the XFST compilation rules which bind components together. They replace the multivariable words ‘GUESSNOUNSTEM’ and ‘GUESSVERBSTEM’ with the relevant alphabet using the ‘substitute defined’ command. The XFST commands in our guesser are stated as follows.

```
define Alphabet
define PossNounStem [[Alphabet]^{2,24}] "+Guess":0;
define PossVerbStem [[Alphabet]^{2,6}] "+Guess":0;
substitute defined PossNounStem for "^GUESSNOUNSTEM^"
substitute defined PossVerbStem for "^GUESSVERBSTEM^"
```

This states that a possible noun stem is defined as any sequence of Arabic non-numeric characters of length between 2 and 24 characters. A possible verb stem is between 2 and 6 characters. This word stem is surrounded by prefixes, suffixes, proclitics and enclitics. Clitics are considered as independent tokens and are separated by the ‘@’ sign, while prefixes and suffixes are considered as morpho-syntactic features and are interpreted with tags preceded by the ‘+’ sign. Below we present the analysis of the noun والمُسَوِّقونَ wa-Al-musaw~iquwna “and-the-marketers”, and the verb سَيَأْخُذُنا sa-ya'xu*unA “will-take-us”.

```

For a list of 40,277 unknown word types, the morphological guesser produces an average of 12.6 possible interpretations per word. This is highly non-deterministic when compared to the finite state morphological analyser (Attia et al., 2011) which has an average of 2.1 solutions per known word. We also note that 97 % of the gold lemmas in our test set are found among the finite-state guesser's choices, which indicates the high performance of the guesser.

4 Testing and Evaluation

To evaluate our methodology we create a manually annotated gold standard test suite of randomly selected surface form types as mentioned in Section 2. For these surface forms, the gold lemma and part of speech are manually provided. In addition, a human annotator indicates a preference on whether or not to include the entry in a dictionary, that is whether a lemmatized form makes a valid dictionary entry or not. We noticed that most of the forms marked by the annotator as not fitting for inclusion in a dictionary were proper nouns, misspelled words, colloquial words, and words that form a part of a multiword expression. By contrast, nouns, verbs adjectives, and proper nouns with significantly high frequency were marked for inclusion in the lexical database. It is to be mentioned that proper nouns in Arabic are not orthographically distinguished from other words, i.e. there is no capitalization in Arabic as is the case in European languages. This feature of lexicographic preference helps to evaluate our lemma weighting algorithm discussed in Section 4.2. The size of the test suite is 1,310 word form types.

We observe that proper nouns are the most frequent category (45 %) among the unknown words types in the data, and they also cover about 61 % of the unknown token instances in the gold annotated dataset. The POS distribution of the unknown token types of our annotated data is shown in Table 3. As expected, most unknown words are open class words: proper names, nouns, adjectives, and, to a lesser degree, verbs.

Gold POS	**Type Count**	**Ratio**
noun_prop	584	45 %
noun	264	20 %
adj	255	19 %
verb	52	4 %
noun_fem_plural (pluralia tantum)	28	2 %
noun_broken_plural	28	2 %
others: noun_masc_plural (*pluralia tantum*) (4) part (3) pron_dem (1)	8	0.6 %
Excluded		
misspelling	55	4 %
not_known	15	1 %
colloquial	19	1.5 %
Lexicographic relevance		
Include in a dictionary	671	51 %
Don't include in a dictionary	639	49 %

TABLE 3 – Gold tag annotation of the test suite

4.1 Evaluating Lemmatization

In the evaluation experiment we measure accuracy calculated as the number of correct tags divided by the count of all tags. The baseline is given by the assumption that new words appear in their base form, i.e., we do not need to lemmatize them. The baseline accuracy is 45 %. The POS tagging baseline proposes the most frequent tag (proper name) for all unknown words. In our test data accuracy stands also at 45 %. We notice that MADA POS tagging accuracy for unknown words is unexpectedly low (60 %) as shown in Table 4. We use Voted POS Tagging, that is we choose the POS tag assigned most frequently in the data to a lemma. This method has improved the tagging results significantly (Table 4).

As for the lemmatization process, our first experiment in the pipeline-based lemmatization approach obtains a higher score (54 %) than the baseline (45 %) as shown in Table 5.

		Accuracy
	POS tagging	
1	POS Tagging baseline	45 %
2	MADA POS tagging	60 %
3	Voted POS Tagging	69 %

TABLE 4 – Evaluation of POS tagging of unknown words

Examining the data further, we notice that when a proper noun is prefixed with the definite article "Al", the definite article is not stripped off in the gold annotation and is considered as part of the lemma, such as القشيري 'Al-qu$ayriy'. In MADA morpho-syntactic tagging, the definite article is considered as a clitic and not part of the lemma. When this difference is ignored in the second experiment, the lemmatization accuracy increases from 54 % to 63 %. A more detailed error analysis will help devise better heuristics to increase the accuracy of the pipeline-based lemmatization. For example, in the gold annotation some regular feminine and masculine plural forms are considered as *pluralia tantum*, while in the automatic lemmatization they are reduced to their singular forms, such as حجوزات HujuwzAt "bookings".

	Lemmatization	
1	Lemmas found among corpus forms	64 %
2	Lemmas found among fst guesser forms	97 %
3	Lemma selection baseline	45 %
4	Pipeline-based lemmatization (selection decision) with strict definite article matching	54 %
5	Pipeline-based lemmatization (selection decision) ignoring definite article matching	63 %

TABLE 5 – Evaluation of lemmatization of unknown words

The test results indicate significant improvements over the baseline. However, we expect that substantial further improvements can be obtained through further extensive error analysis and developing refined heuristics.

4.2 Evaluating Lemma Weighting

We create a weighting algorithm for ranking and prioritizing unknown words in Arabic so that important words that are valid for inclusion in a lexicon are pushed up the list and less interesting words (from a lexicographic point of view) are pushed down. This is meant to facilitate the effort of manual revision by making sure that the top part of the stack contains the words with highest priority.

In our case we have 40,277 unknown token types. After lemmatization they are reduced to 18,399 types (that is 54 % reduction of the surface forms). This number is still too big for manual validation. In order to address this issue we devise a weighting algorithm for ranking so that the top *n* number of words will include the most lexicographically relevant words. We call surface forms that share the same lemma 'sister forms', and we call the lemma that they share the 'mother lemma'. The weighting algorithm is based on three criteria: number of sister forms, cumulative frequency of the sister forms, and a POS factor. The POS factor gives 50 extra points to verbs, 30 to to nouns and adjectives, and nothing to proper nouns. This is meant to penalize proper nouns due to their high frequency which is disproportionate to other categories. The parameters of the weighting algorithm have been tuned through several rounds of experimentation.

```
Word Weight = ((number of sister forms * 800) +
      cumulative sum of frequencies of sister forms) / 2 +
    POS factor
```

We use the gold annotated data for the evaluation of the lemma weighting criteria, as shown in Table 6. We notice that the combined criteria gives the best balance between increasing the number of lexicographically-relevant words in the top 100 words and reducing the number of lexicographically-relevant words in the bottom 100 words.

Lexicographically-relevant words	In top 100	In bottom 100
relying on Frequency alone (baseline)	63	50
relying on number of sister forms * 800	87	28
relying on POS factor	58	30
using combined criteria	78	15

TABLE 6 – Evaluation of lemma weighting and ranking

Table 7 shows a sample of the entries in the unknown words lexicon. The list includes a spectrum of the different word categories such as proper nouns, adjectives, nouns, broken plural and feminine plural forms, as well as verbs.

#	FST Guessed lemma	Gloss	Weight	Forms

TABLE 7 – Sample entries selected from the unknown words lexicon

As the corpus is composed mainly of news articles, we assume that the distribution of proper nouns is artificial and arbitrary as it depends, to a large extent, on the specific date and time of an event or series of events that occupies the news for a certain (short-term or long-term) duration. For example, as Table 7 shows, *Obama* and *Sarkozy* ranked top of the list of unknown words, but

now as Sarkozy is no longer the French president and the fate of Obama will be determined in the next presidential election in America, whether these names will continue to maintain the same level of frequency is questionable. This is why verbs, adjectives and nouns constitute the core of the language lexicon, while proper nouns are, to some extent, temporal and transient and the frequency of their use tends to shift from time to time.

Conclusion

We have developed a methodology for automatically updating an Arabic dictionary by extracting unknown words from data and lemmatizing them in order to relate multiple surface forms to their canonical underlying representation using a finite-state guesser and a machine learning tool for disambiguation. We have developed a weighting mechanism for simulating a human decision on whether or not to include new words in a general-domain lexical database. We have shown the feasibility of a highly non-deterministic finite state guesser in an essential application. Out of a word list of 40,255 unknown words we created a lexicon of 18,399 lemmatized, POS-tagged and weighted entries. We have made our unknown word lexicon available as a free open source resource (http://arabic-unknowns.sourceforge.net/).

ABSTRACT
In this study, we explore the impact of complex lexical information to solve syntactic ambiguity, including verbal subcategorization in the form of verbal transitivity and verb-noun-case or verb-noun-case-auxiliary relations. The information was obtained from different sources, including a subcategorization dictionary extracted from a Basque corpus, the web as a corpus, an English corpus and a Basque dictionary. Functional ambiguity between subject and object is a widespread problem in Basque, where 22% of subjects and objects are ambiguous, and this ambiguity surfaces in 33% of the sentences. This problem is comparable to PP attachment ambiguities in other languages. Our results show that, using complex lexical information, our results are better than a state-of-the-art statistical parser, obtaining a statistically significant error reduction of 20%. The disambiguation system is independent on the actual parsing algorithm used. The analysis revealed that the most relevant information are the case carried by the noun and the transitivity of the verb.

TITLE AND ABSTRACT IN BASQUE

Informazio lexikal konplexuaren ekarpena euskarazko anbiguotasun sintaktikoen ebazpenean

Lan honetan informazio lexikal konplexua erabiltzearen garrantzia aztertzen dugu euskarazko anbiguotasun sintaktikoen ebazpenean. Aditzen iragankortasuna erakusten duen azpikategorizazioaren ekarpena aztertu dugu, baita aditz-izen-kasu eta aditz-izen-kasu-laguntzaile erlazioena ere. Informazio horiek hainbat iturritatik jaso ditugu: euskarazko corpus batetik, webetik berau corpus gisa hartuta, ingelesezko corpus batetik eta euskarazko hiztegi batetik. Subjektu eta objektuaren arteko anbiguotasun funtzionala maiz aurkitzen dugu euskarazko testuetan; subjektua edo objektua bereiztea kasuen %22an ambiguoa da, eta hori gertatzen da perpausen %33an. Horrela, arazo horren garrantzi handia konparagarria da beste hizkuntza batzuek duten PP attachment arazoarenarekin. Gure sistemaren emaitzak hobeak dira artearen egoerako analizatzaile sintaktiko estatistiko batenak baino, estatistikoki esanguratsua den %20ko errore-murrizketa lortzen baitu. Analisi sintaktikoa egiteko edozein algoritmorekin erabil daiteke desanbiguazio-sistema hau.

KEYWORDS: Syntactic ambiguity resolution, subcategorization, web as a corpus.

KEYWORDS IN BASQUE: Anbiguotasun sintaktikoaren ebazpena, azpikategorizazioa, amarauna corpus gisa.

1 Introduction

Due to typological differences, ambiguities in some languages differ from ambiguities in other. For example, while prepositional phrase (PP) attachment ambiguity occurs in about 50% of the English sentences in the Penn treebank (Volk, 2006), it occurs in less than 0.1% of sentences in Basque Dependency Treebank (Aduriz et al., 2003). By contrast, the subject-object ambiguity does not pose any problem in English, but it does in Basque, where 22% of the subjects or objects are ambiguous and 33% of the sentences show this ambiguity. The pervasive nature of this ambiguity makes it worth specific analysis. This problem is relevant to processing similar ambiguities in other morphologically rich languages. For instance, Urdu and Hindi also display subject-object ambiguity due to erg-abs markings, as well as null-case markings (Dixon, 1994; Husain and Agrawal, 2012).

In the literature, we find several approaches to improve syntactic disambiguation. One of them involves focusing on solving a relevant ambiguity by using a problem specific classifier (Kübler et al., 2007; Anguiano and Candito, 2011). This allows to deeply understand the features involved in the ambiguity. The results obtained over the localized ambiguous relations are either used in a post-process by replacing those of a parser (a process also known as *parse correction*) or, after analyzing the most informative features, those are incorporated in the treebank and used to improve a statistical parser (Husain and Agrawal, 2012).

In this paper we will follow the first approach, targeting the resolution of the subject-object ambiguity in Basque, comparing our results to those obtained by the Malt parser (Nivre et al., 2007). In any case, our method is independent of the parser used, and could be incorporated to statistic or rule-based parsers (Aranzabe et al., 2004) as well.

The paper is structured as follows. We will first review the subject-object ambiguity in Basque. In Section 3 we review Basque Dependency Treebank and the methods to acquire verbal subcategorization information. Section 4 presents the features that are informative when resolving the ambiguity. In Section 5 the method to create the gold standard is presented, alongside our disambiguation method and the results. The related work is discussed in Section 6. Finally, the conclusions and future work are drawn.

2 Subject-Object ambiguity in Basque

Typologically, Basque is a highly inflectional head-final language (Ortiz de Urbina, 1989; Laka, 1996). It belongs to what has been called MoR-FWO languages, that is, morphologically rich, free word order languages (such as Czech, Turkish, Hindi etc). In most of the cases the relation between a head and its dependent gets realized through a morphological marker, neither bore by the head nor the dependent. This implies examination of elements occurring in non-local environments.

(1) [***Pertsona*** *nagusi gehien**ek***], *euren etxeetan bizitzen jarraitu nahi dute.*
[**People** aged most-**erg**], their homes live keep-on want auxiliary.
[Most of aged people] want to keep living in their own home.

Example 1 shows a noun phrase headed by *pertsona*, where the ergative marker (**ek**) is carried by the last element of the noun phrase, in this case *gehienek*.

Basque is a morphological ergative language (Dixon, 1994) as well in both case-marking and verbal auxiliary morphology. Thus, case-marking for subjects of intransitive verbs and objects of

$$absolutive = \begin{cases} subject\ \ of\ \ intransitive\ \ verbs \\ object\ \ of\ \ transtive\ \ verbs \end{cases}$$
$$ergative = subject\ \ of\ \ transitive\ \ verbs$$

Figure 1: Two cases in Basque, and their respective syntactic functions depending on the transitivity of verb.

transitives and their morphological cross-reference within the verbal agreement auxiliary are identical and different from subjects of transitive verbs. The case-marking of transitive subjects is the ergative case (-ak when singular,-ek when plural). The case-marking of intransitive subjects and objects of transitives is the absolutive case (-a when singular, -ak when plural). Figure 1 summarizes the functions for each of these case-markers. And the following examples illustrate those ambiguities.

(2) *Etiketatzaile**a*** *agertu* *da.*
Tagger-**abs-singular** showed up intransitive-auxiliary.
The tagger-**subj** showed up.

(3) *Etiketatzaileak* *erlazio**a*** *desanbiguatu* *du.*
Tagger-erg-singular relation-**abs-singular** disambiguate transitive-auxiliary.
The tagger-subj has disambiguated the relation-**obj**.

When an element is in the absolutive case, its function (subject or object) is ambiguous, that is, case-marking by itself does not tell whether the element is a subject or an object; it is the transitivity of the verb, which in finite sentences appear to be lexicalized in the auxiliary, along with the case marking which makes disambiguation possible. Examples 2 and 3 show that elements bearing the absolutive case can be either objects or subjects depending on the transitivity present in the auxiliary. In these examples, the ambiguity is resolved with the information made explicit by the auxiliary, but there are exceptions.

(4) *Erlazio**a*** *erortzean* *gertatu* *zen.*
Relation-**abs-singular** when-dropped happened transitive-auxiliary.
It happened when the relation-**subj** dropped.

(5) *Erlazio**a*** *ikustean* *gertatu* *zen.*
Relation-**abs-singular** when-seen happened transitive-auxiliary.
It happened when the relation-**obj** was seen.

In the case of infinitive verbs, which do not have auxiliaries and thus do not explicitly mark for transitivity, the syntactic function of absolutive noun phrases is ambiguous. Examples 4 and 5 show two sentences where *erlazioa* is either subject or object (respectively) depending on the subcategorization information of the verb (drop or see, respectively).

(6) *Sukaldari**ak*** *egin* *ditu.*
Cook-**erg-singular** make transitive-auxiliary.
The cook-**subj** made it.

(7) *Opil**ak*** *egin* *ditu.*
Cake-**abs-plural** make transitive-auxiliary.
(S)he made the cakes-**obj**.

(8) *Erlazio**ak*** *ikusita,* *ezin* *dut* *asmatu.*
Relation-**abs-plural** seeing, not transitive-auxiliary figure-out.
Seeing the relation-**obj**, I can't figure it out.

Another source of ambiguity arises from the ambiguous morphological marker **-ak**, which can mean absolutive plural or ergative singular. Basque is a 3-way pro-drop language (Ortiz de Urbina, 1989), and thus subjects and objects can be elided (note the difference with English, where there must be always a subject). This means that in Basque we can have sentences like 6 and 7 above, where the object (subject in example 7) does not surface. Note also that position does not help disambiguating subjects and objects, as Basque is a relatively free-word order language. These two examples are syntactically ambiguous, and can only be disambiguated using semantic information, that is, cooks tend to be the subjects of transitive verbs and cakes tend to be objects of transitive verbs.

Both sources of ambiguity can occur together. Example 8 shows an example where the verb is infinitive and there is an ambiguous marker -ak, making the dependent (*Erlazio-ak*) ambiguous between absolutive/ergative and subject/object interpretations.

These ambiguous instances are very common in Basque, making up to 22% of all objects and subjects in Basque Dependency Treebank (cf. Section 5.1).

3 Resources

This section starts by describing Basque Dependency Treebank (Aduriz et al., 2003) which we used to extract potentially ambiguous occurrences and evaluate our methods. Next, it presents the methods to learn subcategorization information for Basque verbs. We finally review Malt parser.

3.1 Basque Dependency Treebank

Basque Dependency Treebank has more than 150,000 tokens, distributed in 11,125 sentences coded in CONLL-X format (Aduriz et al., 2003). Each token (dependent) is represented by the following information: index, word form, lemma, syntactic category (part of speech) and subcategory, morphological features corresponding to the different markers attached to the lemma, index of the head and syntactic relation between the dependent and the head. Example 9 shows a sentence from the treebank. Note the first, second and fourth tokens (nouns (ize) and determiner (det) respectively), which show inesive (ine), ergative (erg) and absolutive (abs) markers in singular (sg) and plural (pl). The verb (adi) shows perfective aspect (buru) and participle (part) form, and the auxiliary (adl) appears in the past form (b1), agreeing with a 3rd person singular ergative (hark) and a 3rd person plural absolutive (haiek). The corresponding treebank file is shown in Figure 3.

index	wordform	lemma	category	subcategory	morp.	head	relation
1	Martxoan	martxo	ize	arr	ine sg	6	ncmod
2	Millarrek	Millar	izb	-	erg sg	5	ncsubj
3	gurpil	gurpil	ize	arr	-	5	ncobj
4	guztiak	guzti	det	oro	abs pl	3	detmod
5	puskatu	puskatu	adi	sin	part buru	0	root
6	zituen	*edun	adl	-	b1 hark haiek	5	auxmod
7	.	.	punt	-	_	6	punc

Figure 2: Treebank file in CONLL-X format corresponding to example 9. See text for explanations of tags.

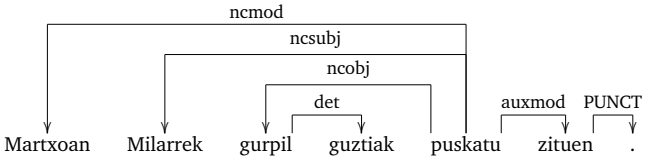

Figure 3: Dependency graph corresponding to example 9.

(9) *Martxoan* *Millarrek* *gurpil* *guztiak* *puskatu* *zituen.*
March-ine-sg Millar-erg-sg wheel all-abs-pl break auxiliary.
Millar broke all the wheels in March.

3.2 Acquisition of verbal subcategorization information

Verbal subcategorization information was extracted from 4 different sources: a subcategorization dictionary built from monolingual Basque corpus, web queries, monolingual English corpus, and a traditional monolingual Basque dictionary.

The subcategorization dictionary was obtained from Basque monolingual corpus, initially built with the purpose of making attachment decisions for a shallow parser on its way to full parsing (Aldezabal et al., 2002). For each of the 2,571 verbs this dictionary lists information about transitivity of the verb, noun[1]-case-verb triples or noun-case-verb-auxiliary quadruples and estimated frequency of each.

This dictionary was automatically built from raw corpora, comprising a compilation of 18 months of news from *Euskaldunon Egunkaria* (a journal written in Basque). The size of the corpus is around 780,000 sentences, approximately 10M words. From the 5,572 different verb lemmas in the corpus, the subcategorization dictionary was compiled for the 2,751 verbs occurring at least 10 times. The corpus was parsed by a chunker (Aduriz et al., 2004) which includes both named-entity and multiword recognition. The chunker uses a small grammar to identify heads, postpositions and verb attachments of NPs and PPs. The grammar was developed

[1]To simplify we just mention nouns, but there are also adjectives, determiner etc, anything that could be the head of a DP or CP.

based on the fact that Basque is a head-final language and it includes a distance feature as well. Phrases were correctly attached to the verb with a precision of 78%. Note that the auxiliary verb in Basque allows to unambiguously determine the transitivity of the main verb. The information captured for each verb corresponds to noun-case-verb triples and the noun-case-verb-auxiliary quadruples.

The second source is an English monolingual corpus. The assumption here is that the subject-object relation is stable when translating across languages, that is, if an element-verb relation is labeled as a subject relation in English it will also be that way in its Basque translation. This is a strong assumption, and we expect it to work better with certain verbs (e.g. activity or achievement verbs) than others (e.g. static verbs), but we did not make any distinction so far. In this approach, for each Basque ambiguous element-verb pair we collected frequencies over unambiguous English examples acquired from automatically parsed English data. We used the BNC corpus parsed with the RASP parser (Briscoe et al., 2006) containing 47,145,584 syntactic relations, where 10,447,129 are verb-noun dependency relations. The method has the following steps:

1. Translate the dependent lemma and the verb lemma using a bilingual dictionary.
2. Build all possible translation pairs.
3. Collect frequencies of each pair in the English corpus, depending on the label (subject or object) assigned by the English parser.

The third source is the result of directly querying the web. The web can be seen as a vast corpus (Bansal and Klein, 2011; Nakov, 2007; Lapata and Keller, 2005) where, in principle, we have bigger chances of finding low frequency combinations not found with the monolingual or crosslingual approaches presented so far. The following steps were pursued:

1. Obtain the lemma of the ambiguous element, create all possible subject and object unambiguous inflected forms using a language generation tool, that is, lemma+ergative+plural and lemma+absolutive+singular pairs.
2. Obtain the three different inflected forms of the verb (verb+future aspect marking, verb+perfect aspect marking and verb+ imperfect aspect marking) using the same generation tool.
3. Generate the corresponding different transitive and intransitive auxiliaries as well. It is not feasible to use all possible transitive/intransitive auxiliaries because the query number would explode so we took into account the 20 most frequent forms.
4. Construct all possible element+case+verb+auxiliary quadruples. For each element-verb candidate we get approximately 60 quadruples,
5. Search Google and collect hits.

Unfortunately Google does not recognize documents in Basque as a separate language. Some authors (Leturia et al., 2008) add certain common Basque words to the query, in order to reduces the number of texts in other languages returned by Google. We solved the problem using another heuristic, restricting to documents not in Spanish nor in English. The first one because Basque borrows vocabulary from Spanish and several times Basque texts are wrongly tagged as Spanish texts, and the other because of the same reason plus the fact that is the most common language on the web. Variability on the web does not cause a problem in this case because all the searches concerning each element-verb candidate are performed at the same time.

The last source is a traditional dictionary (EH dictionary, (Sarasola, 1996)), where each verbal entry carries information on the transitivity of the verb. As each verb usually shows more than one sense, we just considered the first sense. This dictionary uses 7 different markers to capture transitivity: du/da, du, du/dio, dio, da, zaio, da/zaio. For instance, du/da represent verbs that can appear in transitive or intransitive contexts, such as inchoative verbs like *break* that show a transitive/inchoative alternation: Leioa-subj apurtu da (The window-subj broke) or Mikelek-subj lehioa-obj apurtu zuen (Mikel-subj broke the window-obj).

4 Feature Space

In this section we will try to collect the information that we deemed was relevant to disambiguate subjects and objects. Each piece of information configures a separate feature. Our feature space F encodes heterogeneous information representing each candidate element-verb.

The features are presented grouped into sets depending on the nature and source of each one. A value close to 1 means that there is evidence for disambiguating to subject. A value close to 0 means that the feature leans for object. In some cases the feature does not predict anything.

Features related to subcategorization information

These features are based on the information mined from each source of subcategorization information, as presented in the previous section.

Subcategorization dictionary (SubcatDict)

- *TransCase(SubcatDict)*: The probability of the element to be a subject depends on the probability of the verb to be transitive $P(TransCase)$ and the actual case marking assigned by the morphological analyzer to the ambiguous element. $P(TransCase)$ is estimated from the SubcatDict, counting the occurrences of the verb as transitive and intransitive. If the case of the element is ergative and $P(TransCase)$ is bigger than 0.5, then this feature takes the value of $P(TransCase)$, that is, the feature will lean towards a subject interpretation. If the case is the absolutive, then the feature will lean towards being a subject if the verb is intransitive, or to object otherwise. The value of the feature is encoded according to the following formula.

$$\textit{TransCase(SubcatDict)} \begin{cases} P(TransCase) = \frac{\#trans}{\#trans+\#intrans} & case = erg \,\&\, P(TransCase) > 0.5 \\ 1 - P(TransCase) & case = abs \,\&\, P(TransCase) < 0.5 \\ 0 & case = abs \,\&\, P(TransCase) > 0.5 \\ none & otherwise \end{cases}$$

- *NCaseV(SubcatDict)*: The probability of the element to be a subject is related to the tendency of the element to bear the ergative case with that verb in the corpus (*P(Erg)*), independently of whether the verb shows transitive tendency. Here we do not consider the actual case marker assigned by the morphological analyzer, but the tendency of the element to bear ergative case when occurring with the verb.

$$\textit{NCaseV(SubcatDict)} \begin{cases} 1 & P(TransCase) > 0.5 \,\&\, P(Erg) > 0.5 \\ 0 & P(TransCase) < 0.5 \,\&\, P(Erg) < 0.5 \\ none & otherwise \end{cases}$$

- *NCaseVAux(SubcatDict)*: The probability of the element to be a subject is related to the tendency of the element to appear in a subject configuration, that is to say, to bear the ergative case with the verb appearing with a transitive auxiliary, or to bear absolutive case with the verb appearing with an intransitive auxiliary. This is estimated as described in the following formula.

$$NCaseVAux(SubcatDict) \begin{cases} \frac{\#(n+abs+v+intransAux)+\#(n+erg+v+transAux)}{\#(n+case+v)} & \#(n+case+v)>0 \\ none & otherwise \end{cases}$$

Web as a corpus (Web)

- Similar to the features for the SubcatDict, we can estimate the same features using the web queries explained in the previous section. This yields three new features: *TransCase(Web)*, *NCaseV(Web)* and *NCaseVAux(Web)*.

English corpus (BNC)

- *Subj(BNC)*: The value is 1 if the element shows a tendency of being a subject in the English corpus, 0 if the tendency is to object and none if it could not be translated or if it was not found in the English corpus.

Dictionary (Dict)

- *TransCase(Dict)*: This feature corresponds to the combination of two informations. The value is 1 if according to the dictionary the verb is transitive and the case is ergative, or if the verb is intransitive and the case is absolutive. The value is 0 if the verb is transitive and the case is absolutive, and none if transitivity could not be established in the dictionary.

Features related to morphological and syntactic information

Here we group weaker indications, as follows.

- *AspectCtrl*: The value is 1 if the verb is an aspectual or control verb such as *begin, end, stop, quit*. Aspectual verbs that occur a verb in the infinitive, force the verb in the infinitive to miss the surface subject. For example, *I started knowing you*, there cannot be a surface subject for *know* because *start* is an aspectual verb and thus both verbs share the same subject. Control verbs like *want* or *expect* act in Basque quite similarly to aspectual verbs In short, when the head of the verb is an aspectual or control verb, the element would tend to be the object, and thus feature will be 0, and none otherwise.
- *Preverb*: the value is 1 if the element appears in the pre-verbal position, as this is a sign of being a subject.
- *Inf*: 1 if the verb appears to be an infinitival, bare-infinitival, infinitival with a relative marker, infinitival nominalization, or in a finite form, that is to say, with an auxiliary, and finite with relative marker, respectively.
- *Erg*: The value is 1 if the case born in the noun phrase where the element is located is ergative, 0 otherwise. Remember from 2, that the head of a noun phrase does not necessarily bear the case marking, which is found in the last constituent of the noun phrase . We applied feature propagation in order to recover the case.
- *-ak*: The value is 1 if the element bears the ambiguous -ak morpheme.

- *Sing*: The value is 1 if the number of the element is singular, 0 otherwise.
- *Entity*: The value is 1 if the element starts with a capital letter and is not in the first position in the sentence. Since the morphological analyzer does not implement any entity recognition, this is an heuristic to code possible entities.

5 Experimental setup

In this section we review the method to create the gold standard, followed by our disambiguation method, the method to train malt parser, and the results of the experiments.

5.1 Creating the gold standard

The gold standard comprises ambiguous instances of noun phrases, which can either be subject or object. The syntactic structure and gold label is taken from Basque Dependency Treebank. In order to make the setting realistic the morphological tags are taken from an automatic morphological disambiguation tagger for Basque (Aduriz et al., 2000). Note that this tagger is conservative and does not always return a single tag. In those cases we use the first tag, as customary with most parsers. The accuracy of this tagger when selecting ergative and absolutive is 87%.

The procedure to detect ambiguous instances is the following. We first look up the verbs in the corpus. Depending on the finiteness of the verb, we have two cases:

1. If the verb has an auxiliary annotated as finite by the morphological analyzer, then the agreement features in the auxiliary verb resolve all ambiguities, except in some cases with -ak, which can be morphologically ambiguous between ergative singular or absolutive plural, and thus ambiguous between subject and object (respectively). To be more specific, if the auxiliary verb shows agreement with a singular ergative and a plural absolutive (both occurring with -ak) then both dependents could be either subject or object.
2. If the verb is tagged as infinitive, then if the verb has a dependent with the absolutive case, the dependent is ambiguous between subject and object.

The dependents of the verbs are looked up in the treebank, extracting the head and the case marking. The head is given as the root of the dependent, and the case marking of the dependent is given by the last token under the dependent.

Detecting dependents is a difficult task for parsers. So we filter out those dependents which could be difficult for current parsers, as follows. If the sentence contains a single verb, we then check all dependents of the verb. If the verb has multiple verbs, we then need a clause delimiter to identify which phrases are dependents of which verbs. We use a simple heuristic based on the fact that Basque is head-final: all words before the first verb are assigned to that verb, and the rest are assigned to the second verb. This is a strong baseline for any parser, as it attains 86% accuracy in a study of our own.

The above method to extract ambiguous dependents yields 4,525 ambiguous dependents in 3,617 sentences, that is, 22% of all subjects and objects in the treebank, with one ambiguous instance every 33% of sentences.

Note that if we had searched for ambiguous instances using the gold morphological tags in the treebank, we would find 4,400 subject-object ambiguous relations. This smaller amount is

due to errors by the morphological analyzer, as it incorrectly tags some ergative or absolutive cases, or certain auxiliaries as main verbs, considering the sentence as an infinitive sentence and therefore ambiguous with respect to subject-object. Note that the real ambiguity faced by a parser is closer to that of the automatic analysis.

5.2 Methods

We performed a machine learning experiment to examine the impact of the use of those lexical features to solve subject-object ambiguity in Basque. We used Support Vector Machines (Chang and Lin, 2011) with Radial kernels tuning C and G parameters over the training set using cross-validation to find their best values. The 4,525 ambiguous subject-object relations in the treebank were split into training and testing sets in a proportion of 50%. We also evaluated each feature on its own, and also, used an ablation procedure, learning the classifier with all features but one.

5.3 Malt parser

We chose Malt parser (Nivre et al., 2007) to compare our results with. This parser is a history-based deterministic dependency parser, which using the input and a stack and through 4 main actions, *shift* moving a token from the input to the stack, *left-arc* adding an arc from the token on the input to the token on the top of the stack, removing the token from stack, *right-arc* adding an arc from the token on the top of the stack to the token on the input, moving the token of the input onto top of stack and *reduce* removing a token from the top of the stack. The action is chosen according to a machine learning classifier using a variety of features including the stack, the input and past history. This way, dependency tree gets built in one single pass and in linear time. We used version 1.4, and the configuration was selected using the optimization developed by Nivre and Ballesteros Ballesteros and Nivre (2012).

Maltparser has to face a wider range of ambiguity that our classifier, as in some cases a phrase with the absolutive case can play syntactic functions other than subject or object. In order to make comparison to our classifier fair, we substituted all other tags returned by Malt parser with *ncobj*, the most common tag (around 75% compared to 25% for ncsubj).

5.4 Results

Table 1 shows the results of some features evaluated independently over the training set. For the sake of brevity, we only show those features with an accuracy over 60% are displayed. The baseline consists of assigning always the object tag to any ambiguous element, since it is the most frequent tag (75%). We measure accuracy on finding both subjects and objects, but we are also interested in measuring the performance of the system for detecting subjects since this is the most difficult task. Accuracy is the number of correctly tagged elements over all elements. Precision on subjects is the number of correctly recognized subjects divided by all elements tagged as subject by the system. Recall on subjects is the number of correctly recognized subjects divided by the total number of subjects in the gold set. F1 is the harmonic mean between precision and 1.

The table shows that the *Erg* feature performs best. This feature relies in the tag assigned by the automatic morphological analyzer. TransCase(SubcatDict) provides the second best result in terms of accuracy, still over the baseline, beating all the others in F1 and recall for subjects.

Feature	acc (sbj+obj)	prec (sbj)	rec (sbj)	F1 (sbj)
Baseline	75.29	00.00	00.00	00.00

¬NCaseV(Aux)*	87.84	83.84	62.91	71.88

Table 2: Results using 10-fold cross-validation on ambiguous elements in the training corpus. The first lines correspond to the baseline and full classifier, and the rest present the results of feature ablation experiments. Best results and worst results in each column in bold.

Note that the performance of some features suffers from the fact that they only apply to a subset of the elements. In fact, *Erg* is the only one which applies to all.

Table 2 shows the results when training an SVM with Radial kernel and 10 fold cross-validation (All features line). Those results beat the baseline and individual features by a large margin. When compared with the best individual feature (*Erg*) the difference in accuracy is smaller, but note that the classifier is better on detecting subjects, showing that its output is better balanced.

The table also shows the results of feature ablation. Features were grouped by their source (SubcatDict, Web, BNC, Dict) or by the linguistic nature of the information they carry, independently of the source. For example, SubcatInf in Table 2 represents all subcategorization information: TransCase(SubcatDic), NCaseV(SubcatDic), NCaseVAux(SubcatDic),TransCase(Web), NcaseV(Web), NCaseVAux(Web), Subj(BNC) and TransCase(Dict). The highest loss in overall accuracy is for CaseNum features, but all features cause a performance drop when removed. This shows that the features are complementary. The loss in F1(sbj), whenever ablation of any kind is carried out, confirms this fact. The highest loss in precision and F1 also occur when information about case and number are left aside. And the highest loss in recall corresponds to

	acc	prec(sbj)	rec(sbj)	F1(sbj)
All features	89.33	82.48	71.74	76.74
MALT	86.72	76.82	65.69	70.82

Table 3: Final results for ambiguous elements on the test set.

	LAS	UAS		prec	rec	F1
MALT	83.17	83.08	sbj	71.57	75.01	73.24
			obj	76.36	73.61	74.95
MALT Post-processed	83.52	83.08	sbj	72.11	75.52	73.77
			obj	81.10	74.39	77.60

Table 4: Final results over all dependencies in test set.

the elimination of subcategorization information.

Finally we run our classifier with all features in the test set, as shown in Table 3. The performance obtained is comparable to that in the train set using cross-validation. The results of Malt are lower both in accuracy and F1 over subjects, with a statistical significant difference (p-value < 0.005). Note that the error reduction is 19.64%.

The above results show that our approach is competitive over Malt for the subset of ambiguous subject-object relations. In order to show that our system can make a relevant difference over the overall performance of a parser, we corrected the output of Malt parser with the result of our classifier and evaluated over all dependencies. Table 4 shows the usual UAS (Unlabeled Attachment Score) and LAS (Labeled Accuracy Score) scores for both MALT and the post-processed MALT. Of course, the unlabeled score is the same for both, as we just changed some labels. The improvement in LAS is of 0.35 absolute points, statistically significant (p-value < 0.00009). In addition we also show the performance over objects and subjects. Note that the post-processed version improves both object and subject recognition.

6 Related Work and Discussion

As mentioned in the introduction, this work is framed following a parse correction strategy. In parsing, not all ambiguities show the same complexity, and not all the languages behave the same way with respect to the distribution of the ambiguities. In English, for example, prepositional phrase attachment (PP-attachment for short) ambiguity traditionally stirred interest since (Hindle and Rooth, 1993; Ratnaparkhi, 1998), among others, for being both common and difficult to solve. These seminal works presented PP-attachment resolution in isolation, with no evaluation over full sentences or integration with a parser or with the results of a parser. With the proliferation of statistical parsers the attention moved from solving specific ambiguities to treat ambiguities as a whole. Statistical parsers learned from treebanks, though, make it difficult to reach any conclusion on what is the relevant information for resolving specific ambiguities, and whether those need to be encoded explicitly in treebanks.

Focusing on a relevant ambiguity is helpful to achieve a better understanding of the intricacies of parsing structures. Along these lines, we find two main approaches, that of parsing correction, or that of transforming and enriching the treebank with additional information. Work in parse correction consists on the creation of corrective models to solve difficult ambiguities, such as PP-attachment ambiguity in English. Thus correction occurs as a post-process to parsing,

replacing the output of the parser (labels or attachments) with alternatives obtained in an independent classification process.

The literature differs on the languages and the criteria used to choose the target information to be corrected. Hall and Novak Hall and Novák (2005) worked on Czech. They highlight the problem of projectivity as particularly problematic when parsing free word-order languages, such as Czech, due to the frequency of sentences with non-projective constructions. They present a corrective model which recovers non-projective dependency structures by training a classifier to select correct dependency pairs from a set of candidates obtained from parses generated by an automatic parser. In this case, the baseline parsers were Collins (2000) and Charniak (Charniak and Johnson, 2005), and the authors showed an improvement on dependency accuracy from 81.6% to 82.8% and from 84.4% to 85.1% (respectively).

Kilian and Menzel Foth and Menzel (2006) developed a classifier to solve PP-attachment ambiguity in German, and integrating the classifier into a rule-based parser. They report an error reduction of 14% and an improvement of overall attachment accuracy from 89.3% to 90.6%. Kluber, Ivanova and Klett Kübler et al. (2007) dealt with English PP-attachment ambiguity. They used the MaltParser (Nivre et al., 2007), showing an overall labeled parser accuracy improvement from 86.2% to 86.5%, and more precisely an improvement in unlabeled attachment from 71.8% to 77.4% in the case of prepositions. Henestroza and Candito (Anguiano and Candito, 2011) focus on PP-attachment and coordination as being difficult attachment ambiguities for French, presenting an improvement from 89.78% to 90.47% over MaltParser, and an improvement from 91.04% to 91.36% over MSTParser.

Attardi and Ciaramita Attardi and Ciaramita (2007) worked on English and Swedish. They show a slightly different methodology in that they do not focus on a particular ambiguity. They collect parsing errors by comparing correct parse trees with incorrect trees produced by the base parser on a training corpus. From those, they define a learning task where the input is a set of features extracted at each node in the parse trees produced by the parser on the training corpus whose output is a set of revised decisions, allowing correction. Their analysis was based on DeSR (Attardi, 2006), a shift-reduce parser.

Hussain and Agrawal Husain and Agrawal (2012) make an exhaustive analysis of the parsing errors committed by MaltParser over the Hindi Dependency Treebank. Hindi, as Basque, is a MoR-FWO language, and ergative as well. They identified that 50% of the errors were related to verb argument structure. The relevant information to avoid the errors was either contained in the treebank in a way that was difficult to manage by the parser, or had to be added to the Treebank, enriching it. They pursued two different experiments on tree-transformation and enrichment of the treebank using linguistic information from a dictionary and VerbNet. They conclude that only tree transformations lead to improvements, while enriching the treebank seems to have no effect whatsoever. In related work, (Husain et al., 2010) analyze the importance of different linguistic features over two dependency parsers on Hindi. They conclude that case marking and several verbal features such as tense, aspect and modality are the most informative. This is in contrast with our findings, where case is important, but also transitivity and subcategorization models.

In a different tone, Atterer and Schütze Atterer and Schütze (2007) are critic on some parse correction experiments. They deem parse correction as being unrealistic because it relies on using the treebank as an oracle to select the ambiguous candidates to be evaluated. They argue that, in contrast to the use of gold morphological analysis from the treebank to select ambiguity cases, parsers do not have access to those gold annotations at parsing time. They also argue that,

due to wrong attachment decisions, the parser might miss some ambiguous head-dependent relations that were mined from gold standard treebanks. To avoid these inconveniences when selecting the ambiguous candidates in our work, we used the morphological tags assigned by a morphological analyzer. Furthermore, we used a positional heuristic for assigning dependents to verbs, leaving aside the elements that could be potentially problematic for a parser as explained in 5.1. This way, we find 2303 ambiguous candidates in the training set, compared to 2338 if we would use the output of Malt parser. The intersection between the two amounts to 2040. In order not to penalize MaltParser on those non-coincident candidates, we assigned the object relation to those cases.

An important argument in favor of parse correction is that it is parser-agnostic, that is, our classifier is an independent module which disambiguates certain difficult ambiguities, and its results can be replaced over the result of any parser. In this paper we report on the correction over MaltParser for Basque(Bengoetxea et al., 2011), but in the future we plan to use our system to correct the output of a rule-based parser for Basque (Aranzabe et al., 2004).

7 Conclusions and Future Work

This works confirms the relevance of complex lexical information when solving syntactic ambiguity. More specifically, we have focused on subject-object ambiguity in Basque where it is one the main ambiguities, as it surfaces in 33% of the sentences. This problem is relevant to processing similar ambiguities in other morphologically rich languages. For instance, Urdu and Hindi also display subject-object ambiguity due to erg-abs markings, as well as null-case markings.

We have explored the impact of complex lexical information, including verbal subcategorization in the form of verbal transitivity and verb-noun-case or verb-noun-case-auxiliary relations. In addition, we have studied several linguistically motivated features, and trained a supervised classifier. Our results show that all sources of lexical information and features employed contribute positively, proving their complementarity. In fact, our classifier is better than a state-of-the-art statistical parser trained for Basque, obtaining a statistically significant error reduction of 20% in the resolution of subject-object ambiguities. When used to correct the output of the parser, the improvement is small, albeit statistically significant, showing that the classifier impacts in the overall parser performance.

The analysis revealed that the most relevant pieces of information are the case carried by the dependent element and the transitivity of the verb. For the future we would like to study the similarities and differences with typologically related languages. In addition, we plan to incorporate some of the features into the treebank and statistical parsers.

ABSTRACT
A machine learning mechanism is learned from human annotations in order to perform preference ranking. The mechanism operates on a sentence level and ranks the alternative machine translations of each source sentence. Rankings are decomposed into pairwise comparisons so that binary classifiers can be trained using black-box features of automatic linguistic analysis. In order to re-compose the pairwise decisions of the classifier, this work introduces weighing the decisions with their classification probabilities, which eliminates ranking ties and increases the coefficient of the correlation with the human rankings up to 80%. The authors also demonstrate several configurations of successful automatic ranking models; the best configuration achieves acceptable correlation with human judgments (tau=0.30), which is higher than that of state-of-the-art reference-aware automatic MT evaluation metrics such as METEOR and Levenshtein distance.

KEYWORDS: Machine Translation, Quality Estimation, Ranking.

1 Introduction

As machine translation (MT) comes closer to the everyday use, the need to predict the quality of machine-translated text is being of intense interest. For this reason, research has been focusing more and more on developing methods of assessing the translated content and deriving indications of translation performance in a real-time translation environment, without access to the correct (reference) translations.

Here we are focusing on a specific scenario: we need an automatic system able to rank several machine translation outputs for one given source sentence, according to their comparative quality. This kind of ranking, performed by human annotators, has been established as a practice for evaluating MT-output. Therefore, we attempt to perform "machine ranking", by employing Machine Learning approaches in order to imitate the human behaviour. This is done through a statistical classifier, which is trained given existing human ranks and several qualitative criteria on the text.

This idea can serve several existing applications in MT, as it touches the fields of Hybrid MT, System Combination and MT Evaluation. The applicability is even broader, as the approach presented is system-independent and relies on generic automatic analysis applied on any input containing sets of one source and several translation outputs.

2 Previous work

Quality Estimation is a rather recent aspect in research on Machine Translation. As a field, it tries to provide quality assessment on the translation output without the availability of reference translations. Previous work includes statistical methods on predicting word-level confidence (Ueffing and Ney, 2005; Raybaud et al., 2009b), correctness of a sentence (Blatz et al., 2004) and has been recently evolved into a regression problem (Specia et al., 2009; Raybaud et al., 2009a) for estimating correctness scores or correctness probabilities.

Whereas the aforementioned work has been focusing on estimating absolute measures of quality for a single output, our focus is on the comparative estimation of quality among several system outputs. In this direction, Rosti et al. (2007) perform sentence-level selection with generalized linear models, based on re-ranking N-best lists merged from many MT systems. Sánchez-Martínez (2011) uses only source-language information in order to build a classifier which chooses which machine translation system should be used in order to translate a sentence. As an application to statistical MT tuning, Hopkins and May (2011) improve the tuning MERT process by using the pairwise approach of ranking with a classifier. Others (Vilar et al., 2011; Soricut and Narsale, 2012) use machine learning for ranking the candidate translations and then selecting the highest-ranked translation as the final output.

A couple of contributions (Ye et al., 2007; Duh, 2008) introduce the idea of using ranking in MT evaluation, by developing a machine learning approach to train on rank data, though these are using reference translations and are only evaluated by producing an overall corpus-level ranking. METEOR, one of the state-of-the-art evaluation metrics (Lavie and Agarwal, 2007) also gets its components tuned over human rankings. Avramidis et al. (2011) do MT evaluation without references based on learned ranking, by using parsing features and Parton et al. (2011) also show a configuration of their metric which achieves good correlation with human judgments without any reference information, using target features produced by a language correction software.

Reported work has used various aspects of weighing or training over human ranking. Following

on a similar path, we are focusing on the ability of a mechanism to reproduce human preference rankings and compare its outcome with existing evaluation methods.

3 Methods

3.1 Problem description

As already introduced in Section 1, this work is aiming to a mechanism for ranking multiple translation outputs. In detail, the system is given one source sentence and several translations which have been produced for this sentence, with the use of many MT systems. The goal is to derive several qualitative criteria over the translations and use them to order the translations based on their quality, i.e. to *rank* them.

In this ranking process, each translation is assigned an integer (further called a *rank*), which indicates its quality relatively to the competing translations for the same source sentence. E.g. given one source sentence and n translations for it, each of the latter would get a rank in the range $[1, n]$. The same rank may be assigned to two or more translation candidates, if the translations are of similar quality (i.e. there is no distinguishable difference between them); such a case defines a *tie* between the two translation candidates.

It should be thereof clear that such a qualitative ordering does not imply any absolute or generic measure of quality. Ranking takes place on a sentence level, which means that the inherent mechanism focuses on only one sentence at a time, considers the available translation options and makes a decision. Any assigned rank has therefore a meaning only for the sentence-in-focus and given the particular alternative translation candidates.

Finally, one further assumption as part of the current problem specification is that our system is not bound to the MT systems providing the outputs. This means that the usually small number of alternative translations may derive from a bag of many more MT engines with different characteristics and internal behaviour. The systems are therefore seen as *black boxes* and their translation outputs are treated on a merely superficial level, i.e. without any further information of how they were produced. Thus, one assumption is that the source and translated text contain enough information for assessing translation quality, probably approaching the way the task would be perceived by a human annotator.

3.2 Machine learning on pairwise decomposition of ranking

The problem is hereby treated as a typical machine learning paradigm. Ranking is *learned* from a training material containing existing human rankings. The learning process results in a statistical model. This model can later reproduce the same task on unknown sentences or test data. Whereas the setup and the evaluation of the system takes place on a ranking level, for the core of the decision-making mechanism we follow the principle of going pairwise (Herbrich et al., 1999; Hüllermeier et al., 2008): ranking lists are decomposed to pairwise comparisons. Then, given one pair of translation candidates at a time, a classifier has to predict a binary decision on whether the first translation candidate is better than the latter.

In this context, we train one classifier for the entire data set. Each ranking of n candidate translations is decomposed to $n \times (n-1)$ pairs of all possible combinations of two system outputs with replacement. Each of the resulting pairs forms a training instance for the classifier. Each training instance provided to the classifier consists of a class value c and a set of features $(f_1, \ldots, f_n)$ regarding the translation quality/preferences. For the pairwise comparison of two translation candidates t_i, t_j with human ranks r_i and r_j respectively, the class value is therefore

set as:

$$c_{i,j} = \begin{cases} 1 & r_i < r_j \\ -1 & r_i > r_j \end{cases}$$

The approach of pairwise comparisons is chosen because it forms the machine learning question in a much simplified manner. Instead of treating a whole list of ranks, the classifier has to learn and provide a binary (positive or negative) answer to the simple question "*which of these two sentences is better?*". This also gives the flexibility of experimenting with many machine learning algorithms for the classification, including those which only operate on a binary class.

As explained in Section 3.1, ties may exist in the training material. Though, ties that appear on a pairwise level have been filtered out, since this does not add any useful information on the simple comparison explained above. This means that the pairwise comparisons of the tied outputs with the other outputs are not filtered out; only those between the two tied systems are. A further handling of ties by introducing a third class or a cascade of two classifiers would be a possibility to investigate, but we leave this aside for the moment in order to test the basic functionality given the most promising properties. As we will see later in this section, the ties are treated rather as an uncertainty of the system for either of the classes.

3.3 From pairs back to ranking

During the application of the statistical model on test data, data processing follows the same idea: The test instances are broken down to pairs of sentences and given to the classifier for a binary decision. Consequently there is a need to recreate a ranking list out of the binary pairwise classification decisions.

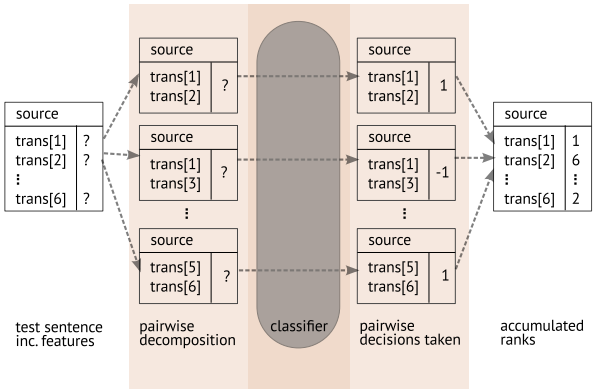

Figure 1: The application of the statistical model, through the pairwise decomposition (left) and recomposition (right)

3.3.1 Hard rank recomposition

The simplest way to go ahead with this is to sum up the decisions of the classifier. For a number of n systems, following the previous annotation, the rank r_i of translation t_i would be:

$$r_i = \sum_{j \neq i}^{n} c_{i,j}$$

The translation output which has "won" the most pairwise comparisons would get first on the list and then the outputs with less pairwise wins would follow accordingly (figure 1). We call this a *hard rank recomposition*, as only the binary decision of the classifier is taken into consideration upon summing up the predicted values.

3.3.2 Soft rank recomposition

One of the problems seen in previous work is that what we described here as a *hard rank recomposition* allows for the creation of ties. Indeed, it is intuitive that the classifier may predict an equal number of wins for two or more translation outputs and therefore generate a tie among them. This may also be intensified by the fact that the pairs have been generated in both directions, which would also result into a tie if the classifier is unable to distinguish the best out of two outputs but is forced to choose one of them.

However, the probabilistic set-up contains information which implies that not all classifier decisions are of "equal importance": statistical classifiers build their binary responses on a probabilistic basis. A translation output which has a number of wins with high certainty should be ranked higher than an output with an equal number of wins but more uncertain. One can therefore use the probability of each decision to weigh the sum described in Section 3.3.1. A translation output which has a number of wins with high certainty should be ranked higher than an output with an equal number of wins but more uncertain. This is thereof referred to as *soft recomposition*. This way, the rank r_i of translation t_i would be:

$$r_i = \sum_{j \neq i}^{n} p_{i,j} c_{i,j}$$

Since the probability $p_{i,j}$ is a long decimal in the range of [0,1] as opposed to a binary value, it is expected that it reduces the cases where two translation outputs end up with an equal sum.

3.4 Feature acquisition

Similar to the previous works on quality estimation, the source sentence and the corresponding translations are analyzed by several tools of linguistic analysis, in order to provide a set of features indicative of the translation quality. Since one of the goals is to not be bound to the systems participating (Section 3.1), these are *black-box* features, i.e. deriving solely from the text. The features used in this work fall into the following categories:

- **Count-based features**: count of tokens, average count of characters per token, count of unknown words
- **Parsing statistics**: One of the common issues that affect MT quality and acceptability is the grammaticality of the generated sentences. This is intense in many statistical systems

(particularly the ones following the phrase-based approach) since they treat the generation process in a rather shallow way. Most often language models are used within the MT systems in order to optimize the output for the highest probability of the consequent *n*-grams. As an additional measure of quality which can capture more complex phenomena (such as grammatical fluency, long distance structures, etc.) we include features derived from Probabilistic Context Free Grammars (PCFG) parsing (Petrov et al., 2006).

PCFG parsing operates by creating many possible tree parses for a given a sentence, forming an *n*-best list of parse hypotheses. These hypotheses are scored probabilistically, leading to the selection of the tree with the highest overall probability. We allowed an n-best list with a size of n=1000 and counted **the number of trees generated**. Although the *n*-best list reaches the limit for the majority of the sentences, some sentences have a smaller number of trees, which signifies less possible tree derivations, i.e. less parsing ambiguity, a feature which would be useful for our use.

Additionally, we extracted and included the basic parsing statistics of the **overall parse log-likelihood**, the **confidence for the best parse tree** and the **average confidence of all trees**.

- **Tree label counts**: In an effort to derive some adequacy features, we relied on the assumption of isomorphism; i.e. the fact that the same or similar grammatical structures should occur on both source and translation(s). Therefore, we counted the basic node labels of the parse tree, namely the NPs, VPs, PPs, verbs, nouns, sentences, subordinate clauses and punctuation occurrencies. The source and target equivalents of labels were manually matched so that their ratios could also be calculated. E.g. the failure to properly translate a Verb Phrase should be indicated by an improportional ratio.

- **Language checking**: Source and target sentences were subject to automatic rule-based *language quality checking* (Siegel, 2011), providing a wide range of quality suggestions concerning **style**, **grammar** and **terminology**, summed up in relevant quality scores.

- **Language-model probabilities**: Language models are also an indication of fluency, since they provide statistics on how likely the sequences of the words are for a particular language. Although Statistical MT systems are expected to already optimize over the language model, as mentioned above, other types of systems may still benefit from this features. This feature category includes the smoothed n-gram probability of the sentence.

- **Contrastive evaluation scores**: Each translation is scored with an automatic metric (e.g. Papineni et al., 2002), using the competitive translations as references. This has shown to perform well as a feature in similar tasks (Soricut et al., 2012).

Keeping the isomorphism assumption, an additional hint for the adequacy of the translation was applied for the features that are apparent in both source and target: The ratio of these features was calculated by diving the feature value of each one of the translation outputs with the respective feature value of the source.

3.5 Machine learning algorithms

The modular approach of the pairwise classification allowed the use of several machine learning algorithms as part of the system core.

- **Naïve Bayes** predicts the probability of a binary class c given a set of features

$$p(c, f_1, \ldots, f_n) = p(c) \prod_{n}^{i=1} p(f_i|c)$$

  $p(c)$ is estimated by relative frequencies of the training pairwise examples, while the probabilities $p(f_i|c)$ for the continuous features f are estimated with the locally weighted linear regression LOESS (Cleveland, 1979).

  Naïve Bayes has the drawback that it requires the features to be statistically independent. However, as an algorithm it can be trained pretty fast and scales well with large amount of data and big feature sets.

- The **k-nearest neighbour** (K-nn) algorithm performs classification to the closed training examples in the search space (Coomans and Massart, 1982). This algorithm does not have a priori assumptions about the distributions of the training data. Though, the method requires a choice for the number (k) of the nearest neighbors, which is problem-specific. For these experiments, we followed the common practice of setting the k equal to the square root of the number of training instances.

- **Logistic regression** tries to maximize a logistic function, whose values range between zero and one (Cameron, 1998). It was fitted using Newton-Raphson algorithm to iteratively minimize least squares error computed from training data (Miller, 2002), whereas Stepwise Feature Selection (Hosmer, 1989) was included. Logistic Regression generally performs better than the previous algorithms, though it has higher computational complexity and therefore its calculation is time-demanding, limiting the possibility to explore many experiment parameters.

3.6 Evaluation

3.6.1 Classification performance

As a classifier is the core part of the system, its robustness and ability to successfully take its binary decisions are indicative of the performance of the entire system. As a basic indications on the success of the learning process we compute **Classification Accuracy** (CA), as a result of cross-fold validation over the training set. This part is useful for evaluating the choice of the learning method and the feature set.

3.6.2 Correlation with human judgments

The system is tested on how well it can rank translation quality, compared to the ranking a human would do for this purpose. After building a model, the system is used in order to perform ranking on a test-set. This test-set has been excluded from the training data and provides human rankings which are hidden during the test classification, but are afterwards used for evaluating the success of the automatic process. The final goal is to measure the sentence-level correlation of the automatically produced rankings with the ones chosen by humans.

For the correlation measurement, we follow **Kendall's tau** coefficient (Kendall, 1938; Knight, 1966), which is suitable for measuring correlation between two ranking lists on a segment level: For every sentence, the machine-predicted and the human ranking are decomposed into

pairwise comparisons. Each automatic pairwise comparison is compared with the respective human comparison and it is counted as *concordant* or *discordant*, depending on whether these two comparisons agree or not. Tau is then given by the fraction:

$$\tau = \frac{\text{concordant} - \text{discordant}}{\text{concordant} + \text{discordant}}$$

with values that range between minus one and one, whereas the closer the value gets to one, the better the ranking is. The calculation follows the formula of the Workshop in Machine Translation (Callison-Burch et al., 2012), in order to be comparable with other methods: Pairwise comparisons with reference translations and pairwise ties in the human-annotated test-set are ignored. On the contrary, every tie on the machine-predicted rankings is penalized by being counted as a discordant pair.

We thereof present two versions of the tau:

- **Overall tau** (τ) where concordant and discordant counts from all segments (i.e. sentences) are gathered and the fraction is calculated with their sums
- **Average segment tau** ($\overline{\tau}_{\text{seg}}$) where tau is calculated on a segment level and then averaged over the number of sentences. This shows equal importance to each sentence, irrelevant of the number of alternative translations.

4 Experiment

4.1 Data sets

Both our training and test data were extracted from human-annotated data containing comparisons of the outputs of several German-to-English MT systems, as a result of the evaluation tasks run by the Workshops on Machine Translation (Callison-Burch et al., 2008, 2009, 2010, 2011), which have been freely available for further research. In the development phase, our training set consisted of the human rankings of years 2008, 2010[1], 2011 and the test-set from the year 2009. In order to re-assure that the system is not overfitting the development environment, the best systems were also tested upon a different set-up, where the human rankings of years 2008, 2009 and 2010 were used for training and the rankings from 2011 system combination task (2011c) were used for testing.

The provided data-sets contain human judgments organized in rankings of at most five sentence at a time. Therefore, the alternative translation outputs for one source sentence are often spanned along many 5-way rankings. For the test set, the multiple rankings of the same source sentence (produced by all available systems) were aggregated into one ranking, and the ties on both pairwise and ranking level were removed. One should also notice that repetitive human rankings of the same systems often disagree with each other, which signifies the existence of some noise in our data.

4.2 Implementation

PCFG parsing features were generated on the output of the Berkeley Parser, with the default grammars based on an English and a German treebank (Petrov and Klein, 2007). N-gram features were based on language models of order 5, built with the SRILM toolkit (Stolcke, 2002) on monolingual training material from the Europarl (Koehn, 2005) and the News (Callison-Burch et al., 2011) corpora. The *Acrolinx IQ*[2] was used to annotate source and target with language checking suggestions and provide style, grammar and spelling scores. The annotation process was organized with the Ruffus library (Goodstadt, 2010) and the learning algorithms were executed using the Orange toolkit (Demšar et al., 2004).

4.3 Strategy

The amount of features and learning options provide an exponential number of experiment parameters. However, in order to be able to draw a fair amount of conclusions in a decent amount of time, we followed an incremental approach: first, we devised some feature sets that have shown to perform well in previous work[3] and used them for learning and testing with the default parameters of all the available methods. Secondly, we repeated the experiments with variations of the most successful parameter set, e.g. by slightly modifying the features or adding promising new features. This approach may have stalled to local maxima, but it should suffice if it can provide a functioning system confirming the original idea.

[1] In all of the experiments we excluded the crowdsourced sentences contained in the set of 2010

[2] http://www.acrolinx.com (proprietary)

[3] We tried to come as close to the original feature set when not all features were technically available

4.4 Results

4.4.1 Searching for the best system

The search through different combinations of feature sets and classification methods is depicted in Table 1. Feature sets 2 - 5 derive from previous work (Soricut et al., 2012; Avramidis et al., 2011; Specia et al., 2012) and are explained in Table 3. Out of these, it appears that feature set 2 is the most successful one for this particular problem, providing a correlation which is acceptable to begin with. *K-nn* slightly outperforms Naïve Bayes.

Consequently, extensions to feature set 2 are considered for further experimentation. Feature set 2.1 provides an improved combination with logistic regression: It derives from the same annotation as feature set 2, with the difference that the features of the target had not been not divided with the features of the source, in order to provide a fixed ratio as a feature; instead, these features were given separately. Due to its power to do a logistic search, we could assume that this learner treats better the factors of the ratio if given separately.

Adding NP counts (feature set 2.2) did not show any improvement. Replacing parsing probability with spelling, grammar and style scores, achieves some improvement, particularly for Naïve Bayes, which has its highest coefficient here.

The most successful feature set is 2.4, which extends 2.1: Learned with logistic regression, it includes the number of unknown words, sentence length, the number of alternative parse trees, the count of VPs and the parse log-likelihood, but also additionally a contrastive METEOR score.

4.4.2 Improvement by soft recomposition

A basic contribution of this paper is the introduction of the soft recomposition of the ranks. This is obvious by reading Table 1 on the horizontal dimension: the soft recomposition achieves higher taus and significantly less ties for all the systems and particularly for the ones which show a positive correlation. In the best cases, using soft recomposition improves the correlation numbers by 40-80%.

4.4.3 Comparisons with state-of-the-art MT evaluation

Although our method uses no reference translations, it still maintains the notion of MT evaluation. Therefore, in lack of openly available competitors of its kind, it makes sense to compare its performance with automatic state-of-the-art MT metrics, to whom reference translations get available. Sentence-level smoothed-BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007) and Levenshtein distance (Levenshtein, 1966) were used. This comparison was also done on a set-up different to that of the development phase. The results (Table 2) show that even without references, the correlation of our best system with human judgment is at least 35% higher than that of the standard metrics.

model		CA	hard recomposition			soft recomposition		
feat	classifier		τ	$\overline{\tau}_{seg}$	ties	τ	$\overline{\tau}_{seg}$	ties

Table 1: Search of the most promising feature sets tested on the development test-set . Feature set #2 from previous work extended with additional features: Logistic Regression with feature sets #2.4 and #2.1 had the highest τ correlation with human rankings. Improvement by using *soft rank re-composition* (Section 3.3.2) is also illustrated

test-set	2009	2011c
SmoothBLEU	-0,23	-0,25
METEOR	0,20	0,12
Levenshtein	0,18	0,07
Machine Ranking (LogReg #2.4)	**0,27**	**0,24**

Table 2: Comparison of our best result with state-of-the-art reference-aware automatic metrics concerning correlation with human judgments (τ). The model is also succesfully tested in order to rank wmt2011-combo translation options (excluded from training)

#1	source:	avg. characters per word, tri-gram probability, count of tokens, NPs
	target:	parse log-likelihood, count of unknown words, ratio of VPs, ratio of PPs, NPs, verbs, ratio of tokens count (Specia et al., 2012)
#2	source:	count of unknown words
	target:	count of unknown words, tokens ratio, ratio of parse trees, ratio of VPs, ratio of parse log-likelihood (Avramidis et al., 2011)
#3	source:	count of unknown words, tokens, dots, commas, avg. characters per word, LM probability
	target:	contrastive-BLEU, LM probability (SVR model from Soricut et al., 2012)
#4	source:	count of unknown words, tokens, dots, commas, avg. characters per word, LM probability
	target:	contrastive-BLEU, LM probability (M5P model from Soricut et al., 2012)
#2.1	source:	count of unknown words, tokens, parse trees, VPs, parse log-likelihood
	target:	count of unknown words, tokens, parse trees, VPs, parse log-likelihood (same as #2 with no ratios)
#2.2	source:	count of unknown words, tokens, parse trees, VPs, NPs, parse log-likelihood
	target:	count of unknown words, tokens, parse trees, VPs, NPS, parse log-likelihood (same as #2.1 including NPs)
#2.3	source:	count of unknown words, tokens, parse trees, dots, commas, spelling score, grammar score, style score
	target:	contrastive-METEOR, count of unknown words, tokens, parse trees, dots, commas, spelling score, grammar score, style score
#2.4	source:	count of unknown words, tokens, parse trees, VPs, parse log-likelihood
	target:	contrastive-METEOR, count of unknown words, tokens, parse trees, VPs, parse log-likelihood (same as #2.1 with contrastive-METEOR)

Table 3: Description of the feature-sets used

5 Conclusion

Machine learning was successfully used as part of a mechanism which is able to perform preference ranking on alternative machine translation outputs. Correlation with human judgments indicates a success in building a mechanism which performs ranking, since even without access to reference information, its performance is higher than other state-of-the-art reference-aware metrics.

The fact that ranking was decomposed into pairwise decisions allowed the integration of several machine learning algorithms with positive results. The recomposition of a ranking from pairwise decisions was facing the problem of creating too many ties as a result of unclear and contradictory pairwise decisions. This was solved by weighing classification decisions with their prediction probabilities.

The best system uses logistic regression with a feature set that includes the number of unknown words, sentence length, a contrastive METEOR score, and parse statistics such as number of alternative parse trees, count of VPs and the parse log-likelihood.

ABSTRACT

Semantic tuples are core component of text mining and knowledge extraction systems in biomedicine. The practical success of these systems significantly depends on the correctness and quality of the extracted semantic tuples. The quality and correctness of the semantic predictions can be measured against a benchmark semantic structure. In this article, we presented an approach for constructing a reference semantic tuple structure based on the existing biomedical knowledge sources in which the evaluation is based on the UMLS knowledge sources. In the evaluation, 7400 semantic triples are extracted from UMLS knowledge sources and the semantic predictions are constructed using the proposed approach. In the semantic triples, 87 concepts are found redundantly classified and 207 pair of semantic triples showed hierarchically inconsistent. 128 are found to be non-taxonomically inconsistent. The quality of the semantic triple is also judged using expert evaluators. The Cohen's kappa coefficient is used to measure the degree of agreement between two evaluators and the result is promising (0.9).

Construire des prévisions de référence sémantique à partir de sources de connaissances biomédicales

Les "tuples sémantiques" forment un élément essentiel à la fouille de texte et aux systèmes d'extraction de connaissances dans le domaine biomédical. Le succès en pratique des systèmes exploitant ces informations sémantique, dépend fortement de l'exactitude et de la qualité des tuples sémantiques. La qualité et l'exactitude des informations sémantiques produites automatiquement peuvent être mesurées par rapport à une structure de référence. Dans cet article, nous présentons une approche pour construire une structure sémantique à base de tuples, basée sur des sources existantes dans le domaine biomédicale. L'approche est évaluée en comparaison du méta-thésaurus UMLS. Dans une évaluation préliminaire, 7400 tuples sémantiques ont été aléatoirement extraits de UMLS et les prédictions de relations on été construites en utilisant l'approche proposée. Dans les triplets sémantiques étudiés, 87 concepts se révèlent être classés de manière redondante et 207 paires de triplets sémantiques ont une relation hiérarchique incompatible, et finalement 128 sont jugées taxonomiquement compatibles. La qualité de la relation sémantique est également jugée en utilisant des évaluateurs, experts du domaine. Le coefficient kappa de Cohen est utilisé pour mesurer le degré d'accord entre deux évaluateurs et le résultat est d'ors et déjà prometteur (0,9).

KEYWORDS: Acceptable semantics, domain semantics, knowledge extraction, semantic triples

1 Introduction

Semantic predictions, semantic triples, are the basic components of text mining and knowledge representation systems. Nowadays, large scale semantic prediction extraction and representation systems are increasingly emerging to sustain text mining and knowledge management systems in biomedicine. These in turn support intelligent and quality healthcare services and management (Abacha and Zweigenbaum, 2011; Cameron, 2011; Denecke, 2008; Harkema et al., 2004).

The practicality and usability of semantic relation extraction systems critically depends on the correctness, accuracy and quality of the extracted semantic predictions. The relations are formed under a general structure of *subject-predicate-object* triples (Harkema et al., 2004; Spasic, 2005), called semantic predictions hereafter. A benchmark is necessary to evaluate the accuracy and quality of the semantic relations generated by the automatic semantic relation extraction systems. This in turn improves the usefulness of the semantic predictions in the knowledge management systems (Abacha and Zweigenbaum, 2011; Denecke, 2008).

Most of the existing semantic triple extraction systems are based on either a shallow (e.g. Wordnet or Ontologies) or a narrower (e.g. terminologies) semantic resources for measuring the accuracy and quality of the extracted semantic relations (Abacha and Zweigenbaum, 2011; Cameron, 2011; Denecke, 2008). These semantic resources either lack the fine-grained semantics (e.g. Wordnet) or focus on narrower domains (e.g. terminological resources), and adopt different semantic representation contexts. This renders difficulties in the semantic resources to use them in benchmarking for independently developed semantic tuple extraction and representation systems (Denecke, 2008).

In biomedicine, various semantic resources have emerged recently (Bada and Hunter, 2007; Herre et al., 2011). They range from terminologies (e.g. UMLS (Keith et al., 1998; Lindberg et al., 1993)) to Ontologies (e.g. BioTop (Beisswanger, 2007)). Most of the ontological resources contain high level semantics of the domain (Beisswanger, 2007), resulting in lack of fine-grained semantic triples that may have significant impact on reasoning and intelligent systems application. Terminologies (e.g. UMLS) are the most common semantic resources utilized as reference in semantic triple extraction and representation because they contain the fine-grained semantic triples in a very specific domain.

For example, the Unified Medical Language System (UMLS) semantics is used to measure the correctness and usefulness of extracted semantic predictions in the work of Abacha and Zweigenbaum (2011), Cameron (2011) and Denecke (2008). According to Keith et al (1998) and Lindberg et al (1993), the UMLS is the integration of many vocabulary sources in biomedicine. It is a widely accepted semantic resource to represent the biomedicine. It has richer semantic content than other terminological resources in biomedical domain yet.

As pointed out previously, most terminological resources, however, are developed using experts for specialized application contexts in the domain (Keith et al., 1998; Lindberg et al., 1993). This makes the semantic tuples to have multiple semantic interpretation contexts and views, which leads to many inconsistencies and ambiguities in the domain representations (Erdogan, 2010; Fan and Friedman, 2008; Freitas et al, 2009).

This problem is intensified if the resources are combined (e.g. UMLS) to integrate the different views and interpretations of the semantic triples. This may significantly affects the accuracy, correctness and quality of the semantic triples (Erdogan, 2010; Morreya, 2009; Mougin and Bodenreider, 2005; Spasic, 2005; Vizenor et al, 2009).

Auditing systems have been developed to asses the semantic inconsistencies and ambiguities in biomedical semantic resources and to suggest corrective measures. For example, in (Erdogan, 2010; Morreya, 2009; Mougin and Bodenreider, 2005; Spasic, 2005; Vizenor et al, 2009), auditing systems are developed to asses the inconsistencies inherent to Unified Medical Language System (UMLS) knowledge sources.

But, while auditing systems have made large contributions in identifying the inconsistencies and ambiguities, the large volume and number of biomedical knowledge sources and many inconsistencies and ambiguities make them difficult to circumvent the inherent problems of the resources (Erdogan, 2010; Friedman et al, 2001). Consequently, using these resources as a benchmark for semantic triple extraction could lead to incorrect interpretation of the semantic triples, which results low accuracy and quality of the semantic predictions.

In this context, a reference semantic tuple structure is required to provide consistent, accurate, and high quality semantic triples for benchmarking semantic prediction extraction systems in biomedicine. The lack of a suitable gold standard reference semantic prediction structure has so far precluded the formal evaluation of semantic triple extraction systems. Most of the existing semantic extraction systems have been informally evaluated using statistical methods through error analysis. A formal evaluation requires measuring the semantic distances of extracted semantics against the benchmark semantics. That is, the spans of texts need to be mapped to concepts and their relationships in the reference semantic structure, which provides a consistent and formal representation of biomedicine.

Constructing such a reference semantic structure needs a comprehensive analysis of the biomedicine semantic knowledge resources (e.g. UMLS) to guarantee the correctness and quality of the semantic triples in them (Erdogan, 2010; Friedman et al, 2001). Furthermore, the analysis is made in perspectives where most inconsistencies and ambiguities are assumed to occur (Erdogan, 2010; Morreya, 2009; Mougin and Bodenreider, 2005; Spasic, 2005; Vizenor et al, 2009).

We have structured our semantic analysis in four perspectives before transforming the semantic knowledge sources into semantic predictions. The first semantic analysis is used to identify redundantly classified concepts to guarantee the correct assignments of concepts in the knowledge source (e.g. UMLS (Fan and Friedman, 2008)). The second semantic analysis is made for ensuring the consistency of hierarchical relationship semantics held by the biomedical knowledge sources (e.g. UMLS semantic network and Metathesaurus (Cimino et al., 2003)).

The third semantic analysis checks the consistency of non-taxonomically related semantic triples in the semantic knowledge sources (e.g. UMLS semantic network and Metathesaurus) (Bodenreider and Burgun, 2004; Vizenor et al., 2009). The fourth analysis verifies the alignment of concepts and semantic types between UMLS knowledge sources. Lastly, the UMLS semantics is transformed into a set of consistent and acceptable semantic predictions.

In this article, we presented a method to construct consistent and domain expert acceptable semantic tuple structure with assessment and analysis of the biomedical knowledge sources applied on Unified Medical Language System (UMLS). The techniques are developed to assess and identify the semantic inconsistencies and ambiguities in the biomedical knowledge sources and transform the knowledge source semantics into a set of semantic triples.

As the approach focuses at the semantic level (concept), it can be applied on languages included in the Unified Medical Language System (UMLS). That is, it can be applied for those languages in the Unified Medical Language System's knowledge sources (e.g. English and some European languages) or the language of its source vocabularies (e.g. SNOMED CT). This makes the proposed approach to have language independent nature.

The approach is based on the language model developed by the National Library of Medicine in designing the Unified Medical Language System to integrate multiple terminologies in the domain of biomedicine. It combines conceptual and lexical representations of the domain semantics. The third Unified Medical Language System (UMLS) resource component, for example, is the SPECIALIST Lexicon, which is designed to have morphological and syntactical language models.

The approach also measures the accuracy, quality and correctness of the transformed semantic tuples using experts. Each semantic tuples are transformed into human readable format and presented to experts. The experts rate the semantics of the tuples by providing judgmental value of 1 or 0, where 1 is acceptable and 0 is unacceptable. The degree of agreement between two evaluators is measured using Cohen's kappa coefficient (k). In this way, three expert evaluators judge the accuracy and quality of the semantic tuples. The result obtained is promising. Finally, the results are discussed and concluded in future works.

2 Background

According to literatures (Freitas and et al, 2009), several semantic resources have been emerging increasingly in biomedical domain. The resources may generally be categorized into lexical, terminologies and Ontologies based on the semantic content they have (Freitas and et al, 2009). For example, Wordnet could be a lexical resource, SNOMED CT or UMLS is a Terminological resource and BioTop is ontological resource.

The Unified Medical Language System (UMLS) is the largest terminological resource in the domain, which has been developed by the National Library of Medicine (NLM) since 1986 as a long term project. Currently, it is an integration of more than 150 biomedical vocabulary sources into its Metathesaurus. The Metathesaurus consists of more than 3 million concepts and their relationships (Keith et al., 1998; Lindberg et al., 1993).

The Unified Medical language System (UMLS) has three semantically correlated components that represent the biomedical domain at various level of semantic granularity. The Unified Medical Language System (UMLS) semantic network represents the high level conceptual domain representations with broader semantic classes, called semantic types. The Unified Medical Language System (UMLS) Metathesaurus also represents the fine-grained domain semantic concepts and the corresponding terms as well as relationships among concepts.

The Unified Medical Language System (UMLS) SPECIALIST Lexicon represents the linguistics knowledge sources and lexical resources. The linguistics knowledge sources include morphological and syntactic attributes of each term in the Metathesaurus. This creates a linkage to span of texts in biomedical documents.

The semantic tuples forming subject-predicate-object triples in the Metathesaurus are logically linked to the semantic network semantic tuples. In Metathesaurus, the concepts are the subjects and objects in the triple whereas the thesauri relationships are the predicates. In the semantic network, the subjects and objects are semantic classes (types) where as the predicate is the semantic network relationships.

The semantic concepts in the Metathesaurus are categorized in at least one semantic type in the semantic network. These concepts are in turn represented by several synonymous terms from multiple vocabulary sources. In this respect, the two knowledge sources of the UMLS, semantic network and Metathesaurus, are semantically linked to structure the semantics of biomedicine.

However, the integration of several vocabulary sources into UMLS has been made using experts with a goal to create a semantic link among the different biomedical resources by preserving the semantics and terms in the original resources. This leads the UMLS to have inherent inconsistency and ambiguity problems in its semantic content (Erdogan, 2010; Fan and Friedman, 2008; Freitas et al, 2009; Friedman et al., 2001; Harkema et al., 2004). According to empirical results in auditing the UMLS (Bodenreider, 2001, 2004; Cimino, 1998; Erdogan, 2010; Fan and Friedman, 2008; Friedman and et al., 2001; Morreya, 2009; Mougin and Bodenreider, 2005; Spasic, 2005; Vizenor et al, 2009), the major sources of these problems are: 1) Due to errors made by experts in the integration process; 2) inconsistencies and ambiguities that arise in the process of preserving the different views and semantic contexts of the original sources in the integration.

Erdogan et al. (2011) quantified the semantic inconsistencies in UMLS concepts from the perspective of their hierarchical relations and showed how inconsistent concepts can help reveal erroneous synonymy relations. The study evaluates consistency by comparing the semantic groups of hierarchically related pair of concepts. As a result, 81, 512 concepts were found to be inconsistent due to differences in semantic groups of a concept and its parents. Morrey et al. (2009), presented Neighborhood Auditing software Tool (NAT), which facilitated the UMLS auditing tasks. It supports neighborhood based auditing, where an auditor concentrates on a focused concept and one of a variety of neighborhoods of its closely related concepts. It also allows an auditor to display knowledge from the two UMLS knowledge sources.

Cimino (1998) developed semantic techniques to audit Metathesaurus for identifying possible inconsistencies. The result of the study showed that out of 57,592 concepts with multiple semantic types, 3.2% were judged ambiguous. Keyword analysis showed 7121 pairs of interchangeable terms. Using the keyword pairs, 5031 pairs of potentially redundant concepts were suggested, of which 65.1% were judged to actually be redundant. Review of the 100,586 parent–child relationships revealed 0.54% that was incorrect. Review of the 219,664 other relationships (RO) (e.g. see in TABLE 1 below) suggested 1299 places in the Semantic Network (SN) where relations between pairs of semantic types could be added.

CHD	Has child relationship	C_1 parent of C_2, inverse_ISA
PAR	Has parent relationship	C_1 child of C_2, ISA
RB	Has a broader relationship	C_1 parent of C_2, inverse_ISA
RN	Has a narrower relationship	C_1 child of C_2, ISA
RL	The relationship is similar or alike	C_1 alike C_2, mapping
RO	Relationships other than CHD, PAR, RB, RN and SY	Associative relationship of C1 & C2
RU	Related, unspecified	Inherited from SN, T1 & T2
SIB	Has sibling relationship	C_1 SIB C_2, sistership

TABLE 1 - META relationships and their mapping

Auditing methods can be classified as logic and non-logic based (Cornet, 2005; Mougin and Bodenreider, 2005). While the logic based methods have been better performing, the semantic structure of UMLS is not consistent with it (Cornet, 2005; Mougin and Bodenreider, 2005). The non-logic based methods (Bodenreider, 2001; Cimino, 1998, 2003; Erdogan, 2010; Fan and Friedman, 2008; Morreya, 2009; Mougin and Bodenreider, 2005; Vizenor et al., 2009) detect and avoid semantic inconsistencies and ambiguities based on semantical and structural properties of the UMLS semantics and fix the problems manually. The methods detect redundant assignments, hierarchical and associative semantics inconsistencies, and hierarchically circular relationships. The purpose of the methods is to enhance the correctness and semantic quality of the UMLS knowledge sources. More comprehensive literature survey about auditing methods can be referred in (Zhu, 2009).

Some semantic predictions systems, in biomedicine, have also used the UMLS semantics for accurate extraction of semantic predictions and measuring the quality of the resulting semantic propositions. For example, in 2008, Denecke the quality and correctness of the extracted semantic predictions are checked against the semantics of the UMLS semantic network in its evaluation. Accuracy is measured in terms of the number of concepts extracted compared to those actually exist in a sentence and the quality of the relation was compared to manually generated semantic structures.

In this context, a semantic structure is correct if it contains all medical concepts in a sentence and if the semantics of the concepts are according to manually constructed representations. Kilicoglu et al (2011) also developed a semantic prediction gold standard from biomedical literatures to evaluate semantic prediction systems (e.g. semRep). However, though the studies were concerned on accuracy, structural and semantical acceptability of the semantic predictions,

manual construction is very limited and consumes more time and effort in large scale semantic prediction systems, which results the need of developing alternative approaches.

3 MATERIALS

The Unified Medical Language System (UMLS) Semantic Network (SN) and Metathesaurus (MT) are used as a baseline semantic resource to evaluate the approach for generating consistent and acceptable semantic predictions under a general structure of object-attribute-value triple. According to the studies in (Keith et al., 1998; Lindberg et al., 1993), UMLS combines many medical vocabularies and provides a mapping structure among them. It is composed of the semantic knowledge components, the metathesaurus and semantic network, and lexical knowledge source, the SPECIALIST Lexicon. The semantic structure in the UMLS is inherently related to the semantic structures of its semantic network and Metathesaurus. Fig. 1 below depicts the semantic relationships of the two UMLS knowledge sources.

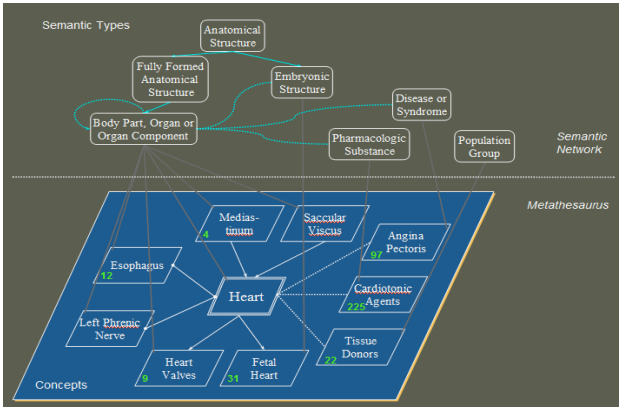

FIGURE 1- Semantic structure of the SN and MT

The upper one is the UMLS semantic network semantic types where as the lower one is the concepts in the UMLS Metathesaurus. The link between the two is the hierarchical relationship. For example, the semantic type **body part, organ and organ component** is a **fully formed anatomical structure**, which is in the semantic network. And **heart** is **body part, organ and organ component,** which is a semantic binding between Metathesaurus and semantic network.

The semantic network consists of 135 semantic types that have been aggregated into a set of 15 semantic groups to reduce complexity (McCray, 2001). For example, the semantic type **Finding** and **Pathologic Function** belong to the semantic group **Disorders**. The semantic types are linked using 54 semantic relationships. For example, the semantic type **Body Part, Organ, or Organ Component** is associated with the semantic type **body substance** by the semantic relationship *location_of*. The semantic type **dysfunction** is related to the semantic type **biologic function** hierarchically, *isa*.

In semantic network, semantic types are related taxonomically in a single inheritance relationship. The hierarchy is rooted at two nodes, the entity and event. Along the hierarchy, the associative relationships defined in the ancestor semantic types are easily inherited by the decedent semantic types unless otherwise the inheritance is blocked explicitly. If a relationship can not be inherited, it is blocked in two ways. The first is inheritance blocking (B), to mean the relationship cannot be inherited by the descendant semantic types. There are also cases where semantic relationships are Defined but Not Inherited (DNI). The relationships are used only in the defining semantic types but not inherited by its decedents.

The semantic types and concepts are related using categorization links. These links are assumed as hierarchical (*isa*) relationships. Intuitively, it is assumed that a semantic relationship defined between two semantic types is also inheritable between pair of concepts categorized in the two semantic types. For example, the relationship *affects* is defined between **Acquired Abnormality** and **organism function** as (*acquired abnormality, affects, organism function*). If it is inheritable, the relationship or its decedents is inherited between concepts categorized in **Acquired Abnormality** (e.g. C0001168) and **Organism Function** (e.g. C0000934) as (C0001168, affects/causes/induces, C0000934).

Fig. 2 below shows the general semantic inheritance structure between the UMLS semantic network and Metathesaurus. In the figure, the semantic types **fully formed anatomical structure** and **biologic function** is related by *location_of*. This semantic relationship can also be inherited by the descendent semantic types of **fully formed anatomical structure** and **biologic function,** which are **body part, organ and organ components**, and **diseases and symptom.** The same semantic relationship can also be inherited by the corresponding semantic concepts in the Metathesaurus between as shown in Fig. 2 below **adrenal cortex** and **adrenal cortical hypofunction**.

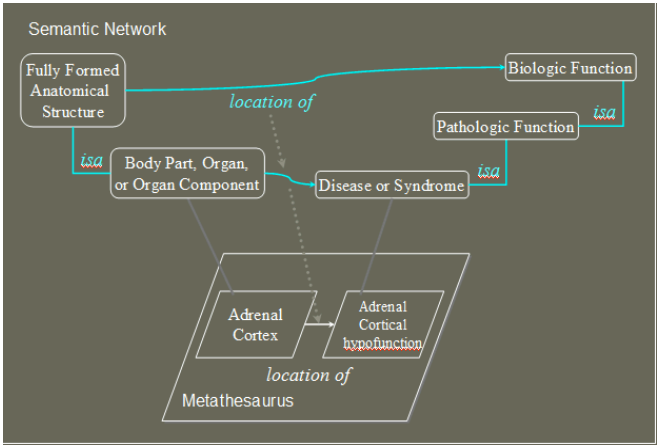

FIGURE 2 – Semantic inheritance between SN and MT

Though difficult and challenging [23], associative relationships (e.g. affects) can be inherited by pair of concepts in MT. They are not explicitly defined among concepts, which results the requirement of mapping the SN relationships. Furthermore, some MT relationships can't map to the existing SN relationships, which also results the need of defining additional SN relationships. In this study, the MT relationships considered are listed in table 1, and only the existing SN relationship mapping is made. Concepts in Metathesaurus are groups of similar terms from the various source vocabularies. These terms create linkage to the SPECIALIST Lexicon, which in turn enables to create linkage to domain texts. Similarly, relationships between concepts can be mapped among terms and in turn between span of texts in the discourse.

In this article, therefore, the UMLS semantic network, Metathesaurus and their semantic binding are used as a semantic resource except co-occurrence relationship. Within these, the SN (e.g. SRSTRE2.TXT) and MT (e.g. MRSTY.RRF, MRREL.RRF) and UMLS relationship files in addition to the semantic groups are used in constructing the semantic predictions.

4 METHOD

In this article, we proposed an approach for constructing consistent and acceptable semantic triples under a framework of *object-attribute-value*/*subject-predicate-object* triple from biomedical knowledge sources. In each semantic triple, the object/subject and value/object are either semantic types or semantic concepts or atoms. The attribute/predicate is the semantic relationship defined/inherited between semantic types or semantic concepts. For example, in the triple (***pharmacologic substance****, treats,* ***pathologic function***), ***pharmacologic substance*** is the *object/subject* and ***pathologic function*** is *value/object* while ***treats*** is *attribute/predicate*.

In the approach, two general steps are made to complete the construction. First, all possible semantic triples in the knowledge sources (e.g. UMLS semantic network and Metathesaurus) are extracted. Second, the consistency and acceptability of the triples are assessed. The notations C=concept, T=semantic type, G=semantic group, R=relationship, D=inheritable, B=Blocked, DNI=Defined but Not Inheritable are used henceforth. Fig. 3 shown below depicts the general semantic prediction process.

4.1 Semantic Triple Extraction

In Metathesaurus, semantic relationships are based at each semantic context of the terms, which we referred as semantic atoms, hereafter. Semantic triples can be constructed at the level of semantic atoms, concepts, types and groups. That is, semantic types in each semantic group, semantic concepts in each semantic type, and semantic atoms in each semantic concept are extracted to have explicit representation of the structure. This enables to identify concepts that a semantic atom belongs, semantic types that a concept belongs, and a semantic group that a semantic type belongs. The extraction is splitted into two steps. The first is the extraction of taxonomically related semantic triples and next, the extraction of non-taxonomically related semantic triples.

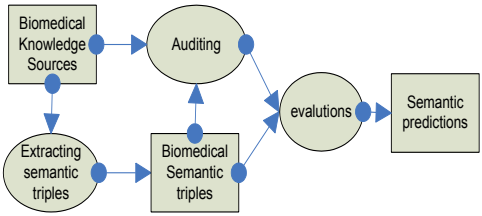

FIGURE 3– Semantic Prediction

Taxonomic (hierarchical) semantic triple extraction is straightforward. Because the taxonomy is transitive, relations that can be derived are easily inferred from the taxonomy. For instance, given a taxonomic hierarchy (C_3, C_2, C_1), the triples (C_2, C_1), (C_3, C_2), and (C_3, C_1) can be derived. The triple (C_3, C_1) is inferred from the transitive characteristics of taxonomic relationships. Fully inherited SN files (SRSTRE2.txt) and the hierarchical relation MT files (MRHIER.RRF and MRSTY.RRF) are used to construct the taxonomic structure. Fig. 4 below shows the result of the taxonomic semantic triple construction.

Algorithm: *building taxonomic semantic triples*

For each sem. group, G, obtain semantic types

For each sem. type, T, obtain semantic concepts

For each sem. concept, C, obtain sem. atoms, A

Build the taxonomic structure, ISA (A, C, T, G)

```
Semanti triples between T and G:
     (T195|Antibiotic, CHEM|Chemicals & Drugs)
     (T118|Carbohydrate, CHEM|Chemicals & Drugs)
     (T103|Chemical, CHEM|Chemicals & Drugs)
     (T200|Clinical Drug, CHEM|Chemicals & Drugs)
     (T111|Eicosanoid, CHEM|Chemicals & Drugs)
     (T126|Enzyme, CHEM|Chemicals & Drugs)
     (T125|Hormone, CHEM|Chemicals & Drugs)
     (T119|Lipid, CHEM|Chemicals & Drugs)
     (T192|Receptor, CHEM|Chemicals & Drugs)
     (T110|Steroid, CHEM|Chemicals & Drugs)
     (T127|Vitamin, CHEM|Chemicals & Drugs)

Semantic triples between C and T:
     (C0014184|Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014185|Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014186|Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014197|Deoxyribonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014207|Deoxyribonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014208|GdoI Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014209|GinI Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014210|GoxI Endonuclease, T116|Amino Acid, Peptide, or Protein)
     (C0014221|MleI Endonuclease, T116|Amino Acid, Peptide, or Protein)
```

FIGURE 4- Snapshot of taxonomic semantic triples

In non-taxonomic semantic triple extraction, all semantic classes (semantic types, concepts and atoms) are considered as concepts. Non-taxonomic semantic triples of a concept C_i in which C_i is the subject of the triple (C_i, R, C_k) are extracted. Then, triples that have the same relationships (in R) and object concepts (in C_k) are merged. Finally, only semantic triples differing with at least one of C_i, *R, C_k,* are considered as useful.

Relationship inheritance between semantic triple in SN (T_1, *R,* T_2) and the corresponding semantic triples in MT (C_1, *r,* C_2) in which C_1 and C_2 are related hierarchically to T_1 and T_2 respectively is the mapping of *R to r*, where *r* is either same as *R* or decedents of *R*. This mapping is valid if the inheritance of *R* is permitted (i.e. D) otherwise the mapping is blocked (B or DNI). The fully inherited SN files (SRSTRE2.txt) and a MT file (MRSTY.RRF and MRREL.RRF) are used to develop the nontaxonomic structure. The algorithm below constructs the nontaxonomic propositions.

Algorithm: *non-taxonomic semantic triples*

For each sem. type (T_i), obtain (T_i, R, T_k)

For each C_i in T_i, map R to r, obtain (C_i, r, C_k)

Collect tuples (T_i, R_{ij}, T_j) and (C_i, r_{ij}, C_j)

Repeat from i=1 to 135, all semantic types

```
Non-taxonomic semantic tuples (T, R, T):
    (Acquired Abnormality, affects, Organism)
    (Acquired Abnormality, affects, Virus)
    (Acquired Abnormality, location_of, Fungus)
    (Acquired Abnormality, location_of, Virus)
    (Acquired Abnormality, occurs_in, Age Group)
    (Acquired Abnormality, occurs_in, Group)
    (Acquired Abnormality, part_of, Amphibian)
    (Acquired Abnormality, part_of, Animal)
    (Age Group, exhibits, Behavior)
    (Age Group, exhibits, Individual Behavior)
    (Age Group, exhibits, Social Behavior)
    (Age Group, interacts_with, Age Group)
    (Age Group, performs, Activity)

Non-taxonomic semantic tuples (C, r, C):
    (C0991536, has_dose_form, C0716419)
    (C0991536, has_dose_form, C0716420)
    (C0991536, has_dose_form, C0716451)
    (C0991536, has_dose_form, C0716453)
    (C0944728, analyzed_by, C0027342)
    (C0944728, measured_by, C0043481)
    (C0944728, system_of, C0027342)
    (C0944728, component_of, C0043481)
    (C0944728, property_of, C1264657)
    (C0944729, system_of, C0005767)
    (C0944729, component_of, C0072980)
    (C0944729, property_of, C0560150)
    (C0944729, class_of, C1315017)
    (C0944730, analyzed_by, C0370231)
```

FIGURE 5 - Snapshot of Non-Taxonomic Semantic Triples

4.2 Consistent Semantic Triples

Consistency is defined as accurate representation of the semantic tuples or non-redundant classification of concepts in MT. Inconsistencies are resulted from inaccurate representation of semantic network and Metathesaurus relations, and inaccurate concept categorizations. Detecting and removing the redundant classifications and the inaccurate representation of semantic tuples could eliminate the semantic inconsistencies.

Redundant classification occurs in cases if T_1 is decedents of T_2 and a concept C_1 is classified under T_1 and T_2. In this situation, the assignment of C_1 to T_2 is redundant. This is because it can be inferred from the assignment of C_1 to T_1 transitively. The redundant assignment (or the semantic tuple C_1 *isa* T_2) is removed or made implicit to make consistent. The algorithm below is developed to detect and remove the redundancy.

Algorithm: *removing redundant classifications*

For each concept C_i *in MT, obtain its sem. types*

Obtain taxonomically related semantic types

Remove the ancestor STs, if any

Hierarchical relationship inconsistencies occur in cases where T_1 becomes an ancestor of T_2 in relationship conditions if C_1 and C_2 are related taxonomically in MT (C_1 *isa* C_2), and C_1 is in T_1 (C_1 *isa* T_1), C_2 is in T_2 (C_2 *isa* T_2). That is, T_1 must be decedent or the same as T_2 to make consistent. The next algorithm is developed to detect and remove such inconsistencies.

Algorithm: *hierarchical inconsistencies*

For each related concepts, C_i *and* C_j

Obtain the semantic types for each, C_i *and* C_j

Remove the intersection STs of C_i *and* C_j

Verify the STs of C_i *are decedents of that of* C_j

Remove the inconsistencies, if any

Unlike the semantic network relationships, Associative relationships in MT are not explicitly defined (Vizenor et al, 2009). This creates difficulties in mapping the SN semantics to the corresponding MT semantics, resulting associative inconsistencies. This occurs when the semantic relationships between two semantic types, T_1 and T_2, have no direct mapping to the semantic relationships made by two semantic concepts, C_1 and C_2, which are categorized in T_1 and T_2 respectively.

For example, the semantic type ***body part, organ and organ component*** is hierarchically related to ***fully-formed anatomical structure***. The semantic type ***disease and syndrome*** is also related to ***pathologic function*** hierarchically. A semantic relationship *location_of* exists between semantic type ***body part, organ and organ component,*** and ***disease and syndrome.*** *Adrenal cortex* and *adrenal cortical hypofunction* are two Metathesaurus concepts categorized in ***body part, organ and organ component,*** and ***disease and syndrome*** respectively**.** However, the relationship

between the two concepts are not explicitly defined or inherited. In order to make consistent semantic mapping, the relationship between the two concepts should be either *location_of* or its decedents, if any.

We assumed that the inheritable relationship (R) between semantic types T_1 and T_2 or its decedents in SN are also inheritable to all concepts categorized in T_1 and T_2. This leads to develop simple algorithm to map the semantic tuples in SN to semantic tuples in MT. In this article, the semantic mapping considers only semantic relationships in MT indicated in table 1. Specifically, for example, other relationships (RO) and unspecified relationships (RU) are considered for associative semantics mapping. After mapping the semantic relations between the two knowledge sources, manual assessment is made to assure the consistency of the mapping.

5 Results and Discussion

The approach is evaluated by extracting a total of 7400 semantic triples from the Unified Medical Language System (UMLS 2010AB). I.e. there is no special consideration for the semantics of either hierarchical or associative relationship triples. Out of 7400, 4040 are found to be hierarchically related semantic triples, which account 55% of the total. 3360 semantic triples, which accounts about 45% of the total, are found to be non-hierarchically (associatively) related.

This seems that hierarchically related semantic triples are provided more emphasis than associative relations. However, according to the empirical analysis, most of the semantic relationships in MT are hierarchical as they brought from thesauri relationships of the source vocabularies.

In an empirical analysis of the different causes of inconsistencies such as redundant classification, hierarchical and associative relationships, we have compared each of them from the total semantic triples and to the count of semantic triples in the two semantic classes, taxonomic and non-taxonomic. This enables to forecast the trend of the possible inconsistencies in about 15 million semantic triples in the UMLS.

Out of 4040 hierarchically related semantic triples, we have obtained 87 redundantly categorized concepts, which they are removed accurately. Similarly, in the taxonomically related semantic triples, only 207 semantic triples are found to have hierarchically inconsistent in the assignments of concepts to semantic types. This account 5% to the taxonomically related semantic triples and 0.03% to the total semantic triples extracted.

In the case of non-taxonomically related semantic triples, we obtained 128 semantic inconsistencies in mapping the semantic network triples to the corresponding Metathesaurus semantic triples. This accounts 0.04% of non-taxonomically related semantic triples. Some of these inconsistencies come from lexical variations of the relationship phrases and the blocking of inheritances.

Finally, one hundred randomly selected semantic triples are presented to expert evaluators. Each semantic triple is judged by the two evaluators and classified in either 1 (acceptable) or 0 (unacceptable). In evaluator A, 87 are accepted and 13 are unaccepted. In evaluator B, 93 are accepted and 7 are unaccepted. Five semantic triples are unaccepted by evaluator A but accepted by B. Three semantic triples are unaccepted by evaluator B but accepted by the A. Twelve semantic triples are unaccepted and eighty semantic triples are accepted in common.

Cohen's kappa coefficient (k) is computed to see the degree of agreements between two evaluators where k= (pr (a)-pr (e))/ (1-pr (e)). Pr (a) is the relative observed agreement and pr (e) is the probability of random agreement. The result is 0.9, which indicates better agreement between the two evaluators.

Conclusion and Future Work

In order to utilize the biomedical knowledge sources as a benchmark for quality semantic prediction extraction, the quality and correctness of the semantic triples should be assured by domain experts and the inherent inconsistency and ambiguity problems need to be alleviated.

In this article, we have developed an approach for assessing inconsistency problems and transforming the knowledge source semantics to consistent and domain expert acceptable semantic triples. In the approach, we have developed techniques to extract semantic triples in the Unified Medical Language System (UMLS) and transform the triple in the form of *subject-predicate-object* triplets. Furthermore, to assess the inconsistencies related to redundant classification, hierarchical and associative relationships, algorithms are developed.

A preliminary evaluation is conducted by extracting 7400 semantic triples from Unified Medical Language System (UMLS) knowledge sources. Though the number of semantic triples considered is small, the result of the evaluation is promising. However, for accurate result and for our purpose, we will increase the number of semantic triples to one hundred thousand. Furthermore, the quality (acceptability and naturalness) of the semantic triples are also judged using domain experts. The Cohen's kappa coefficient (k) is used to measure the degree of agreement between the evaluators and the result is promising (0.9).

The approach developed in this article is limited to the use of the study in knowledge extraction in biomedicine. But, to utilize the full semantic potential of the biomedical knowledge sources, a generic and rigorous approach, which transforms its semantics to standard semantic structure and eliminate the possible inconsistencies and ambiguities are required.

ABSTRACT
Supplementary data selection from out-of-domain or related-domain data is a well established technique in domain adaptation of statistical machine translation. The selection criteria for such data are mostly based on measures of similarity with available in-domain data, but not directly in terms of translation quality. In this paper, we present a technique for selecting supplementary data to improve translation performance, directly in terms of translation quality, measured by automatic evaluation metric scores. Batches of data selected from out-of-domain corpora are incrementally added to an existing baseline system and evaluated in terms of translation quality on a development set. A batch is selected only if its inclusion improves translation quality. To assist the process, we present a novel translation model merging technique that allows rapid retraining of the translation models with incremental data. When incorporated into the 'in-domain' translation models, the final cumulatively selected datasets are found to provide statistically significant improvements for a number of different supplementary datasets. Furthermore, the translation model merging technique is found to perform on a par with state-of-the-art methods of phrase-table combination.

1 Introduction

Statistical Machine Translation (SMT) has grown to be the most dominant machine translation paradigm. A prerequisite for SMT is the availability of sizeable parallel training data. The popularity of SMT has led to the free availability of a variety of parallel corpora on the web. While some such corpora comprise data from wide-coverage domains such as politics or news, others are based on much more focused and narrower domains such as medical texts or software manuals. In order to create an SMT system for a specific domain which does not have sufficient parallel training data, domain adaptation methods are necessary to best utilise supplementary parallel training data from available out-of-domain or related-domain corpora. However, the conventional wisdom of more data being better does not always hold true for domain-specific systems (Axelrod et al., 2011). Adding a lot of out-of-domain data to an in-domain SMT system tends to overwhelm the in-domain characteristics, thereby negatively affecting translation quality. Thus relevant data selection from large supplementary out-of-domain data plays an important part in domain adaptation of SMT systems.

In this paper we focus our efforts on creating an SMT system for translating user-generated forum content in Symantec web forums. Being a multinational company, Symantec supports web forums for its products and services in multiple languages with the English forum being both the oldest and (by far) the largest with considerable amounts of relevant information. Translating the forum content enables this information to be available across all languages. Moreover, these forums have also become effective sources of self-service, thus providing an alternative to traditional customer service options (Roturier and Bensadoun, 2011). However, a major challenge in building a system for forum content translation is the lack of parallel forum data for training. To overcome this challenge, we utilise 'in-domain' (but 'out-of-style') parallel training data in the form of Symantec translation memories (TMs). Symantec TMs comprise internal documentation on its products and services along with user manuals, product descriptions and some customer service communications. The forum data on the other hand, consists of posts where customers and Symantec employees discuss and solve specific problems pertaining to specific products and services. Although the TM and the forum data are in the same domain, the TM data is professionally edited and generally conforms to Symantec's controlled language guidelines. By contrast, the forum data is often noisy, not controlled by any quality guidelines and in general having a wider vocabulary and colloquialisms. This difference between the training data and target domain necessitates the use of supplementary datasets to improve translation quality.

Given the TM-based domain-specific baseline model and an additional general-domain supplementary dataset, we iteratively select batches of sentences from the supplementary dataset and add this to the in-domain translation model of the baseline system and evaluate the translation quality in terms of automatic evaluation metrics on a development set (devset). A batch is approved for addition to the baseline model only upon improvement over the baseline evaluation metric scores. In order to incrementally and rapidly retrain and evaluate the evolving translation models with each additional batch of sentences, a translation model is estimated for each batch under consideration in isolation and subsequently merged with the larger translation model using a novel phrase-table merging mechanism.

Prior to the iterative batch selection process, the supplementary training data is ranked using perplexity (normalised with sentence length) with respect to a source-side forum data language model. This technique allows the selection of batches of sentence pairs from the supplemen-

tary data with perplexity scores within a close range. Our experiments are conducted for the English–French (En–Fr) and English–German (En–De) language pairs. We use three different freely available parallel corpora as supplementary sources of data. Our experiments show that the selected supplementary datasets when incorporated into the baseline translation model consistently improve translation quality over the baseline translations, for different supplementary data sources. Comparing our data selection method with existing data selection approaches confirms the superiority of our approach in terms of translation quality improvements. In addition to the data selection, we develop a phrase table merging technique as an efficient alternative to established methods of model combination. We compare our technique of model combination to the traditional approach of static retraining, use of multiple translation models (Koehn and Schroeder, 2007) as well as mixture modelling with linear interpolation (Foster and Kuhn, 2007) to find that our technique performs at par with most of these techniques in terms of translation quality.

While the translation quality based data selection technique performs well in the experiments presented in this paper, there is a risk that the approach may overfit on the small devsets used (small devsets are a typical situation in real-life domain adaptation scenarios). In particular, this can happen if the set is not 'fully' representative of the target domain in question. Hence the evaluation during the iterative data selection phase should ideally be carried out for multiple devsets and the intersection of selected datasets from each run should be used. However generating multiple devsets for a given target domain (here user forums) is prohibitively expensive involving considerable manual effort. To alleviate this issue, the source data of the devset selected for the set of experiments reported here, is randomly chosen from a large collection of the target domain data and is ensured to be truly representative of the the target domain in terms of meta-statistics.[1] Furthermore, due care is taken during the manual translation process to preserve the characteristics of the target domain.

The rest of the paper is organized as follows: Section 2 reviews related work relevant to the task. Section 3 introduces our approach of data selection and phrase-table merging. Section 4 presents the experimental setup for our and comparative approaches. Section 5 presents the results and analysis followed by conclusions and future work.

2 Related Work

The idea of supplementary data selection from related or unrelated domains to boost the performance of sparse 'in-domain' models has been widely practised in domain adaptation of SMT (Eck et al., 2004). A wide variety of criteria for data selection has been explored ranging from information retrieval techniques (Hildebrand et al., 2005) to perplexity or cross-entropy on 'in-domain' datasets (Foster and Kuhn, 2007; Banerjee et al., 2011). Out-of-vocabulary (OOV) words with respect to training data (Daume III and Jagarlamudi, 2011; Banerjee et al., 2012) are used to mine supplementary data sources for adaptation. (Axelrod et al., 2011) presents a technique of using the difference in cross-entropy of the supplementary sentence pairs on 'in-domain' and 'out-of-domain' datasets for ranking and selection by thresholding. All these techniques rely on selecting supplementary data based on its similarity with the target domain using different measures of similarity like perplexity or OOV word rate. However, perplexity reduction often does not correlate with translation quality improvement (Axelrod, 2006). In this paper we address this issue head-on by directly using translation quality as a

[1]The parameters used are average sentence length, average type-token ratio, average stop word and function word ratio and the standard deviations of the same measures.

guide for data selection. To the best of our knowledge this is a novel approach and one of the main contributions of the paper.

In order to facilitate incremental retraining, we develop a phrase-table merging mechanism that is used to incrementally merge small phrase-tables estimated on incremental batches of supplementary dataset. Incremental updates of translation models have been attempted using a stepwise online expectation-maximization algorithm (Cappé and Moulines, 2009) for stream-based translation models (Levenberg et al., 2010) or using suffix arrays (Callison-Burch et al., 2005) to store the source–target alignments in memory. Our approach differs from these methods primarily in how we update translation model probabilities. The domain-specific aspect of our experimental setup allows us to avoid costly incremental alignment estimations. Furthermore, our approach enables merging independent translation models estimated on different domain-specific word/phrase alignments providing an alternative to other model combination techniques. While simple concatenation of in-domain and out-domain data prior to (re-) training is a commonly used (but costly) technique, multiple phrase-tables (one on each domain) can directly be combined using the decoder (Koehn and Schroeder, 2007), or interpolated using linear or log-linear weighted combination using mixture modelling (Foster and Kuhn, 2007). Our phrase-table merging technique is motivated by the linear interpolation based approach, but differs in our use of phrase-counts to merge multiple phrase-pairs.

3 Incremental Data Selection and Model Merging

This section describes in detail our data selection method and the phrase-table merging technique developed for incremental model updates.

3.1 Batching Sentence Pairs in Supplementary Data

The primary objective of our experiments is to identify the sentence pairs in the 'out-of-domain' supplementary datasets which when incorporated into the 'in-domain' model would improve translation performance. Ideally, for every sentence pair in the supplementary datasets, a new translation model needs to be retrained and its performance evaluated in terms of evaluation metrics. A sentence is suitable for selection only when its inclusion improves the translation quality of the baseline system. However, to manage the scaling issue of this approach, instead of evaluating individual sentence pairs, we group a number of them together in every iteration. In addition, updating any sizeable SMT model with a single sentence pair is unlikely to produce any measurable changes in overall translation output. The supplementary datasets are initially ranked according to their normalised perplexity with respect to a language model estimated on the English user forum dataset. In every iteration, for each batch we pick up a set of sentence pairs whose perplexity lies within a small predefined range (to be supplied by the user as input). For our experiments we use an ad-hoc value of 1 for the range although a further detailed investigation on the effect of the range size on data selection is planned for future. Since perplexity is used as a measure of 'closeness' with respect to the target domain, all pairs in the selected batch have perplexity within a small range (with a value of 1) ensuring uniform closeness of all sentences within the batch with respect to the target domain.

3.2 Selection Algorithm

To decide whether a particular batch of supplementary sentence pairs is suitable for improving translation quality, we use the process outlined in Algorithm 1. The algorithm starts with a baseline translation model BL, a baseline translation score sc_0, a perplexity range r and

Algorithm 1 Supplementary data batch selection for translation performance improvement

Require: $BL \leftarrow$ Baseline Model, $sc_0 \leftarrow$ Baseline Score, $sup \leftarrow \{pp_i, src_i, trg_i\}$, $r \leftarrow$ Perplexity Range;

1: $itn \leftarrow 1$; $step \leftarrow r$;
2: $b_{itn} \leftarrow \{\}$; $i \leftarrow 1$;
3: **while** $not(EOF(sup))$ **do**
4: **if** $pp_i \leq step$ **then**
5: $b_{itn} \leftarrow b_{itn} \cup \{src_i, trg_i\}$; $i = i + 1$;
6: **else**
7: $model_{itn} \leftarrow train\_model\{b_{itn}\} \cup BL$;
8: $sc_{itn} = evaluate\_on\_dev\{model_{itn}\}$;
9: **if** $sc_{itn} \geq sc_0$ **then**
10: $BL \leftarrow model_{itn}$; $sc_0 \leftarrow sc_{itn}$;
11: **end if**
12: $itn = itn + 1$;
13: $step \leftarrow step + r$; $b_{itn} \leftarrow \emptyset$
14: **end if**
15: **end while**

a supplementary dataset comprising source and target sentence pairs along with perplexity scores. Source and target sentence pairs are batched into a group (lines 4-6) as long as their perplexity values fall below the specified range. Once the batch is selected, a new translation model is trained on the batch and the batch model is merged with the baseline model to generate an updated model $model_{itn}$ (line 7). The updated model is then used to evaluate the devset using automatic evaluation metrics (line 8) and generate a new translation score sc_{itn}. The algorithm tests if the new score is better than the previous baseline score (line 9) and if found better updates the baseline model and score with the current model and score value in the iteration. Eventually the perplexity range is extended to the next step, and the batch is cleared for accommodating the next batch of sentences (line 13). This process runs as long as there are no more batches to process. Selected batches are accumulated to produce the final supplementary dataset used for adaptation. Since the batches are ordered according to perplexity-based similarity with respect to the target domain the algorithm makes it increasingly harder for a batch to get into the final selection as (i) later batches are less similar to the targeted domain and (ii) they need to improve on a steadily improving baseline. Therefore the algorithm implements the intuition that only those parts of generic supplementary data are selected which are good enough to generate better translation quality on the devset.

A generic SMT system is usually comprised of three different statistical components: translation model (TrM), language model (LM) and a lexical reordering model (RoM). Algorithm 1 is general enough to handle updates in all these component models. However, in this paper we only report experiments with TrM and RoM model updates and use statically trained LMs (cf. Section 3.5)

3.3 Phrase-table Merging

Ideally for every iteration step, the selected batch of supplementary sentence pairs should be combined with the 'in-domain' training data of the baseline model and a new model should be estimated. Considering the computational cost involved in full retraining, clearly this is not feasible in an iterative framework. In order to facilitate an incremental approach we develop a

set of techniques to avoid full retraining by estimating a model only on the small incremental batch and then merging the models with the existing baseline models.

Word alignment estimation is the most computationally expensive process in TrM training. Thus in order to avoid re-estimation of word-alignments in every iteration, we once and for all pre-compute the word alignments on the entire supplementary dataset and use this in every iteration. This not only reduces the estimation overhead but also addresses the issue of having poor word alignments due to small amounts of parallel data in every iteration. Word-alignments are known to benefit from domain-specific over-fitting (Gao et al., 2011) which motivated us to keep our 'in-domain' (computed on Symantec TM data) and 'out-domain' (computed on supplementary dataset) word alignments separate from each other. Hence the phrase-pairs extracted for each domain (Symantec TMs or Supplementary Datasets) are only based on domain-specific word alignments estimated from the specific corpora.

To achieve lexical table merging, the standard tables are augmented with the source and target word counts (in addition to lexical probabilities). Once new lexical tables are created on the selected batch, the baseline lexical tables are scanned for shared entries and the corresponding probabilities are updated using the formulae in (1):

$$\begin{aligned} lex_{merged}(e|f) &= lex_{bl}(e|f) \times \frac{wc_{bl}(f)}{wc_{bl}(f)+wc_{inc}(f)} + lex_{inc}(e|f) \times \frac{wc_{inc}(f)}{wc_{bl}(f)+wc_{inc}(f)} \\ lex_{merged}(f|e) &= lex_{bl}(f|e) \times \frac{wc_{bl}(e)}{wc_{bl}(e)+wc_{inc}(e)} + lex_{inc}(f|e) \times \frac{wc_{inc}(e)}{wc_{bl}(e)+wc_{inc}(e)} \end{aligned} \tag{1}$$

where $lex_{bl}, wc_{bl}, lex_{inc}$ and wc_{inc} indicate the baseline lexical probability, baseline word count, incremental lexical probability and incremental word count, respectively. e and f indicate the source and target words in this context. Entries which are not shared between the base model and the batch lexical tables are simply added to the new merged lexical table. Equation 1 approximates the lexical probabilities which would result from full retraining.

Once the lexical tables have been updated, the phrase-table estimation is completed on the batch data using the merged lexical tables. Being estimated on the merged lexical table, the inverse and direct lexical weights are already up-to-date in the new phrase-table. Hence only the remaining probabilities and counts require updates. In a similar approach to the lexical table merging, every entry in the new (incremental) batch phrase-table, is compared against the older (baseline) phrase-table and the shared phrase pairs are updated by the formulae in (2):

$$\begin{aligned} \phi_{merged}(e|f) &= \phi_{bl}(e|f) \times \frac{c_{bl}(f)}{c_{bl}(f)+c_{inc}(f)} + \phi_{inc}(e|f) \times \frac{c_{inc}(f)}{c_{bl}(f)+c_{inc}(f)} \\ \phi_{merged}(f|e) &= \phi_{bl}(f|e) \times \frac{c_{bl}(e)}{c_{bl}(e)+c_{inc}(e)} + \phi_{inc}(f|e) \times \frac{c_{inc}(e)}{c_{bl}(e)+c_{inc}(e)} \end{aligned} \tag{2}$$

where $\phi_{bl}, c_{bl}, \phi_{inc}$ and c_{inc} indicate the baseline phrase translation probability, baseline phrase count, incremental phrase translation probability and incremental phrase count, respectively. e and f indicate the source and target phrases in the context. Entries which are not shared are simply copied to the merged phrase-table. Again the updates applied to the inverse and direct translation probabilities (in equation 2) are motivated by the aim to approximate the probabilities which would ideally have been generated by full retraining.

Using these merging techniques, we are able to efficiently merge the smaller incremental models to the larger baseline models to simulate the full retraining effect. Also since the actual training only happens on the smaller batches of selected data, it is computationally much faster than full retraining at every step. Note that (1) and (2) ensure that the updated lex_{merged} and ϕ_{merged} are true probabilities such that the conditions $0 \leq lex_{merged} \leq 1$ and $0 \leq \phi_{merged} \leq 1$ hold true and both probabilities sum up to 1.

3.4 Reordering Model Merging

While the basic idea behind phrase-table merging could also be applied to the re-ordering model, we choose a simpler option for re-ordering model updates. Once a new reordering model is computed on the selected batch of supplementary data, every entry is compared to the baseline reordering table, and only new entries are added to it to generate a merged RoM. For the shared entries the reordering probabilities are retained as in the baseline model. Not only does this allow faster merging of reordering models but also ensures that for common entries 'in-domain' reordering is preferred over the 'out-of-domain' ones.

3.5 Language Models

As already stated, we use statically trained LMs for all our experiments. We use 5-gram models with modified Kneser-Ney smoothing (Kneser and Ney, 1995) and interpolated back-off. With such models adding a single n-gram into an existing model affects the probability and back-off values of all n-grams in the model. Hence incremental merging of LMs can not be achieved as easily as in the case of TrMs. Accordingly, in the current experiments we use statically estimated interpolated LMs. Three different 5-gram LMs are estimated on monolingual German and French forum data, the target side of the entire TM data and supplementary datasets, respectively. We then combine them using linear interpolation. The interpolation weights are estimated by running expectation maximization (EM) (Dempster et al., 1977) on the target side of the devset.

4 Experimental Setup

In this section, we introduce the datasets, tools and software used in our experiments. We also present the experimental setups for comparing our data selection and model merging technique with established techniques in the literature.

4.1 Datasets

The training data for our baseline systems consists of En–De and En–Fr bilingual datasets in the form of Symantec TMs. Monolingual Symantec forum posts in German and French along with the target side of the TM training data serve as language modelling data. In addition, we also have about 1.1M monolingual sentences from the English forum data which is used to create the LM with respect to which the supplementary datasets are ranked. The dev and testsets are randomly selected from this English forum dataset, ensuring that they are representative of the forum data in terms of different statistics, and manually translated by professional translators. Table 1 reports the number of sentences in the different datasets along with the average sentence length (A.S.L.) used for all our experiments.

Apart from the 'in-domain' training data, we also used the following three freely available parallel corpora as supplementary datasets for our experiments.

1. Europarl (Koehn, 2005) version 6: a parallel corpus comprising of the proceedings of the European Parliament.
2. News Commentary Corpus: released as a part of the WMT 2011 Translation Task.[2]
3. OpenSubtitles2011 Corpus:[3] a collection of documents released as part of the OPUS corpus (Tiedemann, 2009).

Table 1: Number of sentences and A.S.L. for training, dev and testsets, and target language forum datasets.

4.2 Software and Tools

The SMT system used in our experiments is based on the standard phrase-based SMT toolkit: Moses (Koehn et al., 2007). Word alignment is performed with Giza++ (Och and Ney, 2003) using the 'grow-diag-final' heuristic. The lexical, phrase and reordering tables are built on the word alignments using the Moses training scripts. The standard training scripts are modified to augment the count information in the lexical tables. The maximum phrase-length is set to 7. The automatic metric used to evaluate translation quality in the incremental setup is BLEU (Papineni et al., 2002), although the selection algorithm is general enough to accommodate any other evaluation metric. The feature weights for the log-linear combination of the features are tuned using Minimum Error Rate Training (MERT) (Och, 2003) on the devset in terms of BLEU. For the LMs used in each of our models, we used the IRSTLM (Federico et al., 2008) language modelling toolkit for estimation as well as for the linear interpolation weight computation. In order to merge interpolated weights into a single LM, we used the weighted mixing mechanism provided by SRILM (Stolcke, 2002). Once the LMs are estimated, they are binarized using KenLM (Heafield, 2011) to ensure faster multi-threaded access during the decoding phase. Finally, translations of the testsets in every phase of our experiments are evaluated using the BLEU and TER (Snover et al., 2006) metrics.

4.3 Experiments

The primary objective of the experiments is relevant data selection from supplementary parallel training data for domain adaptation. In order to evaluate the effect of our data selection technique, we compare our method with established methods in the literature. Additionally we also compare existing mechanisms to combine the selected data with the 'in-domain' data.

4.3.1 Baseline

Prior to running the incremental data selection experiments, the baseline TrMs were estimated on the 'in-domain' (Symantec TMs) datasets. The standard Moses training scripts were modified to augment the actual word counts to the existing lexical table format. The scoring mechanism of Moses was adjusted to handle the variation in the lexical table formats. This modified version of the training scripts was then used to estimate the baseline TrM only on the Symantec TM data. Three different interpolated LMs were estimated using the technique reported in Section 4.2 each with the target side of different supplementary datasets. For experiments with a particular

supplementary dataset, we used the respective interpolated LM as the baseline for fair comparison. Therefore, the baseline for each set of experiments (for every supplementary dataset) had the same TrM but different LMs. The Giza++ alignments for each of the supplementary datasets were pre-computed and used in the iterative setup.

4.3.2 Data Selection Experiments

To evaluate the quality of our data selection approach we compare the following four data selection techniques:

1. Full: The naive approach of using the full data for adaptation.
2. PP: Data selection by ranking the supplementary data using normalised perplexity with respect to the target domain and thresholding (Foster and Kuhn, 2007).
3. PPD: Using difference in cross-entropy between in-domain and out-domain datasets to rank supplementary data followed by thresholding (Axelrod et al., 2011).
4. TQS: Translation quality-based data selection (cf. Section 3).

In order to rank the supplementary dataset sentences by normalised perplexity (PP), we used a LM trained on the English forum data as the target-domain LM. For each sentence on the source side of the supplementary dataset, its perplexity is computed on the target-domain LM. Perplexity is found to have a strong correlation with the sentence length and hence we normalize the perplexity values by sentence length. Once the perplexity values are computed, they are sued to sort the sentences thereby ensuring that the sentences which are closest to the target domain appear at the top. The data selection is performed by selecting the top N sentences from this ranked corpus. The value of N is set by the number of sentences selected using our TQS method for fair comparison.

Following the technique presented in (Axelrod et al., 2011), the difference of cross-entropy based ranking (PPD) requires an out-of-domain LM in addition to the existing in-domain LM. An out-domain LM is built on a randomly selected sub-sample of the supplementary training data having the same number of sentences and the same vocabulary as the in-domain LM. A similar set of in-domain and out-domain language models are also built on the target language side using the German and the French forum datasets for in-domain LMs and random samples from supplementary datasets as the out-of-domain LMs. Eventually each supplementary data sentence is ranked according to the difference in cross-entropy with respect to the in-domain and out-of-domain LMs summed over both the source and the target languages. Like in the case of PP, the sentences are sorted by these scores and the lowest scoring sentences are selected. However in contrast to the previous case, this ranking biases towards the sentences which are both like the in-domain sentences and unlike the average of out-of-domain sentences.

The sentences selected using our translation quality-based technique (TQS) are selected in batches using the approach described in Section 3.2. In order to speed up the translation process in the iterative framework, we utilise the multi-threaded feature of the Moses decoder. Furthermore, the merged phrase-table and the reordering models were filtered using the source side of the devset to reduce memory requirements as well as ensure faster decoding. While the other two ranking techniques require the selection of a thresholding value to select an appropriate subset of the supplementary data for adaptation, our technique is designed to automatically select a subset of the same. Therefore we use the number of sentences selected by TQS methods as the thresholding value for PP and PPD selection schemes.

4.3.3 Data Combination Experiments

Once the supplementary data is selected, this data needs to be combined with the in-domain training data for adaptation. In addition to the naive approach of concatenating the selected data to the in-domain datasets and retraining the model, we investigate three configurations of model combination based on existing methods in the SMT literature.

1. Conc: The naive approach of concatenating the selected data with the in-domain data and retraining the SMT model (Foster et al., 2010).
2. Multiple phrase-table (MPT): Creating separate phrase-tables for the in-domain and the selected data and using the multiple decoding path feature of the Moses decoder (Koehn and Schroeder, 2007).
3. Linear Interpolation (LinMix): Using a weighted linear interpolation to combine the individual phrase-tables (Foster and Kuhn, 2007).
4. PTM: Using the phrase-table merging technique reported in this paper.

In the concatenation approach (Conc), the selected supplementary data is added to the in-domain training data and a new TrM is retrained from scratch. This model is then tuned using the devset and finally tested using the testset to reveal the effect of adaptation. The Multiple phrase-table (MPT) approach requires training separate phrase-tables on the in-domain and selected data and combining them using the multiple decoding feature of the Moses decoder. The decoder uses both phrase-tables to score each of the translation options during the decoding phase. The phrase pairs which occur in both the phrase-tables are separately scored using their respective phrase-tables. In the linear interpolation approach (linmix) the two phrase-tables are combined using weights in a linear interpolation scheme. In order to learn the interpolation weights, LMs are constructed on the target side of the in-domain training set and the selected supplementary data. These LMs are then interpolated using EM on the target side of the devset to learn the optimal mixture weights. These weights are subsequently used to combine the individual feature values for every phrase pair from two phrase-tables using the formula in (3).

$$p_{linmix}(s|t) = \lambda p_{in}(s|t) + (1-\lambda)p_{out}(s|t) \tag{3}$$

where $p_{in}(s|t)$ and $p_{out}(s|t)$ are the feature values of individual phrase pairs from the in-domain and out-of-domain phrase-tables, respectively. λ is the tunable weight between 0 and 1.

The phrase-table merging (PTM) technique outlined in Section 3 was developed to rapidly combine incremental and baseline TrMs to aid our iterative data selection method. However, here we use it as an alternative technique to combine the in-domain and out-of-domain phrase-tables. While the basic idea behind this technique is similar to that of linear interpolation, in our technique each feature is weighted according to its frequency in the respective phrase-tables in contrast to using a global weight for every feature in LinMix. Following model combination, all the models are tuned using MERT on the devset.

5 Results and Analysis

As stated in Section 4.2, the incremental data selection process is performed by evaluating translation quality in terms of BLEU scores on the devset data. Table 2 reports the baseline scores, the best scores and the number of sentences selected during the process of incremental data selection on the devset. Alongside the number of selected sentences, the percentage figures indicate the proportion of the selected sentences with respect to the entire size of the supplementary datasets as reported in Table 1. Note that the BLEU scores reported in this table

are all non-MERT scores and the supplementary data was combined with the baseline model using the PTM method.

Lang-Pair	Model	Europarl		Open-Subtitles		News-Commentary	
		BLEU	Sent #	BLEU	Sent #	BLEU	Sent #
En–De	Baseline	22.97	663,127	22.94	1,464,798	22.91	15,473
	Best	*__24.17__	38.51%	*__24.33__	31.51%	*__23.34__	11.39%
En–Fr	Baseline	31.33	571,736	31.72	1,705,273	31.16	52,797
	Best	*__31.85__	31.60%	*__32.77__	13.66%	__31.43__	45.88%

Table 2: BLEU scores on devset using incremental TrM updates and number of sentences selected.$*$ indicates statistically significant improvement at p$\leq$0.05, best scores are in bold.

The scores in Table 2 clearly show the improvements observed on the devset for both language pairs across all supplementary datasets. While the improvements obtained using the Europarl (EP) and Open-Subtitles (OPS) corpora are statistically significant at the p=0.05 level using bootstrap resampling (Koehn, 2004) for both language pairs, the News-Commentary (NC) corpus only provides significant improvement for En–De translations. Compared to the improvements obtained on the other two sets, NC improvements are much lower, which could be attributed to the smaller size of the corpus and hence consequentially the smaller size of the selected dataset. As already stated in Section 4.3.2, the number of selected sentences as reported in Table 2 for each supplementary dataset is used as the threshold values for data selection for the PP and PPD ranking methods.

5.1 Data Selection Results

The primary objective of our approach being data selection from supplementary sources, we first report the results of our data selection methods in comparison to the other data selection techniques described in Section 4.3.2. In this phase, the selected supplementary data is concatenated with the in-domain training data to train new TrMs which are then tuned using MERT on the devset. Table 3 reports the BLEU and TER scores for the different data selection techniques in addition to our own method.

	System	Europarl		Open-Subs.		News-Comm.	
		BLEU	**TER**	**BLEU**	**TER**	**BLEU**	**TER**

Table 3: Testset BLEU and TER scores using data selection methods. $*, \dagger, \ddagger, \S$ indicates statistically significant improvement in BLEU over baseline, PP, PPD and Full datasets, respectively.

The scores reported in Table 3 show that adding additional supplementary data to the in-domain TrMs improve translation quality scores over the baseline in nearly all cases (quality

only deteriorates over the baseline when the Full NC data is added to the En–Fr training data). The actual data selection methods (PP, PPD and TQS) provide improvements on the baseline scores as well as on the Full scores, indicating the success of the data selection process. Comparing the translation quality scores between PP, PPD and TQS, we observe that while the PPD scores are sightly better than the PP scores, the TQS method performs best, consistently improving over the other two data selection methods in terms of BLEU scores. Using EP as the supplementary corpus the TQS method provides improvements of 1.12 absolute (5.1% relative) and 1.71 absolute (5.37% relative) BLEU points over the baseline scores for En–De and En–Fr translations, respectively. With the OPS corpus, the improvement figures are 0.94 absolute (4.17% relative) and 1.04 absolute (3.2% relative) BLEU points for En–De and En–Fr translations, respectively. For the NC corpus, the method improves the baseline scores by 0.37 absolute (1.67% relative) and 0.74 absolute (2.33% relative) BLEU points for En–De and En–Fr translation, respectively. While the EP and OPS improvements are statistically significant at $p \leq 0.05$ level for both language pairs, for NC only the En–Fr improvement is statistically significant. Although the TQS method provides better scores than the PP and PPD methods on all counts, the differences are not statistically significant in most cases, except for En–Fr improvements using the EP dataset. However, when compared to the Full scores, the TQS method provides statistically significant improvements for nearly all the cases.

5.2 Data Combination Results

The results reported in Table 3 use the Conc approach (cf. Section 4.3.3) to combine the additional data to the in-domain dataset. However, combining in-domain and out-domain datasets using this approach may not always lead to the best results as is evident from the literature (Foster and Kuhn, 2007; Banerjee et al., 2011). Hence in the second phase we compare the translation quality achieved by using the different combination methods explained in Section 4.3.3. Since the data selected by the TQS method was the best-performing dataset using the BLEU scores as per Table 3, we report the results of the different data combination experiments on this particular set only. Table 4 reports the effect of different data combination methods on translation score using data selected by the TQS method.

	System	Europarl		Open-Subs.		News-Comm.	
		BLEU	TER	BLEU	TER	BLEU	TER
En–De	Conc	23.10	0.6190	23.50	0.6122	22.47	0.6292
	MPT	23.15	**0.6134**	23.25	0.6145	21.75	0.6349
	PTM	23.17	0.6161	23.78	0.6116	22.58	0.6270
	LinMix	**23.23**	0.6161	∗†**23.80**	**0.6092**	†**22.66**	**0.6249**
En–Fr	Conc	33.58	0.5410	33.56	0.5424	32.56	0.5503
	MPT	33.31	0.5418	33.34	0.5456	32.20	0.5453
	PTM	33.30	0.5473	33.71	**0.5360**	32.66	**0.5324**
	LinMix	**33.75**	**0.5391**	†**33.84**	0.5398	†**32.79**	0.5494

Table 4: Testset BLEU and TER scores using data combination methods. $*, \dagger, \ddagger$ indicates statistically significant improvement in BLEU over Conc,MPT, and PTM methods, respectively.

The translation quality scores in Table 4 confirm our assumption that concatenation is not always the best option to combine multiple datasets. The results show weighted linear interpolation to be the best-performing system for different datasets and language pairs. However, the difference in the evaluation scores between the different combination techniques are mostly

statistically insignificant. MPT is found to work better than Conc in some of the cases (for EP datasets in En–De and En–Fr) but in most cases is poorer than all the other methods. Weighted linear interpolation is known to work well in multi-domain phrase-table combination (Banerjee et al., 2011) and our experiments confirm the observation. Interestingly, using our phrase-table merging method (PTM) for model combination seems to work reasonably well for all the different datasets and language pairs. While it does not perform the best, it certainly performs at par with the other combination techniques experimented with, the differences being statistically insignificant in all cases.

Using the MPT configuration has a major advantage over the Conc approach in keeping the in-domain and out-domain phrase-tables separate. While this can really be an effective choice in some cases, this model has larger number of parameters which are difficult to optimize using MERT (Chiang et al., 2009). The linear interpolation mechanism avoids the large parameter setting by combining features from multiple tables into a single table. However, this requires the estimation of the interpolation weights and it is not very straightforward to optimize the linear weights directly in terms of translation quality. While the LinMix method uses global weights for all phrase pairs, the PTM method uses different weights based on the frequency of occurrence in each corpora. This avoids the problem of linear interpolation weight optimization as well as the large parameter setting. In our experimental setting, this method slightly underperforms with respect to LinMix, but the difference is statistically insignificant.

5.3 Combining Data Selection and Model Combination

The results in Table 4 clearly indicate that linear interpolation of phrase-tables provides the best scores among different data combination techniques at least for the datasets under consideration. Hence in the final phase we present the results on different data selection methods using linear interpolated mixture models as the combination technique in Table 5

	System	Europarl		Open-Subs.		News-Comm.	
		BLEU	**TER**	**BLEU**	**TER**	**BLEU**	**TER**
En–De	PP	22.96	0.6212	23.13	0.6117	22.33	**0.6237**
	PPD	23.05	0.6225	23.26	0.6188	22.41	0.6258
	Full	22.73	0.6219	22.83	0.6177	22.25	0.6319
	TQS	§**23.23**	**0.6161**	†‡§**23.80**	**0.6092**	**22.66**	0.6249
En–Fr	PP	33.00	0.5476	33.25	0.5412	32.41	0.5487
	PPD	33.29	0.5429	33.32	**0.5379**	32.62	**0.5481**
	Full	32.80	0.5467	33.01	0.5518	31.96	0.5558
	TQS	†§**33.75**	**0.5391**	†‡§**33.84**	0.5398	§**32.79**	0.5494

Table 5: Testset BLEU and TER scores with LinMix as combination method. †, ‡, § indicate statistically significant BLEU improvements over PP, PPD and Full scores.

Using linear interpolation to combine the models built on different datasets results in a more-or-less uniform improvement in all translation quality scores for all datasets and language directions when compared to the results in Table 3. The data selected using the TQS method provides statistically significant improvements over the baseline scores as well as those using the Full dataset. Furthermore, the TQS scores are now significantly better than the PP and PPD scores for the En–Fr translation on both EP and the OPS datasets and for the En–De translations on the OPS dataset. However, the improvements are still not statistically significant for the other datasets and language pair combinations.

The overall results in Tables 3 and 5 strongly suggest the success of data selection as an adaptation technique. While adding supplementary training data widens the coverage of the TrMs, thus reducing the number of untranslated words in the translations, it also provides richer lexical translation probabilities for some phrases and words which although present in the baseline models were sparsely represented. Furthermore, we have empirically shown that our translation quality based data selection method consistently outperforms perplexity ranking-based data selection approaches. While the TQS method directly uses translation quality to select supplementary sentences, the PP and PPD methods rely on the perplexity or cross-entropy for the same task. Since perplexity or cross-entropy have low correlation with actual translation quality, sentences selected using such techniques are not guaranteed to improve translation quality. In contrast the TQS method only selects groups of sentences which improve translation quality, which is our overall objective. Hence, while using the PP or the PPD method all the top sentences from the supplementary data are chosen, the TQS method discards a few of the top batches as they fail to improve translation quality on the devset in the iterative framework.

Conclusion and Future Work

In this paper we have introduced a novel method for supplementary data selection for domain adaptation of SMT systems. Sentence pairs are selected incrementally in batches from the supplementary out-of-domain bitext data and added to the baseline system and evaluated in terms of BLEU scores on a devset. A batch is selected only if it results in improved BLEU scores. Once all the batches in a supplementary dataset are processed, the batches that pass the selection are combined to produce the selected parallel data for domain adaptation. The data selected using this method is found to outperform other existing data selection methods in terms of translation quality on an unseen testset and for a number of supplementary datasets. Additionally we also present a phrase-table merging technique that is developed to facilitate iterative data selection. This technique is effectively used to combine multiple phrase-tables from different domains and performs on a par with other existing techniques in the field. Our experiments also show that data selection is an effective adaptation technique for translating user-generated content using TM based training data. Moreover, the relative comparison of different model or data combination strategies reveals that concatenating supplementary data to existing in-domain data may not always yield the best results and is outperformed by a linear interpolation approach.

Extending the concept of iterative incremental training to LMs is one of the prime future directions for this work. Further investigation into methods to avoid the overfitting issue is also necessary. Finally, some analysis on the effect of batch size on translation quality in an iterative setting would also be an interesting future direction. Furthermore, the phrase-table merging technique could effectively be utilised for incremental training of TrMs.

ABSTRACT

Detecting text reuse is a fundamental requirement for a variety of tasks and applications, ranging from journalistic text reuse to plagiarism detection. Text reuse is traditionally detected by computing similarity between a source text and a possibly reused text. However, existing text similarity measures exhibit a major limitation: They compute similarity only on features which can be derived from the *content* of the given texts, thereby inherently implying that any other text characteristics are negligible. In this paper, we overcome this traditional limitation and compute similarity along three characteristic dimensions inherent to texts: *content*, *structure*, and *style*. We explore and discuss possible combinations of measures along these dimensions, and our results demonstrate that the composition consistently outperforms previous approaches on three standard evaluation datasets, and that text reuse detection greatly benefits from incorporating a diverse feature set that reflects a wide variety of text characteristics.

TITLE AND ABSTRACT IN GERMAN

Erkennung von Textwiederverwendung durch Komposition von Textähnlichkeitsmaßen

Die Frage, ob und in welcher Weise Texte in abgewandelter Form wiederverwendet werden, ist ein zentraler Aspekt bei einer Reihe von Problemstellungen, etwa im Rahmen journalistischer Tätigkeit oder als Mittel zur Plagiatserkennung. Textwiederverwendung wird traditionell ermittelt durch Berechnen von Textähnlichkeit zwischen einem Ursprungstext und einem potentiell wiederverwendeten Text. Bestehende Textähnlichkeitsmaße haben jedoch die starke Einschränkung, dass sie Ähnlichkeit nur anhand von Eigenschaften berechnen, die vom *Inhalt* der gegebenen Texte abgeleitet werden können, und somit implizieren, dass jegliche andere Textcharacteristika vernächlässigbar sind. In dieser Arbeit berechnen wir Textähnlichkeit anhand von drei Dimensionen: *Inhalt*, *Struktur* und *Stil*. Wir untersuchen mögliche Kombinationen von Maßen entlang dieser Dimensionen, und zeigen deutlich anhand der Ergebnisse auf drei etablierten Evaluationsdatensätzen, dass die Komposition generell bessere Ergebnisse liefert als bestehende Ansätze, und dass die Bestimmung von Textwiederverwendung stark von einem breiten Spektrum an Textcharacteristika profitiert.

KEYWORDS: text similarity, text reuse, plagiarism, paraphrase.
KEYWORDS IN GERMAN: Textähnlichkeit, Textwiederverwendung, Plagiat, Paraphrase.

Proceedings of COLING 2012: Technical Papers, pages 167–184,

1 Introduction

Text reuse is a common phenomenon and arises, for example, on the Web from mirroring texts on different sites or reusing texts in public blogs. In other text collections such as content authoring systems of communities or enterprises, text reuse arises from keeping multiple versions, copies containing customizations or reformulations, or the use of template texts (Broder et al., 1997).

Problems with text reuse particularly arise in settings where systems are extensively used in a collaborative manner. For example, *wikis* are web-based, collaborative content authoring systems which offer fast and simple means for adding and editing content (Leuf and Cunningham, 2001). At any time, users can modify content already present in the wiki, augment existing texts with new facts, ideas, or thoughts, or create new texts from scratch. However, when users contribute to wikis, they need to avoid content duplication. This requires comprehensive knowledge of what content is already present in the wiki, and what is not. As wikis are traditionally growing fast, this is hardly feasible, though. To remedy this issue, we aim at supporting authors of collaborative text collections by means of automatic text reuse detection. We envision a semi-supervised system that informs a content author of potentially pre-existing instances of text reuse, and then lets the author decide how to proceed, e.g. to merge both texts.

Detecting text reuse has been studied in a variety of tasks and applications, e.g. the detection of journalistic text reuse (Clough et al., 2002), the identification of rewrite sources for ancient literary texts (Lee, 2007), or the analysis of text reuse in blogs and web pages (Abdel-Hamid et al., 2009). Another common instance of text reuse is plagiarism, with the additional constraint that the reuse needs to be unacknowledged. Near-duplicate detection is also a broad field of related work where the detection of text reuse is crucial, e.g. in the context of web search and crawling (Hoad and Zobel, 2003; Henzinger, 2006; Manku et al., 2007). Prior work, however, mainly utilizes fingerprinting and hashing techniques (Charikar, 2002) for text comparison rather than methods from natural language processing.

A common approach to text reuse detection is to compute similarity between a source text and a possibly reused text. A multitude of text similarity measures have been proposed for computing similarity based on surface-level and/or semantic features (Mihalcea et al., 2006; Landauer et al., 1998; Gabrilovich and Markovitch, 2007). However, existing similarity measures typically exhibit a major limitation: They compute similarity only on features which can be derived from the *content* of the given texts. By following this approach, they inherently imply that the similarity computation process does not need to take any other text characteristics into account.

In contrast, we propose that text reuse detection indeed benefits from also assessing similarity along other text characteristics (*dimensions*, henceforth). We follow empirical evidence by Bär et al. (2011) and focus on three characteristic similarity dimensions inherent to texts: *content*, *structure*, and *style*. Figure 1 shows an example of text reuse taken from the Wikipedia Rewrite Corpus (see Section 3.1) where parts of a given source text have been reused either verbatim or by using similar words or phrases. As the example illustrates, the process of creating reused text includes a revision step in which the editor has a certain degree of freedom on how to reuse the source text. This kind of similarity is detectable by content-centric text similarity measures. However, the editor has further split the source text into two individual sentences and changed the order of the reused parts. For detecting the degree of similarity of such a revision, text similarity measures for *structural similarity* are necessary. Additionally, the given texts exhibit a certain degree of similarity with respect to stylistic features, e.g. vocabulary richness.[1] In

[1]The type-token ratio (Templin, 1957) of the texts is .79 and .71, respectively.

Source Text. *PageRank is a link analysis algorithm used by the Google Internet search engine that assigns a numerical weighting to each element of a hyperlinked set of documents, such as the World Wide Web, with the purpose of "measuring" its relative importance within the set.*

Text Reuse. *The PageRank algorithm is used to designate every aspect of a set of hyperlinked documents with a numerical weighting. It is used by the Google search engine to estimate the relative importance of a web page according to this weighting.*

Figure 1: Example of text reuse taken from the Wikipedia Rewrite Corpus (Clough and Stevenson, 2011). Various parts of the source text have been reused, either verbatim (underlined) or using similar words or phrases (wavy underlined). However, the editor has split the source text into two individual sentences and changed the order of the reused parts.

order to use such features as indicators of text reuse, we propose to further include measures of *stylistic similarity*.

In this paper, we thus overcome the traditional limitation of text similarity measures to *content* features. In contrast, we adopt ideas of seminal studies by cognitive scientists (Tversky, 1977; Goodman, 1972; Gärdenfors, 2000) and discuss the role of three similarity dimensions for the task of text reuse detection: *content*, *structure*, and *style*, as proposed in our previous work (Bär et al., 2011). In Section 2, we report on a multitude of text similarity measures from these dimensions that we used for our experiments. In Section 3, we demonstrate empirically that text reuse can be best detected if measures are combined across dimensions, so that a wide variety of text characteristics are taken into consideration. Our approach consistently outperforms previous work on three standard evaluation datasets, and demonstrates the advantage of integrating text characteristics other than *content* into the similarity computation process.

2 Text Similarity Measures

In this section, we report on a variety of similarity measures which we used to compute similarity along characteristic dimensions inherent to texts.[2] We classify them into measures for *content similarity*, *structural similarity*, and *stylistic similarity*, as proposed by Bär et al. (2011).

2.1 Content Similarity

Probably the easiest way to reuse text is verbatim copying. It can be detected by using string measures which operate on substring sequences. The *longest common substring* measure (Gusfield, 1997) compares the length of the longest contiguous sequence of characters between two texts, normalized by the text lengths. However, the editorial process in journalistic text reuse or the attempt to obfuscate copying in plagiarism may shorten the longest common substring considerably, e.g. when words are inserted or deleted, or parts of reused text appear in a different order. The *longest common subsequence* measure (Allison and Dix, 1986) drops the contiguity requirement and allows to detect text reuse in case of word insertions/deletions. *Greedy String Tiling* (Wise, 1996) further allows to deal with reordered parts of reused text as it determines a set of shared contiguous substrings between two given documents, each substring thereby being a match of maximal length. A multitude of other string similarity measures have been proposed which view texts as sequences of characters and compute their degree of

[2] In addition, we release an open-source framework which contains implementations of all discussed measures in order to stimulate the development of novel measures: `http://code.google.com/p/dkpro-similarity-asl`

distance according to a given metric. We used the following measures in our experiments: *Jaro (1989)*, *Jaro-Winkler* (Winkler, 1990), *Monge and Elkan (1997)*, and *Levenshtein (1966)*.

Starting from the observation that not all words in a document are of equal importance, we further employed a similarity measure which weights all words by a *tfidf* scheme (Salton and McGill, 1983) and computes text similarity as the cosine between two document vectors.

Comparing *word n-grams* (Lyon et al., 2001) is a popular means for comparing lexical patterns between two texts. The more similar the patterns, the more likely is it that text reuse has occurred. After compiling two sets of n-grams, we compared them using the Jaccard coefficient, following Lyon et al. (2001), as well as using the containment measure (Broder, 1997). We tested n-gram sizes for $n = 1, 2, \ldots, 15$, and will use the original system name *Ferret* (Lyon et al., 2004) to refer to the variant with $n = 3$ using the Jaccard coefficient, henceforth.

Following the idea of comparing lexical patterns, we also used a measure which has not yet been considered for assessing content similarity: *character n-gram profiles* (Keselj et al., 2003).[3] We follow the implementation by Barrón-Cedeño et al. (2010) and discard all characters (case insensitive) which are not in the alphabet $\Sigma = \{a, \ldots, z, 0, \ldots, 9\}$, then generate all n-grams on character level, weight them by a *tfidf* scheme, and finally compare the feature vectors of both the rewritten and the source text using the cosine measure. While in the original implementation only $n = 3$ was used, we generalize the measure to $n = 2, 3, \ldots, 15$.

In cases where the editor replaced content words by synonyms, string measures typically fail due to the vocabulary gap. We thus used similarity measures which are capable of measuring semantic similarity between words. We used the following word similarity measures with WordNet (Fellbaum, 1998): *Jiang and Conrath (1997)*, *Lin (1998)*, and *Resnik (1995)*. In order to scale these pairwise word similarity scores to the document level, we follow the aggregation strategy by Mihalcea et al. (2006): First, a directional similarity score $sim_d(T_i, T_j)$ is computed from a text T_i to a second text T_j (Eq. 1). Therefore, for each word w_i in T_i, its best-matching counterpart in T_j is sought ($maxSim(w_i, T_j)$). The similarity scores of all these matches are summed up and weighted according to their inverse document frequency *idf* (Spärck Jones, 1972), then normalized. The final document-level similarity figure is the average of applying this strategy in both directions, from T_i to T_j and vice-versa (Eq. 2).

$$sim_d(T_i, T_j) = \frac{\sum_{w_i} maxSim(w_i, T_j) \cdot idf(w_i)}{\sum_{w_i} idf(w_i)} \quad (1) \qquad sim(T_i, T_j) = \frac{1}{2}\Big(sim_d(T_i, T_j) + sim_d(T_j, T_i)\Big) \quad (2)$$

We also tested text expansion mechanisms with the semantic word similarity measures described above: We used the Moses SMT system (Koehn et al., 2007), trained on Europarl (Koehn, 2005), to translate the original English texts via a bridge language (Dutch) back to English. Thereby, the idea was that in the translation process additional lexemes are introduced which alleviate potential lexical gaps. We computed pairwise word similarity with the measures described above and aggregated according to Mihalcea et al. (2006).

Furthermore, we used the statistical technique *Latent Semantic Analysis (LSA)* (Landauer et al.,

[3] Traditionally, character n-gram profiles have rather been shown successful for authorship attribution. However, the similarity scores of word n-grams and those of character n-gram profiles are highly correlated: Assuming 5 characters per word on average for English texts (Shannon, 1951), we set $n = 3$ for word n-grams and $n = 15$ for character n-grams, and computed Pearson's correlation r between the corresponding similarity scores. We obtained $r = .93$ and $r = .86$ on the datasets introduced in Sections 3.1 and 3.2, respectively, and thus conclude that this measure captures *content similarity* rather than *stylistic similarity*.

1998) for comparing texts. The construction of the semantic space was done using the evaluation corpora (see Section 3). We also used the vector space model *Explicit Semantic Analysis* (ESA) (Gabrilovich and Markovitch, 2007). Besides WordNet, we used two additional lexical-semantic resources for the construction of the ESA vector space: Wikipedia[4] and Wiktionary[5].

2.2 Structural Similarity

As discussed above, we presume that content similarity alone is not a reliable indicator of text reuse. Two independently written texts about the same topic are likely to make use of a common vocabulary to a certain extent. We thus propose to also use measures of structural similarity which compute similarity based on structural aspects inherent to the compared texts.

Stopword n-grams (Stamatatos, 2011) are based on the idea that text reuse often preserves syntactic similarities while exchanging content words. Thus, the measure removes all content words while preserving only stopwords. All n-grams of both texts are then compared using the containment measure (Broder, 1997). We tested n-gram sizes for $n = 2, 3, \ldots, 15$.

For the same reason, we also included *part-of-speech n-grams* in our feature set. Disregarding the actual words that appear in two given texts, computing n-grams along part-of-speech tags allows to detect syntactic similarities between these texts. Again, we tested n-gram sizes for $n = 2, 3, \ldots, 15$, and compared the two sets using the containment measure (Broder, 1997).

We also employed two similarity measures between pairs of words (Hatzivassiloglou et al., 1999). The *word pair order* measure assumes that a similar syntactical structure in reused texts may cause two words to occur in the same order in both texts (with any number of words in between). The complementary *word pair distance* measure counts the number of words which lie between those of a given pair. For each measure, we computed feature vectors for both texts along all shared word pairs and compared the vectors using Pearson's correlation.

2.3 Stylistic Similarity

Measures of stylistic similarity adopt ideas from authorship attribution (Mosteller and Wallace, 1964) or use statistical properties of texts to compute text similarity. The *type-token ratio (TTR)* (Templin, 1957), for example, compares the vocabulary richness of two texts. However, it suffers from sensitivity to variations in text length and the assumption of textual homogeneity (McCarthy and Jarvis, 2010): As a text gets longer, the increase of tokens is linear, while the increase of types steadily slows down. In consequence, lexical repetition causes the TTR value to vary, while it does not necessarily entail that a reader perceives changes in the vocabulary usage. Secondly, textual homogeneity is the assumption of the existence of a single lexical diversity level across a whole text, which may be violated by different rhetorical strategies. *Sequential TTR* (McCarthy and Jarvis, 2010) alleviates these shortcomings. It iteratively computes a TTR score for a dynamically growing text segment until a point of saturation – i.e. a fixed TTR score of .72 – is reached, then starts anew from that position in the text for a new segment. The final lexical diversity score is computed as the number of tokens divided by the number of segments.

Inspired by Yule (1939) who discussed sentence length as a characteristic of style, we also used two simple measures, *sentence length* and *token length*, in our system. These measures compute the average number of tokens per sentence and the average number of characters per token.

Table 1: Performance of selected similarity measures on the Wikipedia Rewrite Corpus, the METER Corpus, and the Webis Crowd Paraphrase Corpus, grouped by similarity dimension

Additionally, we compared the average sentence and token lengths between the reused text and the original source. We refer to these measures as *sentence ratio* and *token ratio*, respectively.

Finally, we compare texts by their *function word frequencies* (Dinu and Popescu, 2009) which have shown to be good style indicators in authorship attribution studies. Following the original work, this measure uses a set of 70 function words identified by Mosteller and Wallace (1964) and computes feature vectors of their frequencies for each possibly reused document and the source text. The comparison of the vectors is then performed using Pearson's correlation.

3 Experiments & Results

We utilized three datasets for the evaluation of our system which originate in the fields of plagiarism detection, journalistic text reuse detection, and paraphrase recognition: the **Wikipedia Rewrite Corpus** (Clough and Stevenson, 2011), the **METER Corpus** (Gaizauskas et al., 2001), and the **Webis Crowd Paraphrase Corpus** (Burrows et al., 2012), described below.

We carried out the same evaluation procedure for each of the three datasets: First, we computed text similarity scores between all pairs of possibly reused texts and their original sources using all the measures introduced in Section 2. We then used these scores as features for two machine learning classifiers in order to combine them across the three dimensions *content*, *structure*, and *style*. We experimented with two classifiers from the WEKA toolkit (Hall et al., 2009): a Naive Bayes classifier and a C4.5 decision tree classifier (J48 implementation).

In a 10-fold cross-validation setup, we ran three sets of experiments as follows: (i) First, we tested only the text similarity scores of one single measure at a time as single feature for the classifiers, in order to determine the individually best-performing measures per similarity

dimension. (ii) We then combined the measures per dimension by using multiple text similarity scores as feature set, in order to determine the performance of multiple measures within a single dimension. (iii) Finally, we combined the measures across dimensions to determine the best overall configuration. We compare our results with two baselines: the majority class baseline and the word trigram similarity measure *Ferret* (Lyon et al., 2004) (see Section 2.1). Additionally, we report the best results from the literature for comparison.

Evaluation was carried out in terms of accuracy and $\bar{F}_1$ score. By accuracy, we refer to the number of correctly predicted texts divided by the total number of texts. As the class distributions in both datasets are skewed, we report the overall $\bar{F}_1$ score as the arithmetic mean across the F_1 scores of all classes in order to account for the class imbalance.

3.1 Wikipedia Rewrite Corpus

Dataset The dataset contains 100 pairs of short texts (193 words on average). For each of 5 questions about topics of computer science (e.g. "What is dynamic programming?"), a reference answer (*source text*, henceforth) has been manually created by copying portions of text from a suitable Wikipedia article. Text reuse now occurs between a source text and an answer given by one of 19 participants. The participants were asked to provide short answers, each of which should comply to one of 4 rewrite levels and hence reuse the source text to a varying extent. According to the degree of rewrite, the dataset is 4-way classified as *cut & paste* (38 texts; simple copy of text portions from the Wikipedia article), *light revision* (19; synonym substitutions and changes of grammatical structure allowed), *heavy revision* (19; rephrasing of Wikipedia excerpts using different words and structure), and *no plagiarism* (19; answer written independently from the Wikipedia article). An example of a *heavy revision* was given in Figure 1.

Results We summarize the results on this dataset in Table 2.[8] In the best configuration, when combining similarity measures across dimensions, our system achieves a performance of

[6] Chong et al. (2010) report $\bar{F}_1 = .698$ in their original work. This figure, however, reflects the *weighted* arithmetic mean over all four classes of the dataset where one class is twice as prominent as each of the others. As dicussed in Section 3, we report all $\bar{F}_1$ scores as the *unweighted* arithmetic mean in order to account for the class imbalance.

[7] While we were able to reproduce the results of the *Ferret* baseline as reported by Chong et al. (2010), our re-implementation of the system by Clough and Stevenson (2011) (Naive Bayes classifier, same feature set) resulted in a much lower overall performance. We observed the largest difference for the *longest common subsequence* measure, even though we used a standard implementation (Allison and Dix, 1986) and normalized as described by Clough and Stevenson (2011).

[8] Figures in italics are taken from the literature, while we (re-)implemented the remaining systems. This applies to all result tables in this paper.

Table 3: Results of the best combinations of text similarity measures within and across dimensions on the Wikipedia Rewrite Corpus

$\bar{F}_1 = .811$. It outperforms the best reference system by Clough and Stevenson (2011) by 5.4% points in terms of $\bar{F}_1$ score compared to their reported numbers, and by 15.3% points compared to our re-implementation of this system[7]. Their system uses a Naive Bayes classifier with only a very small feature set: *word n-gram containment* ($n = 1, 2, \ldots, 5$) and *longest common subsequence*. For comparison, we re-implemented their system and also applied it to the two datasets in the remainder of this paper. We report our findings in Sections 3.2 and 3.3.

In Table 1, we further report the detailed results for a selected set of individual text similarity measures, listed by similarity dimension.[9] Due to space limitations, we only report a selected set of best-performing measures per dimension and compare them with the baselines: While the majority class baseline performs very poor on this dataset ($\bar{F}_1 = .143$), the *Ferret* baseline achieves $\bar{F}_1 = .517$. Some content similarity measures such as *word 2-grams containment* show a reasonable performance ($\bar{F}_1 = .683$), while structural measures cannot exceed $\bar{F}_1 = .554$, and stylistic measures perform only slightly better than the majority class baseline ($\bar{F}_1 = .296$).

In Table 3, we report the best results for the combinations of text similarity measures within and across dimensions. When we combine the measures within their respective dimensions, *content* outperforms structural and stylistic similarity. However, all combinations of measures across dimensions in addition to content similarity improve the results. The best performance is achieved by combining the three similarity measures *longest common subsequence*, *stopword* 10-*grams*, and *character* 5-*gram profiles* from the two dimensions *content* and *structure*. This supports our hypothesis that the similarity computation process indeed profits from dimensions other than *content*. The effects of dimension combination held true regardless of the classifier used, even though the decision tree classifier performed consistently better than Naive Bayes.

Error Analysis We present the confusion matrix for our best configuration in Table 2. In total, 15 texts out of 95 have been classified with the wrong label. While all texts except a single one in the class *no plagiarism* have been classified correctly, 67% of errors (10 texts) are due to misclassifications in the *light* and *heavy revision* classes. We assume that these errors are due to questionable gold standard annotations as the annotation guidelines for these two classes are highly similar (Clough and Stevenson, 2011). For the *light revision* class, the annotators "could alter the text in some basic ways", thereby "altering the grammatical structure (i.e. paraphrasing)." Likewise, for the *heavy revision* class, the annotation manual expected the

[9]Table 1 also lists the detailed results for the METER Corpus and the Webis Crowd Paraphrase Corpus. We will discuss the numbers in the corresponding Sections 3.2 and 3.3.

annotators to "rephrase the text to generate an answer with the same meaning as the source text, but expressed using different words and structure."

As each text of this dataset was written by only a single person for a given rewrite category, we decided to conduct an annotation study, in which we were mostly interested in the inter-rater agreement of the subjects. We asked 3 participants to rate the degree of text reuse and provided them with the original annotation guidelines. We used a generalization of Scott's (1955) π-measure for calculating a chance-corrected inter-rater agreement for multiple raters, which is known as Fleiss' (1971) κ and Carletta's (1996) K.[10] In summary, the results[11] of our study support our hypothesis that the annotators mostly disagree for the *light* and *heavy revision* classes, with fair[12] agreements of $\kappa = .34$ and $\kappa = .28$, respectively. For the *cut & paste* and *no plagiarism* classes, we observe moderate[12] agreements, $\kappa = .53$ and $\kappa = .56$, respectively.

Based on these insights, we decided to fold the *light* and *heavy revision* classes into a single class *potential plagiarism*. This approach was also briefly discussed by Clough and Stevenson (2011), though not carried out in their work. We report the corresponding results and the confusion matrix in Table 4. As the classification task gets easier by the reduction to three classes, the results for the Ferret baseline improve, from $\bar{F}_1 = .517$ to $\bar{F}_1 = .745$. The re-implementation of the system by Clough and Stevenson (2011) achieves $\bar{F}_1 = .788$. Our system again outperforms all other systems with $\bar{F}_1 = .859$.

In our envisioned semi-supervised application scenario, potentially reused texts are presented to users in an informative manner. Here, fine-grained distinctions are not necessary, and we decided to go even one step further and fold all potential cases of text reuse. This variant of the dataset results in a binary classification of plagiarized/non-plagiarized texts. We present

[10] An exhaustive discussion of inter-rater agreement measures is given by Artstein and Poesio (2008).

no reuse	20	**52**

Table 6: Results and confusion matrix for the best classification on the METER Corpus

the results and the corresponding confusion matrix in Table 5. In this simplified setting, even the Ferret baseline achieves an excellent performance of $\bar{F}_1 = .935$. Our approach still slightly outperforms ($\bar{F}_1 = .967$) the re-implementation of the system by Clough and Stevenson (2011).

An interesting observation across all three variants of the dataset is that the same three texts always constitute severe error instances where e.g. a *cut & paste* text is falsely labeled as *no plagiarism*, which is more severe than mislabeling a *light revision* as a *heavy revision*. Two of the three cases account for the texts which describe the PageRank algorithm. One of these instances was falsely labeled as *cut & paste* while it is non-plagiarized, and the other one vice-versa. We attribute the misclassifications to the model built up in the classifier's training phase.

In the envisioned semi-supervised setting, the remaining less severe error instances, where e.g. a *light revision* was classified as a *heavy revision*, can be reviewed by a user of the system. We suppose it is even hard for users to draw a strict line between possibly reused and non-reused texts, as this heavily depends on external effects such as user intentions and the task at hand.

3.2 METER Corpus

Dataset The dataset contains news sources from the UK Press Association (PA) and newspaper articles from 9 British newspapers that reused the PA source texts to generate their own texts. The complete dataset contains 1,716 texts from two domains: law & court and show business. All newspaper articles have been annotated whether they are *wholly derived* from the PA sources (i.e. the PA text has been used exclusively as text reuse source), *partially derived* (the PA text has been used in addition to other sources), or *non-derived* (the PA text has not been used at all).

Several newspaper texts, though, have more than a single PA source in the original dataset where it is unclear which (if not all) of the source stories have been used to generate the rewritten story. However, for text reuse detection it is important to have aligned pairs of reused texts and source texts. Therefore, we followed Sánchez-Vega et al. (2010) and selected a subset of texts where only a single source story is present in the dataset. This leaves 253 pairs of short texts (205 words on average). We further followed Sánchez-Vega et al. (2010) and folded the annotations to a binary classification of 181 *reused* (wholly/partially derived) and 72 *non-reused* instances in order to carry out a comparable evaluation study.

Results We summarize the results on this dataset in Table 6. In the best configuration, our system achieves an overall performance of $\bar{F}_1 = .768$. It outperforms the best reference system by Sánchez-Vega et al. (2010) by 6.3% points in terms of $\bar{F}_1$ score. Their system uses a Naive Bayes classifier with two custom features which compare texts based on the length and frequency of common word sequences and the relevance of individual words. As in Section 3.1, we further report the detailed results for a selected set of individual text similarity measures

Text Similarity Dimension	Acc.	$\bar{F}_1$

Structure + Style	.767	.739
Content + Structure + Style	**.802**	**.768**

Table 7: Results of the best combinations of text similarity measures within and across dimensions on the METER Corpus

in Table 1. From these figures, we learn that many text similarity measures cannot exceed the simple majority class baseline ($\bar{F}_1 = .417$) when applied individually.

In Table 7, we show that the performance of text reuse detection always improves over individual measures (cf. Table 1) when we combine the measures within their respective dimensions. An exception is the combination of structural similarity measures, which only performs on the same level as the best individual measure *part-of-speech* 3-*grams containment*. Combinations of content similarity measures show a better performance than combinations of structural or stylistic measures. Our system achieves its best performance on this dataset when text similarity measures are combined across all three dimensions *content*, *structure*, and *style*. The best configuration resulted from using a Naive Bayes classifier with the following measures: *Greedy String Tiling*, *stopword* 12-*grams*, and *Sequential TTR*. As for the previous dataset, the effects of dimension combination held true regardless of the classifier used.

The influence of the stylistic similarity measures is particularly interesting to note. In contrast to the Wikipedia Rewrite Corpus, including these measures in the composition improves the results on this dataset: Our classifier is able to detect similarity even for reused texts by expert journalists. This is due to the fact that a journalistic text which reuses the original press agency source most likely also shows stylistic similarity in terms of e.g. vocabulary richness.

Error Analysis We present the confusion matrix for our best configuration in Table 6. In total, 50 texts out of 253 have been classified incorrectly: 30 instances of text reuse have not been identified by the classifier, and 20 non-reused texts have been mistakenly labeled as such. However, the original annotations have been carried out by only a single annotator (Gaizauskas et al., 2001) which may have resulted in subjective judgments. Thus, as for the previous dataset in Section 3.1, we conducted an annotation study with three annotators to gain further insights into the data. The results[11] show that for 61% of all texts the annotators fully agree. The chance-corrected Fleiss' (1971) agreement $\kappa = .47$ is moderate[12].

For the 30 instances of text reuse which have not been identified by the classifier, it is particularly interesting to note that many errors are due to the fact that a lower overall text similarity between the possibly reused text and the original source does not necessarily entail the label *no reuse*. The newspaper article about the English singer-songwriter Liam Gallagher, for example, is originally labeled as text reuse. However, our classifier falsely assigned the label *no reuse*. It turns out, though, that the reused text is about four times as long as the original press agency source, with lots of new facts being introduced there. Consequently, only a low similarity score

can be computed between the additional material in the newspaper article and the original source, and the overall similarity score decreases.

We conclude that applications will benefit from an improved classifier which better deals with theses instances. For example, similarity features could be computed per section, not per document, which would allow to also identify potential instances of text reuse for only partially matching texts. The currently achieved performance (see Table 6) of text reuse detection, though, is sufficient for our envisioned semi-supervised application scenario where content authors are provided only with suggestions of potential instances of text reuse and then are free to decide how to proceed, e.g. to merge both texts. The final decision probably also depends on external factors such as user intentions and the task at hand.

3.3 Webis Crowd Paraphrase Corpus

Dataset The dataset was originally introduced as part of the PAN 2010 international plagiarism detection competition (Potthast et al., 2010). It contains 7,859 pairs of original texts along with their paraphrases (28 to 954 words in length) with 4,067 (52%) positive and 3,792 (48%) negative samples. The original texts are book excerpts from Project Gutenberg[14], and the corresponding paraphrases were acquired in a crowdsourcing process using Amazon Mechanical Turk (Callison-Burch and Dredze, 2010). In the manual filtering process[15] of all acquired paraphrases, Burrows et al. (2012) hereby follow the paraphrase definition by Boonthum (2004), where a *good* paraphrase exhibits patterns such as synonym use, changes between active and passive voice, or changing word forms and parts of speech, and a *bad* paraphrase is rather e.g. a (near-)duplicate or an automated one-for-one word substitution. This definition implies that a more sophisticated interpretation of text similarity scores needs to be learned, where e.g. (near-)duplicates with very high similarity scores are in fact negative samples.

Results We summarize the results on this dataset in Table 8. Even though the Ferret baseline is a strong competitor ($\bar{F}_1 = .789$), our approach achieves the best results on this dataset with $\bar{F}_1 = .852$. The results reported by Burrows et al. (2012) are slightly worse ($\bar{F}_1 = .837$). Their best score was achieved by using a k-nearest neighbor classifier with a feature set of 10 similarity measures. They exclusively used similarity measures that operate on the texts' string sequences and thus capture the content dimension of text similarity only, e.g. *Levenshtein (1966)* distance and a *word n-gram* similarity measure. As in the previous sections, we report the detailed results for a selected set of individual text similarity measures in Table 1. These figures show that

[14] `www.gutenberg.org`

[15] Burrows et al. (2012) do not report any inter-annotator agreements for the filtering process, as the task was split across two annotators and each text pair was labeled by only a single annotator.

Text Similarity Dimension	Acc.	$\bar{F}_1$
Combinations within dimensions		
Content	.840	.839
Structure	.816	.814
Style	.819	.817
Combinations across dimensions		
Content + Style	.844	.843
Content + Structure	.838	.838
Structure + Style	.831	.830
Content + Structure + Style	**.853**	**.852**

Table 9: Results of the best combinations of text similarity measures within and across dimensions on the Webis Crowd Paraphrase Corpus

regardless of the similarity dimension many measures achieve a very reasonable performance when applied individually, with the measures *Greedy String Tiling* and *word 2-grams containment* performing best.

As for the previous datasets, our hypothesis holds true that the combination of similarity dimensions improves the results: When we combine the similarity features within each of the respective dimensions, the performance numbers increase (see Table 9 as compared to Table 1). The combination of content similarity measures is stronger than the combination of structural and stylistic similarity measures, and performs on the same level as the original results reported by Burrows et al. (2012). This is to be expected, as their system uses a feature set which also addresses the content dimension exclusively.

When we combine measures across dimensions, the results improve even further. An exception is the combination of content and structural measures, which performs slightly worse than content measures alone due to the lower performance of structural measures on this dataset. The best configuration of our system resulted from combining all three dimensions *content*, *structure*, and *style* in a single classification model using the decision tree classifier, resulting in $\bar{F}_1 = .852$. The final feature set contains 16 text similarity features which are listed in Table 10.

Error Analysis We present the confusion matrix for our best classification in Table 8. In total, 1,172 (15%) out of 7,859 text pairs have been classified incorrectly. Out of these, our classifier mistakenly labeled 759 instances of negative samples as true paraphrases, while 413 cases of true paraphrases were not recognized. However, in our opinion the 759 false positives are less severe errors in our envisioned semi-supervised application setting, as user intentions and the current task at hand may highly influence a user's decision to consider texts as reused or not.

In general, we attribute the errors to the particular properties of this dataset, which differ from those of the Wikipedia Rewrite Corpus and the METER Corpus (see Sections 3.1 and 3.2). For those two datasets, the more similar two texts are, the higher their degree of text reuse. For the Webis Crowd Paraphrase Corpus, however, a different interpretation needs to be learned by the classifier: Here, (near-)duplicates and texts with automated word-by-word substitutions, which will receive high similarity scores by any of our content similarity measures, are in fact annotated as *bad* paraphrases, i.e. negative samples. Unrelated texts, empty samples, or texts alike also belong to the class of negative samples. In consequence, positive samples are only those in the medium similarity range. We assume that the more elaborate definition of positive and negative cases makes it more difficult to learn a proper model for the given data.

Content	ESA (WordNet, with + w/o stopwords), Greedy String Tiling, Jaro, Longest Common Substring, Longest Common Subseq. (2 norm.), n-gram Jaccard ($n = \{6, 14, 15\}$), Resnik (SMT wrapper)
Structure	Lemma Pair Ordering, POS 2-grams Jaccard, Stopword 6-grams
Style	Function Word Frequencies, Sequential TTR, Token Ratio

Table 10: Feature set used to achieve the best results on the Webis Crowd Paraphrase Corpus

4 Conclusions and Future Work

The motivation for this work stemmed from the hypothesis that *content* features alone are not a reliable indicator for text reuse detection. As illustrated in Figure 1, a reused text may also contain modifications such as split sentences, changed order of reused parts, or stylistic variance. We thus devised an architecture which composes diverse text similarity measures in a supervised classification model. In this model, we overcome the traditional limitation of text similarity measures to *content* features and compute similarity along three characteristic dimensions inherent to texts: *content*, *structure*, and *style*.

We evaluated our classification model on three standard datasets where text reuse is prevalent and which originate in the fields of plagiarism detection, journalistic text reuse detection, and paraphrase recognition: the *Wikipedia Rewrite Corpus* (Clough and Stevenson, 2011), the *METER Corpus* (Gaizauskas et al., 2001), and the *Webis Crowd Paraphrase Corpus* (Burrows et al., 2012). Based on the evaluation results, we discussed the influence of each of the similarity dimensions, and demonstrated empirically that text reuse can be best detected if measures are combined across dimensions, so that a wide variety of text features are taken into consideration. The composition consistently outperforms previous approaches across all datasets.

As we showed, similarity computation works best if the similarity dimensions are chosen well with respect to the type of text reuse at hand. For the Wikipedia Rewrite Corpus, for example, the stylistic similarity features perform only poorly, which is why the composition of all three dimensions performs slightly worse than than the combination of only content and structural features. For the other two datasets, however, stylistic similarity is a strong dimension within the composition, and consequently the best performance is reached when combining all three dimensions. Based on these insights, we conclude that for novel datasets it is essential to address the dimensions explicitly in the annotation process, so that text reuse detection approaches can be evaluated precisely against particular characteristics of different kinds of data.

For future work, we expect that considering a dimensional representation of text similarity features will also benefit any other task where text similarity computation is fundamental and which is yet limited to *content* features, e.g. paraphrase recognition or automatic essay grading. For the latter, we see great potential for improvements by including, for example, measures for grammar analysis, lexical complexity, or measures assessing text organization with respect to the discourse elements. However, each task exhibits particular characteristics which influence the choice of a suitable set of similarity dimensions. As discussed above, a particular dimension may or may not contribute to an overall improvement based on the nature of the data.

ABSTRACT

We describe an automatic paraphrase-inference procedure for a highly inflected language like Arabic. Paraphrases are derived from comparable documents, that is, distinct documents dealing with the same topic. A co-training approach is taken, with two classifiers, one designed to model the contexts surrounding occurrences of paraphrases, and the other trained to identify significant features of the words within paraphrases. In particular, we use morpho-syntactic features calculated for both classifiers, as is to be expected when working with highly inflected languages. We provide some experimental results for Arabic, and for the simpler English, which we find to be encouraging. Our immediate interest is to incorporate such paraphrases within an Arabic-to-English translation system.

KEYWORDS : Paraphrases, highly inflected languages, morphologically rich languages, co-training, comparable documents, Arabic

Proceedings of COLING 2012: Technical Papers, pages 185–200,
COLING 2012, Mumbai, December 2012.

1 Introduction

Paraphrases are pairs of sequences of words, both in the same language, that have the same meaning in at least some contexts. Given a text, "paraphrasing" is the act of generating an alternate sequence of words that conveys the same meaning. Since the meaning of a text is determined only when its context is given, paraphrases are sometimes referred to as "dynamic translations" or "semantic equivalents". Identifying paraphrases is an important capability for many natural language processing applications, including machine translation, as a possible workaround for the problem of limited coverage inherent in a corpus-based translation approach (Callison-Burch et al., 2006; Marton et el., 2009). Other applications of paraphrasing include automatic evaluation of summaries (Zhao et al., 2008) and question answering (Duboue and Chu-Carroll, 2006; Riezler et al., 2007).

There are two main directions of work on paraphrases that one can find in this field: investigating an automatic approach for uncovering paraphrases in a given corpus and using paraphrases to improve the performance of a specific task. In this paper, we introduce a novel method for extracting Arabic paraphrases from a corpus of comparable documents as part of our work on improving Arabic-to-English machine translation. *Comparable* documents are ones that deal with the same topic, such as two newspaper reports of the same event. The extraction technique is based on a learning method, known as "co-training" (Blum and Mitchel, 1998) and inspired by the work of Barzilay and McKeown (2001) for finding paraphrases in a parallel monolingual English corpus. In order to validate our technique, we have applied it also to a similar English corpus.

Like many other Semitic languages, Arabic is highly inflected; therefore, data sparseness becomes even more noticeable than in English and extracting paraphrases from a corpus turns out to be even more complicated. Arabic words are derived from a root and a pattern (template), combined with prefixes, suffixes and circumfixes. Using the same root with different patterns may yield words with different meanings. Words are inflected for person, number and gender; prefixes and suffixes are then added to indicate definiteness, conjunction, various prepositions and possessive forms. We will list some of the morpho-syntactic features we use for identifying paraphrases in the corpus. Based on the definition, paraphrases are identified as part of the context they are mentioned in within the corpus. Paraphrase is in fact only one of the semantic relations that can be identified to hold between two word sequences in their contexts; it can be seen as a special case of textual entailment (Dagan and Glickman, 2004), where each sequence entails the other.

There are several existing approaches for inferring paraphrases from a corpus, which differ from one another in the type of corpus they employ. Some require bilingual parallel corpora (Callison-Burch et al., 2006; Zhao et el., 2008), some need monolingual parallel corpora (Barzilai and McKeown, 2001), some need general monolingual corpora (Marton et al., 2009) and others need corpora of comparable documents (Rui and Callison-Burch, 2011; Dolan et al., 2004). Bilingual parallel corpora, pairing Arabic with languages other than English, are very hard to obtain. In this paper we take the last approach, leaving the other directions for future investigation.

Section 2 cites some related work. Our proposal is described in Section 3 with some experimental results reported in Section 4. Conclusions are given in the last section.

2 Related work

To the best of our knowledge, ours is the first work on paraphrasing in Arabic. In our previous work (Bar and Dershowitz, 2010), we extracted Arabic synonyms, that is, single-word paraphrases, using the English glosses provided by SAMA (Maamouri, 2010), along with WordNet for English (Fellbaum, 1998). The inferred synonyms were used to improve a corpus-based translation system. Salloum and Habash (2011) developed a rule-based algorithm for generating Modern Standard Arabic (MSA) paraphrases for dialectical Arabic phrases given to a statistics-based automatic translation system. They focused only on input phrases that do not exist in the translation table used by the translation system, for the purpose of improving its coverage. The MSA paraphrases were generated mostly using different morphological variations of the input words. They reported a slight improvement in BLEU score (Papineni, 2002) over a baseline system that does not use their generated paraphrases. In another work, by Denkowski et al. (2010), 726 Arabic paraphrases were manually generated and confirmed using Amazon's Mechanical Turk, from the NIST OpenMT 2002 development set (Garofolo, 2002). That was mainly done with the purpose of improving the evaluation of an English-to-Arabic machine translation system.

There are also related works in other languages. We only mention a few. Marton et al. (2009) found paraphrases to improve Spanish-to-English and English-to-Chinese statistical machine translation (SMT). For each phrase (as defined in SMT) that was left without a translation, they looked for it in a monolingual corpus and recorded the contexts in which it appeared. They modeled the contexts using a vector that captured phrase occurrences with their context words, and searched for other phrases with the most similar vector of occurrences to improve the translation. Callison-Burch et al. (2006) measured the effect of using paraphrases on Spanish-to-English and French-to-English SMT. They reported a significant improvement in coverage and in the final translation. The paraphrases were automatically extracted following the technique developed by Bannard and Callison-Burch (2005), using several parallel corpora of French and Spanish paired with other languages. This method is usually referred to as "pivoting". Both of these works claimed improvements in the translations. Callison-Burch (2008) and Zhao et al. (2008) developed this approach further by adding syntactic constraints to the extraction algorithms. In a recent work by Wang and Callison-Burch (2011), English paraphrases were found in a corpus of comparable documents. Similar to what we have done, they started with a large English corpus to find comparable documents. Those documents were used to find comparable sentences from which they extracted sub-sentential comparable fragments, that is, paraphrases. They used a chunker for finding linguistically safe boundaries for the fragments they extracted, and matched fragments based on the *n*-gram alignment method.

The most inspiring work for us is the one by Barzilay and McKeown (2001), in which paraphrases are extracted from a corpus containing multiple English translations of the same source. Using this type of corpus allow them to mark initial aligned anchors, chosen based on the results of an alignment algorithm, and to train a classifier to identify the best context environments surrounding potential paraphrases. Based on the resulting contexts, another classifier was trained for finding new paraphrases. This "co-training" process was repeated until no new paraphrases were extracted. In our work, we follow the same idea, implemented on Arabic. Since there is no monolingual parallel corpus available for Arabic, we created a corpus of comparable documents and used it as a resource for paraphrasing. Considering that Arabic is a

morphologically rich language, we incorporated morphological features of the surrounding words as well as the paraphrase patterns themselves.

3 Inferring paraphrases

3.1 Preparing the corpus

As just mentioned, our approach to inferring paraphrases is based on the work of Barzilay and McKeown (2001) on finding paraphrases in different English translations of the same source text. Understanding how powerful such a resource can be for paraphrasing, but finding no such resource for Arabic, we built a corpus of comparable documents, that is, distinct documents dealing with the same topic or event. This corpus was extracted from the Arabic Gigaword 4.0 (Parker, 2009), which contains newswire documents published by several news agencies, grouped by their publication date. Pairing documents, based on their topic, was done automatically using cosine similarity over the lemma-frequency vector of every document, with the lemma of every word extracted using MADA (Habash and Rambow, 2005; Roth et al., 2008). We considered candidates for document pairs only when they were published by different news agencies on the same day. For every document published by one agency, we pair it with a document from the agency that maximizes the similarity score over all the other documents published by the same agency on the same day. Not only that, we require that the score be higher than a predefined threshold that was set, in our experiment settings, to make sure that every candidate pair is composed of two documents sharing at least one third of the largest one. We also tried using lower thresholds for which we retrieved additional pairs; however, precision decreased linearly. It is obvious, then, that this approach prefers precision to recall; in other words, we probably miss a large number of potential candidates, while the candidates that we do extract are likely correct.

All together, we created 690 document pairs, comprising about half a million words. Our corpus of comparable documents was manually evaluated by two Arabic speakers. We randomly selected 120 document pairs out of the 690 and, for each, asked the evaluators for a simple "yes" or "no" answer to the question, "Do both documents discuss the same event?" The results are encouraging: out of the 120 pairs, 100 were classified as correct by both evaluators. Of the other 20 instances, 5 were classified "yes" by one evaluator. The rest of the pairs actually dealt with the same general domain but were not specifically discussing the same event. This positive evaluation allowed us to use this corpus in the next step of our inference technique.

Every document was pre-processed with AMIRAN before being given to the inference classifier, described in the next section. AMIRAN, an updated version of the AMIRA tools (Diab et al., 2004, 2007), is a tool for finding the context-sensitive morpho-syntactic information. AMIRAN combines AMIRA output with morphological analyses provided by SAMA. AMIRAN is also enriched with Named-Entity-Recognition (NER) class tags provided by (Benajiba et al., 2008). For every word, AMIRAN is capable of identifying the clitics, diacritized lemma, stem, full part-of-speech tag (excluding case and mood), base-phrase chunks and NER tags. The corpus is obviously not annotated with paraphrasing-related information and there is no alignment indication included at any level.

3.2 Inference technique

To infer new paraphrases from the corpus, we follow the "co-training" technique, training two different classifiers: one for modeling the context of a potential paraphrase and another for modeling the features of the paraphrase pattern itself. The main idea of the co-training approach applied to unlabeled data is to use the two classifiers on different views of the data. In our case, the two views are the context (CX) and the pattern (PT), with one classifier labeling the most reliable unlabeled data items for training the second classifier. Then, the second classifier can label some of the data items for training the first one. This process is repeated several times, and the labeled data collected during the entire run is returned. The algorithm runs in iterations; each iteration increases the number of words a potential paraphrase may contain, that is, in the first iteration only single-word paraphrases are allowed to be found, in the second one, paraphrases composed of up to two words are allowed, and so on. The input of the algorithm is the pairs of documents that we found on the previous section, from which we extract pairs of word sequences. A *pair of word sequences* is composed of two sequences, one from each of a pair of comparable documents. Since alignment at any level does not exist for comparable documents, we consider all the possible pairs of word sequences, given a pair of documents. To avoid too much noise, we restrict a word sequence for consideration to be composed of at least one non-function word and it to not break a base-phrase in the middle, similar to (Wang and Callison-Burch, 2011). Function words, in our case, are identified based on their part-of-speech and base-phrase tags, as provided by AMIRAN. Otherwise, a huge number of pairs containing only function words, not too important for paraphrasing, would be considered. The number of iterations, and concomitantly, the maximum length of the output sequences, is a parameter we control. As implied before, we start with single-word sequences and increase this parameter with every iteration. During the entire run of the algorithm, we maintain two sets of pairs of word sequences:

1. Labeled – containing pairs of word sequences with their label, "true" to indicate paraphrases and "false" to indicate that the word sequences are not paraphrases of each other. This set starts off empty.
2. Unlabeled – containing pairs of word sequences that are still waiting for their label assignment by the algorithm.

In every iteration, the algorithm performs the following steps:

1. deterministic labeling of potential paraphrases;
2. training the CX classifier using the labeled set as training data;
3. running CX on unlabeled pairs and labeling the most reliable ones;
4. training the PT classifier using the labeled set as training data;
5. running the PT classifier on the labeled set;
6. labeling some unlabeled pairs, based on the labels provided by both classifiers.

We now describe these steps in greater detail.

We cannot estimate in advance the weight of the selected features and their effect on the predictions of the classifiers; therefore, we chose to use support vector machine (SVM) classifiers (Vapnik and Cortes, 1995) because of their good generalization property. Technically, the classifiers are trained on the WEKA platform (Hall et al., 2009) running with the LibSVM library (Chang and Lin, 2011). One drawback of using SVM in this kind of setting is the long running

time of the training algorithm. Because we are running the trainer twice during every iteration, this drawback becomes even more pronounced.

The labeled pairs are used as training data for both classifiers, with every pair formatted as a feature vector. The features for the CX classifier capture some morpho-syntactic information expressed by the window-based context words. In the current experiment, we use a window of size three, that is, three words before each word sequence from the pair, and three words afterward. That gives us twelve words from which we extract features for representing a single pair and that number does not change during the entire learning process. Table 1 shows an example for a context.[1] The two main columns represent two Arabic sentences with their corresponding English translations, for easy reading. The emphasized texts are the actual paraphrases while the surrounding words are composing the context, which is described in the last row. In this case, the paraphrase pair is composed of a single identical lemma, inflected differently for person. The context of a paraphrase pair is composed of four parts: left and right words of each of the paired texts.

	Sentence 1	**Sentence 2**
Sentence	مكتب السنيورة وديوان ألمرط ينفيان خبرا عن لقاء في شرم الشيخ	مكتب السنيورة ينفي خبرا عن لقائه مسؤولين إسرائيليين
Transliteration	*mktb Alsnywrp wdywAn >wlmrt* ***ynfyAn*** *xbrA En lqA' fy $rm Al$yx*	*mktb Alsnywrp* ***ynfy*** *xbrA En lqA}h ms&wlyn <srA}ylyyn*
Translation	Seniora's office and the Olmert administration **deny** a story about a meeting in Sharm al-Sheikh	Seniora's office **denies** a story about his meeting with Israeli officials
Context	*Alsnywrp wdywAn >wlmrt* […] *xbrA En lqA'*	*mktb Alsnywrp* […] *xbrA En lqA}h*

TABLE 1 – An example for a context. The word sequence (here of size one) is highlighted in boldface.

The PT classifier makes its predictions based on the word sequences themselves; their number varies as the iteration number increases. For both classifiers, we use a quadratic kernel for capturing the common effect of all the features on prediction. Tables 2 and 3 summarize the features we currently use for building the feature vectors for the CX and PT classifiers, respectively. NER tags are assigned to persons, organizations, geo-political organizations and locations. The gloss-match rate is calculated for both sides of the context. In the example of Table 1, there is no word that matches on the left side (note that proper nouns usually do not have glosses). However, on the right side خبرا عن لقاء *xbrA En lqA'* ("a story about a meeting") matches خبرا عن لقائه *xbrA En lqA}h* ("a story about his meeting") with all three words on the gloss level; therefore, the left gloss-match rate is 0 and the right one is 1. The same calculation works with lemma-match rates on the lemma level. The morphological features we currently use in the PT classifier capture some common Arabic morphological variations. They are all Boolean values indicating whether the word expresses the feature or not. For example, the word وبكتابه *wbktAbh* ("and in his book") expresses conjunction, preposition and possessive. When working with Arabic, a highly inflected language, morphological features may contribute to the classification

[1] We use the Buckwalter transliteration scheme (Buckwalter, 2002) for rendering Arabic script in Romanization throughout this paper.

performance. We intend to further explore this direction in the future. The *n*-gram score is a simple language model score for capturing the co-occurrence of the candidate sequence words.

Feature	Description
Lemma, POS, NER, BP	of each context word
Gloss-match rate	The rate of gloss match on each side of the context (left and right)
Lemma-match rate	The rate of lemma match on each side of the context

TABLE 2 – The features we use for training the CX classifier on Arabic.

Feature	Description
n-gram score	Normalized *n*-gram frequency score for word sequences up to 4 words (2-4 grams)
POS, NER, BP	of each sequence word
Boolean morphological features (exists / does not exist): Conjunction, Possessive, Determiner and Prepositions	of each sequence word
Sequence length	The number of words in each sequence

TABLE 3 – The features we use for training the PT classifier on Arabic.

The first time one of the classifiers is trained, it needs some labeled items. With "co-training", those items are usually provided by manual annotation of a relatively small fraction of the data or, in this case, by using an automatic deterministic annotation algorithm. Therefore, in the first step of every iteration, the algorithm enriches the labeled set with additional "true" labeled pairs following a deterministic approach. Since it is very difficult to obtain a word or sentence-level alignment of two given comparable documents, our algorithm simply adds all the pairs whose word sequences match on the lemma level, word by word. If the lemma does not exist, we use the word's surface form for matching. Lengths of word sequences are determined by the iteration number, so in the first iteration only sequences of size 1 are added, in the second iteration sequences of size 2 are added, and so forth. Such a pair, matched on the lemma level, is shown in Table 1. Note that paraphrases work on the sense level, rather than on the surface form; however, our assumption is that, because we are using sequences from comparable documents, their senses may be the same with a reasonable high probability. Note that, since we are using the context-sensitive lemmas for matching, one can think of that as matching words on the sense level. However, AMIRAN was trained mostly with morpho-syntactic features and therefore achieves good performance in identifying the common lemma of a context-sensitive part-of-speech tag for every word. When a word may have two or more different lemmas for the same part-of-speech tag that have different senses, AMIRAN does not perform as well. For example, the word أمانة

>mAnp has three different noun lemmas: *>amAnap_1* (“faithfulness”), *>amAnap_2* (“secretariat”) and *>amAnap_3* (“deposit”).

That approach leaves us with some deterministically selected “true” examples; however, it does not provide us with the necessary “false” examples. In the first iteration, we consider word sequences of size 1 only. Our assumption is that word pairs sharing some of their senses in common may be considered paraphrases, thus cannot be naturally selected as “false” examples. Currently we use the English gloss of every word, as provided by AMIRAN, to select word pairs with different gloss values as “false” examples. Therefore, under this condition, the Arabic word pair مجال *mjAl* and منطقة *mnTqp* is not considered as a “false” example because they share the same gloss value: “area”. An alternative approach, which we plan to employ in the future, would be using Arabic WordNet (Black et al., 2006). It implies that, in our first iteration, only word pairs that have the same English gloss and not the same Arabic lemma are put in the unlabeled set. That dramatically reduces the amount of paraphrases of size one, better known as “synonyms”, that we can find. Since we are more interested in longer paraphrases, we can live with this limitation.

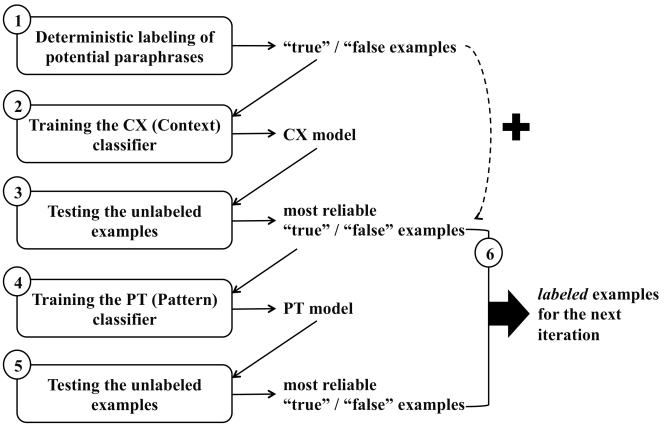

FIGURE 1 – An overview of the paraphrase inference co-training algorithm.

In subsequent iterations, “false” examples will be assigned automatically by the classifiers of the previous one, in the following way: after training the CX classifier in step 2, we use the classifier to tag the unlabeled pairs in step 3. Some pairs are assigned with the “true” label and some with “false”. Those for which the classifier has a “good sense” are added to the labeled set with their corresponding label. “Good sense” is measured with a confidence score that is provided by LibSVM along with every tested pair. Since this score is based on margin length calculations, one should use them carefully. Currently, we only set some threshold values for adding pairs to the labeled set, with a high score, empirically determined. The unlabeled set is also updated with additional examples of length not exceeding the iteration number. In that sense, the iteration number is actually an upper bound on the length of the examples, allowing the algorithm to select sequences of a lower length paired with longer sequences. For example, in the second iteration, the unlabeled set also contains examples that pair a sequence of one word with a sequence of two

words. The labeled set after step 3 contains "true" as well as "false" pairs, added by both the deterministic algorithm and the CT classifier, for training the PT classifier. Steps 4 and 5 train and test the classifier PT on the labeled and unlabeled sets respectively. Finally, in step 6, pairs that receive the same label from both classifiers, with a confidence score higher than the predefined threshold, are added to the labeled set with their corresponding label and stay there forever. This labeled set is used as part of the training data in the next iteration. The number of iterations is manually configured upon initialization of the algorithm and at the end, the "true" pairs are deemed paraphrases. The entire process is summarized in Figure 1.

To get a feeling for the robustness of the methodology, we applied the same technique to the task of generating paraphrases in English. English has shallow morphology as compared with Arabic, on one hand, but, on the other hand, uses more words than Arabic to convey the same meaning. Based on this observation, for English, we changed the settings of the data for using a window of size 4 instead of 3 and removed most of the morphology-related features. The English set of features for the CX and PT classifiers are summarized in Tables 4 and 5, respectively.

Feature	Description
Lemma, POS, NER, BP	of each context word
Lemma-match rate	The rate of lemma match on each side of the context

TABLE 4 – The features we use for training the CX classifier on English.

Feature	Description
n-gram score	Normalized *n*-gram frequency score for word sequences up to 4 words (2-4 grams)
POS, NER, BP	of each sequence word
Possessive form	of each sequence word
Sequence length	The number of words in each sequence

TABLE 5 – The features we use for training the PT classifier on English.

Comparable documents were extracted using the same technique from a relatively small part of the English Gigaword (5th ed.) (Parker et al., 2011). We preprocessed the documents using the OpenNLP library. For every word, we determined its part-of-speech, base-phrase and named-entity tags. The lemma of each word was retrieved from WordNet (Fellbaum et al., 1998) by providing it with the surface form and the part-of-speech tag as inferred by OpenNLP. Overall, we found 294 document pairs, containing about 220,000 words. Similar to the evaluation step of the Arabic corpus, we randomly selected 80 document pairs for vetting their correspondence to each other. Out of the selected 80 document pairs, 65 were classified as "yes" instances by both evaluators. Of the other 15 instances, 3 were classified as "yes" by only one evaluator. As for Arabic, the rest of the pairs were actually dealing with the same general domain but not specifically discussing the same event. The inference algorithm for English worked exactly as described above. Recall that in the first iteration on Arabic, we used a deterministic algorithm for labeling some of the data for training the classifiers for the first time. For Arabic, we used the

English gloss values of the Arabic words for finding "false" examples; for English, we use WordNet for the same task in such a way that synonyms are not considered as "false" examples.

4 Results and evaluation

4.1 Experiment settings

Our initial experiments perform only five iterations on both corpora (Arabic, as well as English), which means that we find paraphrases of no longer than five words. The two classifiers are configured with different thresholds. The confidence score given by LibSVM for every classification is a value between 0 and 1; therefore, we experimented with different threshold values and realized that the best settings in this case are obtained when using 0.85 for "true" pairs for the CX classifier and 0.75 for the PT classifier. For the "false" pairs, we use 0.75 for both classifiers. Since we noticed that the number of "false" pairs is much larger than the number of "true" ones in the training data of every iteration, we defined another parameter (currently 6) that limits the factor of "false" pairs allowed in the training data with respect to the "true" pairs.

In the next section, we show some results when running over 240 document pairs in Arabic, containing about 165,000 words, and 40 English document pairs containing about 11,000 words.

4.2 Results

First, we give some statistics on the results obtained by the inference algorithm on both the Arabic and English corpora, in Tables 6 and 7, respectively.

	"false" pairs	**"true" pairs**	**Unique paraphrase pairs**	**Unlabeled pairs**
Initialization	22,885,104	66,317		19,480
After iteration 1	23,799,787	(+1,726) 68,043		3,166,935
After iteration 2	24,759,791	(+3,757) 71,800	954	2,790,574
After iteration 3	25,349,489	(+2,623) 74,423	416	2,198,253
After iteration 4	26,221,889	(+451) 74,874	331	1,557,931
After iteration 5	26,900,833	(+101) 74,975	72	878,987
Total			**1,773**	

TABLE 6 – Statistics and final results of the inference algorithm running on the Arabic corpus.

In both tables, the initialization row shows the number of "true" and "false" examples as was labeled by the deterministic algorithm and the size of the unlabeled examples set. In the following rows, the numbers refer to the results of the specific iteration. The numbers of "true" and "false" pairs reported on every line are the aggregated numbers collected from all previous iterations. Recall that at the beginning of every iteration, a deterministic algorithm adds pairs of word sequences that match on the lemma level, word by word; hence, the number of "true" pairs in every line is the sum of the pairs from the previous iterations, the pairs added by the deterministic algorithm for the next iteration and the paraphrase pairs inferred by the current iteration. The third column, unique paraphrase pairs, is merely the number of unique paraphrase pairs inferred during the current iteration. The parenthesized numbers indicate the difference in

the quantity of "true" pairs from the previous iteration. So, the total number of extracted paraphrases is the number written on the total line in the unique paraphrases column. In Arabic, we found 1,773 paraphrase pairs and in English we found 525. This process can be scaled up for finding more paraphrases. We do not include paraphrases generated after the first iteration because, by definition, they are composed of synonymous words. Recall that, during initialization, the deterministic algorithm adds pairs to the unlabeled set if their paired words are synonyms in English or share the same English gloss, in Arabic. Table 8 shows some statistics for the entire inference process.

	"false" pairs	**"true" pairs**	**Unique paraphrase pairs**	**Unlabeled pairs**
Initialization	876,947	32,972		3,597
After iteration 1	960,840	(+868) 33,840		86,648
After iteration 2	1,058,970	(+1,633) 35,473	230	58,312
After iteration 3	1,109, 746	(+1,194) 36,667	177	21,332
After iteration 4	1,127,643	(+339) 37,006	94	6,677
After iteration 5	1,128,475	(+52) 37,058	24	1,490
Total			**525**	

TABLE 7 – Statistics and final results of the inference algorithm running on the English corpus.

The raw data corpus size is a rough estimation of the amount of words we had in the corpus at the beginning. Note that currently we did not use the entire Gigaword corpora: in Arabic we used about 30% of the entire set and in English we only used about 10% of the documents. The following column shows the number of comparable document pairs we found using the pairing algorithm described above. Since the pairing algorithm was designed to prefer recall over precision, the number of comparable documents is lower than might be expected considering the relatively large number of words we had in the raw corpus. We expect that this number will grow larger once we improve the pairing algorithm. The next column, number of words used in inference, sums up the number of words of the entire set of comparable document pairs from the previous column. The last column shows the number of paraphrase pairs extracted by the inference algorithm.

	Raw data corpus size	**Extracted comparable document pairs**	**Comparable documents used in inference**	**Number of words used in inference**	**Number of inferred unique paraphrases**
Arabic	~20,000,000	690	240	165,369	1,773
English	~1,000,000	294	40	11,600	525

TABLE 8 – General statistics on the entire inference process.

Comparing the results to the results retrieved by other works is difficult because there is neither a shared task for paraphrase extraction nor common resources for comparison. Therefore, we show some manual evaluations of our results. The evaluation was performed by two Arabic-English speakers by going over the reported paraphrases one by one. For each pair, we assigned one label: *P* – indicating correct paraphrase, *E* – indicating unidirectional entailment, *R* – related (for

other semantic relations except antonyms, e.g. San Diego/Los Angeles) and *F* – wrong (including antonyms). Table 9 and 10 summarizes our preliminary evaluation report on Arabic and English, respectively.

Length	Evaluated	*P*	*E*	*R*	*F*	Precision
2	120	49	12	25	34	71%
3	95	45	10	11	31	69%
4	70	26	4	5	35	50%
5	50	24	2	7	20	66%
Total	335	144	28	48	120	**66%**

TABLE 9 – Manual evaluation summary for Arabic. *P*: paraphrases, *E*: unidirectional entailment, *R*: related, *F*: wrong, i.e. unrelated or antonyms.

The evaluation results reported in both tables are based on the agreement of the two evaluators; in other words, we report here only on pairs that were annotated by both evaluators with the same tag. Note that the first column, length, indicates the number of words of the largest phrase included in the evaluated paraphrase pair. Paraphrase pairs containing a single word in both phrases were not evaluated at all. In the last column, we calculate the precision, considering pairs tagged with *P*, *E* and *R* as positive instances. The last row summarizes the results. In Arabic, 66% of the generated paraphrase pairs are at least considered as semantically related; among them, about 43% are considered real paraphrases. In English, only 63% of the paraphrase pairs are considered related, out of which 30% are real paraphrases. As can be seen from the tables, there is no preferred length for the inference algorithm. We see a slight improvement in the precision of paraphrases up to length three; however, this improvement does not seem significant, considering the relatively small amount of evaluated pairs.

When we increased the threshold on the confidence that is used by the PT classifier on English to 0.9, the number of paraphrases reported by the inference algorithm decreased to 330 and the average number of similar words in a pair, increased. As a results of that, the overall precision got improved to 72%, calculated over 250 evaluated pairs. These results helped us understand the effect of the PT classifier on performance. The pairs with a high confidence score, as reported by the PT classifier, are most likely to be real paraphrases; however, in most cases, the word sequences of such a pair share more words in common than do other pairs (e.g. “the U.S. Air Forces” ⇔ “the United States Air Force”).

Length	Evaluated	*P*	*E*	*R*	*F*	Precision
2	120	23	11	37	49	59%
3	60	28	6	9	17	71%
4	50	15	8	8	21	62%
5	25	8	5	2	10	60%
Total	255	74	30	56	97	**63%**

TABLE 10 – Manual evaluation results for English. *P*: paraphrases, *E*: unidirectional entailment, *R*: related, *F*: wrong, i.e. unrelated or antonyms.

Table 11 gives some examples of Arabic, as well as English, paraphrase pairs that were extracted by our inference algorithm. The third column is the evaluation score given by one of the evaluators.

Language	Paraphrase pair	Evaluation score
Arabic	الرئيس الفلسطيني *Alr}ys AlflsTyny* (“the Palestinian president”) ⇔ السلطة الوطنية الفلسطينية *AlslTp AlwTnyp AlflsTynyp* (“the Palestinian authority”)	Related
Arabic	جورج ووكر بوش *jwrj wwkr bw$* (“George Walker Bush”) ⇔ جورج بوش *jwrj bw$* (“George Bush”)	Paraphrases
Arabic	المؤتمر السادس *Alm&tmr AlsAds* (“the Sixth conference”) ⇔ الاجتماع الوزاري السادس *AlAjtmAE AlwzAry AlsAds* (“the Sixth ministerial meeting”)	Paraphrases
Arabic	دانييل جلازر *dAnyyl jlAzr* (“Daniel Glaser”) ⇔ دانيئل غلاسر *dAny}l glAsr* (“Daniel Glaser”)	Paraphrases
Arabic	كيلي غونزاليز وانجولو *kyly gwnzAlyz wAngwlw* (“Kaylie Gonzales and Angelo”) ⇨ الارجنتينيين الخطيرين *AlArjntynyyn AlxTyryn* (“the dangerous Argentinians”)	Unidirectional entailment
Arabic	البرلمان الجديد *AlbrlmAn Aljdyd* (“the new Parliament”) ⇔ المجلس الوطني السابع عشر *Almjls AlwTny AlsAbE E$r* (“the Seventeenth Parliament”)	Paraphrases
Arabic	الحدود السورية اللبنانية *AlHdwd Alswryp AllbnAnyp* (“the Syrian-Lebanese borders”) ⇔ الحدود السورية *AlHdwd Alswryp* (“the Syrian border”)	Unidirectional entailment
English	could veto ⇔ threatened to veto	Related
English	the U.S. Naval Task Force ⇔ a US Naval Task Group	Paraphrases

English	Beijing's policy ⇔ the China's policy	Paraphrases
English	a poor and little-developed province ⇔ its resource-rich northwestern province	Wrong
English	U.S. beef and related products ⇨ beef products	Unidirectional entailment
English	a magnitude 6.0 earthquake ⇨ the quiver	Unidirectional entailment
English	will only endanger ⇔ will not only endanger	Wrong

Conclusions

The method suggested here has demonstrated its potential for inferring paraphrases from a corpus of comparable documents, using "co-training". As we have seen, incorporating morphological features for a highly inflected language, such as Arabic, is very effective. SVM with its generalization property was a natural option for dealing with combination of features that can play an important role for identifying paraphrases. Finding more features that help to properly match the true senses of word sequences is definitely a direction for future investigation. In a similar experiment performed on English, we still saw encouraging results, despite the smaller corpus. In the next stage of research, we plan to scale up the experiments and use more raw data along with an improved document-pairing algorithm for inferring additional paraphrases. We also plan to use those paraphrases within an Arabic-to-English translation system so as to hopefully improve the quality of the translations.

Abstract
The Web is an ever increasing, dynamically changing, multilingual repository of text. There have been several approaches to harvest this repository for bootstrapping, supplementing and adapting data needed for training models in speech and language applications. In this paper, we present semi-supervised and unsupervised approaches to harvesting multilingual text that rely on a key observation of *link collocation*. We demonstrate the effectiveness of our approach in the context of statistical machine translation by harvesting parallel texts and training translation models in 20 different languages. Furthermore, by exploiting the *DOM trees* of parallel webpages, we extend our harvesting technique to create parallel data for resource limited languages in an unsupervised manner. We also present some interesting observations concerning the socio-economic factors that the multilingual Web reflects.

Keywords: web crawling, parallel text, document model object tree, machine translation.

1 Introduction

The amount of information and knowledge in the World Wide Web (WWW) is increasing at a rapid rate. As of September 2011, approximately 500 million websites were estimated to be present in the WWW; a jump of 1000% from 1995 [1]. An increasingly large proportion of these websites are in non-English languages. For example, the total proportion of English webpages on the WWW has been estimated to have dropped from 80% in 1996 to about 45% in 2008 (Pimienta et al., 2009). Furthermore, only 27% of the internet users claim English as their native language (Miniwatts Marketing Group, 2011). The opportunity to capitalize on this new market has encouraged internet service providers to provide web content in multiple languages. As a result, the Web has become an attractive resource for acquiring structured and unstructured data across several low-resource languages and domains.

Multilingual web data has been especially useful in a variety of natural language processing tasks such as information retrieval, language modeling and machine translation. Statistical machine translation requires the creation of a large corpus of parallel text, i.e., translations of text across languages. Harvesting such data automatically by exploiting multilingual webpages provides a low-cost, scalable alternative to expensive expert human translations. Moreover, bilingual subject matter experts may be extremely difficult to find for certain

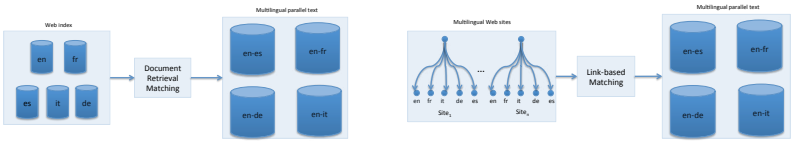
language pairs. As a result, web harvesting of parallel text has been addressed extensively in the recent past (Resnik and Smith, 2003; Shi et al., 2006; Pomikálek, 2008; Utiyama et al., 2009; Hong et al., 2010; Almeida and Simões, 2010; Uszkoreit et al., 2010).

Parallel text acquisition can be performed by examining the Web in either an unstructured or structured way. In the unstructured view of the Web, a large Web index is used as a starting point and the webpages are matched using cross-language document retrieval (see Figure 1(a)). The basic idea behind such an approach is to use a seed translation model to translate the entire index in one particular language and then match the pages using document retrieval techniques (Uszkoreit et al., 2010). The feasibility of such an approach is dependent on the availability of a large Web index as well as computational power to perform large scale machine translation and document alignment. In the structured approach, websites containing parallel text are typically identified using search engine APIs and the crawler proceeds to identify new websites based on the preceding ones (Resnik and Smith, 2003; Shi et al., 2006; Utiyama et al., 2009; Hong et al., 2010). However, such a scheme is amenable primarily for pair of languages.

Our work takes a structured view of the Web and exploits the link structure of websites to collect multilingual parallel text. We leverage the property that multilingual websites typically provide content simultaneously in several languages. Furthermore, a link that represents an entry point to a particular language in these websites usually co-occurs in the DOM tree with entry points to other languages (see Figure 1(b)). The co-occurring language versions of webpages on a particular website is influenced by geographic and economic factors of the underlying service or business. For example, a hospitality website identified as a possible source for harvesting English-French parallel text may also contain German, Italian and Spanish versions of the site, whereas a website with English-Chinese parallel text may have corresponding Japanese and Korean counterparts.



(a) Unstructured view of Web: Web index based parallel text acqusition

(b) Structured view of Web: Multilingual crawling using language co-occurrence

Figure 1: Strategies for harvesting parallel text across multiple languages from the Web

In this work, we present a framework for harvesting parallel text across multiple language pairs using the approach illustrated in Figure 1(b). We present semi-supervised and unsupervised approaches to harvesting multilingual text that rely on a key observation of *link collocation*, i.e., entry points to different languages on multilingual websites are often collocated on the HTML DOM tree. Subsequently, we use an intra-site crawler and a suite of alignment procedures to generate parallel text across multiple pairs of languages and evaluate their utility in machine translation. We demonstrate significant improvements in translation quality for almost all of the 20 language pairs (with English as the source language) in the Europarl corpus (Koehn, 2005) through the addition of parallel text harvested through our approach. We also report experiments in English-Hindi translation

by using a completely unsupervised approach.

The rest of the paper is organized as follows. In Section 2, we describe related work in web mining for parallel text and contrast our work with prior efforts. We describe the semi-supervised approach for obtaining multilingual entry points in a website in Sections 3 and 4 followed by a description of the overall framework for harvesting parallel text from the entry points. In Section 6 we present statistical machine translation experiments using the data harvested through our framework and present a detailed case study for English-Hindi translation in Section 7. We provide a brief discussion in Section 8 and conclude in Section 9 along with directions for future work.

2 Related Work

Prior research on acquiring parallel text from the Web has also focused primarily on a specific pair of languages. Even though in principle the algorithm and framework can be extended to other pairs of languages, it requires either parallel webpages or comparable documents to trigger the process. For example, (Resnik and Smith, 2003) used a crawling procedure to harvest parallel text in English-Arabic starting from the Internet Archive and using several language specific patterns in the URLs. The work in (Munteanu and Marcu, 2005) matches comparable documents in English-Chinese and English-Arabic and subsequently extracts parallel text while (Fung and Cheung, 2004) extract parallel text from quasi-comparable documents in English-Chinese. The work in (Hong et al., 2010; Shi et al., 2006) uses several web crawling strategies for harvesting parallel text in English-Chinese and the work in (Utiyama et al., 2009) addresses the extraction of Japanese-English parallel text from mixed language pages.

Conventionally, the crawling procedure to detect websites containing parallel text has been through a query-based approach (Resnik and Smith, 2003; Chen and Nie, 2000; Hong et al., 2010). They submit carefully constructed queries to a search engine that might yield potential parallel webpages. However, such a procedure depends on the quality of the query strategy as well as the Web index provided by the search engine. Furthermore, the process is typically constrained for particular pair of languages. Subsequently, the websites are mined independently and matched through a variety of techniques ranging from document retrieval (Munteanu and Marcu, 2005) to matching based on HTML document object model (DOM) tree similarity (Resnik and Smith, 2003; Shi et al., 2006). Once the documents are aligned, the sentences are aligned next using dynamic programming based on sentence length and a bilingual dictionary (Resnik and Smith, 2003) or through a classifier (Munteanu and Marcu, 2005).

Multilingual parallel text extraction has been specifically addressed in (Uszkoreit et al., 2010). However, the starting point for harvesting parallel text is a large Web index that is aligned using a seed translation model and subsequent document matching. It may not be feasible to acquire such a large index or run computationally expensive document matching for many efforts. Furthermore, their work reports translation quality experiments for about 7 language pairs and requires a seed translation model from the language of interest into English. Our interest, on the other hand, lies in crawling the Web to detect multilingual pairs of entry points belonging to websites that contain parallel text.. We push the task of identifying parallel web pages upfront to the crawler instead of downstream document matching over a large snapshot of the Web. Our framework can be used with or without a seed bilingual dictionary or translation model. In the absence of a seed dictionary, we

use an unsupervised DOM tree similarity procedure to harvest parallel text as we describe later.

3 Background: Bilingual crawler

The simplest manifestation of a multilingual crawler is for a pair of languages, i.e., bilingual crawling. To perform this task, the crawler needs to detect bilingual sites by traversing interesting regions of the Web. The bilingual site detector (BiSite detector) is the component responsible for determining whether a website contains bilingual content. The detector performs its task in two phases: link-based prediction and language identification. The role of the *link predictor* is to predict links that are entry points to a particular language in a website. The *link predictor* relies on the property that these entry points contain some common link pattern. For instance, entry points to the French content might have words as "fr" or "francais" in their URLS. In order to be able to handle different types of patterns in the links, it uses features in 5 different contexts: tokens in the URL, anchor, around the link, image alt and image src tags. Thus, for each language, a link predictor is built using supervised learning. Subsequently, the BiSite detector verifies if the pages whose links were considered relevant by the link predictor are in the languages of interest. Once a pair of links in a website are hypothesized as entry points in two different languages, the crawler uses an intra-site crawling policy similar to that described in (Rangarajan Sridhar et al., 2011) to traverse the Web sites and collect the parallel content. Figure 2 depicts a simple illustration of the bilingual crawler. Further details about the BiSite detector is presented in (Barbosa et al., 2011).

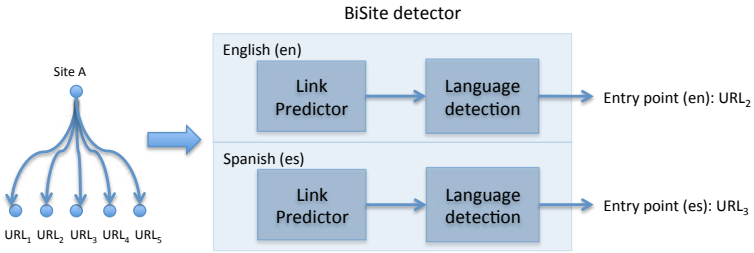


Figure 2: BiSite detector detects entry points to parallel text for a pair of languages on a given website.

4 From bilingual to multilingual crawling

The task of a multilingual crawler is to detect websites that contain content in multiple languages. A simple way to perform this task is to extend the approach used in the BiSite detector by building entry point detectors for each language of interest. The BiSite detector was built by labeling positive and negative examples of entry points in a pair of languages. Although effective, a fully supervised approach is not feasible for building entry point detectors for many pairs of languages as it requires significant labeling effort.

We propose a semi-supervised approach for building multilingual detectors. Our approach relies on the observation that, in a given website, entry points to different languages are

collocated links on the same page. The bootstrapping algorithm works as follows: BiSite detectors in a small set of language pairs are constructed using manual labeling and are in turn used to identify entry points in these languages. The algorithm then extracts links collocated with the detected entry points, generating training data to build detectors in new language pairs. The new detectors can now be used in the first phase of the bootstrapping, and iterated to generate more entry points. Figure 3 describes the components of the bootstrapping algorithm. Therefore, the only supervision provided is positive (entry points) and negative examples for the initial detectors whose accuracy the bootstrapping algorithm heavily relies on.

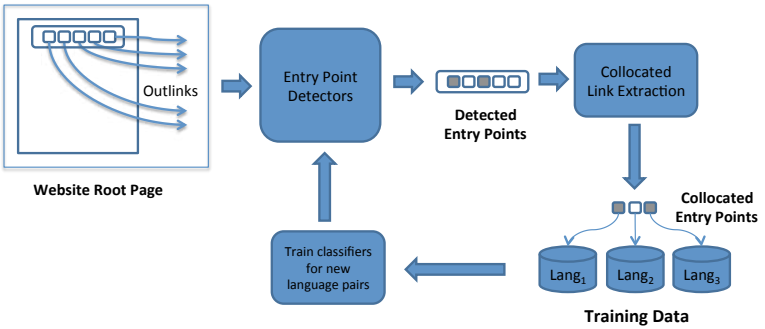

Figure 3: Bootstrapping algorithm for creating classifiers for new pairs of languages

4.1 Extraction of co-occurring links

The extraction of co-occurring links is an important step in the bootstrapping algorithm. Its goal is to extract candidate entry points collocated with entry points identified by the initial BiSite detectors. Formally, let OL be the set of *outlinks*[2] on a given Web page WP, and EP be the set of language entry points in WP ($EP \subseteq OL$). The algorithm's objective is to identify EP, if it exists. Our assumption is that this subset is the one with highest diversity with respect to languages among OL. In other words, while most of the outlinks in OL point to pages in similar languages, the links in EP point to pages in distinct languages. The algorithm then searches for the partition of OL, $\widehat{EP}$, with the maximum normalized entropy with respect to its languages among the subsets ($\mathbf{SL} = \{SL_1, \cdots, SL_K\}$) of OL:

$$\widehat{EP} = \underset{\mathbf{SL_i} \in \mathbf{SL}}{\arg\max}\ NormEntropy(\mathbf{SL_i}) \tag{1}$$

$$NormEntropy(SL_i) = \frac{-\sum_{k=1}^{|L_i|} p(l_k) log(p(l_k))}{log(|SL_i|)} \tag{2}$$

where $L_i = l_{i1}, ...l_{i|L|}$ is the set of the languages in SL_i and $p(l_k) = count(l_k)/|SL_i|$. NormEntropy is equal to 1 when SL_i is composed of distinct languages.

Since finding an optimal subset of links is a combinatorial search problem, our algorithm adopts a greedy approach. The algorithm imposes the following constraints to make the

[2] *Outlinks* are the links pointing out from a given webpage.

solution tractable: (1) $\widehat{EP}$ must contain the entry points, $iniEPs$, detected by initial detectors; (2) the elements of $\widehat{EP}$ are not spread over the entire Web page but located in a similar region in the page's DOM tree. Starting from a detected entry point $iniEP_i$, the algorithm first locates the DOM node ($node_i$), represented by the "a href" HTML tag, associated to $iniEP_i$ and calculates the normalized entropy of the subset of OL contained in the DOM subtree of the parent of $node_i$. In the next step, it goes up one level in the tree and calculates the normalized entropy of the subtree. If the normalized entropy of the current subtree is higher than the previous one, it continues the search up one more level, otherwise stops. The links of the best subtree identified by this process SL_i are considered as the candidates associated with $iniEP_i$. This procedure is repeated for each $iniEP_i$ and the set SL_i with the highest entropy among the candidate sets is considered for the final step. Subsequently, the algorithm discards elements in SL_i that are from the same language as we assume that there is only one single entry point for each language in a given page. Finally, the output of this process is a set of candidate entry points (outlinks) in which each outlink is associated to a particular language. For each outlink, its link neighborhood is extracted (described previously) and used as a positive example for building a *link predictor* for that particular language.

4.2 Evaluation of semi-supervised multilingual crawler

In this section, we assess the quality of the entry points identified through our bootstrapping algorithm. As inputs to the algorithm we provided two entry point detectors (English and Spanish), created using labelled data, and 10,000 Web sites, collected using an unrestricted crawler. We then ran the algorithm over these Web sites and candidate entry points were extracted in 45 different languages. Figure 4 shows the top-10 languages collocated with English and Spanish in this dataset. The most popular languages were European languages while Japanese was the most popular Asian language, beating European languages such as Polish and Slovenian.

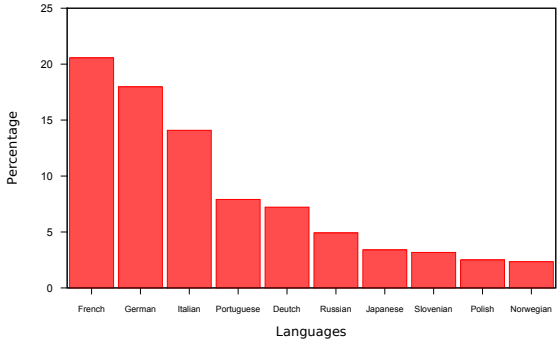

Figure 4: Distribution of languages collocated with English and Spanish

For 5 of the top-10 languages: French, German, Portuguese, Russian and Japanese, we manually labelled test data (about 500 positive and 1,000 negative examples for each language) to evaluate the performance of their respective detectors created using the semi-

supervised approach. We also assessed the accuracy of the co-occurring link extraction (CLE) by manually inspecting how many entry points extracted from the CLE procedure were correct. Table 1 presents the precision of CLE and F-measure of the detectors. For each of the top 5 languages the collocated link extraction algorithm achieves greater than 90% precision. The detectors created automatically by the bootstrapping algorithm have a high F-measure (from 0.8 to 0.87). This is a direct consequence of the high precision obtained by the CLE algorithm that provides the positive examples for training the classifiers.

Language	**F-measure (Detector)**	**Accuracy (CLE)**
German	0.87	0.96
French	0.85	0.93
Japanese	0.85	0.95
Russian	0.8	0.98
Portuguese	0.8	0.95

Table 1: Precision and F-measures for the detectors constructed using the semi-supervised entry point detector approach

5 Parallel text acquisition

The multilingual crawler generates pairs of entry points for multiple language pairs that subsequently need to be mined for parallel text. We adopt a recursive intra-site crawling approach that aligns text and URLs across the initial entry points to harvest parallel text. Our framework uses a document matching framework to align the URLs (Munteanu and Marcu, 2005) and a bilingual dictionary based dynamic programming match to align the sentences across the hypothesized parallel documents (Ma, 2006). The document matching process is constrained by a window size that is dependent on the total number of parallel URLs that need to be aligned. The framework also enables us to highly parallelize mining across multiple language pairs. The bilingual dictionary in this work was obtained by performing automatic word alignment on seed parallel data (Och and Ney, 2003). The harvested bitext was then filtered using a word-overlap filter as well as a source and target vocabulary restriction filter. By varying the thresholds for the various filters, one can control the amount and quality of the bitext. We also check for the fidelity of the translation by matching a subset of the harvested text for each website against translations from Google Translate and Microsoft Bing. We omit the data from the entire website if the translations have a high correlation with the online translation engines (cosine distance ≥ 0.8). This step is performed to avoid the use of machine translated parallel text. A detailed description of the intra-site mining procedure can be found in (Rangarajan Sridhar et al., 2011).

6 Machine translation experiments

In this section, we validate the quality of the parallel text obtained using our multilingual crawling approach through machine translation experiments. Our objective is to evaluate the translation quality with and without the parallel text harvested from the Web for a large number of language pairs. We used the Moses[3] toolkit (Koehn et al., 2007) for performing phrase-based translation experiments. The standard pipeline (sentence alignment using GIZA++, phrase extraction with maximum phrase length of 7 using *grow-diag-final* option, lexicalized reordering model with *msd-bidirectional-fe* option) was used to build the

[3]http://www.statmt.org/moses

models. The language models were interpolated Kneser-Ney discounted trigram models, all constructed using the SRILM toolkit (Stolcke, 2002). The language models were constructed only from the target side of the bitext for each language pair. We performed minimum error rate training (MERT) on a development set to optimize the weights of the log-linear model.

We ran machine translation experiments for all of the 20 languages (English as source language) present in the Europarl corpus (Koehn, 2005). The baseline models were trained on Europarl data. For each of the 20 languages, we harvested parallel text (see Section 5) from the entry points hypothesized by the multilingual crawler. Statistics of the parallel text obtained using our procedure is shown in Table 2. Subsequently, we trained a translation model by combining the Europarl text with the parallel text harvested using our approach.

Language pairs	# websites	# webpages	# parallel sentences	Language pairs	# websites	# webpages	# parallel sentences

Table 2: Parallel text obtained using our framework for the 20 languages in Europarl corpus

Figure 5 shows the BLEU scores across the 20 languages with and without the addition of parallel text from the Web. We performed the decoding experiments on three different test sets: Europarl, Web and Europarl+Web. We chose the three sets to represent a variety of test domains. A total of 1000 sentences was used for testing. The test sentences from the Web were chosen randomly such that they satisfied a sentence length constraint (≥ 5 words). We spot checked a small subset of the test sets to ascertain the fidelity. Ideally, a manually constructed general vocabulary test set for each of the language pairs would have been the best choice. However, it is expensive and difficult to create test sets through human experts for each of the 20 language pairs. All the models are optimized based on a randomly chosen development set from Europarl comprising of 1000 sentences.

Overall, the results in Figure 5 indicate significant improvements in BLEU scores when the harvested parallel text is added to the Europarl data. As expected, the improvements are not quite marked when tested on Europarl data, however, they are significant on data obtained from a general domain (a mix of websites). Our objective is to translate sentences closer to a general domain (hospitality, business, medicine, etc.) and we show that parallel data harvested from the Web provides significant improvement.

7 Unsupervised parallel text acquisition: English-Hindi

In the previous section, we demonstrated the utility of our multilingual crawler for languages with reasonable resources. However, such data may not be present for several other language pairs. One of the main objectives of our Web crawling scheme is to harvest parallel text

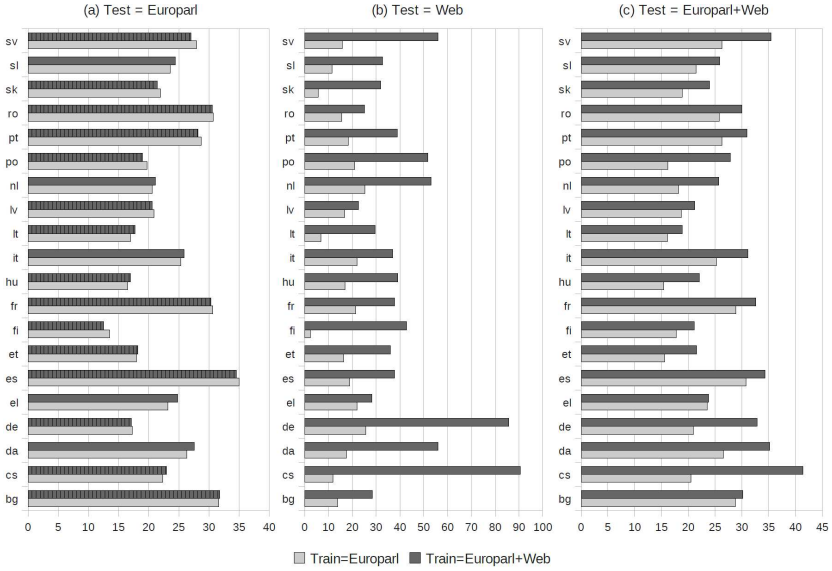

Figure 5: Translation quality as measured through BLEU score for various test sets with and without web crawled parallel text. Hatched bars indicate insignificant difference (Koehn, 2004) with respect to the baseline model built from Europarl data.

for language pairs with limited resources, i.e., lack of publicly available large database or language resources. As an instantiation of this goal, we conducted a detailed study on English-Hindi. We used the collocated link extraction procedure described in Section 4.1 to compile 1638 potential entry points in English-Hindi. Unlike the language pairs used in the previous section, we did not have access to parallel text or a bilingual dictionary for English-Hindi. Hence, we used a completely unsupervised scheme to harvest parallel text from the initial entry points. The intra-site crawler (see Section 5) was modified to perform document matching using the HTML structure of the webpages and the dynamic programming text alignment procedure relied only on sentence length and identity anchor words (words that are present in the source and target sentence). We computed the distance between the DOM trees of two HTML pages to decide if the pages contained parallel text (Pawlik and Augsten, 2011). We ran the crawler for three iterations, each iteration using the parallel entry points identified in the previous step. Figure 6 shows the number of Web sites, pages and bitext harvested using the setup. Since, Hindi characters have a pre-defined range, we could filter out bitext that did not contain Hindi.

From Figure 6 it can be seen that the growth of the entry points hypothesized at each iteration of the intra-site crawling procedure is not linearly related to the bitext harvested. We conjecture that websites containing English-Hindi parallel text do not point to significant number of newer English-Hindi websites. Unlike European languages the domain of the WWW containing English-Hindi parallel text is rather limited.

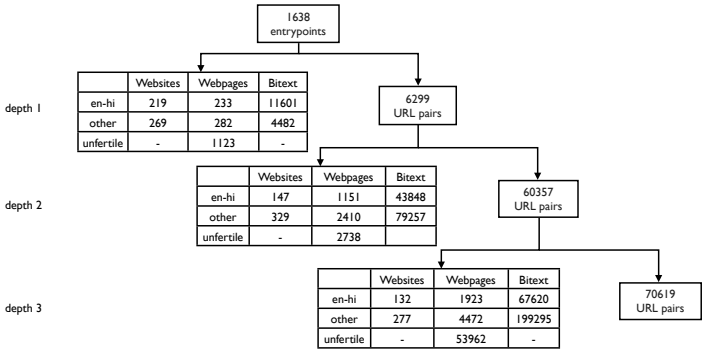

Figure 6: Illustration of the number of websites, webpages and bitext harvested in an unsupervised manner for English-Hindi. *other* refers to bitext in a language pair other than English-Hindi and *unfertile* refers to entry points that did not harvest any bitext.

We also performed machine translation experiments using the English-Hindi parallel text harvested through the unsupervised alignment approach. The baseline model was trained on the Indic multi-parallel corpus (Birch et al., 2011) and a new model was trained by adding the harvested parallel text. Since the parallel text harvested using the unsupervised approach is prone to be noisy, we filtered the sentences using a word-overlap filter constructed from the IBM Model1 dictionary obtained from the baseline translation model. We used the Indic corpus development and test sets for tuning and testing, respectively. The results are reported in Table 3. The results demonstrate a significant improvement ($p = 0.05$) in BLEU score when the Web crawled parallel text is added to the baseline data. The filtering procedure using the dictionary obtained through automatic alignment yields lesser amount of parallel text and hence results in smaller improvement in BLEU score. The experiments clearly indicate the benefit of the parallel text harvested using our scheme. It is important to note that we started this process for English-Hindi with no resources whatsoever.

Training data	**BLEU**
Indic training data	18.6
Indic+unsupervised parallel text	19.4
Indic+ parallel text filtered using IBM Model1 dictionary	19.1

8 Discussion

Languages addressed by multilingual crawler. The multilingual crawler presented in this work generates entry points for over 500 language pairs (with atleast 500 entry points). We have presented machine translation experiments only for a subset of these languages, namely, ones contained in the Europarl corpus and English-Hindi. Some of the prominent language pairs with a large number of entry points are English-Chinese (26893), English-Japanese (25804), English-Russian (24011), English-Turkish (10879), English-Norwegian (6564), English-Arabic (5001), English-Korean (4425), English-Persian (3398), English-

Indonesian (1224), English-Hebrew (1514) and English-Thai (1000). One can potentially harvest parallel text for all of these language pairs and subsequently exploit it for machine translation. Other notable language pairs not containing English as one of the languages are German-French (18874), German-Italian (16275), German-Spanish (14410), German-Dutch (10530), and French-Spanish (16295). It is interesting to note that we can obtain entry points for a multitude of language pairs not containing English. Directly obtaining parallel text for some of these language pairs can obviate the need to use English as a pivot language during translation.

Distribution of parallel text on the Web in European languages. Based on the parallel text extracted for the language pairs in the Europarl data (see Table 2), English-Bulgarian (en-bg) is the poorest language pair in terms of net harvested parallel text. The total bitext of 825 sentences is obtained from 253 websites, i.e., the yield per website is only about 3 sentences. Most of the websites that contained any Bulgarian translations did so only at the top level (menu items, homepage information, etc.) and did not have any significant content translated across internal webpages. English-Greek (en-el) is another language pair with very low parallel content on the Web. English-Estonian (en-et), English-Lithuanian (en-lt), English-Slovakian (en-sk) and English-Slovenian (en-sv) are the language pairs with the highest density of parallel text per website. While there are not many websites with parallel text in these languages, the ones that do contain them are very fertile. As expected English-French (en-fr), English-Spanish (en-es), English-German (en-de), and English-Italian (en-it) language pairs produce large amounts of parallel text in comparison with other languages due to the dominance of these European languages on the Web. Our experiments also indicate that on an average there are approximately 3-6 unique webpages for each website that yields parallel text.

Language co-occurrence. Figure 7 presents a graph showing how the languages are collocated in our data. The edges between languages represent that entry points of these languages are collocated on the same websites. Given a language, we calculated the proportion of languages collocated with it. The edge weight in the graph represents this proportion. Since almost all languages are collocated with each other, we pruned some edges to make the figure clearer. For that, we removed edges with weights lower than 0.05, deleted the English node, since it is the most popular collocated language, and some languages from middle Europe. First thing one can note is that German is the most popular language after English. One can also observe there are some language clusters mainly due to geographic or social/economic aspects: the Western European (German, French, Spanish, Italian, Dutch and Portuguese), the Eastern European (Russian, Estonian, Ukrainian, Latvian, Lithuanian and Bulgarian), the Middle Eastern (Arabic, Urdu and Farsi) and the Far East Asian (Japanese, Korean, Chinese Mandarin and Taiwanese Mandarin). Japanese has a high collocation with European languages because many European websites provide content in Japanese. There is a high collocation of German with Turkish. We believe the reason for that is the high population of Turkish in Germany.

Socio-linguistic observations. Another study that we performed was to obtain the distribution of the languages in the multilingual websites per each country (here we relied on country top-level domain codes). There are countries where very few multilingual sites are available, e.g., India and Cuba, whereas others such as Germany, Netherlands, China and Japan provide a great number of multilingual sites. As one expected, English is the

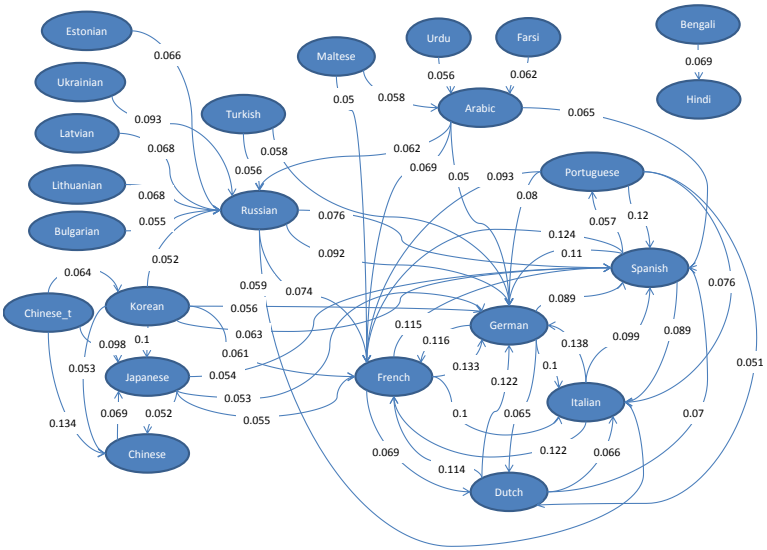

Figure 7: Distribution of language collocations.

foreign language most popular in all countries. It is interesting to note that the popularity of collocated languages in a country depends on geographic and social/economic aspects. Here are some examples:

- Geographic: the most popular foreign languages in Czech multilingual websites (.cz) are in this order: English, German, Russian, Slovak and Polish. These languages are either from neighbouring countries or from economic powers. Interestingly, however Czech is not a very popular language in Polish websites (.pl).
- Social/economic: In Israel, the number of websites in Russian is comparable to Hebrew and English, due to the Russian immigrants. In Iran, French is the most popular language after English, Farsi and Arabic, for historical reasons. Portuguese is the most popular European language in Japanese websites (probably to reach the huge number of Brazilian immigrants that live there).

9 Conclusion

We presented a novel semi-supervised approach for detecting parallel text across multilingual websites. Our approach takes a structured view of the Web and crawls regions of the Web that are likely to produce significant amount of parallel text. First, we constructed supervised classifiers for a few language pairs to detect websites with potential parallel text. By exploiting the property that in many multilingual websites, entry points to different languages are often collocated on the HTML DOM tree, we use a collected link extraction

algorithm to extract entry points for new language pairs. Subsequently, the data is used to train supervised classifiers to detect entry points for new language pairs. Starting from a classifier trained to detect English-Spanish entry points, we were able to obtain entry points in 45 language pairs. We used an intra-site crawling approach to mine the entry points and align the text using document retrieval and dynamic programming techniques. We demonstrated significant improvements in translation quality for all of the 20 languages in the Europarl corpus. We contrasted the experiments conducted on Europarl with those performed on English-Hindi that did not have any resources to learn a seed translation model or dictionary for sentence alignment. Finally, we also presented some socio-linguistic observations inferred through our crawling procedure. We plan to conduct experiments on the other 24 language pairs not reported in this work as part of future work. We are interested in acquiring parallel text for languages with no or low resources and identifying websites that can be mined frequently due to their dynamic nature (e.g., news, broadcasting stations, etc.).

ABSTRACT

Statistical post-editing (SPE) of the output produced by rule-based MT (RBMT) systems has been reported to produce extraordinary BLEU (and other automatic evaluation) score improvements. SPE has also been applied to the output of statistical MT (SMT) systems, albeit with more mixed results. We present a statistical post-editing pipeline and evaluate the outputs using automatic and human evaluation techniques, comparing the two SPE pipeline systems (RBMT + SPE and SMT + SPE) with the pure RBMT and SMT system, in an SPE scenario that uses independently existing bitext data, rather than manually corrected first stage MT output, as its training data. Our results show that although automatic evaluation metrics favour the pure SMT system, human evaluators prefer the output provided by the statistically post-edited RBMT system.

COLING 2012, Mumbai, December 2012.

1 Introduction

Human evaluation is a core component of shared tasks such as WMT, and is often considered the gold standard in evaluation of translation systems. Automatic evaluation metrics, however, are much less costly, much more time efficient and enable automatic tuning of SMT system parameters (e.g. using MERT), which may require a number of iterations to converge.

Statistical post-editing of the output of RBMT and SMT systems is an active field of research and RBMT + SPE pipelines are by now a commercial reality. [1] Automatic post-editing of rule-based machine translation systems (Simard et al., 2007; Terumasa, 2007; Kuhn et al., 2010) has shown (in some cases) spectacular improvements in translation quality measured in terms of automatic evaluation scores. Furthermore, SPE has also been applied to the output of statistical MT (SMT) systems (Oflazer and El-Khalout, 2007; Potet et al., 2011; Béchara et al., 2011; Rubino et al., 2012), albeit with more mixed results. However, to date, despite considerable interest in the area, the comparison between SPE pipelines and pure SMT and RBMT systems is not fully researched.

Previous research can be categorised into roughly two classes: in one approach (Simard et al., 2007; Dugast et al., 2007; Potet et al., 2011), manually corrected (i.e. post-edited) MT output is used as the target side for training the SPE system (i.e. a "mono-lingual" SMT system trained on the output of the first stage MT system as source and the manually corrected first stage MT output as target, and then applied to the output of the first stage MT system on unseen source side input data), while the other approach (Oflazer and El-Khalout, 2007; Béchara et al., 2011; Rubino et al., 2012) simply uses available bi-text training data (such as translation memories (TMs) in industrial applications or more generic SMT training data) and trains the SPE system on the output of the first stage MT system and the target side of the bi-text training data.

In the first approach, the SPE system is effectively trained in such a way as to only fix mistakes committed by the first stage MT system: the difference between the output of the MT system (the source side of the SPE training data) and the target side of the SPE training data is in translation mistakes identified and fixed by human post-editors. By contrast, in the second approach, the SPE system is simply trained on the difference between the MT output and the target side of the training data (which may not necessarily constitute a mistake, but just be an instance of a paraphrase or another valid translation alternative).

One of the central research questions addressed in this paper focuses on the second approach: do the (often spectacular) differences in automatic evaluation scores between RBMT and RBMT + SPE pipelines correspond to to "real" improvements in translation quality, as determined by human evaluators, or are they largely due to SPE moving RBMT output closer to a reference string used in automatic evaluation and rewarded by the automatic metrics?

Note that it is reasonable to assume that in the first approach improvements in automatic evaluation scores do indeed correspond to "real" improvements in translation quality, as determined by human evaluators, as in this case the SPE system is solely trained on genuine translation mistakes or (more generally) translation shortcomings.

At the same time, the second approach arguably addresses an important commercial reality in that in many industrial applications it is often the case that specialised TMs exist that have been developed (over many years) to support translation automation and that can now be used

[1] http://www.systran.co.uk/translation- products/server/systran-enterprise-server

as training data for SMT systems for translating input that yields only low fuzzy matches in the TMs. By contrast, the first approach involves a long term commitment to correct the first stage MT output to collect sizeable training data sufficient to train a successful SPE component, which is not always possible given deadlines and the variety of data that needs to be translated in commercial applications.

A second, related, research question addressed by the paper is to determine how RBMT + SPE pipelines compare with a pure SMT system (trained on the same data) or corresponding SMT + SPE systems (again trained on the same data), and how are these rated by human evaluators? Again we focus on this research question in the context of the second approach to SPE based on independently available bi-text training data such as TMs.

As automatic evaluation metrics are inherently biased by the reference translation, it is difficult to tell if these SPE scores correspond to an actual improvement in translation quality. In this study we use human evaluation to answer that question, and to further discover whether the statistical machine translation system outperforms the SPE combination systems, or whether the bias of the automatic evaluation metric is getting in the way of choosing the better system.

The remainder of this paper is organised as follows. In Section 2, we review related research and how it ties into our experiments. In Section 3 we detail the machine translation systems used in both the first and post-editing stages of our experiments, along with the automatic evaluation results of these systems and their combinations. Section 4 presents the human evaluation results, and Section 5 provides an error analysis that helps to answer some of the questions posed in this paper.

2 Related Work

Statistical post-editing has been applied to different types of MT systems to varying degrees of success. The main idea behind SPE for MT is to capture the mistakes made by the MT system and to automatically correct them. (Allen and Hogan, 2000) conducted early studies on the subject (without actually building a SPE system) by using a parallel corpus composed of three tiers: the source text, its automatic translation and the manually post-edited (i.e. corrected) automatic translation. This study inspired the original work on SPE by (Simard et al., 2007), who used the Portage System (a PBSMT system) to automatically post-edit the output of an RBMT system, using the raw RBMT output and the manually post-edited (i.e. corrected) output as "source" and "target" side, respectively, of the SPE training data.

SPE is generally mono-lingual, operating on the target side of the translation direction. In a sense, it can be viewed as a re-writing step on MT output a posteriori, usually unpacked as a supervised learning problem. In one approach, such as that of (Simard et al., 2007), SPE directly negotiates between specific errors in the RBMT (or generally first stage MT) output and the corresponding manual corrections (where mistakes in first stage MT output are corrected by human translators), in the other approach independent bitext data (such as TMs) are used to train SPE systems on the output of the first stage RBMT (or more generaly any MT) system on the sorce side of the bitext data and the corresponding target side of the bitext data. We present both approaches in the two subsections below:

2.1 SPE with Manually Post-Edited MT Output

Amongst the published work on SPE with manually post-edited MT output, several studies have been conducted by combining RBMT and PBSMT as the MT and the SPE systems, respectively.

(Simard et al., 2007) show that a commercial RBMT system combined with the PBSMT system Portage (Sadat et al., 2005) in an SPE pipeline achieve improved translation quality. On a translation task from French to English, using SPE shows an improvement of 13.7% BLEU (Papineni et al., 2002) (absolute) over the RBMT system alone. The authors also conduct experiments combining two PBSMT systems, both in the translation and the post-editing phase, and show that this approach leads to higher BLEU scores if the training corpora for the translation and the post-edition systems are different.

(Dugast et al., 2007) carry out a qualitative analysis at the linguistic level, conducted on the MT and the SPE outputs. They combine Systran with the PBSMT systems Moses (Koehn et al., 2007) and Portage. The output of the combined systems (Systran+SPE) shows significant improvements in terms of lexical choice. They also report gains in terms of BLEU scores up to 10 points absolute on a German to English translation task, compared to the RBMT system individually.

More recently, (Potet et al., 2011) combine a full PBSMT pipeline (SMT+SMT) for translation and post-editing from French to English. The first system translates the French text into English. The MT output is then manually post-edited and introduced into the pipeline following three approaches:

- as supplementary material to enrich the training corpus used to build the translation model,
- as the target side of the parallel corpus used to build the post-editing model,
- as a the target side of the development corpus used to optimize the translation model components weights.

This preliminary study shows a slight improvement over a standalone MT system, but further experiments on larger corpora are needed in order to obtain significant results.

2.2 SPE with Independent Bitext Data

Due to the time and expense involved in manually post-editing MT output, using independently available parallel training data (such as TMs) in SPE pipelines is often a less expensive (and arguably commercially more frequent) scenario. (Terumasa, 2007) combines RBMT with SPE to translate patent texts, and reports an improved score the NIST evaluation compared to that of RBMT alone.

In (Kuhn et al., 2010), the authors compare the two SPE approaches: the first using manually post-edited MT output and the second using the target side of the bilingual training data. They use Systran RBMT and Portage PBSMT systems, and combine them into a post-editing pipeline, with the RBMT system as first stage and the PBSMT system as the SPE system. The SPE system shows a gain of 10.2 BLEU points compared to the RBMT system alone, on a French-to-English translation task. However, the authors also show that a PBSMT system alone can reach results similar to those obtained by the post-editing pipeline.

The first mention of a pure SMT-based SPE pipeline (SMT + SPE) is likely to be in (Oflazer and El-Khalout, 2007), who in one of the experiments as part of their work on selective segmentation based models for English to Turkish translations, employ statistical post-editing (which they call model iteration). In the study conducted by (Béchara et al., 2011), two PBSMT systems are combined into a post-editing architecture. Two sets of experiments are presented. The first is a naive post-editing approach, were the output of the first SMT system is post-edited by the SPE

system without introducing additional information. The second is a source-context enriched SPE approach. Following the full PBSMT post-editing pipeline approach, (Rubino et al., 2012) use statistical post-editing to adapt out-of-domain machine translation systems to a specific domain and show that a generic MT system can be adapted through an automatic post-editing step.

In the first approach, SPE with manually post-edited MT output, the SPE directly addresses translation mistakes or inadequacies caused by the first stage MT system. By contrast, in the second approach, SPE with independently available bitext data, it is not guaranteed that a divergence between first stage MT output and the target side of the bilingual training data actually corresponds to a translation mistake by the first stage MT system. Our research focuses on this second scenario, in particular on whether (sometimes spectacular) SPE improvements in automatic evaluation scores correspond to actual improvements in translation quality verified by human evaluators. Our experiments follow the general design put forth by (Dugast et al., 2007) and (Kuhn et al., 2010), where the output of a Systran RBMT system on the source side of some bitext data as well as the target side of this bitext data is used to train a monolingual second-stage SPE system to post-edit the output of the RBMT system. The objective is to compare the output of the combined RBMT+SPE system with the RBMT system on its own, with an SMT system on its own trained on the bilingual training data, as well as with an SMT+SPE pipeline. We investigate whether the RBMT+SPE pipeline is actually better than Systran (or any of its other rivals: SMT and SMT+SPE), or just closer to the reference translation. In order to do this, we enlist the help of human evaluators.

3 Machine Translation Systems

In this section, we present the data and the translation systems used in our experiments. We also give details about the two SPE pipelines and the automatic evaluation metrics used to measure system performance.

3.1 Translation Memory Bitext Data

The data for our experiments are part of a French-English translation memory provided by Symantec. The data itself is in the domain of technical software user help information. We preprocessed the translation memory and removed all TMX markup and meta-information. We extracted 53,000 unique sentences from the translation memory, and from this data we randomly select 50,000 French-English sentence pairs as our training set. The sentences are between 1 and 98 words in length for English, and 1 and 100 words in length for French. The average sentence length in the training set is 13 words for English and 15 words for French, with a vocabulary size of 9,273 for the English side of the data, and 12,070 for French. Given the specific domain of the data, these are only 11 out-of-vocabulary (OOV) in the test set relative to the training data. The remaining sentences were split into a test set of 2000 sentences, and a development set of 1000 sentences. As we are working with a translation memory, all the sentences are unique. That is to say there are no repetitions in the data, and hence no overlap between the training, development, and test sets. Table 1 summarises the statistics of our data.

3.2 Rule-Based Translation

Despite the success of machine learning based and statistical approaches, rule-based machine translation systems still constitute a significant part of the current commercial MT landscape. RBMT systems work off built-in linguistic rules and bilingual dictionaries in order to construct

	French	English
TM Vocabulary Size	12,070	9,273
Training Vocabulary Size	11924	9159
Average Sentence Length	15	13
Range of Sentence Length	[1,100]	[1,98]

Table 1: Vocabulary and sentence length statistics for the French-English Translation Memory

translations for a given language pair. Wide-coverage systems rely on large-scale lexical and morphological, semantic, and syntactic information. Rule-based systems have been found to provide fluent and predictable quality translations.

As our rule-based machine translation system for the first stage MT in our experiments, we used the Systran Enterprise Server 6 production system, specifically customised with the use of 10K+ dictionary entries specific to the text type and domain of the Symantec translation memory data, as described in (Roturier, 2009).

3.3 Statistical Phrase-Based Machine Translation

Statistical machine translation builds statistical models based on the analysis of existing parallel corpora, both monolingual and bilingual. For our statistical machine translation system we used the PBSMT system Moses, 5-gram language models with Kneser-Ney smoothing trained with SRILM (Stolcke, 2002), the GIZA++ implementation of IBM word alignment model 4 (Och and Ney, 2003), with refinement and phrase-extraction heuristics as described in (Koehn et al., 2003). We used minimum error rate training (MERT) (Och, 2003) for tuning on the development set. During decoding, the stack size was limited to 500 hypotheses.

3.4 Statistical Post-editing

The first pipeline, which combines RBMT output with SPE (statistical post-editing) system, uses Systran to translate the entire source side of the TM-based training set, and the output together with the corresponding target side of the TM is then used as the training data for the SMT-based SPE system. The second-stage system therefore produces a monolingual translation based on the output produced by the first stage RBMT system and the target side of the TM training data (Figure 1).

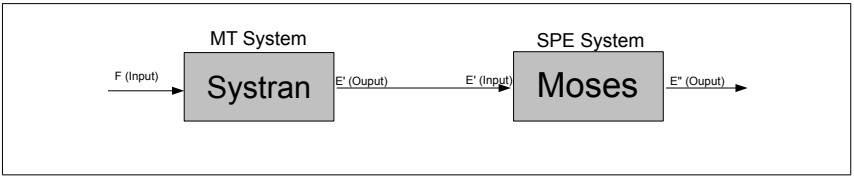

Figure 1: The RBMT+Moses pipeline, using the output of Systran as the input for the second stage SMT system (Moses)

The second pipeline uses SMT in both stages of the post-editing system. The first-stage PBSMT system is trained on the French to English parallel training data, and the output E' (MT output English) will be the source data for the second-stage (SPE) system. Once again the second-stage system produces a monolingual translation, this time using the output of the SMT system as its

input. The source side for the training data for the second-stage system is obtained by training another first-stage PBSMT system from French to English, using a 10-fold cross-validation approach on the French to English training set. This approach will ensure that we do not translate already seen data, and that the source side of the training set for the SPE system is as close in quality to the test set source as possible. Figure 2 illustrates the SMT+SPE pipeline.

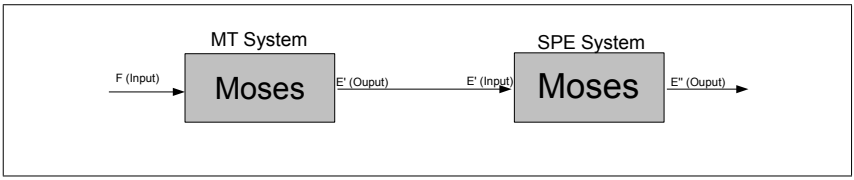

Figure 2: The Moses+Moses pipeline, using the output of Moses as the input for the second stage SMT system (Moses)

3.5 Automatic Evaluation Metrics

We used two metrics for automatic evaluation; BLEU (Bilingual Evaluation Understudy) and TER (Translation Edit Rate) (Papineni et al., 2002; Snover et al., 2006). Both of these metrics depend on a reference translation to estimate the quality of machine translated output. BLEU matches n-grams between the MT output and the reference translation, using n-gram precision with a brevity penalty as the score, as demonstrated in (1)

$$\text{BLEU}(n) = \prod_{1}^{n} PREC_i^{\frac{1}{n}} \cdot bp \tag{1}$$

where n is the order of n-gram, $PREC_i$ is the i-gram precision and bp is the brevity penalty. The brevity penalty is defined as (2):

$$bp = exp(max(\frac{len(Ref)}{len(Out)} - 1, 0)) \tag{2}$$

where $len(Ref)$ is the length of the reference and $len(Out)$ is the length of the output.
This n-gram matching scheme makes BLEU very sensitive to small changes in the output, and fails to capture linguistic variations, especially in the case where only one reference translation is being used. (Callison-Burch et al., 2008) show that that BLEU has a lower correlation with human judgement than metrics such as TER, which take into account linguistic resources and better matching strategies. Furthermore, BLEU is designed to evaluate MT output on a document level. For this reason, we have used S-BLEU (Sentence-Level BLEU) and TER to compare individual sentences.

TER is an Edit Distance-style evaluation metric that measures the amount of editing that a human post-editor would have to perform to change a system output so it matches the given reference translation. It calculates how many insertions, deletions, substitutions and sequence shifts are required to make the output identical to the reference. TER is defined in equation(3):

$$\text{TER} = \frac{\#INS + \#DEL + \#MOD + \#SHIFT}{len(Ref)} \tag{3}$$

	RBMT	SMT	RBMT+SPE	SMT+SPE
BLEU	23.26	65.43	64.63	65.14
TER	61.07	23.92	24.62	24.12

Table 2: BLEU and TER scores for the RBMT, SMT and the SPE systems

System	Ins	Del	Sub	Shift	TER
SMT	5.1	5.05	10.5	3.5	23.92
RBMT	17.04	4.39	30.24	9.3	61.07
SMT+SPE	5.47	4.95	10.1	3.56	24.61
RBMT+SPE	5.2	5.5	10.5	3.27	24.11

Table 3: Normalised number of translation errors for the RBMT, SMT, and SPE systems according to TER edit statistics

3.6 Automatic Evaluation Results

In order to evaluate the RBMT, SMT, RBMT+SPE and SMT+SPE approaches, we train and tune the SMT system on the French-to-English training and development sets, and decode the 2,000 sentence test set using this first-stage system. We also translate the complete training data using a 10-fold cross training approach (tuning on the same development set as above) to avoid translation of seen data to create the source side of the SPE system for the SMT+SPE pipeline. Furthermore, we translate the complete training data (as well as the test set data) using the Systran RBMT system, to create the source side training data for the SPE system in the RBMT+SPE pipeline. The target side of both SPE systems is provided by the target side of the training data from the TM. We evaluate automatically the post-edited translation of the test set using BLEU and TER. Despite the fact that the RBMT system was tuned to the TM data (section 3.2), Table 2 shows that SMT, RBMT+SPE and SMT+SPE outperform RBMT by more than 40 BLEU points absolute on our TM data set (with similar improvements for TER).[2] While the RBMT+SPE system improves over the RBMT output, it fails to improve over the pure SMT output, and performs similar to the SMT+SPE output in terms of the automatic evaluation scores.

Table 3.6 presents the number of average edits per sentence, based on the TER edit types. The errors are divided into four categories: insertion (Ins), substitution (Sub), deletion (Del) and shift. The numbers have been normalised using sentence length to make them comparable. The table suggests that applying SPE to the RBMT system achieves significant gains in the insertion and substitution categories, and to a lesser extent to the shift category. This reflects the fact that the SPE system can improve the pure RBMT translation in terms of better lexical choice and better reordering. Furthermore, the large number of substitutions and insertions in the RBMT system shows that the majority of the errors that account for the lower quality of the RBMT system are lexical. The number of deletions remains largely unaffected by the post-editing system, indicating that little information is actually lost during the second stage. Neither the RBMT+SPE nor the SMT+SPE systems achieve any significant gains over the pure SMT system.

4 Human Evaluation

In order to further investigate the quality of the RBMT+SPE output compared to the pure RBMT, pure SMT as well as the SMT+SPE output, we complement automatic evaluation metrics with a study involving human evaluators. Human evaluation can be an important source of

[2]Note again that there is no duplication between the test and training data extracted from the TM.

information, providing insight as to whether or not (and why) the SMT system actually performs better or worse than the RBMT+SPE pipeline, how these compare with the SMT+SPE output, and whether, and if so to what extent, the spectacular differences in automatic scores between the RBMT and the SMT and SPE pipeline systems actually correspond to human judgements.

4.1 The Evaluation Task

Evaluation was carried out by ten different translators of varied backgrounds. While none of them are professional translators, all of them have experience with machine translation or localisation. Six of these evaluators are native French speakers, and the others have a good grasp of French, evidenced by school and professional certificates. All of the evaluators speak English fluently.

The evaluators were asked to evaluate a pair of sentences from two of the four MT systems: pure SMT, pure RBMT and the two SPE pipelines RBMT+SPE and SMT+SPE. The evaluators were shown a source sentence (in French) and asked which of the two MT outputs (presented in random order) is a better translation, or if they are of equal quality. In order avoid biasing the evaluator, we did not provide a reference translation. The task spanned 200 sentences, and was available to be completed online. The subjects were paid for their time and were given a week to submit the task, which did not have to be completed in one sitting. Figure 3 shows a screenshot of the user interface with an example sentence included in the task. The evaluators generally rated the task as difficult, especially as the domain was highly technical and the sentences often fragmented and containing a large number of symbols and abbreviations.

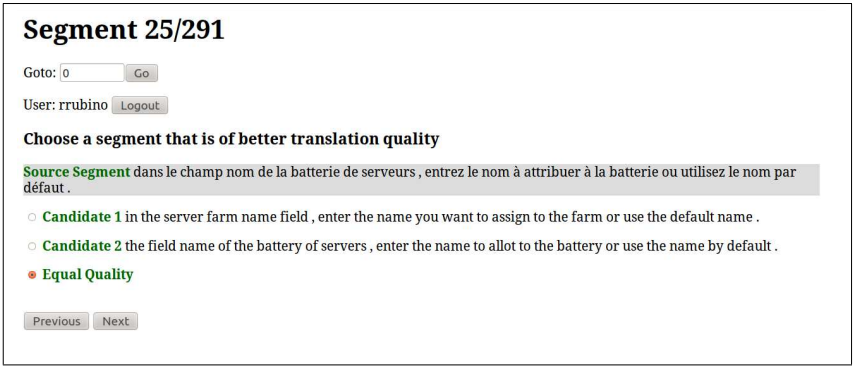

Figure 3: A screen-shot of the manual evaluation task

4.2 Annotator Agreement

Since a reasonable degree of agreement must exist to support the validity of our human evaluation experiment, we calculated pair-wise inter-annotator agreement between all of the different evaluators. For this agreement, we used Cohen's κ measure. κ is a more robust measure compared to simple percent agreement calculation, as it takes into account the

agreement occurring by chance. κ is defined by the formula in 4.

$$\kappa = \frac{Pr(a) - Pr(e)}{1 - Pr(e)} \tag{4}$$

Pr(a) is the proportion of times two annotators are observed to agree, and *Pr(e)* is the expected proportion of times the two annotators are expected to agree by chance. Agreement occurs when two annotators compare the same systems and agree on their rankings. In our case there are three possible choices; either one system is better than the other, or it is worse, or there is a tie. κ ranges between 0 and 1, with 1 indicating a higher rate of agreement, and 0 indicating low or no agreement.

According to (Landis and Koch, 1977), a moderate agreement falls between 0.4 and 0.6. A substantial agreement falls between 0.6 and 0.8, and 0.2 to 0.4 indicate a fair agreement, while anything below that is considered slight. Full results for all ten evaluators ($\kappa = 0.42$) are on the border between moderate to fair. As two of our evaluators scored an average agreement under 0.4, we discarded their results as weak. Without the outliers, our average agreement for the evaluators is 0.47. This amounts to low moderate agreement.

4.3 Human Evaluation Results

We tallied up the number of times that each system was chosen as "best system" based on the 200 sentences that were evaluated. The human annotators' results were normalised and divided by the number of annotators (in our case 8, as we discarded the outliers). In order to evaluate the document on a sentence-level, we used S-BLEU instead of BLEU. S-BLEU will still positively score segments that do not have highern-gram (n=4 in our setting) matching, unless there is no unigram match.

We compared the S-BLEU and TER scores for the sentences of each of the outputs, and tallied up the number of times each system was given the best score by either S-BLEU or TER. We then compared the results from the human evaluators with the S-BLEU and TER results. We found that while the automatic metrics seem to favour a pure SMT system, the human annotators were leaning more towards the combined rule based and post-editing system. Furthermore, while automatic evaluation metrics chose Systran as the best system less than 7% of the time, human evaluators chose it as the best system more than twice as often as S-BLEU or TER did. The results are further detailed in Table 4.

In order to assess the difficulty to compare different systems, we recorded the time each evaluator spent evaluating a translation pair. We assume that spending more time on an evaluation indicates that it is more difficult to select the best translation amongst the two alternatives. We report averaged results in Table 5. The results show that comparing the two stand-alone MT systems (RBMT and SMT) is hard because on average more than 20 seconds are spend to select the best translation. This is most likely due to the profound differences in terms of syntax and vocabulary between the SMT and the RBMT outputs. By contrast, when comparing SMT versus SMT+SPE, the time spent drops by nearly 10 seconds (on average). This is most likely due to the fact that SMT and SMT+SPE outputs are very similar, requiring less time to scan and judge. A similar trend can be observed comparing SMT with RBMT+SPE, where again outputs are more similar than between SMT and RBMT on their own. Finally, choosing between RBMT and RBMT+SPE requires the least amount of time. This is consistent with the observation that (according to the human evaluation) the quality difference between

	Human Evaluation	S-BLEU	TER
	SMT vs RBMT		
SMT	97	162	161
RBMT	52	16	9
Tie	51	26	30
	SMT vs RBMT+SPE		
SMT	28	125	124
RBMT+SPE	40	50	46
Tie	132	25	30
	SMT vs RBMT+SPE		
RBMT	40	16	11
RBMT+SPE	99	162	162
Tie	61	22	26
	SMT+SPE vs RBMT		
SMT+SPE	107	167	161
RBMT	46	11	9
Tie	47	25	30
	SMT+SPE vs RBMT+SPE		
SMT+SPE	27	46	46
RBMT+SPE	47	49	41
Tie	126	105	113

Table 4: Number of sentences chosen as "best" by each of the evaluations

RBMT and RBMT+SPE is the most pronounced, and therefore more "obvious" than in the other cases.

	SMT vs RBMT	SMT vs SMT+SPE	SMT vs RBMT+SPE	RBMT vs RBMT+SPE
Average time	23.4	14.12	12.61	9.52

Table 5: Average time spent (in seconds) by human evaluators on each system comparison.

5 Error Analysis

In order to obtain a better understanding of the translation quality gains between the RBMT system and the RBMT+SPE system, and to gain insight into why there are discrepancies between the manual and automatic evaluation results, we performed an additional manual sentence-level error analysis in a bid to reveal the advantages and disadvantages of the SPE pipelines compared with the RBMT and SMT systems.

Table 6 shows the detailed number of error types by system, based on the error typography provided by (Vilar et al., 2006). Our error analysis confirms what the TER edit statistics in Table 3.6 suggest, that most of the errors that account for the considerably lower quality of the RBMT system are lexical, both in terms of simple lexical choice and the repercussions of this on the phrasal level. Even though the RBMT system was tuned to the domain of the TM via domain specific lexical resources (Section 3.2), most of the errors appear to be due to the RBMT system's inability to pick the right term for the technical domain data set. However, compared to SMT and SMT+SPE, both the RBMT and RBMT+SMT system seem to produce a significantly lower number of grammatical errors, according to our evaluators. This is mostly obvious in the determiner and preposition categories, where combined, the SMT system produces three times as many errors as the RBMT system. Our results also show that while the SPE considerably

	RBMT	SMT	RBMT+SPE	SMT+SPE
Not Found Words	1.5	5	0	5
Simple Terms	34.5	10.5	6	9.5
Phrases	20.5	2.5	2	3
Meaning	20.5	2.5	2	3
Determiners	1	4.5	2	2.5
Prepositions	3	8.5	2.5	6
Tense	1.5	2.5	2.5	3
Number	0	1	1	1
Other Grammar	2.5	6.5	3.5	5.5
Punctuation	1	3.5	3.5	3.5
Word Order	7	4	4	4.5

Table 6: Normalised number and types of errors found in manual evaluation results

changes the error typography when applied to RBMT, reducing the overall number of errors, it has has a much smaller effect when applied to the SMT system. SMT+SPE fails to improve on a lexical choice where SMT has failed, and only marginally improved grammatical errors. Example 1 shows a very common RBMT lexical choice error. Errors such as these are almost always corrected in the statistical post-editing (SPE) phase.

Example 1

Source	options de planification de modification d'a pour **un travail de sauvegarde**
RBMT	options of planning of modification of has for **a work of backup**
RBMT+SPE	schedule options to change for **a backup job**
SMT	scheduling options has changed for **a backup job**
SMT+SPE	scheduling options has changed for **a backup job**
Reference	to change schedule options for for **a backup job**

Example 2 shows a similar case where the RBMT+SPE pipleline is superior when it comes to picking the right phrases within the correct domain. Due to the highly technical nature of the translation memory, the intended meaning is often lost if the wrong lexical choices are made.

Example 2

Source	pour installer **une version d évaluation**
RBMT	to install **a version of rating**
RBMT+SPE	to install **a trial version**
SMT	to install **a trial version**
SMT+SPE	to install **a trial version**
Reference	to install **an evaluation version**

On the other hand, RBMT often performs better when it comes to general grammar, especially in terms of prepositions and, to a lesser extent, determiners. This carries over to the RBMT+SPE system, which leads to a better grammatical quality than the pure SMT system (or the SMT+SPE pipeline, for that matter). Example 3 shows a common case where the preposition is missing from the Moses translation, but is inserted correctly in both the RBMT and RBMT+SPE translations.

Example 3

Source	pour ajouter le **le nom de compte** de connexion
RBMT	to add the name **of account** of login
RBMT+SPE	to add the name **of logon account**
SMT	to add the name **logon account**
SMT+SPE	to add the name **logon account**
Reference	to add the **logon account** name

Another interesting aspect concerns out-of-vocabulary (OOV) words. RBMT seems to be better at finding words than SMT (this is probably a reflection of the fact that the RBMT system used in our experiments was a production system tuned with a domain-specific 10k+ dictionary to the TM-based data-set), and even though these are not always perfectly correct words, they are sometimes fixed in post-editing, as seen in Example 4. As a result, RBMT and RBMT+SPE produce few if any out of vocabulary items given the output.

Example 4

Source	**enregistrera** l'image .iso idr amorçable ou non amorçable
RBMT	will **record** the or not bootable image .iso idr bootable
RBMT+SPE	will **save** the idr bootable or non-bootable .iso image
SMT	**enregistrera** the idr bootable or non-bootable .iso image
SMT+SPE	**enregistrera** the idr bootable or non-bootable .iso image
Reference	will **save** the bootable or non-bootable idr .iso image .

The results also show that in a few cases SMT+SPE can produce some grammatical improvements over the pure SMT system as well. Example 5 is one such case, where SPE applied to SMT corrected a grammatical error (the missing preposition **for**).

Example 5

Source	le nombre de secondes **pendant lesquelles le processus de restauration** ...
RBMT	the number of seconds **during which the process of restoration** ...
RBMT+SPE	the number of seconds **for the restore process** ...
SMT	the number of seconds **the restore process** ...
SMT+SPE	the number of seconds **for the restore process** ...
Reference	the number of seconds **for the restore process** ...

Conclusion and Perspectives

Previous research on automatic post-editing has shown spectacular improvements in automatic MT evaluation scores of RBMT + SPE pipelines over RBMT systems. In this paper we set out to answer two open questions for an SPE scenario that uses independently existing bitext training data, rather than specifically and manually corrected first stage MT output, as its training data:

- Is statistical post-editing (SPE) improving the output of the first-stage RBMT system, or is it just pushing the output closer to the reference translation?
- Does the RBMT+SPE pipeline improve the quality of the output over that of the pure SMT system as well as that of an SMT+SPE system trained on the same data set?

In order to answer these questions we used human evaluation from annotators who were unbiased by the reference translation. Our human evaluators agreed with the automatic evaluation metrics that the RBMT + SPE system does indeed perform better than the RBMT system on its own. Additionally, while they did not find the improvement as pronounced as the automatic evaluation metrics indicate, they consistently rated the RBMT + SPE system higher than the RBMT system by a factor of two.

While automatic evaluation metrics indicate that SPE does not improve RBMT systems over pure SMT system, a manual evaluation shows that human evaluators prefer the RBMT + SPE output over the pure SMT output. We conclude that this discrepancy is a result of S-BLEU and TER being biased towards the SMT system. Error analysis shows that SPE makes better lexical and phrasal choices, which leads to superior translation quality. We also observed that the human evaluators spend more time to select the best translation when the MT systems are very different (SMT and RBMT for instance), which reflects the underlying difficulty of the evaluation task.

We would like to use what we learnt about the nature of the errors and the strengths and weaknesses of the post-editing system to automatically predict which sentences can be corrected using SPE. Many sentences do not benefit from the post-editing phase, and a subset of sentences even degrade after post-editing. Using machine learning techniques, we plan to classify the output of the RBMT system, based on a variety of features, into two categories: those that benefit from SPE, and those that do not. Furthermore, we plan to train a classifier to choose better sentences of the two systems, RBMT+SPE and pure SMT, in order to reach the upper bound given by the two systems together. Furthermore, results obtained from the error analysis should enhance feature selection methods.

We will research ways to further refine statistical post-editing techniques for both RBMT and SMT systems. In previous work, we developed a contextualised SPE system that attempts to preserve the original context of the source material with a novel method of context modelling (Béchara et al., 2011). We intend to take this work further and refine our use of context information. We will also experiment with different system combinations: in addition to RBMT and PBSMT systems, we will utilise a hierarchical phrase based SMT system (Chiang, 2005).

Acknowledgments

This work is supported by Science Foundation Ireland (Grant No. 07/CE/I1142) as part of the Centre for Next Generation Localisation (www.cngl.ie) at Dublin City University. We would like to thank Symantec, in particular Dr. Johann Roturier and Dr. Fred Hollowood, for providing us with the data and with access to the Symantec Systran Machine Translation Production System. We would like to thank Dr. Stephen Doherty, from the School of Applied Language and Intercultural Studies at Dublin City University, for providing us with access to masters in translation students to act as our evaluators. We would also like to thank the reviewers for their many insightful comments, suggestions, and corrections.

ABSTRACT
We present the Prague Dependency Treebank 2.5, the newest version of PDT and the first to be released under a free license. We show the benefits of PDT 2.5 in comparison to other state-of-the-art treebanks. We present the new features of the 2.5 release, how they were obtained and how reliably they are annotated. We also show how they can be used in queries and how they are visualised with tools released alongside the treebank.

TITLE AND ABSTRACT IN CZECH

Pražský závislostní korpus 2.5 – rozšířená verze PDT 2.0

Představujeme nejnovější verzi Pražského závislostního treebanku PDT 2.5, který bude poprvé vydán pod veřejnou licencí. Výhody PDT 2.5 ukážeme na srovnání s nejmodernějšími treebanky. Představíme nové vlastnosti verze 2.5, popíšeme, jak byly anotovány i jak spolehlivá tato anotace je. Ukážeme, jakými dotazy lze nové jevy hledat a jak se zobrazují v nástrojích dodávaných spolu s treebankem.

KEYWORDS: treebank, linguistic theory, PDT, annotation, syntax, semantics, multiword expressions, pair/group meaning, clauses.

CZECH KEYWORDS: treebank, lingvistická teorie, PDT, anotace, syntax, sémantika, víceslovné výrazy, souborovost, klauze.

1 Introduction

The task of grammatical theories is to explicitly describe phenomena of language with the purpose of creating a description that analyses and/or generates language as natural as possible. The creation of a treebank then serves as an ultimate test of a linguistic theory.

Treebanks that have not been based on an elaborate theory which takes into account most phenomena of natural language start with a simple design. If they become popular, various additional, more-or-less ad hoc linked projects end up being piled upon the original simple design.

On the other hand, there are very complex theories that have been being developed for decades to take into account all of the possible phenomena of natural language but have not yet undergone the ultimate test of large-scale treebanking (e.g. Mel'čuk and Polguère, 1987).

In this paper we introduce the Prague Dependency Treebank 2.5 (PDT 2.5), the latest instance of a large treebank whose design is based on the Functional Generative Description. It is a step from PDT 2.0 towards PDT 3.0 (coming in 2013 with additional large-scale annotation of discourse, anaphora and more) which brings annotation of three new features finished so far and a number of corrections.

The rest of the paper is organised as follows: we introduce some basic facts about PDT 2.5 and the previous version of the treebank in Section 2. In Section 3, we provide some background on treebanking projects in general and compare PDT 2.5 with other popular treebanks. Next we present the new features of PDT 2.5: annotation of multiword expressions in Section 4, new semantic distinction of pair/group meaning of nouns in Section 5, and identification of clauses in Section 6. We summarise the state of the treebank and its general ecosystem in Section 7.

2 Prague Dependency Treebank 2.5 and the previous version

Functional Generative Description (FGD) is a relatively complex linguistic theory and as such it has provided many fundamental ideas that are directly reflected in the PDT design, e.g. multiple layers of linguistic description and the dependency approach to syntax based on the theory of valency (Sgall et al., 1986; Sgall, 1967). Nonetheless, FGD does not encompass all phenomena either, not even in the language core.

In this paper we focus on PDT 2.5, which is an updated release of PDT 2.0. For this new release, the data of PDT 2.0 have been enriched with annotation of three new phenomena (see Sections 4 to 6). Furthermore, some of the errors in the PDT 2.0 data have been corrected in the new release (they mostly involved morphological tags and lemmas[1] for personal names and abbreviations, yet some of these changes were also reflected on the higher layers). However, the design of the PDT 2.5 annotation as well as the size of the data are identical with PDT 2.0.

PDT 2.0 (Hajič et al., 2006) is a collection of Czech newspaper texts from 1990s with annotation added on four layers: on the word layer (w-layer), the source texts have been tokenized and segmented. The morphological layer (m-layer) provides a lemma and a positional tag for each token (word form or punctuation mark). On the analytical layer

[1] About 10 thousand morphological nodes were fixed.

(a-layer), a sentence is represented as a dependency tree with labelled nodes and edges, which correspond to surface-syntactic relations (such as subject, object etc.); one analytical node corresponds to exactly one morphological token. On the tectogrammatical layer (t-layer), the meaning of the sentence is represented as a dependency tree structure with additional features and constraints.

Tectogrammatical nodes (t-nodes) represent content words (including pronouns and numerals), whereas functional words such as prepositions have no separate node in the tree.[2] All t-nodes are labelled with t-lemmas, dependency relations (functors, such as an actor ACT, addressee ADDR or location specification LOC) and grammatemes (see Section 5). Furthermore, annotation of valency, coreference, and topic-focus articulation are all available in tectogrammatical trees as well (Mikulová et al., 2006).

The PDT data consist of 7,110 manually annotated textual documents containing 115,844 sentences with 1,957,247 tokens (word forms and punctuation marks). All these documents were annotated on the m-layer, 75 % of them were annotated on the a-layer (5,330 documents, 87,913 sentences, 1,503,739 tokens). 59 % of the a-layer data were annotated also on the t-layer (i.e. 45 % of the m-layer data; 3,165 documents, 49,431 sentences, 833,195 tokens).

As we are improving the PDT by providing more explicit and consistent annotation guidelines, we are also improving the theoretical framework of FGD. The same is true when we add analysis of phenomena not tackled by the original theory. The theoretical studies preceded the annotation stage.

2.1 Prague Markup Language

PDT uses the PML format (Pajas and Štěpánek, 2006) based on XML. Each token and node has been assigned a unique identifier; any layer built atop of another uses the identifiers from the lower layer as reference targets, effectively creating inter-layer links (of various types). Each node can be assigned an attribute-value structure, an *attribute* in short, that represents various grammatical categories.

Another advantage of the PML format is the availability of the framework surrounding it. The tools provided include the tree editor `TrEd` (Pajas and Štěpánek, 2008), the query language and engine PML-TQ (Pajas and Štěpánek, 2009, see also Figure 2) and a highly modular NLP system Treex (Popel and Žabokrtský, 2010).

3 Related work

During the past decade, plenty of treebanks have been published. New treebanks keep appearing at least bi-monthly.[3] There are some features, though, that set PDT 2.5 apart from most of them.

The most popular treebank of all times is the Penn Treebank (Marcus et al., 1993). It has been since extended by several projects: PropBank (Palmer et al., 2005), NomBank (Meyers et al., 2004), BBN Pronoun Coreference and Entity Type Corpus (Weischedel and Brunstein, 2005), and a few more.

[2] There are several exceptions of a technical nature. For instance, counterparts of coordinating conjunctions are included in the tree because they are used for the representation of coordinating constructions.

[3] LDC has published 5 new treebanks so far in 2012: `http://www.ldc.upenn.edu/Catalog/ByYear.jsp`

The pitfall of this process can be demonstrated on the Chinese Treebank (Xue et al., 2010), whose development followed the Penn Treebank pattern. The additional layers of annotation follow the stand-off principle, linking them to the original data. What remains problematic, though, is the format of these links: for example, both the proposition and word sense annotations use a "token number" to refer to a particular token in a sentence, but the latter only counts terminals with a surface form, while the former includes various added nodes as well (e.g. traces, pro's). Similarly, the coreference annotation (and named entity annotation, too) operates directly on the text, not taking the underlying phrase structure into account. Therefore, units that enter the coreference relations sometimes do not correspond to a continuous subtree of a tree.

As a result, it is substantially non-trivial to search for phenomena that involve several such layers (e.g. "list all the verbs at which a given named entity or a pronoun corefering to it can appear as Arg0").

The PML format (see Section 2.1), on the other hand, results in unambiguous interconnection of the annotation layers.

There are other projects aiming at standardisation of the solutions and conversion of old formats to new ones, cf. (Ide and Suderman, 2009). The solution used in the PDT is comparable to these efforts and standards (such as the LAF or TEI and its variants), but it has the added advantage of being supported by a complete suite of tools for annotation, search and processing mentioned earlier.

Finally, not all treebanks are freely available. Various license restrictions (and usage fees) exist. PDT 2.5 is now being distributed under the standard Creative Commons license (3.0-BY-NC-SA) allowing free access and distribution of additions and modifications.

4 Multiword expressions

Multiword expressions (MWEs) such as idioms, phrasemes, and multiword named entities are an important and sometimes overlooked part of natural languages. Usually they form a significant portion of the vocabulary, particularly in special domains where terminology is in play, but not only there: 16.3% of content words in the PDT are part of a MWE.

Multiword expressions are a boundary phenomenon on the interface of grammar and lexicon. We understand them, in accordance with Sag et al. (2002), Baldwin et al. (2003), Pecina (2009), and other authors, as phrases that contain some *idiosyncratic element* that differentiates them from normal expressions. This idiosyncratic element can be morphological, syntactic, or semantic. Although the annotation belongs to semantic layer, we have means for annotation on the other layers as well.

As a practical guideline for how idiosyncratic the expression must be to constitute a MWE, the most important criteria are the absence of *compositionality of meaning* and *word-for--word translation*. Neither of these criteria is absolute either by itself or together, but they are strong indicators, nonetheless. If these or any other secondary criteria compel a native speaker to add the expression to a dictionary because it requires an explanation, we consider it a MWE. For examples, see page 6.

Although some grammatical theories have accounted for MWEs decades ago (see e.g. Mel'čuk and Polguère, 1987), the annotation of MWEs is one of the least developed phenomena in treebanks. There were some MWEs annotated in PDT 2.0 (such as per-

sonal names or foreign phrases) and there are other treebanks that include named entities and/or MWEs to some extent, e.g. the German TüBa-D/Z or the Bulgarian BulTreeBank.[4]

In PDT 2.5, we annotate all occurrences of MWEs, including named entities (see below). We do not inspect various linguistic subtypes of MWEs in the treebank because we believe it is not the right place to analyse their grammatical attributes—only their instances should be identified in the treebank. Once that is done, a lexicon linked to their occurrences in corpora can be compiled and the MWEs (MWE types) can be analysed, taking into account all the information that can be acquired from the annotated occurrences in the data, as well as other resources. We have compiled a preliminary version of such a lexicon. It is complete with regard to lexemes occurring in the PDT 2.5 data and it is freely available.[5] The elaborate lexicographic analysis of all its entries, however, has yet to be performed. That is why the dictionary is not part of the PDT 2.5 release.

We distinguish a special type of MWEs: **named entities (NE)**.[6] In their case we are interested mainly in their *type* (see the list below) and their *basic form*. Since Czech is an inflectional language, a *basic form* of a MWE often differs from the form used in the sentence, but also from the sequence of basic forms (lemmas) of the individual words. This is illustrated by Examples 1 and 2. In the current release of PDT 2.5, basic forms have been manually added to some types of MWEs (see the full list below): lexemes, persons, locations, objects and some institutions. Treatment of NEs together with other MWEs is important, because syntactic functions are more or less arbitrary inside a NE (consider an address with phone numbers, etc.) and so is the assignment of semantic roles. That is why we need to be able to display each NE as a single node, just like we do it with MWEs in general. See details in Section 4.1.

Tectogrammatical layer is the layer of linguistic meaning, so the MWE annotation belongs there. MWEs can be more easily captured on the t-layer, because: (i) there are added nodes for words not present in the surface sentence (ellipses), (ii) each MWE constitutes a **continuous** subtree on the t-layer; such subtree is consequently collapsible and it can be represented as a single t-node, and (iii) the t-layer also does not feature nodes for auxiliary words,[7] which significantly simplifies the annotation process.

All the multiword expressions in a given sentence are stored in the attribute mwes of the root node of the tectogrammatical tree. The attribute mwes is a list, whose members represent MWEs in the tree. Each MWE contains an ID, a basic-form, a type and a list of identifiers of t-nodes that are a part of the MWE. The type of a MWE can have one of the following values:

- lexeme,[8]
- person (a name of a person or an animal),
- institution,
- object (e.g. a name of a book, a unit of measurement, a biological name of a plant or an animal),
- location,
- address,
- time,
- biblio (a bibliographic entry),
- foreign (a foreign expression),
- number (esp. a numerical range).

[4] See http://arbuckle.sfs.uni-tuebingen.de/en_tuebadz.shtml and (Osenova and Kolkovska, 2002).
[5] http://ufal.mff.cuni.cz/lexemann/mwe/
[6] An easier annotation of *single-word named entities* is left for future versions of PDT.
[7] Auxiliary words are instead accessible through attributes and links.
[8] "Conjunction of the lexical form and the individual meaning" (Filipec, 1994). Compare also "lexical unit"

Examples:

(1) *Prezident Havel by měl 15. července*[*] *na Pražském hradě*[†] *jmenovat třináct soudců Ústavního soudu*[‡] .
transl.: *President Havel is expected to appoint thirteen judges of the Constitutional Court on 15th of July at the Prague Castle.*

[*] *'on 15th of July'* – date, basic-form: "15. červenec" (nominative case)
[†] *'at Prague Castle'* (locative case) – location, basic-form: "Pražský hrad" (nominative case)
[‡] *'[of] Constitutional Court'* (genitive) – institution, basic-form: "Ústavní soud" (nominative)

(2) *Funkce ústavního soudce*[*] *je neslučitelná s členstvím v politických stranách*[†] .
transl.: *The role of a constitutional judge is incompatible with political party membership.*

[*] *'[of a] constitutional judge'* (genitive) – lexeme, basic-form: "ústavní soudce" (nominative)
[†] *'in political parties'* (locative, plural) – lexeme, basic-form: "politická strana" (nominative, singular)

4.1 MWE display and search

There are two modes of viewing the MWEs in TrEd: they can be seen either as coloured groups of t-nodes in a tectogrammatical tree (see Figure 3C), or they can be collapsed into a single node (see Figure 3B). When collapsed, children of the members of a MWE become children of the MWE node itself as we can see with *deficit* and its parent *miliarda* in Figure 3. In the "node group" mode the groups are drawn in different colours representing different types of MWEs. In Figure 3 (B) and (C) there is a subtree (*'a 33 billion budget deficit'*) with 2 MWEs (NE *'33 billion'* and a lexeme *'budget deficit'*)[9] in a compact collapsed form (B) and in a coloured group-view (C). Orange colour represents a multiword number and pink represents a lexeme in (C).

4.2 Annotation procedure

We annotated all occurrences of MWEs (including named entities, see below) at the tectogrammatical layer of PDT. A large part of the data was annotated in parallel. A table below shows how much data was annotated by 1, 2, or 3 annotators in parallel, compared to the size of the t-layer.

	number of annotators			$\sum$ annotated	$\sum$ parallel
	one	two	three	(100% of PDT t-layer)	(in % of PDT t-layer)
t-files	1,288	1,412	465	3,165	59
t-nodes	248,448	343,834	82,683	674,965	63

Table 1: Parallel annotation of data

The data produced by individual annotators is not part of PDT 2.5, but it is freely available at the project web page.[10] For the present release it was used to produce gold standard MWE annotation in the following manner: if the annotators agreed, the MWE was kept as gold. Disagreement was decided as follows:

of Cruse (1986).

[9] Multiword numeric entity is always annotated. The reason for annotation of "budget deficit" (translatable, as you can see) is non-compositionality: it is different than, e.g., "oxygen deficit", because there is no budget shortage, but shortage of money in the budget (or even an income shortage comparing to costs).

[10] http://ufal.mff.cuni.cz/lexemann/mwe/

In case a MWE was recognised by only one annotator, we kept it, since a test had shown that it was much more common for an annotator to miss a MWE than to annotate a false MWE. In case one annotator annotated a subset of the other's MWE, we kept the larger MWE. On the other hand, when one annotator chose several small MWEs covering the other's larger MWE, the smaller ones were kept.[11] The cases when the annotators created intersecting MWEs were judged by a third annotator, as were the cases when one annotator identified several subsets of the other's MWE but the subsets didn't cover the full extent of the large MWE.

5 The grammateme typgroup representing the pair/group meaning

In Czech, nouns typically have two sets of forms according to the grammatical category of number: singular forms and plural forms. Forms of the former set are used to denote a single entity (singularity meaning), plural forms express, in general, more than one entity (plurality meaning). Within the theoretical linguistic framework of FGD as well as in the annotation scenarios of PDT 2.0 and PDT 2.5, the semantic opposition of singularity and plurality is represented by the values sg vs. pl of the grammateme number; grammatemes are attributes of nodes of the tectogrammatical tree, which capture the semantically relevant morphological categories.

In addition to the existence of nouns accompanied in the lexicon with the feature "singulare tantum", which blocks the semantic opposition of sg vs. pl (e.g. *kamení 'stones'*) and "plurale tantum", where sg and pl are expressed by the same form (e.g. dveře 'door/doors'), there are nouns in Czech that have both singular and plural forms but their plural forms are used to refer to a pair or to a typical group of entities rather than to a plurality of them. For instance, the plural *ruce 'arms'* denotes a pair or several pairs of arms rather than several upper limbs, the form *boty 'shoes'* denotes a pair or several pairs of shoes, the form *klíče 'keys'* means a bundle or more bundles of keys. The meaning is referred to as the "pair/group meaning" in the present paper.

As the pair/group meaning is compatible with most Czech concrete nouns and it manifests in some peculiarities as to the compatibility of the particular nouns with numerals,[12] we proposed to treat the pair/group meaning as a grammaticalized meaning constituting a new grammatical category of Czech nouns (Panevová and Ševčíková, 2011).

5.1 Grammateme typgroup

For the purpose of including the pair/group meaning into the tectogrammatical annotation of PDT 2.5, a new grammateme typgroup was added to the existing set of 15 grammatemes used in PDT 2.0. For the typgroup grammateme, three values were defined: group for the pair/group meaning, single for the meaning of single entities, and nr ("not recognised") for unresolvable cases.

The pair/group meaning is closely related to the meanings of the number category. In connection with the annotation of the grammateme typgroup, values of the grammateme

[11] Because it is typically a case like the composer and a symphony annotated together as a concert performance.

[12] The counting of pair/group nouns requires using a set numeral instead of a cardinal one. This is a strong argument in favor of considering the pair/group meaning a grammatical category. Cf. the set numeral *dvoje 'two sets'* in the example *Máme dvoje sklenice – na bílé a červené víno. 'We have two-sets of glasses – for the white and for the red wine'* vs. the cardinal numeral *dvě 'two'* if counting single entities in the sentence *Postavil na stůl dvě sklenice. 'He put two glasses on the table'.*

number as implemented in the PDT 2.0 data had to be changed in some cases. For instance, if the plural form was identified as denoting a pair or group, the value pl (assigned to the node representing this form in PDT 2.0) was changed to sg in the PDT 2.5 data.

5.2 Manual annotation of the typgroup grammateme with selected nouns

In the PDT 2.5, the grammateme typgroup was assigned semi-automatically with all nouns; the manual annotation concerned the nouns for which a higher frequency of the pair/group meaning was expected, the rest of the nouns was assigned a value of the typgroup grammateme automatically.

Occurrences for manual assignment were selected on the basis of a list of tectogrammatical lemmas (t-lemmas) of prototypical pair/group nouns. Nouns which co-occur with a set numeral in the PDT 2.0 and in the SYN2005 (ÚČNK, 2005) corpus data were analyzed as good candidates for this list. The list was further enriched using grammar books and theoretical studies on number in Czech as well as linguistic introspection. In the resulting list, 141 Czech nouns were involved, only 67 of them with 618 instances of plural forms were found in the PDT 2.5 data. Most of the nouns belong to one of the following groups:

- nouns denoting body parts occurring in pairs or groups (*uši 'ears'*, *prsty 'fingers'*, *vlasy 'hair'*),
- nouns denoting clothes and accessories for these body parts (*náušnice 'earrings'*, *rukavice 'gloves'*),
- nouns denoting family members such as *rodiče 'parents'*, *sourozenci 'siblings'*, and
- nouns denoting objects of everyday use and foods sold or used in typical amounts (*klíče 'keys'*, *sirky 'matches'*, *cigarety 'cigarettes'*, *sušenky 'biscuits'*).

The plural forms to be annotated were extracted from the data together with a short, both preceding and following context. In order to make the annotation task as simple as possible, the annotators did not specify the values of both the typgroup and number grammatemes, but they were asked to choose one of the annotation choices 1 to 6; the correspondences between the annotation choices and the grammateme values are described in Table 2. All 31 files were annotated manually by two annotators (native Czech speakers) in parallel during four months, the annotation was preceded by a short training period. The language intuition of native speakers played a crucial role in the annotation process. The annotators agreed on 464 (75.1%) out of 618 instances annotated, with a Cohen's Kappa score of 0.67. After the manual parallel annotation, instances of disagreement were adjudicated by a third annotator and the instances on which annotators agreed were revised in order to check the correctness and consistency of the annotation. The frequency of the choices in the revised annotation is summarized in the last column of Table 2.

5.3 Automatic assignment of the typgroup grammateme to the remaining nouns

Nouns which were not in the list (and consequently in the manual annotation) were assigned a value of the typgroup grammateme fully automatically. A simple, two-step procedure was provided for the automatic annotation: in the first step, nouns accompanied

Annotation choice	Grammateme values typgroup	number	# of instances (percentage)	
1 - plurality	single	pl	133	(21.5%)
2 - one pair/group	group	**sg**	230	(37.2%)
3 - several pairs/groups	group	pl	30	(4.9%)
4 - one pair/group or several pairs/groups	group	**nr**	154	(24.9%)
5 - cannot be resolved	nr	**nr**	70	(11.3%)
6 - —	*to indicate a mistake*		1	(0.2%)

Table 2: Manual annotation: annotation choices and corresponding combinations of the values of the grammatemes typgroup and number and their frequency in the manually annotated data. The number values marked in bold were changed from the pl value (as available in the PDT 2.0 annotation) to the marked value, influenced by the annotation of the pair/group meaning.

Grammateme values typgroup	number	# of instances
single	sg	185086
single	pl	59912
single	nr	10232
group	sg	237
group	pl	35
group	nr	153
nr	nr	66

Table 3: Combinations of values of the grammatemes typgroup and number and their frequency in the PDT 2.5 data.

with a set numeral *jedny 'one-pair/group'* (except for pluralia tantum) were assigned the value group of the grammateme typgroup and the value of the grammateme number was changed to sg in this connection; if the noun collocated with a set numeral of a higher numeric value (*dvoje 'two-pairs/groups-of'*, *troje 'three-pairs/groups-of'* etc.), the value group was filled in the grammateme typgroup whereas the grammateme number remained unchanged (i.e. pl). Secondly, all the other nouns were assigned the value single in the grammateme typgroup, the value of the grammateme number was not changed in these cases, compared to the original (PDT 2.0) annotation.

Combinations of the values of the grammatemes typgroup and number in the full PDT 2.5 data and their frequency is displayed in Table 3.

6 Automatic annotation of clause segmentation

Analytical trees in PDT 2.5 have been enriched with annotation of clause segmentation. Clauses are grammatical units out of which complex sentences are built. A clause typically corresponds to a single proposition expressed by a finite verb and all its arguments and modifiers (unless they constitute clauses of their own).[13] Annotation of clauses can be

[13]Given that Czech is a pro-drop language (pronouns in subject positions are often dropped, since their gender, number and person values are already expressed by verb inflection), this definition based on finite verbs matches

used for training clause boundary identifiers, which are generally supposed to be helpful in a number of NLP tasks such as parsing (since most dependencies do not cross clause boundaries), text summarisation (for instance, relative clauses might contain information of lesser importance and thus are more likely to be removable), machine translation (most reordering patterns are to be applied inside clauses), and speech applications (clause boundaries often imply prosodic boundaries).

We believed that clause boundaries could be identified automatically with very high reliability, since gold-standard morphological and more importantly, analytical annotation had already been available. Therefore clause boundaries were annotated manually only in a small portion of the PDT data and this annotation was used for developing a rule-based clause-identification procedure. To make the annotation consistent across the whole data, all the clause annotation distributed in PDT 2.5 was generated by this procedure; the original manually annotated samples are not included in PDT 2.5.

6.1 Basic conventions for clause representation

Technically, clause boundaries are represented by the dedicated attribute `clause_number` added to analytical nodes. If two analytical nodes in a tree share the same non-zero value of this attribute, then they belong to the same clause. Zero value of this attribute is reserved for boundary tokens, i.e. tokens that are located on the boundary of two clauses and cannot be unequivocally assigned to either of these clauses. Boundary tokens are typically various types of punctuation marks or coordinating conjunctions.[14]

Coindexing by the dedicated attribute is rendered by colours in the PDT 2.5 clause segmentation samples below:

(3) *U sochy básníka seděl vlasatý mladík a⋆ hrál Vysockého písně.†*
transl.: *There was a hairy guy sitting at a statue of a poet playing Vysockij's songs.*
⋆ Clause boundary is formed by the coordinating conjunction between the two clauses.
† Sentence boundary is manifested by the final punctuation.

(4) *Pokud jde o kupní smlouvu a⋆ všechny náležitosti s ní spojené,† musí si to zařídit a⋆ zaplatit strany samy.*
transl.: *Considering the buying contract and all related requirements, it has to be set and paid by contracting parties themselves.*
⋆ The coordinating conjunction that joins *sentence constituents* belongs to the clause.
† Clause boundary manifested by the punctuation symbol.

(5) *Lidé na nás tehdy chodili, aby⋆ se odreagovali od přítomného režimu.*
transl.: *People in those days used to attend our sessions, so that they could lay off the present government.*
⋆ The subordinating conjunction belongs to the subordinate clause.

(6) *Posunovač, který prý vstoupil do kolejiště, aniž se rozhlédl, je nyní v nemocnici⋆ .*
transl.: *The switchman that is said to enter the railyard without even looking around is in the hospital.*
⋆ The matrix clause is split into two parts by the embedded relative clause, which is further modified by the dependent clause.

(for Czech) the traditional notion of a clause as a group of words having a subject and a predicate.

[14] Note that subordinating conjunctions are systematically annotated as part of the respective dependent clause. The reason for this decision lies in their linguistic properties: subordinating conjunctions in Czech make an integral part of the dependent clause and, if omitted, the clause might become ungrammatical.

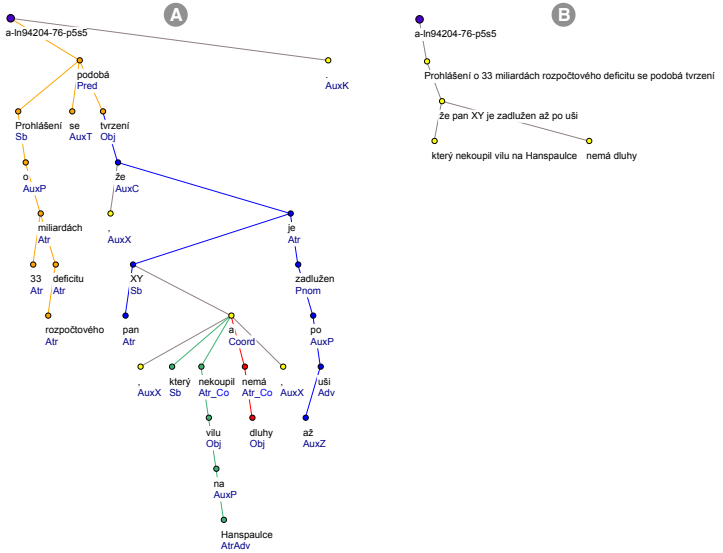

Figure 1: Two ways to visualise sentence segmentation in TrEd. Translation in Figure 3.

Clause segmentation can be comfortably visualised in the tree editor TrEd (see Figure 1) in two styles: either in full (unfolded) or in folded trees. In the former case, the tree topology is displayed as usual and clause segmentation is signalled by node and edge colours (see Figure 1A). In the latter case, the set of nodes belonging to one clause collapses to a single node which represents the whole clause (see Figure 1B).

6.2 Annotation procedure for clause segmentation

The automatic clause identification procedure can be outlined as follows:

1. Clause seeds are identified. Every occurrence of a finite verb form (the POS tag identifies finiteness reliably) is marked as a distinct clause seed.
2. Seeds forming a compound verb are joined together. Seeds with the analytical function of an auxiliary verb (AuxV) cannot constitute a clause on their own.
3. The tree is recursively traversed (post-order) and each coordination head is temporarily added to the clause of its rightmost member that already belongs to a clause.
4. Clause completion step. The tree is traversed recursively and the children that do not yet belong to any clause are typically added to the clause of the parent node (special handling of coordinations is needed here), or to their nearest left or right sibling that already constitutes a clause.
5. All potential boundary nodes are excluded from the clauses and their clause membership is re-estimated. The criteria is based mostly on the linear order of tokens but attention is also paid to the tree structure.

```
t-root [
    atree.rf $aroot,
    2+x member mwes [  ],
    descendant t-node [
        gram/typgroup = "group"
] ];

a-root $aroot := [
    1+x descendant a-node [
        clause_number = 3
] ];
```

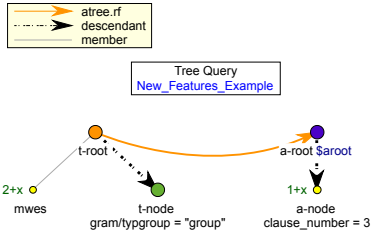

Figure 2: The PML-TQ query used to obtain Figure 3 in a textual and in a graphical form. It searches for a sentence with at least three clauses, two MWEs, and one word with the pair/group meaning.

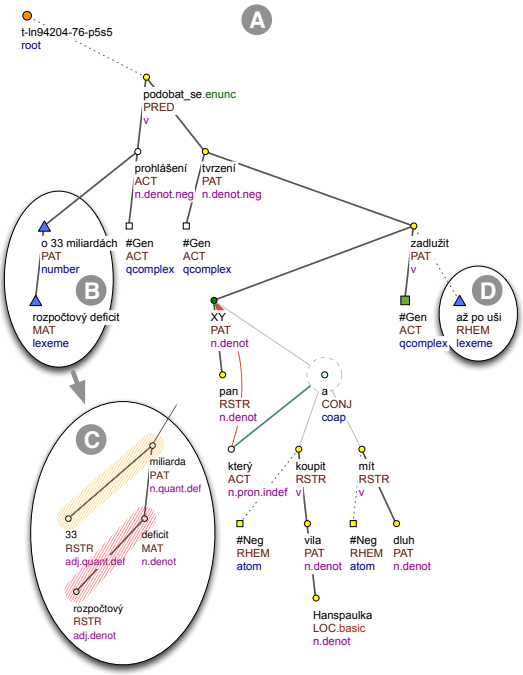

Figure 3: An example tree showing all the new features of PDT 2.5 as shown in TrEd: *Prohlášení o 33 miliardách rozpočtového deficitu se podobá tvrzení, že pan XY, který nekoupil vilu na Hanspaulce a nemá dluhy, je zadlužen až po uši**.
transl.: *The statement on 33 billion [of] budget deficit is similar to the statement that Mr. XY, who didn't buy a luxury villa and doesn't owe to anyone, is up to his ears* in debt.*
* pair meaning

6.3 Evaluation and application on PDT 2.5 data

For the purpose of evaluation, we obtained data from a pilot project on annotating sentence structure, whose methodology is thoroughly formulated in (Lopatková et al., 2012). The project provided us with a valuable collection of 2505 manually annotated sentences. We use these gold-standard sentences for evaluation of our automatic clause-identification procedure. Despite being a subset of the PDT data, the manually annotated sentences are not shipped with PDT 2.5 due to reasons explained below; for clause boundaries, all the PDT 2.5 data are annotated automatically.

Mostly because of the different scope of the project, we have adopted a slightly different annotation scheme. Let us summarise the original concepts and emphasise the differences.

The theory behind the pilot project (Lopatková et al., 2012) is centred on *segmentation charts*. Prior to manual annotation, tokenised and morphologically annotated sentences are automatically split into individual *segments*. All punctuation marks and coordinating conjunctions serve as *segment boundaries*. A single clause then consists of one or more segments. This scheme is viable given the very strict rules for punctuation in Czech – there must be some kind of a boundary between two finite verb forms, be it a sentence boundary, punctuation or a conjunction. The task of the annotators was to identify individual clauses, i.e. to group the segments forming a single clause, and to assign the appropriate level of embedding, thus allowing the distinction between coordination and super- or subordination. The usage of analytical layer during the annotation was intentionally quite limited. Only the analytical functions of tokens were used to help the annotators decide on the correct level of embedding and to disambiguate if more readings of a particular sentence were possible.

Unlike the manual annotation, the automatic clause-identification procedure does not rely on the boundary segments and extensively uses analytical trees. There are three key differences in the annotation rules:

(a) The automatic procedure does not attempt to assign levels of embedding, as the interclausal relations are explicitly captured in the analytical tree.
(b) Segment boundaries delimiting segments within the scope of a single clause are annotated as part of the clause, so that the distinction between coordination of sentence members and coordination of clauses is made obvious.
(c) A parenthetical expression is not considered a separate clause unless it contains a finite verb form.

Especially the last rule created the need of further post-processing of the gold-standard data, to make automatic evaluation possible. During the post-processing, parenthetical expressions were automatically merged with their surrounding clauses. In the original manually annotated data there are 2,505 sentences divided into 5,311 clauses. After post-processing, the number of clauses drops to 4,948.

The evaluation was performed on the basis of clauses using standard precision, recall, and f-measure metrics, reaching values 0.973, 0.978, and 0.975 respectively.[15] This confirmed the initial hypothesis that a highly reliable segmentation can be induced from the already available dependency annotations. As for the few remaining wrongly recognized

[15] Each automatically recognised clause was considered correct if and only if there is a clause in the manually annotated data spanning the very same set of nodes.

boundaries, the error analysis has shown that they have no single dominating cause that could be easily fixed. Such sentences are often difficult to annotate even for a human, for instance because of elipsis or intricate interplay of hypotactic and paratactic structures.

The automatic clause-identification procedure was used to annotate all sentences provided with gold-standard analytical trees in PDT 2.5, which amounts to 87,913 sentences. The procedure identified 153,434 clauses.

7 Conclusion

The Prague Dependency Treebank has been used as a model for several other treebanks, showing that both the general linguistic model of FGD and the technical realisation of PDT using PML are flexible and generic. They are not limited to a particular language, or a language family. By now there are at least five treebanks[16] annotated in the "PDT style".[17]

We have shown that PDT is exceptional in the richness of the information it provides. PML fits this richness well and thus all the PML-based tools such as the `TrEd` editor and the PML-TQ tree-query language (Pajas and Štěpánek, 2009) can be seamlessly used with PDT. PDT 2.5 is the most complex release of PDT to date. It is an intermediate step on the way to PDT 3.0, which will add even more annotation (discourse and extended anaphora, for example). It also contains corrections of more than 10,000 technical and annotation errors found in the previous release.

In Sections 4 through 6 we have presented major new features of PDT 2.5: what they are, how they were obtained, and what is the resulting quality and reliability. In Figures 2 and 3 there is an example of a complex query involving all of these features using the PML-TQ search tool and a result found together with its visualizations.

PDT 2.5 and all of the tools mentioned above are freely available (not just) for research purposes under standard, permissive licenses at `http://ufal.mff.cuni.cz/pdt2.5` and in the LINDAT-Clarin repository at `http://lindat.cz`. The Prague Dependency Treebank 2.5 itself has a citable persistent identifier `http://hdl.handle.net/11858/00-097C-0000-0006-DB11-8`.

Acknowledgement

This work has been using language resources developed and/or stored and/or distributed by the LINDAT-Clarin project of the Ministry of Education of the Czech Republic (project LM2010013). The work on this project was supported by the grants P406/2010/0875, P406/12/P175, and P406/10/P193 of the Grant Agency of the Czech Republic.

[16] Prague Dependency Treebank, Prague Arabic Dependency Treebank, Prague Czech-English Dependency Treebank, Index Thomisticus Treebank, Slovak Treebank (analytic layer).

[17] The markup language PML is even more generic. In fact, it has no direct connection to FGD and can be used to represent treebanks in any linguistic formalism (phrase-based or dependency, or any other variety based on trees in the basic graph-theory sense). Currently almost thirty treebanks are available in PML and can be queried online using our PML-TQ server. We have yet to meet a treebank that can't be converted to PML.

Deriving a Lexicon for a Precision Grammar from Language Documentation Resources: A Case Study of Chintang

Emily M. BENDER[1] *Robert SCHIKOWSKI*[2]

ABSTRACT
Language documentation projects typically invest a lot of effort in creating digitized lexical resources, which are used in the creation of dictionaries and in the glossing of collected texts. We present and evaluate a methodology for repurposing such a lexical resource developed for Chintang (ISO639-3: ctn), a language of Nepal, for use with a precision implemented grammar developed in the DELPH-IN formalism. The target lexicon, when combined with a set of morphological rules, achieves 57% type-level coverage and 50% token-level coverage of held-out texts, while maintaining a feature-level accuracy F-measure of 70%. As lexicon development is typically one of the most expensive aspects of creating a precision grammar, this represents a significant savings of effort.

TITLE AND ABSTRACT IN GERMAN

Ableitung des Lexikons für eine Präzisionsgrammatik aus dokumentationslinguistischen Ressourcen anhand einer Fallstudie zum Chintang

Typische Sprachdokumentationsprojekte investieren viel Zeit in den Aufbau digitaler lexikalischer Ressourcen, die für die Erstellung von Wörterbüchern und für die Glossierung von Korpustexten genutzt werden können. Dieser Vortrag stellt eine alternative Verwendung eines elektronischen Wörterbuchs vor, das für das Chintang (ISO639-3:ctn), eine bedrohte Sprache Nepals, entwickelt wurde. Die Kombination dieses Wörterbuchs mit einer nach dem DELPH-IN-Formalismus entwickelten Präzisionsgrammatik in Form morphologischer Regeln kann erste Texte auf der Type-Ebene zu 57% und auf der Token-Ebene zu 50% abdecken, wobei auf der Merkmalsebene ein F-Maß von 70% gewahrt wird. Da der Aufbau lexikalischer Ressourcen zu den zeitintensivsten Komponenten der Entwicklung einer Präzisionsgrammatik gehört, bringt diese Methode eine signifikante Zeitersparnis mit sich.

1 Introduction

Endangered languages represent an especially urgent type of low-resource languages: Not only do they generally lack computational resources, but they also unfortunately have the property that the window in which to create such resources is small and closing. Thus to the extent that any computational resources are created, they are particularly valuable, and if they can be repurposed for applications beyond their original target, this extends their value further.

This paper describes a case study in the repurposing of a lexical resource for an endangered language, Chintang. The original lexical resource is a Toolbox[1] lexicon developed to assist in the glossing of collected texts and in the development of a conventional dictionary. We present a methodology for automatically translating this lexicon into one which can be used as part of a precision grammar for the language, suitable for both parsing and generation and eventually in applications including machine translation. The grammar is a starter grammar generated by the LinGO Grammar Matrix grammar customization system (Bender et al., 2010), and includes an initial implementation of Chintang verbal morphology. As a starter grammar, it still has very limited coverage. However, even broad coverage grammars rely heavily on the size and quality of their lexicons. Our focus here is therefore on the extent to which the existing resources for Chintang can be used to bootstrap a lexicon for this implemented grammar.

This paper is structured as follows: In Section 2, we provide background on the Chintang language, the project which is documenting it, and the relevance of precision grammars for language documentation. Section 3 describes our methodology for creating the Grammar Matrix-compatible lexicon on the basis of the Toolbox lexicon and the implementation of the morphology. We evaluate the lexical coverage of the resulting grammar over held-out texts in Section 4. Section 5 situates this work with respect to related initiatives.

2 Background

2.1 Chintang Language

Chintang (ISO639-3: ctn) is a Kiranti language spoken in the hills of Eastern Nepal. The next bigger city close to the village of Chintang is Dhankuta, which is a six hours footwalk away. The local economy is centered around agriculture, both for subsistence and for trade.

The Chintang language belongs to the large Sino-Tibetan (Tibeto-Burman) family. The exact position of the Kiranti languages within this family is unclear (Ebert 2003). Within Kiranti, Chintang belongs to the Eastern branch, which is characterized by the development of the preglottalized stops reconstructed for Proto-Kiranti by Michailovsky (1994) to aspirated stops.

The number of speakers of Chintang is generally estimated to be around 5000 (e.g. Bickel et al. 2007), and this is in accordance with the speakers' own estimations. There are no reliable official data. Most speakers are bilingual, speaking Nepali, the national language of Nepal, as the second language. Many in addition speak Bantawa, a big neighboring Kiranti language. Chintang is still being learned by children (Stoll et al., 2012), but language knowledge and transmission are clearly on the decline, especially in the more easily accessible parts of the village.

[1] http://www.sil.org/computing/toolbox/index.htm

2.2 Research projects and resources

Research on Chintang started with the Chintang and Puma Documentation Project (CPDP), which ran from 2004 to 2009. Since 2009, research has been continued by a group of several collaborative projects together referred to as the Chintang Language Research Program (CLRP).[2] Several native speakers of Chintang and Nepali were employed during the projects to make recordings, conduct interviews, and to transcribe and translate recordings. Presently there is an office at the Tribhuvan University, Kathmandu, where five transcribers and translators are constantly working on the corpus, but no new recordings are being made.

The corpus comprises about 280 hours of video recordings, the majority of which have been transcribed by now (250 hours, containing 1,130,000 words; Bickel et al., 2009ff). Transcribed sessions are first translated from Chintang to Nepali and then from Nepali to English. The English translation is an important aid for the final step of glossing, which is done by student assistants studying linguistics. So far approximately 620,000 words have been glossed. Additional annotations are added to parts of the corpus depending on the needs of individual projects. Examples include the annotation of pointing gestures or of referential properties such as identifiability.

The compilation of the corpus is tightly coupled with the Chintang dictionary, which presently has about 9,000 words. The electronic version was created along with the corpus, so all words in the corpus are in the dictionary. Some systematic elicitation work to cover semantic fields that do not frequently come up in everyday conversation was carried out in 2010, and a printed version for the speaker community was published in 2011 (Rāī et al. 2011). The electronic dictionary keeps growing as more and more words are glossed. New words collected by the glossers are integrated into the main dictionary twice a year.

Both the corpus and the dictionary are in Toolbox format. In Toolbox, files are divided into structurally similar records (utterances in the case of the corpus, entries in the case of the dictionary). Each record consists of several lines where each line starts with a so-called field marker indicating the type of information (e.g. phonological words, morphemes, morpheme glosses) followed by content (see Section 3 below for details). It is possible to align the tiers thus defined, enabling composite searches (e.g. "find all morphemes of the shape *cekt* which have been glossed as 'speak'"). Since a major revision of the dictionary in 2010, all dictionary entries have IDs, which are inserted and aligned with morphemes upon glossing. This makes it possible to automatically look up detailed information for each corpus morpheme in the dictionary.

The entries in the dictionary include stem forms, alternate forms, glosses in English and Nepali, as well as some grammatical information. In particular, the dictionary lists coarse-grained part of speech (drawn from a set of 30 tags) as well as fairly detailed information about the syntactic and semantic valence of verbs, that is, the number of arguments expected, the cases for each argument, and an indication of which argument(s) the verb agrees with. This information is encoded as a string. (1) gives the valence information for *bhend* 'loosen', indicating that this verb takes two arguments. The most agent-like argument ("A") is marked with ergative case, the other (patient-like, "P") with nominative, and the verb will be inflected to agree with both of them.

(1) `\val A-ERG P-NOM V-a(A).o(P)`

[2] `http://www.spw.uzh.ch/clrp`.

This information reflects rich linguistic knowledge, the product of the analysis done by the annotators, and it is digitized. However, it is not really machine interpretable. While Toolbox can assist with morphological parsing (and thus with glossing of sentences), it does not make use of such syntactic information for syntactic parsing.

2.3 Precision Grammars for Language Documentation

Precision grammars are machine-readable sets of rules developed by hand to capture linguistic generalizations. Large-scale precision grammar projects have been carried out in a variety of linguistic frameworks, including HPSG (Pollard and Sag, 1994; Flickinger, 2000) (described further below), LFG (Kaplan and Bresnan, 1982; Butt et al., 2002)) and TAG (Joshi et al., 1975). DELPH-IN-style[3] HPSG grammars map surface strings to semantic representations in the format of Minimal Recursion Semantics (MRS; Copestake et al., 2005), and are reversible, i.e., suitable for use in both analysis (strings-to-MRS) and generation (MRS-to-strings).

Precision grammars can be deployed in transfer-based machine translation (e.g., Lønning et al., 2004), grammar checking applications (e.g., Suppes et al., 2012), and other NLP applications which benefit from a strong distinction between grammatical and ungrammatical strings (e.g., in generation) and/or detailed semantic representations. While broad coverage precision grammars can be expensive to build, the alternative of treebank-derived grammars presupposes resources which don't typically exist for endangered languages and are themselves costly to create. Furthermore, precision grammars, by locating analytical decisions in specific rules, can be more easily updated than treebanks, as more is understood about the language being described. Using the methodology of the Redwoods project (Oepen et al., 2004), precision grammars can be used to create treebanks which can be kept up to date with the grammar as it evolves. Both precision grammars and their associated treebanks can be valuable resources in language documentation (Bender et al., 2012).

2.4 The LinGO Grammar Matrix

As noted, precision grammars are time-consuming to develop. However, because similar structures recur across languages, the development time for new grammars can be reduced by repurposing grammar code developed for other languages. This is the idea behind multilingual grammar engineering projects, including the LinGO Grammar Matrix (Bender et al., 2002, 2010), ParGram (Butt et al., 2002; King et al., 2005), PAWS (Black and Black, 2009), and GF (Ranta, 2007). The Grammar Matrix stores a core grammar which includes (partial) analyses hypothesized to be cross-linguistically applicable, including basic phrase structure rule types for combining heads with different types of dependents, as well as an implementation of semantic compositionality, i.e., constraints which relate the semantic representation associated with a phrase to the semantic contributions of its daughters. In addition, the Grammar Matrix provides a series of libraries of analyses of cross-linguistically variable phenomena. These analyses are accessed through a web-based questionnaire which elicits a linguistic description of a language from a linguist and outputs a corresponding set of grammar files describing phrase structure rules, lexical rules, and lexical entries.

The information provided by the linguist is encoded in a plain text 'choices' file, where each 'choice' is a simple attribute-value pair. The customization system interprets the choices to output grammar files. The grammar files are encoded in the framework of Head-Driven Phrase

[3] `http://www.delph-in.net`

Structure Grammar (HPSG; Pollard and Sag, 1994), providing representations in the format of Minimal Recursion Semantics (Copestake et al., 2005) and are compatible with the DELPH-IN suite of grammar development and deployment tools, including the LKB (Copestake, 2002).

For the purposes of this work, the most important aspects of the Grammar Matrix are its support for the creation of lexical rules, which handle the ordering, basic form, and syntactico-semantic contributions of affixes, and its set of lexical types. Both the lexical rules and lexical types pair forms with complex feature structures. These feature structures encode syntactic and semantic information and are compatible with the feature structures for phrase structure rules, meaning that the lexical entries can be used as part of a grammar capable of both paring and generation.

The resources of the Grammar Matrix represent another rich source of linguistic knowledge, but in this case, the knowledge is not specific to a particular language. In order to create a grammar for a particular language, they need to be paired with information about that language: The forms and lexical meanings of individual words, their valence patterns, and the forms and effects of individual affixes. While affixes generally form a relatively small closed class, lexicons are another matter. The goal of this work is to see how effectively we can use the existing lexicographic work of the CLRP to flesh out a Grammar Matrix-derived lexicon for Chintang.

3 Methodology

3.1 Matrix Lexicons and Toolbox Lexicons

As described above, Toolbox lexicons are structured by user-designed fields (marked with initial tags) that store information including the orthography of a form, its gloss, example sentences, and any other information the lexicon developers would like to collect. In the case of the CLRP, this includes part of speech and detailed valence information (case and semantic roles). These are each encoded as a string in the value of the associated tag.

A lexicon for a DELPH-IN style grammar associates orthographic forms with complex feature structures representing morphological, syntactic and semantic information, encoded in such a way that this information can interact with lexical and phrase structure rules to license syntactic analyses of full sentences which furthermore embed compositionally created semantic representations. The relationship between the strings and these complex feature structures is mediated by lexical types which bear the constraints that describe the feature structures. The lexical types, in turn, are arranged into a multiple inheritance hierarchy so that each constraint need be stated only once and can be inherited by all lexical entries which require it.

```
\lex kond
\id 179
\psrev v
\val A-ERG P-NOM V-a(A).o(P)
\ge search; look.for
\dt 22/Feb/2011
```

Figure 1: Sample Toolbox entry from CLRP

A sample Toolbox entry is shown in Figure 1 while Figure 2 illustrates the corresponding Matrix entry. (Both are abbreviated, to focus on the most relevant information.) In Figure 1, the value of the tag `\lex` encodes the stem, `\ge` gives an English gloss, `\psrev` the part of speech, and `\val` the detailed valence information. Other fields not shown in the figure encode alternate forms of the entry, examples, and glosses in Nepali.

The Matrix entry in Figure 2, is a typed feature structure. The type of the whole structure is *trans-verb-lex*. This type provides (or inherits from its supertypes) most of the constraints on the entry. The only constraints provided directly in the lexical entry are the STEM value (*kond*, corresponding to `\lex` in Figure 1) and the PRED value *_search;look.for_v_rel*, i.e., the predicate symbol for the semantic relation associated from this entry. This is built on the basis of the `\ge` field of the Toolbox entry.

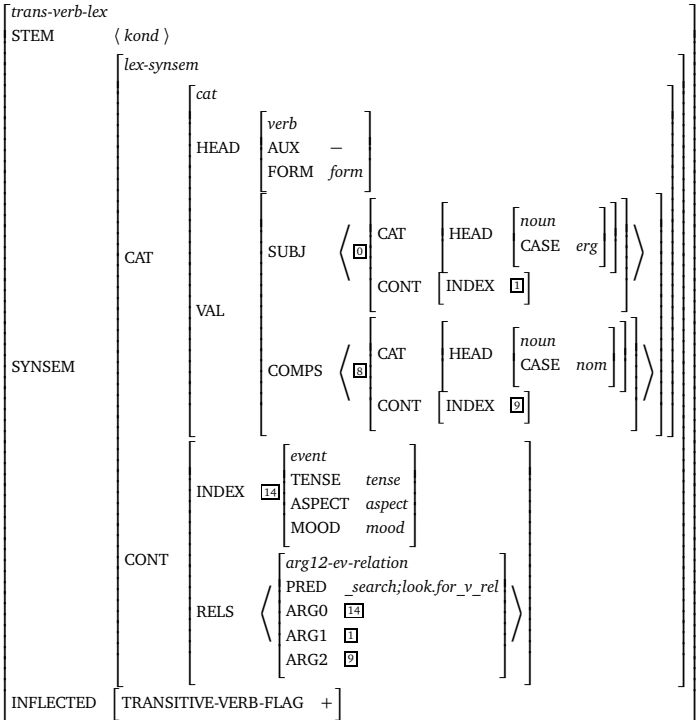

Figure 2: Sample Matrix entry corresponding to Figure 1

Turning to the information contributed by *trans-verb-lex*, the HEAD value indicates that this is a verb (and will head verbal projections such as VP and S), that it is not an auxiliary ([AUX −]), and that its form value is as yet underspecified ([FORM *form*]). When this lexical entry is inflected as either a finite verb or a non-finite verb, the FORM value will be constrained accordingly. The INDEX value is linked to the ARG0 of the relation contributed by the verb, and has underspecified values for TENSE, ASPECT, and MOOD. These, too, can be filled in via lexical rules for affixes that mark these values.

The VAL information indicates that this verb is seeking a subject and a complement, both headed

by nouns, where the subject must be in the ergative case and the object in the nominative.[4] Furthermore, the INDEX values of each are linked to the ARG1 and ARG2 positions in the semantic predicate, respectively. The number of arguments and the linking to the semantic roles is part of the cross-linguistic definition of a transitive verb in the Matrix. The constraints that both arguments are NPs (rather than, say, PPs) and the information about case come from specializations to the transitive verb type defined for Chintang by hand through the Grammar Matrix customization system questionnaire.

Finally, the feature INFLECTED is related to the morphotactic system. The value of this feature is a bundle of further 'flag' features (Goodman, 2012) tracking whether certain lexical rules have or have not applied, in order to encode dependencies between lexical rules and between lexical rules and lexical types. Here, we have shown only the TRANSITIVE-VERB-FLAG feature, whose + value will ensure that affixes throughout the affix chain will only be those that are compatible with transitive verbs.

3.2 Import of Lexical Entries from Toolbox Lexicons

The Grammar Matrix customization system provides facilities for the definition of lexical types. This is in principle unbounded: the user can define, for example, types for both common and proper nouns, as well as types for nouns of different genders and types for verbs with different case frames. The user can specify constraints on these types through the customization system (e.g., constraints on noun gender or case frames). Many other constraints, particularly those concerned with semantic composition, are inherited from the Matrix core grammar.

We extended the Grammar Matrix customization system to include a subpage that allows the user to define mappings between sets of properties encoded in a Toolbox lexical entry and user-defined lexical types. Figure 3 gives an example. This type maps entries from the Toolbox lexicon which are specified to have the part of speech 'v' and the valence 'S-NOM V-s(S)' to the type 'verb1'. This type is defined on another page of the customization system questionnaire to describe intransitive verbs with nominative case on their sole argument. Types inherited from the Matrix core grammar provide the constraints that contribute a one-place semantic predicate and link the sole syntactic argument to the semantic argument. The import facility creates the name symbol for that semantic predicate on the basis of the gloss or alternatively of the orthography of the stem (as specified by the user).

Since Toolbox allows users to define their own tags, the extension we designed for the Grammar Matrix customization system does not make any assumptions about the name or number of tags which will be relevant to each import class. Users fill in the name of the tag in the 'Toolbox tag' field for each tag-value pair, and can add arbitrarily many tag-value pairs with the 'Add' button. Another part of the page allows the user to specify the location of a Toolbox file to import from and upload it. Though Chintang was the initial test case for this import facility, there is (to our knowledge) nothing specific to Chintang nor the CLRP in the design of the system. It is available for use through the Grammar Matrix customization system's web-based

[4] The Grammar Matrix uses the names SUBJ and COMPS for the valence features, but makes relatively few assumptions about which properties accrue to the argument in SUBJ as opposed to those in COMPS cross-linguistically. For example, as case and agreement are both handled lexically, the system is flexible enough to model even tripartite case and agreement, where the sole argument of intransitives is handled differently from either argument of transitives (Drellishak, 2009). Similarly, grammar developers using the Grammar Matrix customization system can define multiple different classes within transitive and intransitive which behave differently with respect to agreement and/or case.

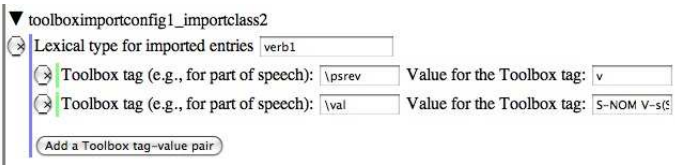

Figure 3: Sample Toolbox import class

questionnaire.[5]

The Grammar Matrix core grammar provides support for a wide variety of semantic valences. However, the present system only exposes simple intransitive and transitive valences to the customization page. As soon as the customization system is updated to expose more valence possibilities in the definition of lexical types, types using such valence possibilities will be available as targets for the import of corresponding Toolbox lexical entries, without any further updates to the extension we created. For the purposes of this study, however, we are limited to nouns and simple transitive and intransitive verbs.

The final 'choices' file for the Chintang grammar specifies import configurations for common nouns and two types each of transitive and intransitive verbs: native Chintang verbs which take the full range of inflectional morphology and verbs borrowed from Nepali which must co-occur with an auxiliary. This results in imported lexical entries for 4,741 common nouns, 282 native Chintang intransitive verbs, 142 borrowed Nepali intransitive verbs, 285 native Chintang transitive verbs, and 190 borrowed Nepali transitive verbs. Thus 5,640/9,034 (62%) of the entries in the Toolbox lexicon resulted in entries for the Matrix grammar, including 899/1,440 (62%) of the verbs. The most frequent remaining part of speech categories in the Toolbox lexicon file are adverbs (866), adjectives (515), interjections (377), and affixes (286).[6][7]

3.3 Implementation of Morphology

Chintang has a relatively complex morphological system, especially for verbal inflection. Schikowski (2012) identifies 12 suffix positions following verbs. On the other side of the stem, a verb root may take up to 4 prefixes, and additionally endoclitics can appear inside the prefix chain. One special type of prefix is that found in bipartite stems, where a specific prefix is idiosyncratically selected by the verb and is in effect part of the stem, though not always realized contiguously with the rest of the stem. To add to the complexity, the prefixes do not occur in a fixed order (Bickel et al., 2007). Beyond that, a single verbal word can contain up to four verb roots, each of which can host prefixes and suffixes. In these 'verb chains', any given prefix can appear only once, while suffixes are frequently repeated (Bickel et al., 2007; Schikowski, 2012). Finally, there is a host of morphophonological effects, some categorical

[5] `http://www.delph-in.net/matrix/customize/matrix.cgi`

[6] The Toolbox lexicon includes words from four different languages (Chintang, Nepali, Bantawa, and English), as words from all four of these languages appear in the collected data. These numbers reflect the full Toolbox file, and so are not directly representative of only Chintang. For example, Chintang has only two adjectives; the rest of the adjective entries come from other languages.

[7] These part of speech counts are based on the `\ps` field in the lexicon. The import of lexical entries was done based on the `\psrev` field. This field does not cover as many words as the older `\ps` field, but has been thoroughly reviewed.

and some variable, which change the surface form of any given morpheme depending on its phonological context (as well as on sociolinguistic factors).

The Grammar Matrix customization system provides extensive support for the definition of the morphotactic and morphosyntactic aspects of lexical rules, i.e., the order in which morphemes appear, co-occurrence restrictions between morphemes, and the syntactico-semantic constraints associated with each (Goodman, 2012). For this study, we defined a set of lexical rules through this system on the basis of the prose description of Chintang morphology in Schikowski 2012 and consultation between Schikowski (field linguist) and Bender (grammar engineer). Here we briefly describe the phenomena handled by this rule set.

There are a total of 160 verbal lexical rules (grouped into 54 position classes) and 24 nominal lexical rules (6 position classes) in the implementation. The position classes define the order of the affixes, including whether they are prefixes or suffixes and their relative order to other prefixes/suffixes. We handle verb chains by treating only the first verb root as an actual root in the model; this is facilitated by the fact that the first V position in a verb chain has the widest lexical variation. The current system allows up to three verb roots per chain, with the verb roots appearing in the second and third position treated as affixes. The position classes for each of these positions contain 32 rules, one for each verb root which can appear in non-initial position. The prefixes and suffixes which intervene between roots in the verb chain are treated as separate lexical rules for suffixes. This duplication of the lexical rule types is partially responsible for the high overall total of lexical rules.[8]

Elsewhere in the choices file we have specified information about the case system (number of cases and their names), possible values of tense, aspect and mood, possible values of person and number (including inclusive/exclusive distinctions in first person dual and plural), and other similar information. This allows us to model or partially model the syntactico-semantic effects of 131 of the 160 rules. The features targeted by these rules are shown in Table 1.[9] Examples of affixes whose syntactico-semantic effects are not modeled include the causative marker, possessive prefixes on nouns, and verb chain elements indicating the direction of motion or resulting position of a participant in the event. This information is not modeled because it is not directly supported by the customization system. The grammar output by the customization system is suitable for further hand-development, however, and nothing in HPSG theory or the DELPH-IN formalism would prevent encoding such information.

There are a few other ways in which this model of Chintang morphology is incomplete. First, it should be noted that we are abstracting away from most of the morphophonology by targeting the underlying representation given in the Toolbox files (both lexicon and corpus), rather than the transcription. Second, we are not modeling the phenomenon of free prefix order. This is possible in the DELPH-IN formalism but not supported by the Grammar Matrix customization system. Again, it would be relatively straightforward to modify the grammar to accommodate this, but we have chosen to focus our evaluation on the grammar as produced by the customization system. While the customization system can handle bipartite stems, and the facility for importing lexical entries from Toolbox anticipates this, we are not modeling them

[8] HPSG's type hierarchy in principle would allow us to define the morphosyntactic effects of these rules just once and cross-classify those types with the types encoding the position class information. The Grammar Matrix customization system interface, however, does not allow cross-classification of position class types with other kinds of types, so this kind of generalization must await hand-editing of the grammar files output by the customization system.

[9] Note that NEGATION isn't really a feature but rather a flag that causes the customization system to create a lexical rule which adds negation to the verb's semantic representation (Crowgey, ip).

Feature	# Rules	Notes
PERNUM	103	Person and/or number of verb's dependent or of noun
CASE	17	
FORM	35	Form (finite/non-finite) of verb
TENSE	27	
ASPECT	5	
MOOD	17	
NEGATION	8	

Table 1: Features constrained by lexical rules

at this time. Finally, while verb chains can in principle have four verbal roots, this model only allows up to three, because the four-root forms are extremely rare.

4 Evaluation

We created a choices file for Chintang which gives general grammatical information as well as definitions for lexical classes and lexical rules as described above. In addition, this choices file defines 11 closed-class lexical entries: 10 pronouns and one auxiliary. We used three sample narratives (totaling 2,906 word tokens) from the corpus as development data to refine the choices file. This process involved creating a grammar from the choices file using the customization system, loading the grammar into the LKB grammar development environment (Copestake, 2002) and processing the utterances in the narratives with the grammar using the [incr tsdb()] grammar profiling platform (Oepen, 2001). [incr tsdb()] provides facilities for browsing both results and errors encountered during parsing. These were used to identify forms that were not being handled appropriately. We then used the grammar exploration tools provided by the LKB to diagnose the source of the problem and then updated the choices file accordingly.

We then selected an additional four narratives to use as test data. The narratives range in length from 200 to 489 tokens (total: 1,453) and represent a range of domains: 'Durga_Exp' is a biographical monologue; 'pear_6-1' is a Pear Story (Chafe, 1980) elicited by asking the speaker to recount a story shown in a short, non-verbal film; 'story_rabbit' is a story about a clever rabbit who escaped a tiger; and 'choku_yakkheng' is a recipe for cooking nettle curry. We extracted the morpheme segmented line of each line in the narratives. An example is shown in (2), where the second line is the line we are targeting.

(2) thupro wassace uyuwakte pho
thupro wassak-ce u-yuŋ-a-yakt-e pho
many bird-NS 3NSS/A-live-PST-IPFV-IND.PST REP
'There lived many birds.' [ctn] story_rabbit.005

The performance of the grammar was evaluated in two ways. First, we evaluated coverage at both the type and token level over the test narratives. Table 2 gives the results. A word was counted as 'covered' if the grammar assigned it a morphological analysis that the grammar considered fully inflected. As shown in the table, the grammar found analyses for at least 50% of both word types and tokens across all the narratives, with the exception of 'story_rabbit' where the token-level coverage was only 35%. The ambiguity numbers in Table 2 reflect the

average over those words which had at least one analysis. These numbers reflect low ambiguity, with the maximal analyses per word form being only 8.

Narrative	total		# analyzed		% analyzed		avg ambiguity	
	type	token	type	token	type	token	type	token
Durga_Exp	206	489	120	265	58	54	1.24	1.14
choku_yakkheng	152	331	89	184	59	56	1.26	1.20
pear_6-1	206	433	105	203	56	51	1.20	1.62
story_rabbit	85	200	43	69	51	35	1.37	1.23
All	568	1453	324	721	57	50	1.40	1.27

Table 2: Coverage of customized grammar over test narratives

To get a sense of the accuracy of the resulting grammar, we randomly selected 10 word types from each of the four narratives (while ensuring that no word type was selected from more than one narrative). We used the LKB to parse each of these word types and compared the information in the resulting feature structure to the information in the gloss of the first instance of that word type in the narrative it was chosen from. We calculated precision and recall for each piece of grammatical information in the gloss and the feature structure.[10] In cases where the grammar found more than one analysis, we chose the best match to the gloss. The results are shown in Table 3.

Narrative	Total gold attributes	Precision	Recall	F-measure
Durga_Exp	16	.48	.88	.62
choku_yakkheng	21	.57	.62	.59
pear_6-1	31	.71	.92	.80
story_rabbit	29	.62	.83	.71
Total	97	.61	.82	.70

Table 3: Accuracy of customized grammar over 40 word types from test narratives

A large portion of the precision errors in this evaluation relate to cases where the grammar interprets the non-marking of some category as informative. For example, nouns that do not bear any affix for number as marked as singular in the grammar, and nouns not bearing any affix for case as nominative. These disagreements between the grammar and the glosses are counted as errors in Table 3, as the glosses are taken as the gold standard for this evaluation. However, the glosses reflect a systematic decision by the CLRP to not mark the contribution of zero morphemes. In most of these cases, the grammar is likely correct. Finally, verbs inflected for tense are considered to be finite by the grammar, and this is reflected in a (syntactic) feature FORM in addition to the semantic feature TENSE. The glosses mark non-finiteness explicitly, but do not mark finiteness separately from tense. Default singular number on nouns accounts for 19 errors, default nominative case 15, and finite form 9, of a total of 52 errors in precision. The 18 errors in recall are primarily due to cases where the intended lexical root is not available in the grammar but a homophone is.

Finally, we performed an error analysis to get a sense of the range of reasons a word form might

[10]For the gloss, we included all information provided. For the feature structure, we included only the predicate symbol from the root and any information that is added by some lexical rule in the grammar.

not be analyzed by the current grammar. We randomly selected 10 word forms from the four narratives that were not assigned analyses by the grammar. The failure of analysis of these 40 forms can be attributed to the following causes:

- [29 forms] Stems not imported to the grammar, because they don't match any of the import classes. These stems include verbs taking three arguments, adverbs, numerals, demonstratives, and other function words.
- [2 forms] Stems that are not in the version of the Toolbox lexicon used to import from.
- [4 forms] Affixes not implemented in the grammar.
- [5 forms] Other problems with the grammar, such as not allowing for case stacking and not allowing the affix order attested.

In general, we find the results of this evaluation encouraging: They suggest that the methodology presented here is effective at repurposing the results of the work on the Toolbox lexicon towards additional computational linguistic ends. Furthermore, the error analysis points the way towards effective means of improving the resulting grammar further, including fixing the specific errors with affixes that were identified, broadening the classes of verbs handled, adding adverbs, and creating lexical entries for high frequency closed-class words by hand.

5 Related Work

This work is similar in spirit to Bender's (2008) development of an implemented grammar for Wambaya (ISO639-3: wmb) based on the Grammar Matrix and a descriptive grammar. However, that work focused on hand-development of the grammar and included a manually entered lexicon, in contrast to our work on automatically populating the lexicon for the implemented grammar.

Other work applying grammar engineering and shared resources (including typological information) to endangered or other resource poor languages includes the Parser and Writer for Syntax system (PAWS; Black and Black, 2009) and Linguist's Assistant (Beale, 2011). We are not aware of any work addressing lexicon repurposing for these systems, but methodology analogous to what we propose in this paper should be applicable to them as well.

More generally, our work is situated within a broader context of reuse of lexical resources across formalisms and across systems. Other work along these lines includes the work of Kamei et al. (1997) and Bond et al. (2009) on making it possible to share user dictionaries across different MT systems, that of Bond et al. (2008) on repurposing a variety of resources (both WordNets and other lexical resources) in order to create a WordNet for Japanese and that of (McConville and Dzikovska, 2007) on creating lexical entries for a TRIPS grammar (Dzikovska, 2004) on the basis of FrameNet (Baker et al., 1998).

Conclusion and perspectives

The target lexical entries for a precision grammar derived from the Grammar Matrix are much more complex than the information explicitly encoded in even a thorough Toolbox lexicon. The work of developing the Toolbox lexicon is, however, the hard part. In this paper we have shown how it is possible to use a language-independent (i.e., explicitly multi-lingual) tool to leverage

the effort and linguistic analysis encoded in a Toolbox lexicon to create the kind of resource required for a machine-readable, precision grammar.

However, it is important to note that this is only a first step. Previous work building medium to large scale grammars with the DELPH-IN technology, including the broad-coverage English Resource Grammar (Flickinger, 2000, 2011) and a medium-sized grammar for Wambaya (Bender, 2008) suggest that it should indeed be possible to build a substantial grammar fragment for Chintang that uses this lexicon. The Wambaya grammar is especially pertinent for two reasons: first, like Chintang, it represents an application of the Grammar Matrix to a language not considered in its initial development, and second, its lexical types are based on the same general supertypes as those developed here for Chintang. Nonetheless, every language is different, and it is not possible to know without building the grammar whether the lexical types will be compatible with the specific grammatical phenomena attested in Chintang. We intend to develop such a grammar to test this in future work.

ABSTRACT
Though it is generally accepted that language models do not capture all aspects of real language, no adequate measures to quantify their shortcomings have been proposed until now. We will use n-gram models as workhorses to demonstrate that the differences between natural and generated language are indeed quantifiable. More specifically, for two algorithmic approaches, we demonstrate that each of them can be used to distinguish real text from generated text accurately and to quantify the difference. Therefore, we obtain a coherent indication how far a language model is from naturalness.
Both methods are based on the analysis of co-occurrence networks: a specific *graph cluster measure*, the *transitivity*, and a specific kind of *motif analysis*, where the frequencies of selected *motifs* are compared. In our study, artificial texts are generated by n-gram models, for $n = 2, 3, 4$. We found that, the larger n is chosen, the narrower the distance between generated and natural text is. However, even for $n = 4$, the distance is still large enough to allow an accurate distinction.
The motif approach even allows a deeper insight into those semantic properties of natural language that evidently cause these differences: polysemy and synonymy.
To complete the picture, we show that another motif-based approach by Milo et al. (2004) does not allow such a distinction.
Using our method, it becomes possible for the first time to measure generative language models deficiencies with regard to semantics of natural language.

KEYWORDS: quantitative linguistics, network analysis, motif analysis, co-occurrence networks, language models.

1 Introduction

Language models are used in many text processing systems (e.g. machine translation, document classification, language generation etc.) and are undoubtedly a standard building block of natural language processing. However, there exist hardly any methods that characterize language models quantitatively, in order to measure their deficiencies with respect to real language: the commonly used perplexity measure is known to be insensitive to semantic aspects (Chang et al., 2009). To this end, we propose an automatic approach that not only can distinguish language-model-generated text from real text, it also quantifies their distance. Moreover, we can quantify language model shortcomings with respect to two semantic phenomena of natural language, namely polysemy and synonymy. The ability to measure, to what extent language models in fact model these and other characteristics of real language, is a prerequisite for improving language models to closer adhere to the many-layered structure of natural language.

Before laying out the details of our approach, we would like to briefly sketch the general idea: If we accept that different language models capture natural language semantics to different extents, and if we had a measure that indicates and quantifies this extent, then this measure enables us to drive the development of language models towards a better reflection of semantics. We propose such a measure, which is based on the assumption that the structure of the co-occurrence graph of a (real or generated by a language model) text reflects semantic adequateness. Computing and comparing different characteristics of these co-occurrence graphs allows us to quantify the differences.

This paper summarizes a series of computational studies to characterize the uniqueness of co-occurrence networks from real natural language, as opposed to co-occurrence networks from artificial "natural" language. We developed two testing methods to decide whether a corpus of text was written by humans or generated by a language model. For that, we analyze the structural difference of the co-occurrence networks induced by real text and generated text, respectively. As generative language models, we chose the 2-gram, 3-gram, and 4-gram models.

We examine co-occurrence graphs.[1] In that, we consider two types of co-occurrence: sequential occurrence between neighbors and co-occurrence within a whole sentence. Our measures are based on two network metrics. Traditionally, the structures of language networks are analyzed either on the global level or on the level of single nodes and edges (e.g. the degree distribution). Our first method is based on a global clustering metric, the *transitivity*.

Our second method is based on *motif analysis*. This approach addresses an intermediate level, where a structural entity is composed of a small number of nodes and edges. Networks are compared by counting the number of times a certain *k-node motif*, i.e. a small graph of k nodes, appears as an induced subgraph. In case of the directed sequential co-occurrence graphs, 3-node motifs are analyzed (see Fig. 1), whereas the bidirectional sentence co-occurrence networks are compared based on their 4-node motifs (see Fig. 2).

In case of sentence-based co-occurrence, each of these methods enables us to distinguish natural from generated text and to quantify the differences in a reasonable way. Such a quantification can be viewed as an indicator how far a language model is from naturalness. In fact, it turns out that this indicator conforms well to what one would expect: higher-order n-gram models generate a better approximation of real texts. However, no n-gram model is able to capture long-

[1] In accordance with the established terminology, we will use the terms *graph* and *network* synonymously, and choose the appropriate word in view of the respective context.

range semantic dependencies well, which we will exploit in our analysis techniques. Moreover, we will show that motifs can be related to specific semantic properties of natural languages that do not occur in *n*-gram generated text and hence explain the observed differences to a large extent. Here, the above-mentioned domain-specific phenomena are of a semantic kind. In particular, we show that two specific phenomena, *polysemy* and *synonymy*, are reflected by the counts of two motifs, the *chain motif* and the *box motif* (#2 and #4 in Fig. 2).

In summary, the presented work follows a new, successful, path and opens new, promising, perspectives on the analysis of language models. This is the first application of motif analysis to language networks and their underlying semantics. So, besides the specific computational results and the novel method to obtain them, the presented work is also relevant due to this general methodological innovation.

The paper is organized as follows. In Section 2, we briefly review the most relevant related work. Then, in Section 3, we will describe our approach in full detail. In Section 4, we present and discuss the conjectures that structure our research. In Section 5, we present our results, and finally discuss future perspectives in Section 6.

2 Related Work

2.1 Network Analysis

There is a large scientific body of methods and applications of network analysis (Aggarwal and Wang, 2010; Aggarwal, 2011). Graph mining – the art of detecting and analyzing patterns and structures in graphs – is the specific focus of the surveys (Cook and Holder, 2006; Fortunato, 2010).

It seems reasonable to classify network analysis techniques by the level of granularity they address. Elementary statistical measures such as the node degree distribution operate on the level of single nodes and edges. In the opposite extreme case, on the global level, the structure of a network is captured in a single (scalar) numerical value. Examples for global measures are the average shortest path length, the diameter, as well as simple characteristics such as node and edge count. See the above-mentioned surveys for a systematic discussion.

For our analysis, a global clustering metric, the *transitivity*, is considered, however, our main focus is on *motif analysis*. *Motif analysis* addresses an intermediate level: local structures consisting of a small number of nodes and edges. Networks are compared by comparing the number of occurrences of selected motifs.

Motif analysis has first been investigated in computational biology (Shen-Orr et al., 2002) and has since been applied to a variety of network types in biology and biochemistry (Schreiber and Schwöbbermeyer, 2010). The underlying insight is that biological and biochemical dynamics are statistically related to the occurrence of small functional blocks, which have specific structures. This insight is well captured by motif signatures, and in fact, many computational studies reveal significant relations. Due to this success, it did not take long time until this technique has been applied to networks from other domains. For example, (Milo et al., 2002, 2004) compare networks from biology, electrical engineering, natural language and computer science and find that the motif signatures from different domains are so different that they may serve as a "fingerprint" of the respective domain.

The idea of functional blocks applies in domains beyond biology and biochemistry as well, surprisingly, even in social networks. In (Krumov et al., 2011), we analyzed citation networks,

which we modeled as undirected graphs on the authors. An edge indicates at least one joint publication. In a sense, the citation numbers of individual publications within an occurrence of a motif can be aggregated to a citation number of the entire occurrence. We considered four natural ways for aggregation. Roughly speaking, the main result of (Krumov et al., 2011) is this: the average citation number of the box motif, taken over all occurrences, is statistically significantly larger than expected. This effect occurs for all four ways of aggregation. A deeper look revealed that certain occurrences of the *box motif* (#4 in Fig. 2) explain this result: two "seniors," A and B, have jointly published, A has published with a "junior" C, B with a junior D, and C and D have joint publications as well, but neither A with D nor B with C. Among these occurrences, the ones that serve as "bridges" in the network in a certain sense are particularly responsible for the observed effect.

In view of the outlook (Section 6), we further mention recent work that uses the concept of motifs for other purposes than network analysis. (Krumov et al., 2010a,b) developed an algorithm to optimize the structure of peer-to-peer networks based on local operations only. Each node manipulates the local structure in its vicinity in order to thrive the local motif signature towards the average local motif signature of an optimal network.

2.2 Complex Networks of Natural Language

The structure of natural language networks has been extensively investigated, see e.g. (Masucci and Rodgers, 2006) and references therein.

(Ferrer-i-Cancho and Solé, 2001) have shown that co-occurrence networks of natural language are scale-free small world graphs. Whereas scale-freeness seems to be a consequence of the Zipfian word-frequency distribution (Biemann, 2007), Steyvers and Tenenbaum (2005) find the small-world property in co-occurrence networks and lexical-semantic resources, which indicates that co-occurrence networks reflect semantic properties.

There is only very little work on operationalizing complex network analysis for natural language processing applications. (Pardo et al., 2006) evaluate the quality of automatic summaries by analyzing the degree distributions of networks generated from words at different fixed offsets in the text, and (Amancio et al., 2012) characterize texts for authorship attribution by quantifying their consistency index, which is measured by the number of authors that use content words in a sequence. A related work is (Köhler and Naumann, 2010), where segments of words with increasing length and frequency are used to characterize texts of different authors.[2] We are not aware of any other research that uses network analysis to assess the quality of language models trained from real text.

3 Methodology

Our results have been generated in a three-step process: First, the text needs to be selected, respectively generated, before the graphs can be derived from the texts according to a parameterizable strategy. In the last step, our proposed metrics are evaluated on these graphs. These three steps are explained in detail in Sects. 3.1–3.3, respectively.

[2]**Note:** (Köhler and Naumann, 2010) also use the term 'motifs', but they refer to the aforementioned sequences of words, not to subgraphs as in our work.

3.1 Text Basis

Text corpora For our experiments, we use corpora of different languages of one million sentences each, provided by LCC[3] (Biemann et al., 2007). We use the same corpus of real language for training the n-gram model and for comparison. For comparison between real and generated language, we generate text according to the same sentence length (number of tokens) distribution as found in the respective real language corpus, since we have found in preliminary experiments that co-occurrence network structure is dependent on the sentence length distribution. We have found in further experiments, that the general picture of results is stable for corpora of different sizes, starting from about ten thousand sentences.

Text generation with n-gram models For the scope of this work, we chose n-gram models, which are the standard workhorses of language modeling. A language model assigns a probability to a sequence of words, based on a probabilistic model of language. This can be used to pick the most probable/fluent amongst several alternatives, e.g. in a statistical machine translation system (Koehn, 2010). An n-gram language model (cf. (Manning and Schütze, 1999)) over sequences of words is defined by a Markov chain of order $(n-1)$, where the probability of the next word only depends on the $(n-1)$ previous words, and the probability of a sentence is defined as $P(w_1...w_k) = \prod_{i=1..k} P(w_i|w_{i-1}..w_{i-n+1})$. We add special symbols, BoS and EoS, to indicate sentence beginning and end. Then we generate sentences word by word, starting from a sequence of $(n-1)$ BoS-symbols, according to the probability distribution over the vocabulary. As soon as the EoS symbol is generated, we generate the next sentence. Probabilities are initialized by training on the respective corpus of real text (see above) from the relative counts, i.e. $P(w_i|w_{i-1}..w_{i-n+1}) = count(w_i..w_{i-n+1})/count(w_{i-1}..w_{i-n+1})$. In our study, we used n-gram models with $n \in \{2,3,4\}$ (in some contexts, we additionally consider $n = 1$ for completion).

Shortcomings of n-gram models are obvious: no long-range relations are modeled explicitly, thus n-gram models produce locally readable but semantically incoherent text. This study is, to our knowledge, the first attempt to quantify this phenomenon. Despite their simplicity, n-gram models still excel in NLP applications (cf. (Ramabhadran et al., 2012)).

In NLP applications, n-gram models are usually subject to smoothing and back-off techniques (cf. (Manning and Schütze, 1999)). Smoothing is necessary to account for unseen words, which is not an issue for generation. We only present results for language models without back-off in this work, although we did some experiments with texts generated from n-gram models with back-off estimated through deleted estimation. Note that we found no substantial differences to text generated without back-off.

3.2 Network Construction

Next, we describe the construction of a complex network from a text corpus of (real or generated) language. The nodes of the derived graphs correspond to the m most frequent words in the considered text. An edge from node A to B exists if the word corresponding to A *co-occurs*, i.e. occurs together in a well-defined context, with the word corresponding to B significantly often. Different kinds of co-occurrence contexts are considered, as well as significance thresholds and graph sizes m.

[3] see `http://corpora.informatik.uni-leipzig.de/`

Network size The number of nodes m in the graph, corresponding to the most frequent words in the considered text, was set to be $5,000$, as to match the commonly assumed size of the core vocabulary of a language (Dorogovtsev and Mendes, 2001). In preliminary experiments, we have verified that, qualitatively, our results are stable across vocabulary sizes between $1,000$ and $20,000$, as long as the *most frequent* words are considered.

Co-occurrence contexts We consider two different kinds of contexts: co-occurrence as immediate neighbors in a sequence, and co-occurrence within a sentence (sequences as limited by BoS and EoS). Thus, for each corpus of text, composed of sentences, we can compute the co-occurrence graph by connecting word nodes with edges, if words co-occur. Edges are directed in the case of neighbor-based co-occurrence, and undirected for the sentence-based case. It is known (Biemann et al., 2004) that sentence-based co-occurrences, besides capturing collocations, often reflect semantic relations and capture topical dependencies between words.

Significance threshold Since mere co-occurrence results in a large number of edges and very dense networks, we apply a significance test that measures the deviation of the actual co-occurrence frequency from the co-occurrence frequency that would have been observed if the two co-occurring words would be distributed independently. Here, we use the log-likelihood test (Dunning, 1993) to prune the network: We only draw edges between word nodes, if the words co-occur with a significance value above a certain threshold. For our experiments, we used a threshold of 10.83[4] . During preliminary experiments, we have found the reported results to be stable across a wide range of significance thresholds. See (Biemann and Quasthoff, 2009) for an analysis of global properties of significant co-occurrence graphs of natural language. The co-occurrence graph was computed using the TinyCC[5] corpus production engine (Quasthoff et al., 2006).

3.3 Network Analysis

Transitivity Let $G = (V, E)$ be an undirected graph. A *closed triangle* is a set of three nodes such that all three possible edges do exist. On the other hand, a *triple* is any set of three nodes and two edges (in other words, a chain of two edges). The *transitivity* of $T(G)$ of G is three times the total number of closed triangles divided by the total number of triples, as defined by (Newman et al., 2002). This can be calculated by iterating over every node v and counting the triangles and triples in which v is incident to two edges:

$$T(G) = \frac{\sum_{v \in V} \delta(v)}{\sum_{v \in V} \binom{k(v)}{2}} \tag{1}$$

with $\delta(v) = |\{u, v, w\} \in V, \{\{u, w\} \in E \text{ and } \{v, u\} \in E \text{ and } \{v, w\} \in E\}|$, and $k(v)$ the degree of v.

Motif analysis A k-node motif is a small connected graph of k nodes. An *occurrence* of a motif M in a network $G = (V, E)$ is a set $V' \subseteq V$ of nodes such that the subgraph of G induced by V' is isomorphic to M.[6] For a set of motifs, the *motif signature* is the vector of number of instances

[4] which corresponds to an error level of 0.1% of falsely rejecting the hypothesis that words co-occur independently

[5] available for download at `http://wortschatz.uni-leipzig.de/~cbiemann/software/TinyCC2.html`

[6] For a graph $G = (V, E)$ and a node set $V' \subseteq V$, the *subgraph* of G *induced* by V' is the unique graph (V', E'), where $E' \subseteq E$ is the set of all edges of E with both endnodes in V'. Note that this really means *all* edges. In fact, if E' is only required to contain *some* of the edges with both endnodes in V', (V', E') is usually called just a subgraph, not *the*

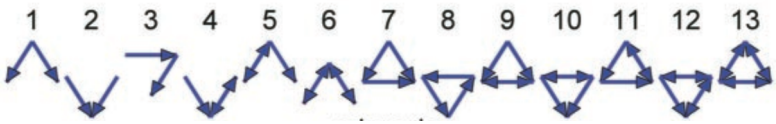

Figure 1: Directed motifs of size 3 as used in (Milo et al., 2004)

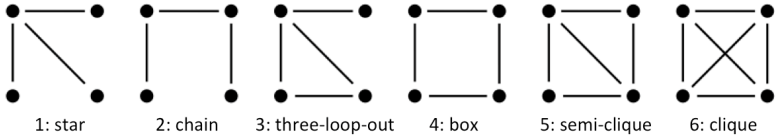

Figure 2: Undirected motifs of size 4 with names used throughout this paper

of each motif in G (typically, but not exclusively, all motifs in the set have the same number of nodes). Alternatively, the fraction of each motif to the total number of motifs is frequently considered, i.e. for m motifs M_1,...,M_m with counts $c(M_1)$,...,$c(M_m)$, the *motif signature* is the vector $(s(M_1), ..., s(M_m)$ with

$$s(M_i) = \frac{c(M_i)}{\sum_{j=1}^{m} c(M_j)}$$

To compare graphs of different sizes and edge counts, we generally present fractions instead of absolute counts. Our results are mainly presented in the form of xy-diagrams, mapping the motif to the corresponding frequency. Due to the high diversity in frequency, a logarithmic scale is used on the y axis. For presentational purposes and in accordance with the literature, we connect the dots in the plots, although they represent discrete values.

Throughout this paper, we consider two kinds of motifs, directed 3-node motifs (see Figure 1) and undirected 4-node motifs (see Figure 2). For directed and undirected graphs, respectively, these are the smallest meaningful motifs for our purposes. In fact, undirected 3-node motifs are triangles and triples and, hence, implicitly covered by our transitivity analysis. The motif counts were computed efficiently with the MotifAnalysis[7] software.

4 Conjectures

In the following, the term *(network) parameter* can refer to either the transitivity or a component of the motif signature.

Distinction We conjecture that a significant difference between the network parameters from real and generated text can be observed. Informally speaking, this conjecture is affirmatively substantiated within the scope of our computational studies if there is at least one network parameter such that for each language, the three values from generated text are on the same side of the value from natural text (either all smaller or all larger), and the distance between the former three values and the latter value is substantial.

induced subgraph.

[7] available for download at `https://github.com/stef-roos/MotifAnalysis`

Quantification We conjecture that the network parameters induce a reasonable quantitative measure how far a language model is from naturalness. In our studies, the investigated language models are the 2-gram, 3-gram, and 4-gram models. It is quite reasonable to say, the larger n is, the closer the n-gram model is to naturalness. Therefore, the conjecture is affirmatively substantiated within the scope of our computational studies, if we find at least one network parameter whose values for the n-gram models show a strictly monotonous convergence behavior towards the value for natural language, and this behavior is consistent throughout all languages.

Relation to semantics We conjecture that some of the motifs substantiate the first two conjectures, and that these motifs also allow a deeper insight into the semantic reasons for the observed differences. This conjecture is affirmatively substantiated within the scope of our computational studies, if we can identify semantic phenomena that (1) occur in natural text more often than in generated text and (2) significantly increase respectively decrease the number of occurrences of some motifs.

Relation to local syntax We conjecture that the motif profile of the neighbor-based graph does reflect local syntactic dependencies. A comparison of the motif profiles of the neighbor-based graphs should quantify the extent, to which language models capture local syntactic dependencies between adjacent words. Since n-gram models are trained on short word sequences, we conjecture that there is no difference between real and n-gram generated text with respect to local syntax for $n > 1$.

5 Results

With regard to sentence co-occurrence, the computational results in Sections 5.1 and 5.2 confirm that transitivity fulfills the first and second conjecture, and motif analysis fulfills all three conjectures. The local syntactic conjecture, based on neighborhood co-occurrence, is proven valid in our computational studies, as detailed in Section 5.3.

5.1 Distinction and Quantification

Transitivity Table 1 shows the transitivity values of the sentence-based co-occurrence networks for six languages, in each case for the 2-gram, 3-gram, and 4-gram models and for real natural language. The gap between natural text and any generated text is nowhere smaller than 15%. This substantiates the first conjecture. Evidently, the values for the n-gram models converge strictly monotonously towards the value of natural language in each case, which substantiates the second conjecture.

As an explanation, we attribute this to missing links in n-gram networks that result from the deficiency of such models to capture semantic coherence. The linguistic interpretation of transitivity is the following: if two words A and B co-occur significantly, and A occurs significantly with a third word C, what is the probability that B and C also co-occur significantly? Semantic cohesion (Halliday and Hasan, 1976) means that a text, thus a sentence, is about a certain topic, and there are several sentences that refer to the same topic in corpora. Topics manifest themselves in a certain set of words that will be used frequently together to describe this topic, which results in cliques in the co-occurrence network. While n-gram models capture topical relations between words if they co-occur within a short distance, they miss semantic relations between words that occur at long distances.

Clique motif The differences in the relative shares of the clique motif (#6 in Fig. 2) are even stronger. In fact, Table 2 shows the relative number of cliques in n-gram generated text normalized by the relative number of cliques in real text. The gap between natural text and any generated text is dramatic for $n = 2, 3$ and still always greater than 38% for $n = 4$. The Lithuanian language is the only exception to monotonous convergence. However, even for this language, the discrepancy is greater than 35% for $n = 3$. Except for the Lithuanian language, strictly monotonous convergence is evident, and most of the convergence steps are quite large. In summary, the first conjecture is completely substantiated by this particular motif as well, and the second conjecture is substantiated to a very large extent.

Table 1: Transitivity $T(G)$ in absolute and relative terms to real language networks for six languages, comparing networks from real text with networks from n-gram generated text

To exemplify this, the closed neighborhood graph of "Monday" for its 20 most significant co-occurrences, which is the subgraph consisting of all edges involving "Monday" and the edges between all involved nodes, is depicted in Figure 3 for our real and n-gram networks of English. While collocations like "Monday evening" are present in all graphs, words like "Football" and "Saturday" do not get connected in the 3-gram graph: although they are generated significantly frequently with "Monday", this happens in different generated sentences, whereas they significantly co-occur in real language. Further, the density of these graphs is monotonically increasing with n and highest for real language.

5.2 Semantic Conjecture

Recall the concept of *functional blocks* from Section 2. Next we will show that, in our context here, the chain and the box motif are functional blocks in quite an analogous sense.

Figure 4 shows the motif profiles of networks on a log-scale. In Fig. 4 (left upper), we depict the

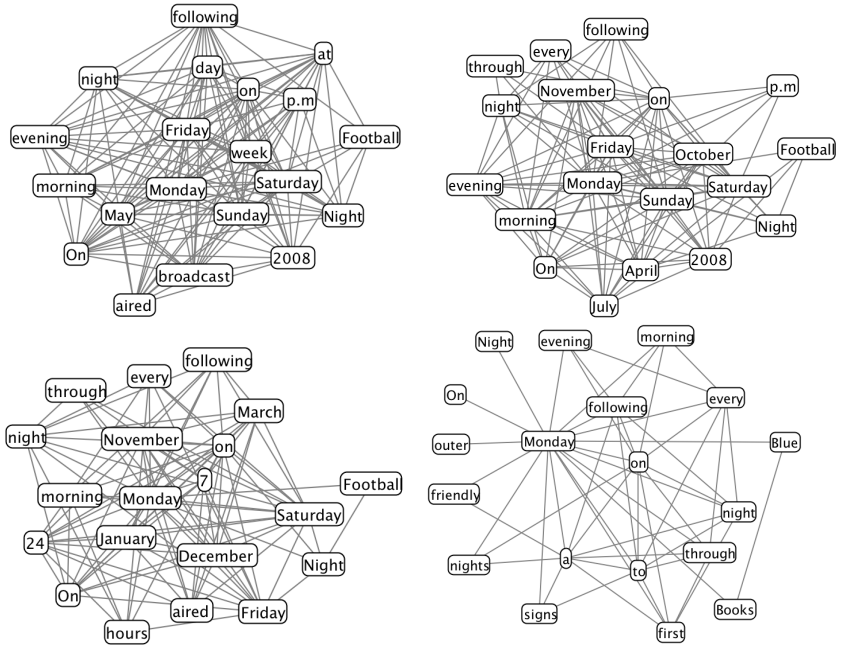

Figure 3: Neighborhood graphs of "Monday" in the English networks for real (upper left), 4-gram (upper right), 3-gram (lower left) and 2-gram (lower right) language, which exemplify the deficiency of n-gram models to capture long-range semantic relations

motif profiles for English networks of real and generated language for $n = 1, 2, 3, 4$; The other plots in Fig. 4 shows the profiles for all other languages for $n = 2, 3, 4$. It is clearly visible that real language networks exhibit fewer star (#1) motifs and a higher amount of all other motifs. Differences for the chain (#2) and the box (#4) motifs are especially pronounced. Examining instances of these motifs more closely, we are able to link these differences to properties of natural language semantics, which will be explained more thoroughly in the remainder.

Polysemy and chain motif *Semantic polysemy* refers to the phenomenon that a word, denoted as a string of characters, can have different denotations in different contexts, e.g. "board" as an assembly or a piece of wood. In real sentences, words are not co-occurring at random, but usually revolve around a certain topic. Thus, it is not likely to find the word "wood" in a sentence that talks about a "board of directors", and sentences about wooden planks usually do not contain the word "chairman".

In co-occurrence networks, polysemy leads to chains: ambiguous words connect words that are not connected to each other, and act as a bridge between different topical word clusters. In a chain of length four, one more word from a topical cluster is observed, which does not connect to the polysemous word since it seems that their occurrences are deemed rather independent

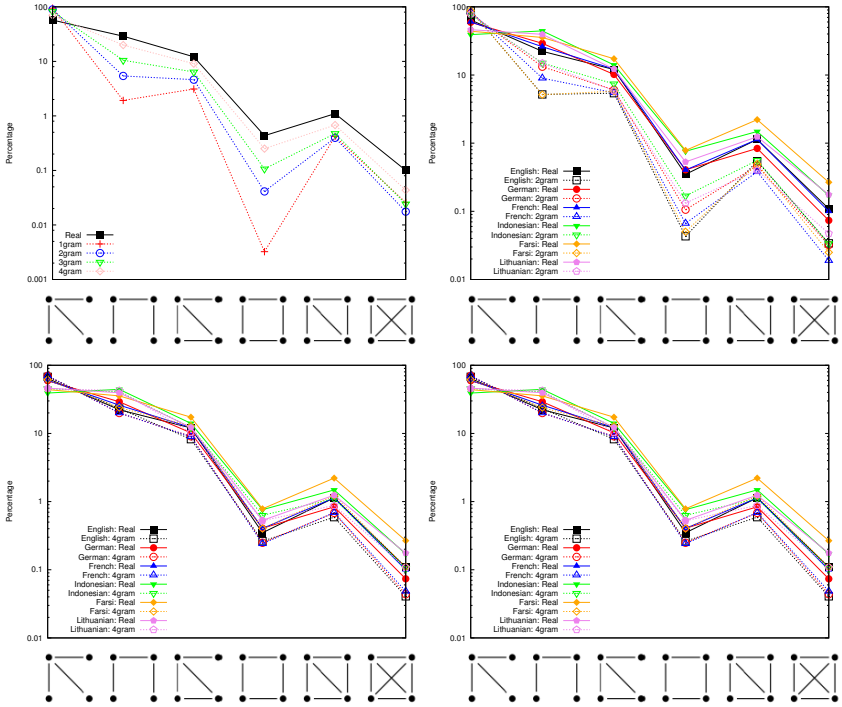

Figure 4: Motif profiles for real and generated text networks based on sentence co-occurrence. Upper Left: motif signature for English, comparing real language to $n = 1, 2, 3, 4$. Upper Right: Comparison Real vs. 2-gram for six languages. Bottom Left: Comparison Real vs. 3-gram for six languages. Bottom Right: Comparison Real vs. 4-gram for six languages. High congruence across languages of different language families demonstrates language independence of our analysis method

by the significance measure.

Enumerating the chain motif instances of the English real network, we exemplify this point with the following chains (the ambiguous word is emphasized in each line):

- total - km^2 - **square** - root
- Democrats - **Social** - Sciences - Arts
- Number - **One** - Formula - Championship
- Abraham - **Lincoln** - Nebraska - Iowa

N-gram models are oblivious to these sense distinctions. Thus, nothing prevents e.g. a 3-gram model from generating e.g. a sequence "Abraham Lincoln , Nebraska" with high likelihood,

confusing the two senses of "Lincoln" as a last name and a city. In the co-occurrence network, this can result in a connection between "Abraham" and "Nebraska", which decreases the chain motif count. The remaining chains of *n*-gram networks, on the other hand, consist mostly of highly frequent words that occur next to each other, e.g. "slowly started on finals", "personal taste good advice". These are also present in the real language network. We observe a much smaller number of chains formed of words of lower frequencies in *n*-gram generated text. Note that it is neither the case that all polysemous words cause chains, nor do all words in the central positions of a chain exhibit lexical ambiguity – differences in chain motif counts rather quantitatively measure the amount of such polysemy than qualify as an instrument to find single instances.

Hence, the lower amount of chain motifs can be explained by the creation of links that are not present in real language. On the first glance, this should lead to a higher clustering, contradictory to the results for motifs #3,5,6. However, as explained in Section 5.1, the clustering of *n*-grams is drastically lower than for real language. Although some of the 4-nodes sets that represent boxes or chains in real languages form (semi-)cliques in *n*-grams, instances of motif #3,5,6 in real languages are replaced by stars in *n*-gram graphs more frequently.

From these observations it becomes very clear that chain motif counts reflect polysemy. The lower *n* is chosen in the generating *n*-gram model, the smaller is the modelling context for ambiguities, resulting in lower chain motif counts.

Synonymy and box motif *Synonymy* means that different words refer to the same concept. Two words are synonyms if they can be used interchangeably without changing the meaning, but there are also rather syntactic variants of words that refer to the same concept, such as nominalizations of adjectives or verb forms of different inflections.

In natural language, the principle of *parsimony* leads to the effect that the same concept is rarely referred to several times in the same sentence. In fact, synonyms usually do not co-occur, but they share a large number of significant co-occurrences – an observation that leads to the operationalization of the distributional hypothesis (Miller and Charles, 1991). When two such concepts are mentioned together frequently since they belong to the same topic, this leads to box motifs, as the following examples from the English real language network illustrate:

- - Ancient - Greek - ancient - Greece -
- - winning - award - won - price -
- - Ph.D - his - doctorate - University -
- - said - interview - stated - " -
- - wrote - articles - published - poems -

We observe different kinds of word pairs for the same concept: synonyms like (award, price), same word stem within or across word classes like (winning, won) or (Greek, Greece), and artifacts of punctuation or spelling (ancient, Ancient) or (interview, "), Thus, box motifs capture a very loose notion of synonymy: "interview" and the double quote " e.g. both refer to a (indirect or direct) speech act.

Again, *n*-gram models are not aware of concepts and references to them, so there is no mechanism that prevents the *n*-gram model from generating sentences that refer to the same concept several times or even use the same word repeatedly. This possibly results in a connection

between those pairs, reducing the box motif count. Box motifs that can be found in both real and n-gram language are again resulting from local sequences of highly frequent words that are possibly circular, not necessarily from the same contexts. Examples include "desktop cover art background", "hall nearby on church" and "these will ask why".

These observations lead to the conclusion that synonymy of natural language leads to box motifs in sentence-based co-occurrence networks, and the difference in the box motif count quantifies the amount of capability of the language model to inhibit the generation of words that refer to concepts which already have been mentioned. N-gram models have this capability only for a very limited context, which again increases with higher n.

5.3 Local Syntactic Conjecture

To assess whether n-gram models really grasp local syntactic dependencies, we examine the motif profile of directed motifs of size 3 on the neighbor-based co-occurrence graph as described in Section 3. In this, we follow Milo et al. (2004), who unfortunately do not specify their procedure of graph construction from language in detail. Figure 5 shows the directed motif profiles of real text and 2-gram-generated text for four languages, and for English for $n = 2, 3, 4$. As Milo et al. (2004) observe, different languages have a very similar motif profile, and the corresponding graphs belong to the same superfamily of networks, i.e. the mostly bipartite networks. We also observe that there is no systematic difference between the neighbor-based networks of real language and generated language, even for $n = 2$. This substantiates our fourth conjecture: n-gram models do in fact grasp local syntactic dependencies very well.

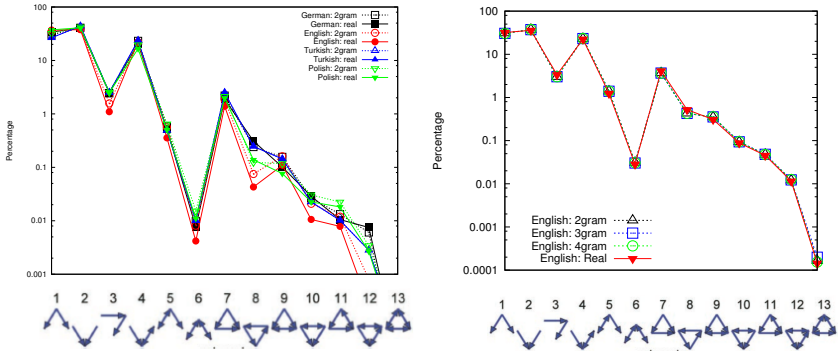

Figure 5: Motif profile of the directed neighbor-based co-occurrence graphs for real and 2-gram generated language (left), respectively for English with n-gram generated text for $n = 2,3,4$ (right), showing a high inter-language agreement and the inability of this measure to distinguish real from generated language

This renders the result of Milo et al. (2004) as not being very influential for natural language research, since the neighbor-based motif profile of real language can be generated by a highly deficient 2-gram language model.

6 Conclusion and Outlook

The methods presented in this paper open new ways to the assessment of the quality of language models, as reflected in the first and second conjecture. We showed that both a global graph metric, transitivity, and an intermediate metric, motif signatures, quantify the difference between natural and generated language. With our third conjecture, we go even one step further by presenting a way to relate semantics to network structure. Looking at the motif signature of real and generated language, we can identify differences due to polysemy and synonymy, which are not adequately modeled by *n*-grams.

Our analysis builds on the fact that generation with language models is not tied to any target application, and generative language models that do not have mechanisms to ensure cohesion will fail to show the same patterns as real language, especially regarding semantic properties such as synonymy and polysemy. In applications like Machine Translation, where language models are used to rank alternatives rather than free generation and are thus bound to the cohesive structure of the source language text, the shortcomings discussed in this paper do not necessarily impede the performance on the task. In fact, preliminary experiments involving comparisons of real translations with automatic translations of the same text did not result in motif profile differences. However, as e.g. (Tan et al., 2012) point out, there is a need for more coherent language models even in these applications: e.g. speech-to-text in noisy environments might greatly benefit from better language models.

Our computational studies with regard to co-occurrence graphs based on sentences and neighboring words indicate that language models based on *n*-grams reflect local syntax well, but fail to model semantic cohesion and topicality. Further, these language models do not have means of regulation for referring to the same concept several times. While these results confirm the common intuition of *n*-grams, we present the first study to actually quantify this deficiency.

The presented series of experiments are but a first step towards a more systematic analysis of the relation between the global characteristics of language and the structure of co-occurrence networks. Varying the notion of co-occurrence, for example, to involve positional offsets, could possibly unveil grammatical differences for a quantitative typology of languages. Further work should include more sophisticated language models such as the syntactic topic model (Boyd-Graber and Blei, 2008), which explicitly models topicality. The restriction to a subset of word classes, for example, nouns or verbs, or to class-based *n*-gram models (Brown et al., 1992) may also be interesting.

All of these ideas still address the *analysis* of language models. As mentioned in Section 2, the concept of motifs has recently been used for a constructive purpose. We anticipate that this change of perspective is also promising in the realm of language networks and may well guide the design of new, semantically more adequate, language models.

{richbill,james}@it.usyd.edu.au

ABSTRACT
Many parsers learn sparse class distributions over trees to model natural language. Recursive Neural Networks (RNN) use much denser representations, yet can still achieve an F-score of 92.06% for right binarized sentences up to 15 words long. We examine an RNN model by comparing it with an abstract generative probabilistic model using a Deep Belief Network (DBN). The DBN provides both an upwards and downwards pointing conditional model, drawing a connection between RNN and Charniak type parsers, while analytically predicting average scoring parameters in the RNN. In addition, we apply the RNN to longer sentences and develop two methods which, while having negligible effect on short sentence parsing, are able to improve the parsing F-Score by 0.83% on longer sentences.

KEYWORDS: Parsing Recurrent Neural Network Restricted Boltzmann Machine.

Proceedings of COLING 2012: Technical Papers, pages 279–294,
COLING 2012, Mumbai, December 2012.

1 Introduction

Fast and accurate constituent parsing is critical for many natural language processing systems (Curran et al., 2007), as it enables rich information to be extracted from text.

Charniak (2000) parsed text by learning to compute top down production probabilities. The Stanford (Klein and Manning, 2003) and Berkeley (Petrov and Klein, 2007) parsers represent a parse as a sub-class distribution on a tree, and maximize the entropy of predicting label probabilities for each node. Advanced parsers use techniques like training on unlabeled text (McClosky et al., 2006), and parse re-ranking (Charniak and Johnson, 2005) to improve their accuracy.

To achieve such accuracy requires conditional probabilities to be computed correctly far up the parse tree, and requires plenty of sub-class labels (typically over 4000) to produce a sufficiently fine grained analysis that accommodates subtle distinctions in text. The resulting transition matrices become large very quickly.

Titov and Henderson (2007) used vectors of real numbers to represent words in a history based model with a mean field representation. Such word vectors have the advantage of maintaining expressive power with much lower dimensionality, typically just 100 dimensions. Garg and Henderson (2011) extended this model to use a Restricted Boltzmann Machine (RBM, Hinton et al., 2006) representation.

Socher et al. (2010) constructed a parse tree using word vectors in a Recursive Neural Network (RNN, Bengio et al., 1994), and applied a similar unsupervised approach for sentiment analysis (Socher et al., 2011).

We focus on the RNN models of Socher, which perform well on short (up to 15 word) sentences, achieving a parse F-score of 92.06% on right binarized text, and we obtain a baseline of 83.94% by applying this to all sentences.

We develop an abstract fully generative model of parsing by considering a Deep Belief Network (DBN, Hinton et al., 2006), and by examining the mean field approximation, contrast this with the conditional RNN model to discover underlying properties of the scoring function.

Motivated by insights from the DBN model, we use an RBM to implement a better model for scoring production probabilities. While this has negligible affect on short sentences, it achieves a 0.83% gain in parsing performance on long sentences.

Noting that the RNN parser's CKY performance drops over large trees, we also develop a novel method of applying gradient methods during evaluation time that improves the parsing F-score by 0.38% for long sentences.

While demonstrating these methods over an RNN model, the gradient method can broadly be applied to a wide range of conditional tree-based models.

2 Background

The Charniak (2000) parser represents a parse probability as the product of the top down production probabilities of a parse. One intuition is that the head node represents the entire sentence, and lower nodes are the probabilities of expressing a span of the text in each possible way. This makes each parse a downwards pointing conditional graphical model, and as explained by Charniak (1997), parser performance increases as more conditional information is used in calculating these production probabilities.

The more recent Stanford (Klein and Manning, 2003) and Berkeley (Petrov and Klein, 2007) parsers use increasingly fine grained sub-class schemes to convey rich information to each parse node to increase performance.

2.1 Berkeley Parser

The Berkeley parser solves the graphical model using the inside-outside algorithm to calculate the distribution of latent subcategories from transition probabilities, β:

$$\beta(A_x \to B_y C_z) := \frac{\#\{A_x \to B_y C_z\}}{\sum_{y'z'}\{A_x \to B_{y'} C_{z'}\}} \tag{1}$$

The algorithm is an application of the Expectation Maximization algorithm (Dempster et al., 1977) for a tree based graphical model. Each tree node maintains a distribution of being in each class with probability A_x. The Berkeley parser uses about 4000 different classes, requiring the optimization algorithm to learn 16 million transition probabilities. This makes computation slow. Other parsers like the C&C parser (Clark and Curran, 2004) speed up this process by effectively limiting the transition space through operator rules that reduce the transition space.

2.2 Word Vectors

Instead of representing the sparse high dimensional distributions of word selection, classes and transitions directly, the word-vector approach attempts to encode such sparse distributions into a much shorter (say 100 dimensions) dense vectors of latent states.

This method was used in the adjacent field of language modeling (Chen and Goodman, 1996), which aims to predict the smoothed frequency of n-gram distributions. Using Neural Networks in a method similar to Principle Component Analysis (Pearson, 1901), Mnih and Hinton (2007) show a log-bilinear model having a low perplexity in predicting the last word of an n-gram. This approach effectively encodes words into same-sized word vectors which can be combined to maximally represent n-gram distributional information through a neural network.

2.3 Neural Networks

Neural Networks are the natural extension of logistic regression that can be used to transform word-vectors into sub-class distributions.

Given a dataset of inputs X and their corresponding outputs Q, a simple logistic regression predicts an output $q_x \in Q$ for each input $x \in X$ by learning a matrix W such that

$$p_x = P(q_x|x;W) = \sigma(Wx) \tag{2}$$

where σ is the sigmoid or hyperbolic tangent function. Learning consists of training W to minimize the loss error function $E = \sum_{x \in X} E_x$, commonly using the square or cross entropy loss

$$E_x = (q_x - p_x)^2 \text{ or } E_x = q_x \log(p_x) + (1 - q_x)\log(1 - p_x) \tag{3}$$

which can be solved through Stochastic Gradient Descent (SGD, Bottou, 2010) by subtracting from W the gradient of E_x for each training example, multiplied by a learning rate.

Stacking logistic regression layers into neural networks (Rumelhart et al., 1986) is possible by passing back the gradient of the error using the derivative chain rule, but learning may become slow if both the outputs and inputs to a logistic regression are latent. This can be overcome by pre-training with Restricted Boltzmann Machines (RBM, Hinton et al., 2006).

2.4 Neural Network Parsing

Costa et al. (2003) previously used a Neural Network for parsing. Titov and Henderson (2007) achieved successful results, with an F-score of 89.3% on sentences of up to 15 words of the WSJ dataset Marcus et al. (1993) by implementing a recurring neural network, predicting the constituents and label decisions at each step based on text features and previous decisions.

Garg and Henderson (2011) used RBM in a similar approach to dependency parsing. Here, while the prediction step stays the same, the learning method is adjusted. Instead of trying to learn $p_x = P(q|x;W)$ over the dataset $\{X,Q\}$, the goal is to learn the generative probability of $P(x,q;W)$. Garg and Henderson implements a recurrent model, with weight biases derived from previous parse decisions, achieving 89% dependency parser score on short sentences.

3 Recurrent Neural Network Parsing

Socher et al. (2010) used a Recurrent Neural Network (RNN) that represented a parse tree consisting of real-valued node vectors from which the various sub-class distributions and parse decisions were computed through logistic regression classifiers. The conditionally independent nature of the elements of each node vector allows the normally sparse sub-class distributions to be compressed into a length of just 100 dimensions.

3.1 Leaf Layer

At the lexical leaf node layer, each tokenized word in the text is represented by a word vector t_i that is supplied from a pre-generated word-to-vector table L. This table L (the Lexicon) is generated through a distributional similarity process (Collobert and Weston, 2008) using back-propagation through a series of transformations of word and feature distributions.

The text is padded with a pair of start-of-sentence and a pair end-of-sentence tokens, each pair with their own vector. A direct 300→100 feature word-to-leaf logistic regression combines the 100 dimensional word-vectors for the current word t_i, previous word t_{i-1} and next word t_{i+1}, to generate the 100 dimensional real-valued vector v_i that acts as a leaf-vectors for the parse tree, as shown on the left of Figure 1. The word-to-leaf logistic regression learns a 300x100 element matrix Y, which is composed of three 100x100 element matrices Y_1, $Y_2$and Y_3, so that the leaf vectors v_i for each word are calculated by:

$$v_i = \sigma(Y_1 t_{i-1} + Y_2 t_i + Y_3 t_{i+1}) \tag{4}$$

For example, in Figure 1, the leaf node a above the word "John" would be calculated as:

$$v_a = \sigma(Y_1 t_{[start]} + Y_2 t_{[John]} + Y_3 t_{[eats]}) \tag{5}$$

As well as predicting parse information, the leaf-vectors predict Part of Speech (POS) tags which, when given a gold standard POS tag during training, provides an additional error gradient to help learn the word-to-leaf logistic regression layer.

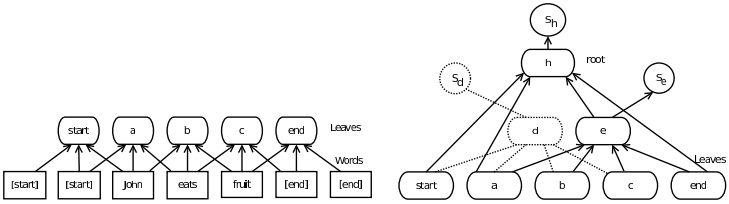

Figure 1: (left) Word to leaf network for text "John eats fruit" and (right) parse tree for parse $T_1 = a, (b, c)$ and (dotted) $T_2 = (a, b), c$ showing scoring nodes s_d, s_e and s_h. For clarity the predictions for the POS and phrase classes are not shown, however these are logistic regression classifications directly from the tree leaf nodes, and tree non-leaf nodes respectively.

3.2 Non Leaf Layer

The non-leaf node (i.e., parent node) vectors, p, of the tree are predicted using a 400→100 feature child-to-parent logistic regression layer. This logistic regression takes four lower tree node vectors as inputs. Two of these input vectors c_1 and c_2 are the vectors of p's left and right children, which may themselves be either parent or leaf node vectors. The other two input vectors are the leaf-node vectors v_1 and v_2 of the two words that directly surround the span of text represented by p. The child-to-parent logistic regression uses a 400x100 element matrix W, which is composed of four 100x100 element matrices W_1, W_2, $W_3$and W_4, so that the parent vectors p are calculated by:

$$p = \sigma(W_1 c_1 + W_2 c_2 + W_3 v_1 + W_4 v_2) \tag{6}$$

In Figure 1, the parent node h for the parse "John (eats fruit)" would be calculated as:

$$p_h = \sigma(W_1 v_a + W_2 p_e + W_3 v_{start} + W_4 v_{end}) \tag{7}$$

As well as being used to predict parent vectors higher in the parse tree, the parent vectors are used to predict node class labels (like VP or NP), and a real-valued score feature s_p which is used to predict whether a particular parent node is part of the gold-parse tree. The score is calculated using the output of a 100→1 logistic regression classifier, with parameter R:

$$s = \sigma(r) \text{ where } r = Rp \tag{8}$$

3.3 Parse Generation

Parse trees are built from the leaves up. The leaf nodes vectors are first calculated, and then parent vectors are calculated for each pair of adjacent leaf nodes. These parent vectors are then scored using the node-to-score classifier.

For subsequent layers up the parse tree, each new parent vector is computed using each combination of potential children vectors that might constitute the new parent vector. These new parent vectors are each scored using the node-to-score classifier. The computed score is added to the scores for sub-trees below, and the CKY algorithm (Kasami, 1965) is used to store and select the highest scoring overall tree.

The RNN's continuous vector model does not have a direct class representation, so there are no equivalence classes as needed for a packed chart. To overcome this, the RNN uses a beam to store a selection of high-scoring parses and their node vectors. A beam size of one was used in most experiments, as larger beam sizes gave little improvements. This is consistent with Socher et al. (2010)'s experiments and observations.

3.4 Updating the Weights

The parameters for each regression layer are updated using gradient descent, back propagating the error gradient through both the gold and the generated tree. The error function used is a hinge loss error gradient for the predicted scores s_i.

$$\frac{dE}{dr} = \begin{cases} -1 & \text{predicted, not gold} \\ 0 & \text{predicted+gold} \\ 1 & \text{gold, not predicted} \end{cases} \tag{9}$$

For gold trees, the gradient is 0 if the computed parse includes the gold node, and 1 if it does not. This is added to the gradients for the logistic regression POS tagger and node category tagger. For computed trees, the error for the predicted score s is 0 if the node is included in the gold parse, and -1 if it is not.

The errors for each tree are propagated down through each tree to the leaves, to update the word-to-leaf classifiers and eventually update the word vectors in the lexicon L. Note the gradient is calculated on r, not s (i.e. before the sigmoid function is applied), which has the effect of making it an entropy based gradient.

4 Generative Model

The RNN model is an upwards pointing conditional model in which the parents are conditioned on the children. This ignores aspects of a generative nature. By contrast, the intuition of Charniak shows a parse can be generated top down through a conditional generative process from a root node. To bridge these two models, we develop a novel expressive generative model (using a Deep Belief Network) that is conditional both up and down a tree, and examine the similarity of the equations with those of an RNN.

We are also motivated towards using a generative top-down conditional model because of the intuition that the speaking and writing process starts with ideas, which are reformulated into phrases and expressed in words. This process supports the notion that words are conditionally chosen based on ideas which would be found higher in the tree. A counter argument might exist that for the listener, the ideas heard are selected conditionally on the words of the text, however, the words and ideas were chosen by the speaker, so this is a weaker argument.

This bidirectional approach does not require these arguments to be mutually exclusive, as learning to speak and learning to listen might be shared aspects of one bidirectionally conditional model, transforming ideas into words, and back again.

4.1 Hypothetical Model

First we consider a (completely impractical) hypothetical model of parsing that follows the top-down approach, so we can later constrain it and compare it with the RNN model.

In this hypothetical model, the structure and meaning of any sentence can be represented by a 100 dimensional root vector. This root vector generates two child vectors, one representing a span of text on the left, and one representing a span on the right, and each of these child vectors continue generating their own two children vectors until some stopping process makes leaf vectors that generate words.

In this way, the process implements a top down generative conditional probability model (Charniak, 2000) in which the children are conditionally dependent on their parents.

To parse of a piece of text, samples from every possible root node vector generate every possible tree and their resulting texts. These trees and latent variables are then selected only where the generated text equals the supplied text. From this sample, the most likely parse is determined to be the most likely tree that generated the text.

The parameters of this hypothetical model would be tuned to create an optimum distribution at the root node, and an optimum conditional child generation distribution and stopping process to best model the parses of the text.

4.1.1 Constrained Model

We take this hypothetical model, and explore whether applying the constraints found in a Deep Belief Network (DBN, Hinton et al., 2006) would severely limit the model's expressive power.

A DBN consists of an RBM which generates a stationary distribution vector of binary values that acts as the complementary prior (CP, Hinton et al., 2006) for a downwards pointing directed acyclic graph (DAG) of binary vectors, each conditional on the parent. The complementary prior is defined by Hinton et al. to be the prior distribution that contains exactly the correct correlations necessary to enable the posterior parent distribution to be factorial (independent of one-another) given the child vector.

To implement a parse tree using a DBN, we firstly require that elements of each latent node-vector p (including the root vector) only take values 0 and 1. These vectors could potentially predict any other latent multi-class variable from p through soft-max classifiers, so a binary constraint should not be too onerous.

Secondly, we require that the root node be able to generate a stationary distribution that is optimum to generate the text. We note that RBMs can flexibly generate any distribution of child vectors, limited only by the number of hidden units (the dimension of p) (Le Roux and Bengio, 2008). For modeling text, this should be sufficient, since the text is independent of the trees when given the leaf vectors' distributions.

Thirdly, we require that the DBN generates a tree with downwards pointing conditional distributions. The DBN will naturally support the conditional distribution with function F:

$$P(c_1, c_2|p) = F(p, c_1, c_2) \tag{10}$$

and the probability of generating a tree T given its root will be:

$$P(T) = \prod_{nodes\ p \in T} F(p, c_1, c_2) \tag{11}$$

Finally, however, using a DBN within a tree structure presents the problem of maintaining a complementary prior at every parent node throughout the tree. Typically, the DAG used

with RBMs only recover the original complementary prior at every alternate layer. This can be overcome by initializing W with a symmetric weight matrix with $W = W^T$.

A second issue is that as we travel down the tree, the total vector count grows, so an issue of double-counting the prior arises. The prior must be a prior of both its children together, and not each child taken separately. While constructing a Deep Boltzmann Machine (DBM), Salakhutdinov and Hinton (2009) discuss how to manage the asymmetric application of DBN so the downward posterior has twice the dimensionality of the upwards posterior.

4.1.2 Parent Probability

The main feature of the DBN is that inference can be performed quickly to calculate the parent vector given the children vectors. Given a tree T, this allows us to calculate up the tree, even though it is through a downwards pointing conditional model, so the ith element of p can be predicted by:

$$P(p^{(i)} = 1|c_1, c_2) = \sigma(c_1 W_1 + c_2 W_2)^{(i)} \tag{12}$$

It is important to note that here c_1, c_2 and p are binary sampled values, not their probabilities or averages, whereas the resulting probabilities are distributions. However, used as a mean-field approximation, Equation (12) is essentially the same as that of the RNN. The DBN overcomes this limitation by sampling at each step within the tree.

4.1.3 Tree Probability

For each word sequence, there are multiple tree structures that could generate the same text, each with varying probabilities. Occasional examples exist like 'I saw that gas can explode' having two different parses of similar probability. To select the most likely parse, we must compare the generative probability of the two trees.

When two parses differ only at some parent node h, and the trees beneath h are of the form $T_1 = a, (b, c)$ and $T_2 = (a, b), c$ (see Figure 1) and d is the parent of (a, b) and e is the parent of (b, c), then we approximate the relative probability each tree was generated as follows:

Given the supplied text under nodes a, b, c being respectively x, y, z, the conditional vector distributions can be calculated through sampling going up each tree. In both T_1 and $T_{2,}$, when we arrive at nodes a, b and c, they will each have the same sampled distributions, as below a, b, and c, the two trees are identical. The mean field approximations for the most probable combinations of each vector a, b, c will be near their expected values $\bar{a} = E(a|x)$, $\bar{b} = E(b|y)$ and $\bar{c} = E(c|z)$.

Given no information, the prior probability of h will be the complementary prior, so taking a mean field approximation, the probability T_1 generates the text will be:

$$P(x, y, z|T_1) = \sum_h \sum_d P(h, \bar{a}, d) P(\bar{b}, \bar{c}|d) P(x|\bar{a}) P(y|\bar{b}) P(z|\bar{c}) \tag{13}$$

Ignoring the common terms $P(x|a)$ etc, we get:

$$P(x, y, z|T_1) \propto \sum_{hd} P(h, \bar{a}, d) P(\bar{b}, \bar{c}|d) \tag{14}$$

If again we make the mean field approximation that $P(\bar{b}, \bar{c}|d)$ only has probability mass at the point $E(\bar{b}, \bar{c})$, and apply Bayes rule ignoring common terms we get:

$$P(T_1|x, y, z) \propto P(\bar{a}, d) \tag{15}$$

4.1.4 Scoring the Tree Probability

The relative log probabilities for T_1 and T_2 is (where d and e are as shown in Figure 1):

$$\log(P(a, d)) : \log(P(e, c)) \tag{16}$$

So for children u, v of an arbitrary parent node h, where the parent node h has the distribution of the complementary prior, we can model the log probability $\log(P(u, v))$ by summing each one of the $2^{|h|}$ combinations of h using:

$$\log(\sum_h P(h, u, v)) = \log(\sum_h \exp(hW_1u + hW_2v + \gamma h + \alpha u + \beta v)) - \log(Z) \tag{17}$$

where α, β and γ are the biases to be learned with W_1 and W_2. We can ignore $\log(Z)$ as it is found in both T_1 and T_2. A common rearrangement is to multiply out the contributions made for each element $h^{(i)}$ of h being a 0 and a 1 (writing $\sum_i g^{(i)}$ as the sum of g's elements):

$$= \alpha u + \beta v + \sum_i \log(1 + \exp(\gamma + W_1u + W_2v))^{(i)} \tag{18}$$

$$= \alpha u + \beta v - \sum_i \log(1 - \sigma(\gamma + W_1u + W_2v)))^{(i)} \tag{19}$$

$$\log(P(u, v)) = \alpha u + \beta v - \sum_i \log(1 - h_i) \tag{20}$$

where $h_i = P(h^{(i)} = 1)$. Since u and v are factorial in h, the resulting log probability is also largely factorial in h making it suitable for a regression layer. As the RNN operates with mean-field values, it can learn $\log(P(u, v))$ through regression based on h using:

$$s(h) = \sigma(Rh) \simeq \log(P(u, v)) \propto \log(P(T_1)) \tag{21}$$

In this way, the approximate conditional probability of each parent is calculated upwards using the RNN model, and the log probability of each parse can be estimated by summing the expected values of s, and learned through back-propagation.

4.1.5 Estimating the Scoring Function

We can estimate the value of s by taking the Taylor expansion of the log probability of $\log(P(u, v))$ in terms of h_i:

$$log(P(u,v)) \simeq C + \sum_i -\log(1-h_i) \simeq C + \sum_i h_i + O(h_i^2) \tag{22}$$

The Taylor expansion of the logistic function used by the classifier by contrast is:

$$\sigma(Rh) = C + \sum_i \frac{1}{4} R^{(i)} h_i + O(h_i^2) \tag{23}$$

Comparing the linear h_i terms in Equations (22) and (23) would suggest an expected value of $R^{(i)} = 4$

It is interesting to note that in our experiments with the RNN model, the average value of $R^{(i)}$ was 1.77. However, the implementation of the RNN used the tanh function, instead of the sigmoid function σ found in the abstract DBN model for the node to node matrices W_1 and W_2 which generate the input to the scoring function. Since $\tanh(x)$ outputs values in twice the range as $\sigma(x)$, this gave the RNN model an effective average value for $R^{(i)}$ of 3.54, within 13% of the predicted value.

4.1.6 Reducing Divergence

In practice, the mean-field distribution diverges from the true combinatoric binary distribution. This becomes most noticeable when a node's distribution is sharply constrained by its own parent node, and is the result of each node being conditioned only on its children, and not on its parents. To reduce this effect, conditioning each node's probability on leaf-node vectors adjacent to the span (as in Equation 6) helps bring in some of the conditional information of the parent's node vector, since the parent node-vector is itself conditioned on its two children, one being the original node, the other being an ancestor of one of the adjacent leaf node.

4.2 RBM to Improve Modeling S

The RNN can be thought of as a mean-field approximation of the DBN model that learns to model the log probability of $P(T_1)$ through Equation (21). The R term implies that s is computed through a logistic regression.

Although the DBN abstract model indicates logistic regression on h should provide a good solution of $P(T_1)$, the mean-field approximation diverges sufficiently enough that incorporating contextual features makes a significant improvement to the results (Socher et al., 2010). This suggests that a superior scoring classifier might also further improve the results. Recalling that RBMs are better at modeling general distributions, and that when given the complementary prior, the probability of $P(T_1)$ takes the form of Equation (17), this motivates that $s(p)$ would be better modeled by a Restricted Boltzmann Machines (RBM).

RBMs have been used before in parsing (Garg and Henderson, 2011). They aim to model a generative probability $P(x,h) \propto \exp(xWh)$ and are often trained through Gibbs sampling, one layer at a time. Layer-wise training is harder for a recursive model, however, they can be used to model the distribution of the scoring function $s(p)$ in the approximate RNN model:

$$s(p) \propto \sum_h \exp(hUp + ap + bh) \tag{24}$$

4.2.1 Configuration

RBMs can be used in several configurations for modeling the probability of $s(p)$.

One method involves using two RBMs, one with energy functions $E_1 = h_1 U_1 p$ to model the probability that the parent node is part of the correct parse, and one with $E_2 = h_2 U_2 p$ to model the probability that it is not. In this case, the probability the parent node is part of the parse is given by $\exp(E_1)/(\exp(E_1) + \exp(E_2))$.

Another configuration uses a single RBM, $E = hMp$ and regression $s = \sigma(Vh)$. This model most naturally extends to a three layer neural network.

The discriminative RBM (Schmah et al., 2009) which we use goes one step further, by assuming that s is itself a latent feature of the RBM which has energy $E = hMp + hVs$. This means that $P(s = 1|p) = \sigma(Vh)$, while $P(h_i = 1|p) = \sigma(Mp + Vs)$. By including the Vs term in the calculation of $P(h_i = 1)$, it enhances the expressiveness of the model.

4.2.2 Training

Instead of using Contrastive Divergence (CD, Hinton et al., 2006) to learn the parameters of M and V, we perform discriminative RBM training, since the dimensions of s are so small. This is done by calculating the RBM twice, once for $s = 0$ and once for $s = 1$. These results can be combined to give a value of $P(s = 1|p)$, and the gradient can be used to update M and V.

We train this model for s as a post-process to training the RNN, while holding fixed the parameters of the underlying RNN model. The motivation was to effectively implement the top layer-wise training seen in deep RBM training models. We do not allow the gradient to back-propagate to update W or other parameters, as it did not improve our overall results.

4.3 Improvement to CKY through Leaf Vector Nudging

Different parse decisions made at lower levels of the tree result in different parent vectors. Even when the structure of two trees differs only slightly, as T_1 and T_2 did in Section 4.1.3, the changes to the parent vectors are not local but propagate up all the way to the root node.

This affects the ability of the CKY algorithm to find the parse with the highest log likelihood score. For longer sentences, the scoring model may give the gold parse the highest parse score, but using the CKY algorithm with a small beam may fail to find this highest scoring parse.

In this situation, there must be a node where the CKY algorithm made an incorrect decision. For the parent of this node, the gold parse's local sub-tree score was lower than several incorrect parse's sub-tree scores, enough to incorrectly fill the CKY beam with the wrong parent node vector. In this case, there will be some group of higher nodes that would have scored higher had the gold node's children vectors been used, rather than the incorrect parse node's children vectors found in the CKY beam (and by a more significant margin), but the CKY algorithm would have never calculated them.

With this motivation, we examine how to temporarily nudge some parameters of the model to encourage the CKY algorithm to find the best overall parse and, in particular, how the gradient of higher node scores can be back-propagated at evaluation time to lower nodes to encourage the CKY algorithm to favour parse decisions at a lower level that will do better at higher levels.

4.3.1 Learning Leaf Vectors

Another motivation for this approach comes from considering the process of updating the word-vectors during learning. The back-propagation for the RNN passes through the tree and leaves into the lexicon L. One can imagine that words with multiple senses will be given a blended vector representation, sometimes being tugged towards one sense's vector, and sometimes tugged towards another. In this instance, even during testing, where a parse is mostly correct it is likely that the vector would have been tugged mostly in the correct direction.

With this in mind, we found it possible to back-propagate the parse score gradient down through the tree and into the leaf vectors temporarily, just for the current parse. The goal of this is to temporarily give the leaf vector a value closer to the sense that is currently being used, thereby giving a chance of fixing any errors in the parse.

During testing, however, we do not know the correct parse, so cannot use the correct gradient for back-propagation. Instead, we use the parse scores s as a measure of confidence on each parse node, and back-propagate the direction of the gradient $\frac{ds}{dp}$ from the most confident nodes.

4.3.2 Method of Gradient Improvement

First, a parse of the sentence is generated using the RNN model and scores s_i for each parse decision calculated. The average score $\hat{s}$ is computed for the entire tree, and a reliability variable $g_i = \max(0, s_i - \hat{s})$ calculated to determine the most confident parse decisions. These values are then used as the error model and the gradient $kg_i \frac{ds_i}{dp}$ is back-propagated to the leaf-node level. This gradient is temporarily added to the leaf vectors and the sentence is re-parsed and the highest scoring parse selected. Finally the new parse is re-scored using the original leaf vectors and the new parse is only selected if the total score exceeds the sentence's original total parse score. Since we expect half the nodes to contribute gradients, we set $k = 2/(10 + \text{len(sentence)})$ which empirically worked well with the development set.

5 Results

We used the WSJ corpus of the Penn Treebank (Marcus et al., 1993), using sections 2-21 for training, 22 as a development set and 23 as the test set.

We require binary branching parse trees so, before commencing we made the following adjustments to the WSJ data that was kept for both training, development and final evaluation: all traces were removed; all unary rules (nodes with a single child) were collapsed (the resulting label was the POS tag of the leaf word); all nodes with more than 2 children were right branched (except for the most right node if it was punctuation) and the resulting node labels of the newly generated parents was made the same as for the original multi-branched parent; for short sentence experiments only sentences containing 15 or fewer tokens (including punctuation) were used.

The networks were trained with 500 passes over the training corpus with an initial learning rate of 0.005 that decreased by 2% of its value after pass. The parameters were stored whenever evaluation against the development set revealed a higher result, which was tested every 1000 sentences. Final testing was performed against section 23.

The word-vector table was initialized from pre-computed values in the lexicon (Collobert and Weston, 2008) and the word vectors took the values $L_{u(S,i)}$ according to each word $u(S, i)$ of the

Method	F1	significance
Socher ⩽ 15 words	92.06%	
RNN ⩽ 15 words	92.41%	
RNN all sentences	83.94%	
Gradient	84.32%	+0.38% (p=0.0001)
RBM	84.77%	+0.83% (p=0.0008)

Table 1: F1 Test scores for section 23 of the WSJ

text. For tokens found in WSJ but not in the table, we added a fresh token with a value given by either the lowercase version of the token (if found) or with the value of the *UNKNOWN* token. All numeric characters were replaced with the digit '2'.

5.1 De-Binarization

The RNN and DBN model both require binarized trees. The standard WSJ corpus is not binarized, but (especially at the leaf layer) contains many nodes consisting of more than two children. For example, tokens of multi-word nouns like "`New York Stock Exchange`" will all be children of the same node, while binarized trees might nest these as `(New (York (Stock Exchange)))`. During evaluation, the computed F-scores for binarized trees will appear inflated compared to those of un-binarized trees, since it is easier to learn and reproduce the additional right bracketings.

For comparison with other systems, we consider how the binarization process could be reversed so that generated trees may be compared with the original unbinary WSJ corpus. This could be done through coded compounding rules based on predicted phrase categories labels, or by learning a de-binarize feature. The method we used was as follows.

There are 28 non-terminal labels that are applied to the gold-standard text (e.g. `S, VP, NP`). During the process of right binarizing the text, we label the newly created nodes with one of 28 newly created categories (e.g. `!S, !VP, !NP`) generated by adding '`!`' to the label of the new node's parent node. In this manner we identify which nodes to delete when debinarizing generated parses.

Unless otherwise noted, the results we show are for binarized trees, as binarized trees were used in the original experiments by Socher (2012).

5.2 Evaluation

Testing was performed using evalb. The F1 score (precision and accuracy are are identical for binarized trees) was taken as the overall reported performance.

A result of 92.41% was achieved by training on all the text, and testing on just the sentences up to 15 tokens long. A result of 83.94% used the same model, testing on the entire test set, both short and long sentences (refer to Table 1). For comparison with other parsers, we obtained a debinarized F-Score of 89.47% on short sentences.

Significance was calculated using Dan Bikel's Randomized Parsing Evaluation Comparator. [1]

token	$error^2$	token	$error^2$
.	0.128	if	0.032
?	0.125	It	0.029
:	0.077	get	0.028
.	0.054	what	0.026
–	0.046	That	0.025

Table 2: Tokens and square errors of modifications during testing

5.3 RBM

The discriminative RBM model was used as a post-process to learn an improved model of the scoring function. It was trained in about 24 hours, holding the other parameters of the model fixed. It out-performed the original model by 0.83% (with a p-value of 0.0008). The training was entirely discriminatively performed with no back propagation through the structure.

5.4 Gradient Update

The gradient update method was used entirely during evaluation time. It improved the F-score by just 0.38% (with a p-value of 0.0001). The significance was higher because more of the mistakes it made were also made in the baseline model.

The tokens with the greatest average modification were mostly punctuation and function words that shaped the structure of the sentence (see Table 2). These words control the sentence structure but have little distributional information. Other highly modified words were those with low frequency counts in the corpus.

Conclusion

We have demonstrated the performance of a Recursive Neural Network parser to binarized forms of all sentences in the WSJ corpus, obtaining a baseline of 83.94%. We have presented a method to improve parser performance by using a discriminative Restricted Boltzmann Machine for scoring productions increasing F-score by 0.83%. We have also presented a gradient method that can be used during evaluation that augments the CKY algorithm and improves accuracy by a separate 0.38%. We have provided a framework to draw a connection between top-down generative conditional parsers with bottom-up conditional RNN parsers, and using this framework have analytically calculated estimates of the learned RNN parameters.

In future work, we hope to implement the generative model described in this paper using Contrastive Divergence starting with just the leaf layer and increasing one parse layer at a time.

The methods we presented are easily applied to other recursive tasks and network structures and provide a link between generative and conditional parsing. These improvements can be used in future down-stream tasks.

Acknowledgments

We would like to thank the reviewers and Schwa-Lab for their comments. This work was supported by Australian Research Council Discovery grant DP1097291, the Capital Markets CRC and an Australian Postgraduate Award. We are grateful to Richard Socher for his guidance reproducing his results in our system.

Thread Specific Features Are Helpful For Identifying Subjectivity Orientation of Online Forum Threads

ABSTRACT
Subjectivity analysis has been actively used in various applications such as opinion mining of customer reviews in online review sites, question-answering in CQA sites, multi-document summarization, etc. However, there has been very little focus on subjectivity analysis in the domain of online forums. Online forums contain huge amounts of user-generated data in the form of discussions between forum members on specific topics and are a valuable source of information. In this work, we perform subjectivity analysis of online forum threads. We model the task as a binary classification of threads in one of the two classes: subjective and non-subjective. Unlike previous works on subjectivity analysis, we use several non-lexical thread-specific features for identifying subjectivity orientation of threads. We evaluate our methods by comparing them with several state-of-the-art subjectivity analysis techniques. Experimental results on two popular online forums demonstrate that our methods outperform strong baselines in most of the cases.

KEYWORDS: Online Forums, subjecitivity, dialogue act.

Proceedings of COLING 2012: Technical Papers, pages 295–310,
COLING 2012, Mumbai, December 2012.

1 Introduction

A large number of online forums in various domains (e.g., health, sports, travel, camera, laptops, etc.) exists today, containing huge volumes of user-generated data in the form of discussions between members. The topics discussed in the threads of these forums are very unique in nature as they are often related to practical aspects of life (e.g., *How much to tip after bad service?*). Since such information is not available in other webpages, online forums are increasingly becoming very popular among internet users for discussing real life problems.

In this work, we *analyze subjectivity of online forum threads*. We identify two types of threads in an online forum: *subjective* and *non-subjective* and we model the subjectivity analysis task as a binary classification problem. Subjective threads discuss subjective topics that seek opinions, viewpoints, evaluations, and other private states of people, whereas non-subjective threads discuss non-subjective topics that seek factual information. Figure 1 shows a subjective thread from an online forum, Trip–Advisor New York. Figure 2 shows a non-subjective thread from the same forum. In the former, the topic of discussion is *whether to tip or not after bad service?*, which seeks opinions, whereas the latter seeks factual information about *bands/artists playing in December in Madison Square Gardens*. To the best of our knowledge, previous work on subjectivity analysis has not tackled the problem of identifying subjectivity orientation of online threads.

1.1 Why Subjectivity Analysis of Online Forum Threads?

- ***Improving forum search***: Internet users search online forums, generally, for two types of information. Some of them search the forums for subjective information such as different viewpoints, opinions, emotions, evaluations, etc., on specific problems instead of a single correct answer. Other users want short factual (objective) answers. Previous works on online forum search have focused on improving the lexical match between searcher's query keywords and thread content (Seo et al., 2009; Bhatia and Mitra, 2010; Duan and Zhai, 2011). However, these works do not take into account a searcher's intent, i.e., the *type of* information a searcher wants. Let us consider the following two example queries issued by a searcher to some camera forum: 1) How is the resolution of Canon 7D, 2) What is the resolution of Canon 7D. The two queries look similar, but they differ in their intents. In the first query, the searcher wants to know what other camera users think about the resolution of the Canon 7D, how are their experiences (good, bad, okay, excellent, etc.) with the camera as far as its resolution is concerned and other such types of *subjective* information. The second query, however, is *objective* in nature in which the searcher wants a factual answer, which, in this case, is the value of the resolution of the camera. Hence, queries having similar keywords may differ in their intents. Search algorithms based only on keyword search would perform badly for these types of queries. We believe that by knowing the type of information (subjective or objective) contained in a forum thread, these types of queries can be addressed in a better way. A forum search model can then match the searcher's intent with the type of information a thread contains in addition to the keyword match between the two and thus, handle the queries more intelligently.
- ***Abuse detection***: Online forums are informal in nature. Often, discussions in threads get heated with users getting engaged in abusive conversations. Forum administrators continuously monitor forums for such contents and remove them as they are against the community rules. These conversations are subjective in nature and hence can potentially

be detected by analyzing threads for subjectivity.

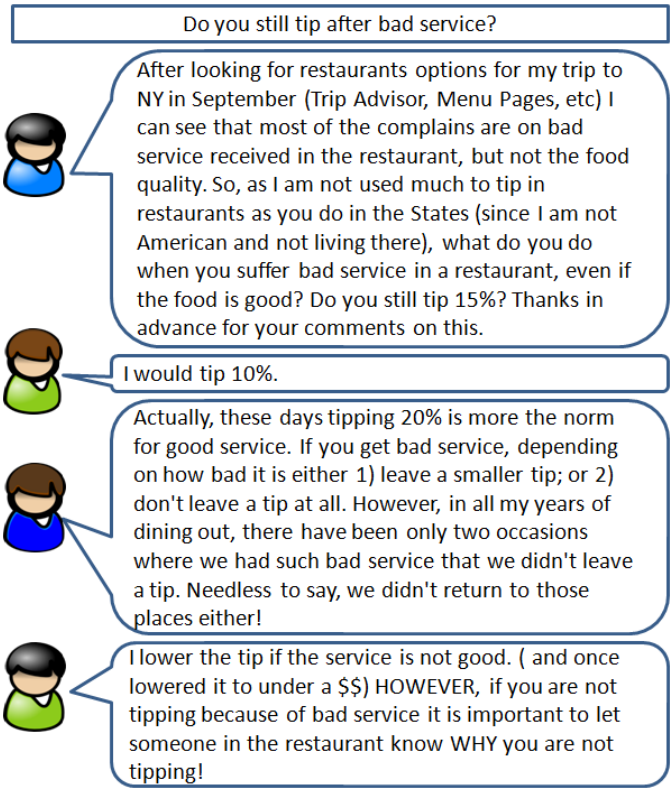

Figure 1: An example thread with subjective topic.

Previous works on subjectivity classification have extensively used lexical features such as bag-of-words, n-grams, combinations of n-grams and parts of speech tags, etc (Yu and Hatzivassiloglou, 2003; Li et al., 2008a; Aikawa et al., 2011). A major issue with these features is their high dimensionality feature space and hence there is a risk of model overfitting especially with small training data. In this work, we explore the possibility of using non-lexical and thread specific features for the subjectivity classification of threads. Specifically, we explore the following research question: *Can non-lexical thread specific features (e.g., number of users in a thread, number of posts in a thread, etc.) help in inferring the subjectivity of online forum threads?* To address the question, we propose and evaluate several thread specific features for subjectivity classification. We compare the performance of our classification model with various state-of-the-art techniques and show that our model outperforms the baselines in most of the cases.

Figure 2: An example thread with non-subjective topic.

1.2 Contributions

Our work has the following contributions:

1. We are the first to perform subjectivity analysis of online forum threads automatically.
2. We propose two new types of non-lexical features for subjectivity analysis of online forum threads: *structural* features and *dialogue act* features. Previous works on subjectivity analysis have mainly used lexical and syntactic features like n-grams, POS tags, subjectivity clues, etc. In this work, we empirically show that, for online forum threads, in addition to the traditionally used features, thread's structure and information about dialogue acts of its posts also help in analyzing thread's subjectivity.
3. We extensively evaluate our methods by comparing with various state-of-the-art baselines.
4. The dataset used in this paper for subjectivity analysis of online forum threads is being made publicly available for the research community [1].

The rest of the paper is organized as follows: The next section overviews the related work in the field of subjectivity analysis. Section 3 describes the problem and the features used for subjectivity classification. In Section 4, we describe our dataset, experimental settings and present and analyze the results of the classification. Section 5 concludes the paper and discusses the future work.

2 Related Work

Subjectivity analysis has been an active field of research due to its important applications in opinion mining, sentiment analysis, question-answering, summarization, etc. Here, we first provide a brief survey of works on subjectivity analysis in general and then we review the works that performed subjectivity analysis in different domains (online review sites, community answers, etc.) and used it in different applications (opinion mining, question-answering, etc.).

2.1 Subjectivity Analysis

Wiebe et al. (1999) did a seminal work on generating and using a gold standard dataset for subjectivity classification. They performed subjectivity classification of sentences using

[1] http://www.personal.psu.edu/pxb5080/dataSubj.html

basic features such as presence of a pronoun, an adjective, a modal, etc. in the sentence. Bruce and Wiebe (1999) performed a case study of manual subjectivity tagging. Wiebe and Riloff (2005) performed subjectivity classification of sentences in World Press articles using unannotated data. They used high precision rule-based classifiers for generating an initial training data and then used semi-supervised learning to iteratively learn subjectivity patterns and augment the training data. Su and Markert (2008) performed word sense subjectivity classification using the training data generated from the existing opinion mining resources and showed that the performance is comparable with that of the classifier trained on a dedicated training set. Other works have performed subjectivity classification across different languages (Mihalcea et al., 2007; Banea et al., 2008). They discussed and evaluated methods to develop subjectivity analysis tools for selected languages by applying machine translation on the available subjectivity analysis tools and resources for English language. Banea et al. (2010) performed subjectivity classification in six different languages and showed that including multilingual information improves the classification performance across all the languages. Mukund and Srihari (2010) proposed a vector-space classification algorithm boosted by co-training for subjectivity classification of sentences in Urdu Language.

2.2 Opinion Mining

An integral part of opinion mining and sentiment analysis is to separate subjective sentences from objective ones and then to identify the polarity (negative, neutral or positive) of the opinions expressed in the subjective sentences (Liu, 2010). Works in this area have mainly focused on online review sites for summarizing product reviews given by different users of those products (Hu and Liu, 2004; Ly et al., 2011). Our work, in contrast, deals with online forum threads. A review in a review site is a continuous piece of text written by a person with additional information such as ratings, date and time. On the other hand, a thread in an online forum has a distinctive structure due to the presence of messages posted by multiple users. Also, a review, usually, has a single role of providing user's feedback on a product whereas posts in a thread have multiple roles, e.g., a post can be a question, solution, feedback, junk, etc (Bhatia et al., 2012). These differences make subjectivity analysis of online forum threads different from that in review sites in both nature and the approaches that can be used for the analysis. For example, thread structure, role of posts and other thread-specific information can be used as features for subjectivity analysis (as will be described later in the paper).

2.3 Question-Answering

Subjectivity analysis has also been used to improve question-answering in online communities and social media (Li et al., 2008b; Gurevych et al., 2009; Stoyanov et al., 2005; Yu and Hatzivassiloglou, 2003; Somasundaran et al., 2007). Yu and Hatzivassiloglou (2003) classify documents and sentences from news data into facts and opinions with the aim of improving answering of complex opinion questions. Stoyanov et al. (2005) separate opinion (subjective) answers from factual (objective) answers and then filter out factual answers for opinion questions to improve answering of opinion questions in multi-perspective question answering. Somasundaran et al. (2007) identify different types of attitudes in questions and answers and then use it to improve opinion question answering on web-based discussions and news data by matching the attitude types of questions and answers. Li et al. (2008a) classify questions in Yahoo QA as subjective or objective using semi-supervised learning by utilizing the text of labeled questions and their unlabelled answers for learning subjectivity patterns.

Gurevych et al. (2009) used an unsupervised lexicon based approach to classify questions as subjective or factoid (non-subjective). They manually build a lexicon of subjective words and word patterns from annotated questions and classify test questions based on a score calculated using the number of patterns present in them. These works did subjectivity analysis of questions and answers given by single authors in community sites. In contrast, we analyze the subjectivity of online forum threads that contain replies from multiple authors. These differences have implications described in the previous paragraph.

2.4 Online Forums

In the domain of online forums, there have been two recent works that are close to our work. Hassan et al. (2010) performed sentence-level attitude classification in online discussions to model user interaction that may be helpful in facilitating collaborations. Zhai et al. (2011) classified sentences in online discussions as evaluative or non-evaluative for getting relevant opinion sentences. In contrast, our work does thread-level subjectivity classification as we are interested in knowing the subjectivity of the overall topic of discussion of a thread and plan to use it for improving online forum search in the future.

3 Problem Formulation and Feature Engineering

In this section, we state our problem and describe various features used in the subjectivity classification task.

3.1 Problem Formulation

An online forum thread discusses a topic specified by thread starter in the title and the initial post. The topics of discussion in the threads can either be subjective or non-subjective (See Figures 1 and 2 for examples of subjective and non-subjective threads, respectively). Based on the definitions of subjective and objective sentences given by Bruce and Wiebe (1999), we define a subjective topic of discussion as a topic that seeks people's opinions, viewpoints, evaluations, speculations, and other private states and a non-subjective topic as a topic that seeks factual information. We call a thread subjective if its topic of discussion is subjective and non-subjective if it discusses a non-subjective topic. We assume that in online forum threads subjective topics have discussions in subjective language (i.e., expressing different private states) and non-subjective topics have discussions in objective language (ie., expressing facts and verifiable information). We note that there may be some cases where the assumption does not hold good, however, analysis of such exceptional cases is not the focus of this paper and is left for future work.

Problem statement: Given an online forum thread T, our task is to classify it into one of the two classes: *Subjective* (denoted by *s*) or *Non-Subjective* (denoted by *ns*).

In this work, we assume that a thread has a single topic of discussion which is specified by the thread starter in the title and the initial post. Analyzing subjectivity of threads with multiple topics is a separate research problem that is out of scope of this work.

3.2 Feature Engineering

As discussed before, we wanted to explore the effect of using various thread specific features for subjectivity analysis of online forum threads and compare them with the state-of-the-art

subjectivity analysis techniques. In this section, we describe the features used and intuition behind using them. Table 1 lists the features used.

3.2.1 Structural Features

We posit that subjective threads have different structural properties than non-subjective threads. Since subjective topics have more scope of discussion, we expect the subjective threads to be longer and invoke more participation of users than non-subjective threads. We use the length of a thread and the participation of users in a thread as features. For the length, we use the length of the initial post, the length of the thread and the average of the length of all the reply posts in the thread as features. All the lengths are measured in terms of the number of words. For the participation, we use the number of users that participated in the given thread, the number of posts and the average number of posts by a user in a thread as features.

Feature Name	Description
	Structural Features
InitPostLength	Total number of words in the initial post.
ThreadLength	Total number of words in the thread.
NumPost	Total number of posts in the thread.
NumUser	Total number of users in the thread.
AvgPostAuthor	Average number of posts by a user in the thread.
AvgLengthPost	Average number of words in a post in the thread.
	Dialogue Act Features
numQues	No. of *question* posts in the thread.
numRepeat	No. of *repeat question* posts in the thread.
numClar	No. of *clarification* posts in the thread.
numDetails	No. of *further details* posts in the thread.
numSol	No. of *solution* posts in the thread.
numNegFB	No. of *negative feedback* posts in the thread.
numPosFB	No. of *positive feedback* posts in the thread.
numJunk	No. of *junk* posts in the thread
	Subjectivity Lexicon-based Features
NumSubjTitle	No. of subjectivity clues in the title of the thread.
NumSubjInit	No. of subjectivity clues in the initial post of the thread.
NumSubjReply	No. of subjectivity clues in all the reply posts of the thread.
	Sentiment Features
InitSentiAvgPos	Positive sentiment score of initial post based on all the indicative word patterns in it.
InitSentiAvgNeg	Negative sentiment score of initial post based on all the indicative word patterns in it.
InitSentiStrngPos	positive sentiment score of initial post based on the strongest indicative word patterns in it.
InitSentiStrngNeg	Negative sentiment score of initial post based on the strongest indicative word patterns in it.
ReplySentiAvgPos	Average of positive sentiment scores of all the reply posts based on all the indicative word patterns in them.
ReplySentiAvgNeg	Average of Negative sentiment scores of all the reply posts based on all the indicative word patterns in them.
ReplySentiStrngPos	Average of positive Sentiment scores of all the reply posts based on the strongest word patterns in them.
ReplySentiStrngNeg	Average of Negative Sentiment scores of all the reply posts based on the strongest word patterns in them.

Table 1: Description of various features used for subjectivity classification.

3.2.2 Dialogue Act Features

Online forum threads have conversational nature and hence there are different types of dialogue acts (question, solution, feedback, etc.) expressed in thread posts (Bhatia et al., 2012;

Jeong et al., 2009; Joty et al., 2011). For example, a thread starts with a *question* posted by the thread starter. Then, there are posts (by other users) that ask for some *clarifying* details about the question and the thread starter provides *further details* to make the question clearer. After getting the details, users suggest *solutions* and finally there are *feedbacks* (by the thread starter or other users) to the suggested solutions that can be *positive* or *negative*. Also, there may be posts that ask the *same question* (as asked in previous posts) and posts that are *junk* and not related to thread discussion. We posit that dialogue acts expressed in the posts maybe helpful in identifying thread's subjectivity. In a subjective thread, there could be multiple solutions suggested for a question (e.g. *Sony or Nikon which is better?*) as there is no single correct answer to subjective questions and hence multiple feedbacks would be given. In contrast, in non-subjective threads, since questions seek factual materials (e.g., *what do the numbers on camera lens mean?*), there is little scope of discussion or disagreement among solution providers and hence there would be less solutions suggested and less number of feedbacks. Also, in subjective threads, the discussions can get heated due to disagreements with users posting inappropriate content such as abuses which are *junk* as they are not related to the discusion whereas in non-subjective threads, these situations are unlikely to happen. To explore the impact of dialogue acts on a thread's subjectivity, we used eight dialogue acts in thread posts as proposed by Bhatia et al. (2012) and used their presence in a thread as features for the subjectivity classification. The dialogue acts are as follows: 1. Question, 2. Repeat Question, 3. Clarification, 4. Further Details, 5. Solution, 6. Negative Feedback, 7. Positive Feedback, 8. Junk. We implemented their classification model to identify the dialogue acts in thread posts. We designed 8 features corresponding to the 8 dialogue acts for a thread. Each feature represents the number of posts in a thread that belong to a given dialogue act class.

3.2.3 Subjectivity Lexicon Based Features

Subjective threads discuss subjective topics seeking private states such as opinions, emotions, evaluations, etc. whereas non-subjective threads seek factual information. This difference should result in differences in the vocabularies of these two types of threads. Subjective threads should contain words that are used to express subjectivity whereas non-subjective threads should either not have these words or have less number of these words. We call these words *subjectivity clues* in this paper. Hence, the frequency or term counts of subjectivity clues in a thread should be a good indicator of its subjectivity. We use a publicly available subjectivity lexicon compiled from MPQA corpus by Wiebe et al. (2005) to get the subjectivity clues. The lexicon contains 8221 subjectivity clues. Some of the examples of subjectivity clues from the lexicon are *abhor, abuse, bother, champion*. We count the number of subjectivity clues in the title, initial post and all reply posts of a thread, normalize the subjectivity clue counts with the number of words in the corresponding element (title, initial post, reply posts) and use them as features. For a thread, we computed three lexicon features: NumSubTitle, NumSubInit and NumSubReply. We calculated NumSubTitle and NumSubInit by normalizing the frequency counts of subjectivity clues in the title and the initial post, respectively, by their total number of words. For computing NumSubReply, we first calculated the normalized frequency counts of subjectivity clues for all the reply posts and then added all the normalized counts.

3.2.4 Sentiment Features

These features take into account the sentiment/emotion of a thread. We expect subjective threads to have posts with higher sentiments (as they expose private states) than the posts in

non-subjective threads. To calculate sentiment features for a thread, we compute sentiment strength of its individual posts using the SentiStrength algorithm (Thelwall et al., 2012). We use the implementation of the algorithm available at http://sentistrength.wlv.ac.uk/. The algorithm is developed specifically to compute sentiment strength scores for short informal pieces of text common in social media such as forum posts, blog comments, etc. SentiStrength calculates both positive as well as negative sentiment scores for a piece of text. This feature is desirable as the posts can express sentiments of multiple polarity and a single sentiment score (positive, negative or neutral) will not be able to capture the individual sentiments. For both polarities, the algorithm gives two types of scores for a piece of text (i) using the strongest sentiment-indicative word patterns and (ii) using all the sentiment-indicative word patterns and taking their average. Thus, we get four different sentiment strength scores for each post. We use the four sentiment strength scores for the initial post and averages of the four sentiment scores for all the reply posts as features, thus getting eight sentiment features for a thread (see Table 1).

4 Experiments

4.1 Data

To conduct our experiments, we used threads from two popular online forums: 1. **Trip Advisor–New York** that contains travel related discussions mainly for New York city [2] and 2. **Ubuntu Forums** that contains discussions related to the Ubuntu operating system [3]. We used a publicly available dataset [4] (Bhatia and Mitra, 2010). We randomly sampled 700 threads from both the datasets to conduct our experiments. Table 2 provides various statistics of the data. We selected these two forums because we wanted to evaluate our methods on two different genres of online forums. Ubuntu forums generally have technical discussions that tend to be non-subjective in nature whereas Trip Advisor is a travel related forum having discussions on topics like transport, hotels, restaurants, tourism, etc that are generally non-technical in nature and hence tend to be subjective.

Statistic	Trip–Advisor	Ubuntu
Total # threads	609	621
Total # posts	6591	3603
Total # users	1206	1786
Average thread length (in terms of # posts)	10.82	5.80
Average thread length (in terms of # words)	907	387.57
Average # users in a thread	1.98	3.41

Table 2: Statistics of the Dataset

We hired two human annotators for tagging the threads. The annotators were asked to tag a thread as subjective if its topic of discussion is subjective or non-subjective if the topic of discussion is non-subjective. The annotators were provided with a set of instructions for annotations. The set contained definitions of subjective and non-subjective topics with examples and guidelines for doing annotations. The annotations for each dataset were conducted in three stages. First, the annotators were asked to annotate a sample of 20 threads from the

[2] http://www.tripadvisor.com/ShowForum-g60763-i5-New_York_City_New_York.html
[3] http://ubuntuforums.org
[4] http://www.cse.psu.edu/ sub194/datasets/ForumData.tar.gz

dataset using the instruction set. Second, separate discussions were held between the authors and each annotator. Each annotator was asked to provide his arguments (for his annotations) and, in case of inconsistent arguments, he was educated through discussions. Next, he was given the full dataset for annotation.

The overall percentage agreement between the annotators and Kappa value for the Trip Advisor dataset were 87% and 0.713 respectively and for the Ubuntu dataset were 88.7% and 0.732 respectively, indicating substantial agreement between the taggers in both the cases. For our experiments, we used the data on which the annotators agreed. There were 412 subjective and 197 non-subjective threads in Trip Advisor dataset and 231 subjective and 390 non-subjective threads in Ubuntu dataset. The tagged dataset can be downloaded from the authors' website. [5].

4.2 Baseline

Lexical features such as n-grams and parts-of-speech tags have been shown to perform well for subjectivity analysis tasks. Many works have used these features for subjectivity classification (Li et al., 2008a; Yu and Hatzivassiloglou, 2003; Aikawa et al., 2011). In this work, we use classifiers built on these features as our baselines. We used the *Lingua-en-tagger* package from CPAN[6] for part-of-speech tagging. The extracted features and their description is given in Table 3. The table describes feature generation on a sentence containing three words W_i, W_{i+1} and W_{i+2}. POS_i, POS_{i+1} and POS_{i+2} are the parts-of-speech tags for the words W_i, W_{i+1} and W_{i+2}, respectively. For feature representation, we used term frequency as the weighting scheme (we empirically found it to be more effective than *tf-idf* and *binary* representations), and used minimum document frequency for a term to be included in the vocabulary as 3 (we experimented with minimum document frequency 3, 5 and 10 and 3 gave the best results).

Feature type	**Generated feature**
Uni	W_i, W_{i+1}, W_{i+2}
Uni+Bi	$W_i, W_{i+1}, W_{i+1}, W_iW_{i+1}, W_{i+1}W_{i+2}$
Uni+Bi+Tri	$W_i, W_{i+1}, W_{i+1}, W_iW_{i+1}, W_{i+1}W_{i+2}, W_iW_{i+1}W_{i+2}$
Uni+POS	$W_i, POS_i, W_{i+1}, POS_{i+1}, W_{i+2}, POS_{i+2}$
Uni+Bi+POS	$W_i, POS_i, W_{i+1}, POS_{i+1}, W_{i+2}, POS_{i+2}, W_iW_{i+1}, W_iPOS_{i+1}, POS_iW_{i+1}, W_{i+1}W_{i+2}, W_{i+1}POS_{i+2}, POS_{i+1}W_{i+2}$
Uni+Bi+Tri+POS	$W_i, POS_i, W_{i+1}, POS_{i+1}, W_{i+2}, POS_{i+2}, W_iW_{i+1}, W_iPOS_{i+1}, POS_iW_{i+1}, W_{i+1}W_{i+2}, W_{i+1}POS_{i+2}, POS_{i+1}W_{i+2}, W_iW_{i+1}W_{i+2}, W_iW_{i+1}POS_{i+2}, W_iPOS_{i+1}W_{i+2}, POS_iW_{i+1}W_{i+2}, W_i, POS_{i+1}POS_{i+2}, POS_iW_{i+1}POS_{i+2}, POS_i, POS_{i+1}W_{i+2}$

Table 3: Feature Generation for sentence $W_i\ W_{i+1}\ W_{i+2}$. Uni, Bi, Tri and POS denote unigrams, bigrams, trigrams and parts-of-speech tags respectively.

We extracted the above features (Table 3) from the textual content of different structural units (title, initial post, reply posts) of the threads. First, we built a basic model where we used only the text of the titles (denoted by t) for classification. Then, we used the text of initial posts and reply posts. We experimented with the following four settings: title (t), initial post (I), title and initial post (t+I), entire thread (t+I+R).

[6] http://search.cpan.org/dist/Lingua-EN-Tagger/Tagger.pm

4.3 Experimental Setting

We used various supervised learning algorithms to perform our classification experiments. We experimented with Multinomial NaiveBayes, Support Vector Machines, Logistic regression, Bagging, Boosting and Decision Trees. Logistic regression gave the best results with our features whereas in case of the baseline lexical features, Multinomial NaiveBayes outperformed all the other classifiers. We used Weka data mining toolkit with default settings to conduct our experiments (Hall et al., 2009). To evaluate the performance of our classifiers, we used macro-averaged precision, recall and F-1 measure. For a metric M, macro-average M_{mav} is calculated by taking weighted average of M for both subjective and non-subjective classes for each fold and then taking mean of the weighted averages across all the folds. For n-fold cross validation, M_{mav} is mathematically defined as follows:

$$M_{mav} = \frac{1}{n}\sum_{i=1}^{n}\frac{n_{s_i}M_{s_i} + n_{ns_i}M_{ns_i}}{n_{s_i} + n_{ns_i}} \quad (1)$$

where n_{s_i} and n_{ns_i} are the number of subjective and non-subjective threads in the test set in the i^{th} fold . M_{s_i} and M_{ns_i} are the values of metric M for the subjective and the non-subjective classes, respectively, in the i^{th} fold . We used $n = 10$ in our experiments. We use F-1 measure to compare performances of two classifiers. A naive baseline that classifies all the threads in the majority class will have a macro-averaged precision, recall and F-1 measure of 0.457, 0.676 and 0.545 respectively for Trip–Advisor and 0.394, 0.628 and 0.485 respectively for Ubuntu. We consider these values to be the lower bounds for any of our methods.

4.4 Classification Results

4.4.1 Baseline Results

Table 4 reports the results of the subjectivity classification obtained from different baselines. A total of 24 experiments (using the six types of features for the four settings (t, I, t+I, t+I+R)) were conducted for both the datasets. From the table, we note that titles give fair estimate of thread's subjectivity and initial posts (I) provide a better estimate. Incorporating text from initial post and title (t+I) improves the performance slightly over the initial post (I) setting. Further, adding the text of reply posts (t+I+R) gives the best performance. This is expected as titles only contain some keywords related to the discussion topic whereas initial posts contain the entire problem of discussion and reply posts constitute a major portion of the discussion in the thread. We also note that unigrams+bigrams+POS and unigrams+bigrams consistently perform better than the other features for all the settings except for the title (t) setting where unigrams and unigrams+POS performed the best.

4.4.2 Performance of the Proposed Classification Model

Table 5 reports the results of our classification model. We achieve an overall accuracy of 77.01%, a precision of 0.763 and an F-1 measure of 0.764 on the Trip–Advisor dataset and an overall accuracy of 70.05%, a precision of 0.692 and an F-1 measure of 0.684 on the Ubuntu dataset. We further analyze the classification performance of our classifier by analyzing its performance for the two classes. Table 6 reports precision, recall and F-1 measure for subjective and non-subjective classes for both the datasets. We observe that the classification performance for the subjective class is better than the non-subjective class for the Trip–Advisor dataset. This

U+B+T+POS	0.551	0.557	0.554	0.646	0.631	0.636	0.64	0.63	0.633	0.705	0.657	0.662

Table 4: Classification performance of different baseline features (Table 3) extracted from different structural components of the forum threads. t, I and R are title, initial post and set of all reply posts of a thread respectively. U, B, T and POS are unigrams, bigrams, trigrams and parts-of-speech tags respectively.

can be attributed to the significantly more number of subjective threads than non-subjective threads (refer to Section 4.1) in the Trip–Advisor dataset and hence more patterns for the classifier to learn for the majority (subjective) class leading to the better performance for that class. Similarly, for the Ubuntu dataset, we see a better performance for the non-subjective class whose number of threads are significantly more than that of the subjective class.

Next, we compare the performance of our classification model with the baselines. As can be seen from Table 6, our classification model outperforms the best performing baseline (U+B for the t+I+R setting, refer to Table 4), thus outperforming all the 24 baselines, for the Trip–Advisor dataset. For the Ubuntu dataset, our model achieves an F-1 measure of 0.684 whereas the best performing baseline (U+B+POS for the t+I+R setting, refer to Table 4) achieves an F-1 measure of 0.701. In this case, our model outperforms 21 out of the 24 baselines. The other two baselines that achieved a better performance than our model are unigrams (U) for the t+I+R setting and unigrams+POS (U+POS) for the t+I+R setting with an F-1 measure of 0.691 and 0.69 respectively. Thus, we see that we achieve classification performance which is similar to, and, in most cases, better than that obtained from the baseline features by using thread specific features which are much less in number (no. of baseline features is of the order of the size of the vocabulary whereas no. of features in our model = 25.)

Metric	**Trip–Advisor**	**Ubuntu**
Classification Accuracy	77.01%	70.05%
Precision	0.763	0.692
F1-Measure	0.764	0.684

Table 6: Classification performance of the proposed model for subjective and non-subjective classes on the two datasets.

4.4.3 Relative Performance of Different Types of Features

In this subsection, we investigate the effect of different types of features used for the subjectivity classification task. We perform the classification experiment using only one type of feature at a time. Table 7 shows the relative performance of different types of features. We see that, for both the datasets, structural features gave the best performance which confirms our hypothesis that thread structure is a strong indicator of its subjectivity orientation. Lexicon-based and Sentiment features are the second best performing features, outperforming the dialogue act features, for the Trip–Advisor forum whereas for the Ubuntu forum, dialogue act features outperform the two types of features with sentiment features being the worst performing and Lexicon-based features being the third best performing features. This difference in the relative performance of Sentiment and Lexicon-based features across the two forums may be attributed to the difference in the nature of the two forums. Trip–Advisor is a non-technical forum where majority of discussions are subjective in nature and hence there are more number of subjectivity clues and sentiment indication patterns for the classifier to learn, whereas discussions in Ubuntu forum are technical and hence, usually, non-subjective in nature. Further, the combined performance of all the features is better than the performances of all the individual types of features.

	Trip–Advisor			Ubuntu		
Class	**Precision**	**Recall**	**F-1**	**Precision**	**Recall**	**F-1**

Table 7: Classification results for NYC and Ubuntu datasets obtained using different types of features.

4.4.4 Most Informative Features

We study the importance of individual features by measuring the chi-squared statistic with respect to the class variable. Table 8 shows top 10 features, ranked by their chi-square values. From the table, we note that, for both the datasets, five out of six structural features (ThreadLength, NumPost, AvgPostLength, NumAuthor, InitPostLength) are among the top 10

most informative features which again confirms that a thread's structure is a strong indicator of its subjectivity. We note that the lexicon-based features and the sentiment features have relatively higher ranks in Trip Advisor dataset as compared to the Ubuntu dataset. We also note that, for Trip–Advisor, two of the three lexicon-based features (NumSubReply, NumSubInit) are among the top 10 features whereas for Ubuntu, only one lexicon-based feature (NumSubReply) is ranked among the top 10 features. This observation is consistent with our previous observation where we noted that sentiment and lexicon-based features performed relatively better in Trip–Advisor as compared to Ubuntu and can be attributed to the difference in the nature of the two forums as explained in the previous subsection. Among the lexicon-based features, NumSubReply is the most informative feature which suggests that, for a thread, reply posts are more helpful than initial post and title of the thread in identifying the thread's subjectivity. This is also manifested in case of sentiment features where features corresponding to reply posts (ReplySentiStrngPos, ReplySentiAvgNeg, etc.) are ranked higher than the corresponding features for the initial post (which are not in the top 10 list). These observations are consistent with the results we got from our baselines where we found that incorporating text from reply posts gave the best performance across all the features. We note that, for Ubuntu, there is one dialogue act feature (NumSol) in the top 10 list, whereas for Trip–Advisor, none of the dialogue act features are in the list.

Trip–Advisor	**Ubuntu**
ThreadLength	ThreadLength
NumSubReply	NumPost
AvgPostLength	NumSubReply
NumPost	NumUser
NumUser	AvgPostLength
ReplySentiStrngPos	InitPostLength
ReplySentiAvgNeg	NumSol
InitPostLength	ReplySentiAvgNeg
ReplySentiAvgPos	ReplySentiStrngPos
NumSubInit	ReplySentiStrngNeg

Table 8: Top 10 features ranked by chi-square values for the two datasets.

5 Conclusions and Future Work

In this work, we proposed a supervised machine learning model for subjectivity classification of online forum threads. We used various novel thread-specific features in addition to lexicon-based and sentiment features for the classification task. We evaluated our model by comparing it with various state-of-the-art techniques used for subjectivity classification and showed that our model outperformed them in most of the cases. A major contribution of this work is the introduction of thread-specific features for subjectivity classification of online forum threads which significantly reduces the complexity of the learning model compared to that of the models built on lexical features without compromising the performance of the model. In future, we plan to investigate semi-supervised and unsupervised learning for subjectivity classification of online forum threads. We also plan to use the subjectivity analysis to improve the search in online forums.

ABSTRACT

This paper explores the use of Natural Language Generation (NLG) for facilitating the provision of feedback to citizen scientists in the context of a nature conservation programme, BEEWATCH. BEEWATCH aims to capture the distribution of bumblebees, an ecologically and economically important species group in decline, across the UK and beyond. The NLG module described here uses comparisons of visual features of bumblebee species as well as contextual information to improve the citizen scientists' identification skills and to keep them motivated. We report studies that show a positive effect of NLG feedback on accuracy of bumblebee identification and on volunteer retention, along with a positive appraisal of the generated feedback.

KEYWORDS: NLG, Natural Language Generation, Educational Application, Bumblebee Conservation, Citizen Science, Generating Feedback.

Proceedings of COLING 2012: Technical Papers, pages 311–324,
COLING 2012, Mumbai, December 2012.

1 Introduction

There is a growing realisation of the potential of digital approaches, including the use of websites and social media, to increase participation in "citizen science", which includes observing and monitoring the natural world. For instance, in the UK, the Open Air Laboratories (OPAL) network (www.opalexplorenature.org) is a large current initiative led by Imperial College, which aims to create and inspire a new generation of nature-lovers by getting people to explore, enjoy and protect their local environment (Silvertown, 2009). Within OPAL, iSpot (www.ispot.org.uk) is an online nature community that connects beginners with experts and fellow enthusiasts. Other groups have explored the use of standard social networking sites to generate public interest and collect data about the distribution of species (Stafford et al., 2010). Publicly available resources include www.thewildlab.org, which provides software for a number of mobile platforms, and www.scienceforcitizens.net, which acts as a forum for citizen scientists to find out about projects they can participate in and for researchers to publicise their projects.

Although digital tools can enthuse the public and be used to enlist (for a short time at least) willing volunteers for nature conservation projects, initiatives such as the above have to contend with at least the following issues:

1. Data quality: participants are generally untrained, and not necessarily motivated to produce high-quality data (Stafford et al., 2010). This is not a problem if a project is primarily an "outreach" activity, but many projects also have specific scientific goals.

2. Retention of volunteers: in order to secure continuing participation, systems need to constantly renew to keep users interested and engaged.

Existing digital support for nature conservation volunteers can only give them feedback and encouragement by allowing them to interact with human experts or by showing them pre-prepared material. Human experts are in short supply, and pre-prepared material is inherently limited in scope. We believe that this latter is a problem, and that the level of interest and motivation for people to participate in ecological monitoring activities is in part a function of the richness of information they are provided with on an ongoing basis. Through the use of a Natural Language Generation (NLG) component, we automate the provision of rich information to address the two key issues listed above: improving the accuracy of volunteer contributed records, and volunteer retention over time.

The Bumblebee Conservation Trust[1] is seeking to map the current distribution of bumblebee species across the UK through a collaborative project with the University of Aberdeen called BeeWatch[2]. BeeWatch allows volunteers from the general public to submit photos of bumblebees they have seen in the wild, along with the location and date of sighting. The submission interface includes an online identification guide (see Fig. 1) to help classify the bumblebee in the photo as one of 22 bumblebee species[3]. Through this interface, the volunteer can select visual features of the bumblebee (types of thorax, abdomen, etc.) to narrow down the possible species. Once the image and the user's identification have been submitted, an expert identifies

[1] http://www.bumblebeeconservation.org

[2] http://bumblebeeconservation.org/get-involved/surveys/

[3] There are actually 24 species of bumblebee in the United Kingdom, but three of these (*Bombus lucorum*, *Bombus cryptarum* and *Bombus magnus*) cannot be reliably distinguished from each other based on visual charecteristics alone. These form a species complex, and for the purposes of BeeWatch they are treated as one species— *Bombus lucorum*, the White-tailed bumblebee.

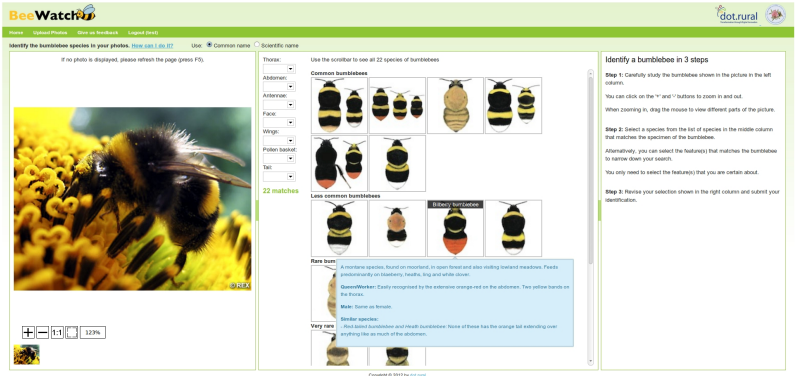

Figure 1: Screenshot of online identification tool

the bumblebee in the photo. Before the current collaboration, this expert communicated the correct identification to the volunteer by email. In the case of incorrect identification, the conservation charity would have liked to provide explanations as to why this was the case, but their experts only rarely found the time to do this. The goal of the NLG component described in this paper is to automate the provision of feedback to the volunteer based on the expert's identification.

Fig. 2 shows an extract of the computer generated feedback for a user who has incorrectly identified a photo as a broken-belted bumblebee. The key element in this automatically generated extract is the comparison between the user-identified species and the correct species as identified by the expert. Although there are only 22 species of bumblebees in the UK, this means that there are almost 500 bee comparisons to be generated, and the overall number of possible texts would be orders of magnitude greater when contextual information (e.g., based on location and time of sighting) is included in the feedback. On the other hand, the NLG

> Thank you for submitting this photo. Our expert identified the bee as a Heath bumblebee rather than a Broken-belted bumblebee. You correctly identified the face, the wings and the pollen basket; however, the abdomen (rear body) and the thorax (central body) are different. Although some of these features may not be visible in your photograph, the following advice might be helpful for next time you are in the field.
>
> The Heath bumblebee's thorax is black with two yellow to golden bands whereas the Broken-belted bumblebee's thorax is black with one yellow to golden band. The Heath bumblebee's abdomen is black with one yellow band near the top of it and a white tip whereas the Broken-belted bumblebee's abdomen is black with one yellow band around the middle of it and a white to buff tip.

Figure 2: Example of NLG feedback explaining why a user identification was incorrect

Thank you for submitting this photo. You have correctly identified the bumblebee as a White-tailed bumblebee.

As you are already aware all individuals of this species have two yellow bands and a white tail. Although they can be difficult to separate from Buff-tailed workers, the tail of the White-tailed bumblebee is pure white, with a complete absence of any buff-coloured hairs. The colour of the two yellow bands is brighter and more lemon than that seen in the Buff-tailed bumblebee.

Figure 3: Example of NLG feedback when a user has made a correct identification

system relies on just a model of each of the 22 species found in the UK. So, whereas it would be infeasible to produce a human-authored text for each possible situation, this use of NLG can even scale up to, for example, bumblebees in other countries (there are over 250 known species worldwide), or likewise, other genera.

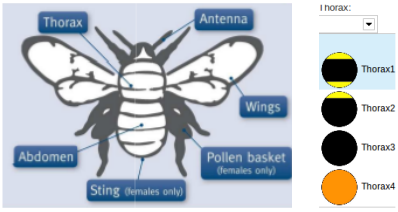
We also use feedback to reinforce relevant information when a user has made a correct identification. Fig. 3 provides an extract from computer generated feedback that illustrates this.

A key contribution of this paper is an evaluation of the effect of the automatically generated text on volunteers. It is unusual for an NLG application (that typically aid decision making in the workplace) to have as diverse a set of users as we do. Our results demonstrate the potential for NLG in real world applications targeting members of the general public. The automation of feedback provision, as described in the rest of this paper, has removed a major bottleneck for the charity we are working with, and is allowing them to scale up what was initially just a public engagement exercise generating around 200 records a year into an initiative that has produced 650 records a month.

2 Related work

Much of the recent focus within NLG applications research has been on data-to-text systems, which typically generate summaries of technical data for professionals such as engineers or nurses (Goldberg et al., 1994; Theune et al., 2001; Portet et al., 2009). These are capable of generating high quality texts; e.g., offshore oil rig workers preferred weather forecasts generated by the SumTime system to texts written by professional human forecasters (Sripada et al., 2003). There is some previous work on the use of data-to-text for lay audiences; e.g., generating narratives from sensor data for automotive (Reddington et al., 2011) and environmental (Molina et al., 2011) applications, generating personal narratives to help children with complex communication needs (Black et al., 2010), and summarising neonatal intensive care data for parents of premature babies (Mahamood et al., 2008).

There are some notable examples of NLG systems that make use of structured textual records rather than numeric data. Peba-II (Milosavljevic, 1997) was an online animal encyclopedia that provided descriptions and comparison of animals using HTML pages. The Power (Daley et al., 1998) and ILEX (O'Donnell et al., 2001) systems in the virtual museum domain dynamically generated descriptions of museum objects based on the user's discourse history and user model. Dial Your Disc (Van Deemter and Odijk, 1997) generated spoken monologues about classical music, with the aim of generating engaging texts, attempting to keep its users amused by



(a) (b)

Figure 4: Bumblebee Model: (a) Visual bumblebee features, (b) List of Thorax types

focusing on the expression of *unusual* content. Our work shares commonalities with these systems, in that it targets non-expert audiences and has educational goals.

The main mechanism employed by us in the current work is the use of comparisons for generating feedback. This builds on a body of previous work. Milosavljevic (1997) described comparisons as a useful tool for augmenting the user's existing knowledge with new knowledge. Karasimos and Isard (2004) showed that texts which contained comparisons and aggregations helped readers retain more information and perform better on factual recall while also finding these texts more interesting and pleasant to read. Later, Marge et al. (2008) performed a similar experiment to isolate the effects of comparison from those of aggregation. These two experiments provide evidence that comparisons can help to improve the knowledge of users on a given domain, and are a basis for our work.

3 Implementation of the NLG module

Our NLG system uses the architecture proposed by Reiter and Dale (2000) and is compatible with a wide range of work within the field. There are three main components in this architecture; a document planner, a micro planner and a surface realiser. Additionally, the document planning makes use of a domain model. We describe our implementation in this section and the evaluation of the system in Sections 4 and 5.

3.1 Domain model

Our domain model is primarily the representation of each bumblebee species as a set of visual features, as implemented in the online identification guide (see Fig. 1). The tool contains information about the thorax and abdomen colour patterns, face length, wing type and the presence of a pollen basket (shown in Fig. 4 (a)). The model includes a textual description of each visual feature. For example, the thorax with visual pattern `Thorax2` in Fig. 4 (b) has the associated text: "black with one yellow to golden band".

Note that the domain model used in the identification tool only covers the main bumblebee features. This is important for usability, and also makes it easier to port to other insect species. However, this means that some bumblebee species are indistinguishable in terms of the modelled features. To distinguish such species, each model of a bumblebee species has associated with it a list of similar bumblebee species and a description of how it can be distinguished from them. An example of this similarity can be seen between the Moss carder bee and the Common carder bee (shown in Fig. 5(a)). They share the same values for all their domain features (e.g., both have thorax type 4, etc.), and their only distinguishing feature is the black hairs on the

(a) (b)

Figure 5: Difficult cases: (a) Similarity of Moss Carder and Common Carder Bumblebee, (b) Differences between castes for the White-tailed bumblebee

abdomen of the Common carder bee. The model also contains contextual information; for instance, where the species is usually found, what time of year they are usually seen and how rare they are in the UK.

A further point worth noting is that bumblebees have a caste system of queens, males (drones) and females (workers). These castes can sometimes have different visual features (e.g., see Fig. 5(b)). We do not model castes explicitly because it is difficult for novice recorders to identify caste, and there is thus limited gain in using caste information in the feedback. As an alternative, we allow features for the abdomen and thorax to sometimes have multiple values for the same species.

3.2 Document planner

The NLG system described here primarily uses comparisons of bumblebee species to improve the user's identification skills. Milosavljevic (1997) introduced three types of comparison that are useful for educational purposes: direct, clarifactory and illustrative. Briefly, direct comparison is used to describe to the user attributes that two objects share and the attributes that distinguish them. This comparison is bi-focal; neither object is more important than the other. Clarifactory comparison is used to describe an object by distinguishing it from a similar object that it may be confused with. This confusion usually arises from the two objects sharing similar attributes or features. Illustrative comparison is used to describe an attribute (or attributes) of an object by referring to the same attribute(s) of another object that the user is familiar with.

The main methods used in this work are direct comparisons, which allows the user to understand the differences between species, and clarifactory comparisons to distinguish similar species (those with identical features in our visual model). Illustrative comparison is currently not used but could be employed when the system has access to a user's history of interaction with the system. For example if the user had identified a Garden bumblebee previously and has just identified a Heath bumblebee, illustrative comparison could be used to explain that the colour pattern of the Garden bumblebee is similar to that of the Heath bumblebee. However, users typically submit records only once or twice a week, so past submissions might not be salient.

Our document planner first determines content, and then decides document structure.

3.2.1 Content determination

Before the system can decide what to include it needs a data representation to store this content. This representation will, later on, map to a sentence (or a group of related sentences) that will be generated in the final output. We represent content using *messages*, i.e. Java objects that contain domain specific entities and information.

The creation of message objects is handled by the message generator at run-time. The message generator looks at the input the system has been given and then analyses it to determine which of a set of content determination rules match. These rules determine which messages are created and what they contain.

A `thankYou` message is always generated with canned text content thanking the user for the submission. Then a message is generated that holds information about whether the user has identified the bee correctly or not. For example, if the identification by the user is incorrect then a `result` message is generated containing the value "incorrect" along with the bumblebee species as identified by the expert and by the user. Further along the line, this message will be realised as a sentence such as "*Our expert identified the bee as a Heath bumblebee rather than a Broken-belted bumblebee*" (see Fig. 2). If the identification is correct, a similar message is generated with the value "correct", which could later be realised as a sentences such as "*You have correctly identified the bee as a Heath bumblebee*".

If the user has incorrectly identified the bumblebee species, the system needs to explain to the user why the identification was incorrect. This is handled through the `features` message. This message compares the visual features of the two species and stores similar features and dissimilar features as two separate sets. Due to the fact that some features (e.g., thorax and abdomen) can have multiple values in a bumblebee model due to variation between castes, the similarity of features is determined through set intersection. A feature goes into the "similar" list, if there is any value that is common to both bumblebee models. This message is later realised as a sentence such as "*You correctly identified the face, the wings and the pollen basket; however, the abdomen (rear body) and the thorax (central body) are different.*"

One of our communicative goals is to help the user improve their identification skills. This is pursued by explaining to the user why they were incorrect (if that were indeed the case). For each feature that is dissimilar, a `featureIdentification` message is created that contains the values of this feature in both bumblebee models. These messages will be used to explain the differences between the two species using direct comparison.

The message generator also searches the "similar species" list in the model of the bumblebee as identified by the expert. If the bumblebee as identified by the user is found, then a `similarSpecies` message is created, containing the canned text from the model describing the distinguishing features using clarifactory comparison.

If there is any contextual information available about the identified species, this is realised through a `contextualInformation` message. In our current implementation, we only use a summary of the known habitat and behaviour of the species in a non-adaptive manner. We plan to use such information more intelligently in the future, notably to help contextualise a user's record.

When all the messages have been constructed, they are passed on to the Document Structuring component.

3.2.2 Document structuring

The messages are structured in a specific way by the document planner using schemas, resulting in a document plan which takes the form of a tree. Groups of related messages are represented by the internal nodes while the messages themselves are the terminal nodes. In this case, the internal nodes will represent actual textual structures such as paragraphs. These structures are

represented in Java as objects that are instantiated from classes. The design of these structures is heavily influenced by the structures proposed by Reiter and Dale (2000).

The exact structure is determined by how many messages have been generated. There are four possible groups that the messages can be placed in: the intro group, the features group, the similar species group and the contextual information group. The intro group will always be present but the other three may or may not be present depending on the outcome of the identification and the two species that are being compared. For example, if two species are not classed as similar species then the similar species group will not be present at all. The schema loops through the entire message list and decides what groups are needed based on the type of messages present.

3.3 Microplanner

The microplanner is the second stage of the generation architecture. Here, the document plan produced by the first stage, the document planner, is refined to produce a text specification. This includes phrase specifications and their aggregation into sentences. The phrase specification is structured in a way that it can be realised by the surface realiser. We use SIMPLENLG (Gatt and Reiter, 2009), and the design of these structures is therefore influenced by the functionalities of the SIMPLENLG library.

To allow for the generation of more complex sentence structures and sentences that are easier to understand, the microplanner also carries out aggregation. The aggregation performed in this system focuses on the formation of sentences. For example, in the paragraph that deals with comparisons (see Fig. 2), the system knows that it will be comparing different features. This means that the phrase specifications can be aggregated through subordination, using conjunctions such as “whereas” or “although”.

The descriptions of the visual features, specifically the abdomen and thorax, are also analysed to check if they are a candidate for aggregation. These two features can have multiple values due to morphological differences among castes within a species. Our system does not explicitly model castes and therefore when describing a feature that has multiple values the system has to use disjunctions. For example, the White-tailed bumblebee has two possible thorax values: `thorax1` (“black with two yellow to golden bands”) and `thorax2` (“black with one yellow to golden band”; see Fig. 5). Rather than generating:

> “the thorax is either black with two yellow to golden bands or black with one yellow to golden band,”

we use aggregation to generate the more natural sounding succinct phrase:

> “the thorax is black with either one or two yellow to golden bands.”

Once the microplanner has built all the sentence specifications (by the processes mentioned previously) and organised them into paragraphs, the resultant text specification document is passed on to the surface realiser.

3.4 Surface realiser

The role of the surface realiser is to convert the text specification received from the microplanner into text that the user can read and understand. This includes linguistic realisation (converting

the sentence specifications into sentences) and structural realisation (structuring the sentences inside the document). Both the linguistic and structural realisations are performed by using functionalities provided by the SIMPLENLG realiser library (Gatt and Reiter, 2009).

4 Experiment 1

This section details the evaluation of how volunteer recorders perceive the NLG, and the effect of feedback on their bumblebee identification accuracy. Later, in Experiment 2 (Section 5), we study the effect of NLG feedback on volunteer retention. For Experiment 1, we distinguish between two types of feedback, which differ with respect to the richness of information they communicate:

Type 1: Acknowledgement of submission + Correct Answer

Type 2: Type 1 + Feedback based on comparisons of visual features

4.1 Method

We designed an evaluation interface that steps each participant through twenty distinct images of bumblebees for which we have an expert identification. There were seven species of bumblebee represented in this data set, each occurring between one and four times. At each step, the participant identified the bumblebee species in the photo using an identification guide, and then received feedback on their identification. All participants viewed the photos in the same order. Upon completing the identification task for all 20 photos, each user was asked:

- To rate how helpful they found the feedback (on a scale of 1–5)
- What they thought of the exercise in general (free text)
- What extra types of information they would like to see in the feedback (free text)?
- What information they would like to see removed (free text)

To test the effect of feedback type on recording accuracy, we randomly divided our participants into two groups. Group A always received Type 1 feedback, while Group B always received the richer Type 2 feedback[4]. 48 participants completed Experiment 1, 21 in Group A and 27 in Group B. All participants were undergraduate students studying biology at the University of Aberdeen and none had prior experience with bumblebee identification. The use of naive participants was deliberate. Most of the volunteers to the BEEWATCH program start out as naive participants, and the role of training through feedback about identification features is likely to be most useful at this stage.

4.2 Results

4.2.1 Effect of feedback on accuracy

The accuracy of bumblebee identification for both groups was analysed. We expected that initially there would be no difference between the two groups, but that over time, Group B would improve their identification accuracy faster than Group A due to the more informative

[4]There is a further Type 3 feedback that our system generates, which includes contextual information about the bumblebee species. However this is mainly useful for identification in the real world, and we did not consider it for Experiment 1. We use Type 3 feedback later in Experiment 2, which was conducted with volunteers submitting photos to the live BEEWATCH website

Identifications	Acc(Type2) - Acc(Type1)	Significance of Difference
images 1-10	-2.7%	p=.55
images 11-20	7.4%	p=.10

Table 1: Accuracy for identifications 1-10 and 11-20

feedback received. Table 1 shows that the difference in accuracy between the two groups for the first ten identifications is minimal. For the last ten identifications, however, there is a bigger difference between the means of the two groups, and the group receiving NLG feedback is performing better by 7.4% points.

To understand the effect of Type 2 feedback in more detail, we performed a generalised linear mixed model fit by the Laplace approximation. The dependent variable was Accuracy (whether a photo was identified correctly). The independent variables were Time (the order of presentation of photos) and Condition (Type 1 or Type 2 feedback). We expected that there would be differences between participants and that some bee species would be easier to identify than others. To accommodate these expectations, Participant and BeeSpecies were included as random factors in the model.

We found a significant main effect of Time (z=-1.768; p=0.0423) and Condition (z=2.03l; p=0.017); i.e, both groups improved over time, and Group B was overall more accurate. More importantly, we also found a strong interaction between Time and Condition (z=-3.260; p=0.001); i.e., the accuracy of Group B increased faster over time than Group A. Thus, the richer Type 2 feedback proved useful for improving recorder skills over time.

The graph of the difference in accuracy between the two groups over time in Fig. 6 illustrates this finding. Positive values indicate that the mean accuracy of Group B is greater while negative values indicate that the mean accuracy of Group A is greater. The mix of positive and negative values for the first fifteen identifications show that neither of the groups are consistently more accurate than the other. However, the last five identifications show continually positive values, indicating that the richer feedback received by Group B was beginning to take effect.

These results are consistent with those reported in Karasimos and Isard (2004) and Marge et al. (2008), which collectively suggest that the use of comparison helps users to retain information.

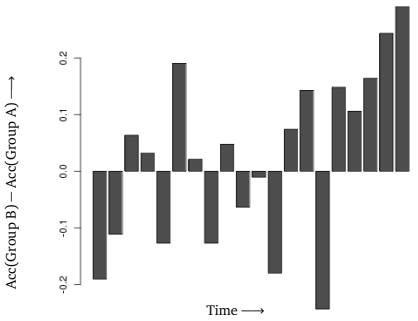


Figure 6: Graph of difference in accuracy between groups over time

Type 1 (no NLG)	Type 2 (NLG)
3.09	3.85

Table 2: Helpfulness of feedback: Mean score for each condition

4.2.2 Feedback helpfulness

One of the questions that participants were asked was to rate how helpful they found the feedback on a scale of 1–5. The NLG feedback was perceived to be significantly more helpful (t-test; t=2.78; p <0.01), as shown in Table 2.

The 21 participants in Group A who received Type 1 feedback overwhelmingly requested more feedback in their free text answers:

- Would like to have been given information on why their identification was incorrect (14 participants)
- Would like none of the information to be removed (12 participants)
- Would like to see more information (3 participants)
- Thought there was a lack of information (3 participants)
- Would like to have been told some facts about the bumblebee species that had been identified (2 participants)

From the feedback listed above, it is clear that participants would like to see more information than just a "correct/incorrect" response; specifically, explanation as to why their identification was incorrect was requested my most participants. There was also a small proportion who would like to be presented with contextual information about the bumblebee identified.

The 27 participants in Group B who received Type 2 feedback were more satisfied with the richness of information in the feedback:

- Would like none of the information to be removed (11 participants)
- Thought that no more information should be added and that the level of detail was sufficient (8 participants)
- Found the information to be useful (5 participants)
- Would like to see comparative pictures between the two bumblebee species (2 participants)
- Some comparisons didn't go into a lot of detail, specifically between similar species (2 participants)
- Face shape was rarely visible so did not help in identification (2 participants)
- Would like to see some contextual information about the bumblebee species (rarity, life history etc) (1 participant)

It is clear from the user feedback that users were more or less satisfied with Type 2 feedback, and that Type 1 users would have preferred Type 2 feedback. Further, a small proportion from both groups wanted more contextual information. As we report next, the inclusion of such information in Type 3 feedback has a positive effect on volunteers.

5 Experiment 2

The experiment described above showed that the richer feedback provided by our NLG component helped improve recorder accuracy. The other key issue we are interested in is volunteer motivation. We present an initial evaluation of this using our live system, by comparing the number of submissions made by users who receive three different types of feedback (volunteer return rates).

Feedback	No. of Submissions	No. of Users	Submissions/User	χ^2
Type 1	356	110	3.23	
Type 2	412	123	3.35	$p = 0.04$
Type 3	542	104	5.21	$p < 0.0001$

Table 3: Number of submissions by feedback type

5.1 Method

The NLG component described in this paper is being used live by the Bumblebee Conservation Trust since June 26 2012. When a photograph and volunteer identification of the bumblebee therein are submitted, the information is logged in a database. Periodically an expert reviews the database using a special administrator tool. When an expert calls up a particular submission and enters their own identification of the bumblebee in the photo, the NLG text is automatically provided. The expert can then edit this text if necessary (to address a question asked by the recorder, for instance) and then clicks on a button to send the feedback by email. This interface has dramatically increased the throughput of the experts, enabled them to spend more time on difficult cases, and giving the charity the confidence to publicise the project in the media and scale it up in size. The interface also means that the expert feedback reaches volunteers quicker, which presumably helps to motivate users and encourage further submissions.

When users register for the live system, they are randomly allocated to one of the three groups, by dividing their unique user IDs by 3 and using the remainder. We thus expect similar numbers of users in each group. As not everyone who registers submits records, group sizes are not identical (see Table 3). Each group always received feedback in only one of the following three types:

Type 1: Acknowledgement of submission + Correct Answer

Type 2: Type 1 + Feedback based on comparisons of visual features

Type 3: Type 2 + Contextual information

For the experiment, the administration interface made the experts aware of the three feedback conditions and which users were in which group. The automatic NLG feedback reflected the feedback condition and the experts were instructed to only make edits compatible with the prevailing condition.

5.2 Results

We report preliminary results from the first 2 months of the system going live. We received 1310 submissions from 337 participants during this period. Table 3 shows the number of submissions by experimental condition. There was a significant difference in submission numbers ($\chi^2 = 41.338$; 2 degrees of freedom; $p < 0.0001$) for the three treatment groups. The table shows the pair-wise significance for differences of Type 2 and 3 from Type 1 feedback.

As users who received the richer Type 2 or Type 3 feedback submitted more records on average than users who received Type 1 feedback, it appears that increasing the richness of information provision through NLG feedback has a positive effect on return rates of participants to the website. However, this analysis is preliminary and these figures are potentially skewed by the presence of a small number of dedicated volunteers in each feedback group.

On average, users submitted 3.7 photos during this period. This is insufficient to test improvement in accuracy from the live system at this point in time.

Conclusion and perspectives

We have described an NLG system that is being used by a nature conservation charity for a citizen science initiative. The automation of feedback provision has removed a major bottleneck for the charity, and has allowed them to scale up what was initially just a public engagement exercise generating around 200 records a year into an initiative that has produced 650 records a month. We are also investigating crowd sourcing models to reduce the time commitments on experts even further and allow a further scaling up of the initiative. These models work better with more accurate identifications by individuals; thus improving recorder accuracy is vital.

Our results show that the feedback generated by the NLG system described in this paper helps users to improve their identification skills faster that those who only receive the correct answer as feedback. Users also found the feedback produced through NLG more helpful than the simple feedback with no NLG elements, as evident from both qualitative and quantitative data reported for Experiment 1, and more motivating, as evident from the return rates reported for Experiment 2.

Acknowledgments

This research was supported by an award made by the RCUK Digital Economy programme to the dot.rural Digital Economy Hub; award reference: EP/G066051/1. We would also like to thank the Bumblebee Conservation Trust for making available their resources, including the use of their organisational infrastructure to recruit volunteers, the provision of experts to identify submitted records, and their contributions towards the testing of the NLG component. Further, this research has depended on records submitted by volunteer recorders participating in the BeeWatch programme.

ABSTRACT
Studies of computational models of language acquisition depend to a large part on the input available for experiments. In this paper, we study the effect that input size has on the performance of word segmentation models embodying different kinds of linguistic assumptions. Because currently available corpora for word segmentation are not suited for addressing this question, we perform our study on a novel corpus based on the Providence Corpus (Demuth et al., 2006). We find that input size can have dramatic effects on segmentation performance and that, somewhat surprisingly, models performing well on smaller amounts of data can show a marked decrease in performance when exposed to larger amounts of data. We also present the data-set on which we perform our experiments comprising longitudinal data for six children. This corpus makes it possible to ask more specific questions about computational models of word segmentation, in particular about intra-language variability and about how the performance of different models can change over time.[1]

KEYWORDS: word segmentation, language acquisition, resources, Bayesian modelling, unsupervised learning.

1 Introduction

Segmenting a stream of sounds into discrete words is one of the first tasks that children acquiring their native language have to tackle. Computational models of word segmentation enable us to study this problem in a controlled and detailed manner, allowing for example for an examination of the usefulness of different kinds of cues or different learning strategies. Just as important as the actual models, however, is the adequacy of the input used to evaluate them — if we are interested in answering questions about human language acquisition, the data we evaluate our models on needs to be comparable to what children are likely to have access to. To this end, several datasets of phonemically transcribed child directed speech (CDS) have been constructed in several languages, ranging from English to Italian, Polish, Sesotho and Chinese (Brent and Cartwright, 1996; Gervain and Erra, 2012; Boruta and Jastrzebska, 2012; Johnson, 2008a; Johnson and Demuth, 2010). In addition to cross-linguistic variation, however, adequate computational models also need to handle language-internal variation along several dimensions, a topic that has so far received little interest. In this paper, we look at a basic point of variation, namely the actual size of the input to the learner. The longer children are exposed to language, the more data they are exposed to and the better at their language they become, something one would expect from adequate models of language acquisition as well.

We run our experiments on a novel dataset that contains longitudinal data for six children from the Providence Corpus (Demuth et al., 2006). It has two advantages over the current defacto standard for word segmentation studies for English, the Bernstein-Ratner-Brent corpus (Brent, 1999, in the following, BRB Corpus). First of all, it cleanly separates the CDS that is directed at different children whereas the BRB Corpus contains data from 9 different children with no clear indication of the different portions. In addition, recording for some of the children in the BRB corpus began as late as month 21 and for others as early as month 13, making the data available for some of the children hard to compare. In contrast, the Providence Corpus provides data for all of the children starting from month 16 at the latest and starting from month 11 at the earliest and thus constitutes a much more homogeneous data set. Finally, the overall size of the BRB Corpus with a little less than 10,000 utterances altogether is relatively small, in particular if one considers the individual sub-parts which, on average, have only around 1,100 utterances; in contrast, our dataset contains more than 90,000 CDS utterances in total and spans a period of several months for all of the children. This makes it possible to both compare inter-child variability in word segmentation across comparable situations and to study developmental changes in individual children over a period of several months. As such, the resource will allow researchers to ask a wider range of questions than is currently the norm, in particular with respect to the study of incremental models that have recently received a lot of interest (Pearl et al., 2011; Börschinger and Johnson, 2012; Phillips and Pearl, 2012). While for our own experiments on the effects of input size we focus on one of the six sub-corpora of the dataset, we describe and make available the full data so as to enable other researchers to take advantage of this new resource as well.

The contribution of this paper is two-fold. We present a new CDS corpus for computational word segmentation that is derived from the Providence Corpus (Demuth et al., 2006), comprising data from six different children that have been collected in comparable situations over several months. The second and major contribution of our paper is the identification of a so far unreported "overlearning" effect of certain word segmentation models that runs counter to the plausible intuition that more data should lead to better learning outcomes. We also discuss these findings and propose an explanation for the behaviour exhibited by different models, highlighting the

importance of linguistic structure for computational models of language acquisition. The outline of the paper is as follows. First, we provide background about the original Providence Corpus, our way of phonemically transcribing it and the properties of the new data-set we created. In section 3, we introduce the models of word segmentation which we examine with respect to the effect of input size in section 4. Section 5 discusses our findings and the final section concludes.

2 The Providence Corpus

The Providence Corpus was collected during 2002-2005 from participants in southern New England. It contains longitudinal audio/video recordings of 6 monolingual English-speaking mothers and their children from approximately 1-3 years during spontaneous interactions at home. The children included 3 boys (Alex, Ethan, William) and 3 girls (Lily, Naima, Violet). Each was recorded for approximately 1 hour every 2 weeks beginning at the onset of first words. Two of the girls have denser corpora, with weekly recordings from 1;3-2;10 (Naima) and 2;0-3;0 (Lily), and Naima's recordings tended to be 1.5 hours long. There is therefore more data for this mother and child. Lily's mother also talked quickly; there is therefore much data from Lily's mother as well. Recording began around one year or once the parent reported that the child was producing approximately four words.

Digital audio/video recordings took place in each child's home. Although parent and child could move freely about, the video information was useful in determining the context of what was being discussed, including possible target words. The availability of video would allow future work along the lines of Frank et al. (2009) and Jones et al. (2010) although so far, we haven't made direct use of the video recordings.

The digital audio/video recordings were downloaded onto a computer, and both adult and child speech were orthographically transcribed using CHAT conventions (cf. MacWhinney (2000)). The child data — but unfortunately not the caregivers' — were then also transcribed in phonemic transcription. All mother and child transcriptions, as well as audio/video files, can be found on the CHILDES database `http://childes.psy.cmu.edu/`. We used the XML version of the data for our transcription process.

2.1 Producing a phonemically transcribed version

To find CDS utterances, for all six children we extract the orthographic transcriptions for all utterances made by caregivers from the XML transcripts of the Providence corpus, starting from 11 months up to and including 22 months.[2] This makes our data qualitatively comparable to the BRB Corpus that includes CDS from between 13 and 21 months of the children's age. In total, we extract 101,451 utterances with a 9395 distinct (orthographic) types but the number of utterances we use is smaller than this because we do not keep all of the utterances in the process of transcription (see below).

To turn the orthographic representations into a phonemic format that is suitable for studying language acquisition, we perform a four step process of filtering, dictionary look-up, heuristic construction of pronunciations for unknown types and manual transcription of unknown types not covered by our heuristic as well as correction of mistakes made during earlier steps.

[2] Available at `http://childes.psy.cmu.edu/data-xml/Eng-USA/Providence.zip`

2.1.1 Filtering words

We manually remove types that we consider to be obvious non-words, in particular interjections such as *hmmmhmmm* or *mmmmhmmm*, obvious onomatopoeic wordplay such as *nananana* and unintelligible words which are transcribed in the Providence Corpus as *xxx* and *yyy*. This is consistent with the procedure followed by Brent (1999) and, more recently, Boruta and Jastrzebska (2012), making our corpus comparable in this respect to theirs. We do not, however, remove these items in cases where the resulting utterance would have been rendered fully unintelligible or where a word that should have been excluded according to the above criteria was used as an actual word in a large number of cases.[3]

In total, we identify 785 such non-words and we remove all occurrences of these types from the transcript, leaving the remaining words in the utterance:[4] utterances including any of the stop-words are still transcribed as long as there is at least one word left after removing all stop words. A total of 7,362 utterances are thus completely ignored, with 6,123 utterances consisting of exactly one of these filtered elements, in particular *xxx* (unintelligible, 2215), *oh* (525) and *hmmm* (521).

2.1.2 Dictionary lookup

After filtering, we perform a simple dictionary-lookup transcription using a phonemic dictionary. We use the current version of the VoxForge dictionary which uses a standard phone set for American English, corresponding to the current DARPABET coding.[5] We also provide a script that maps this representational scheme into one-character-per-phoneme representations that are required by some of the currently common word segmentation tools.[6]If there are multiple pronunciations available for a type, we always pick the first one. While this constitutes an idealization we believe that a well-understood and explicit idealization is to be preferred over an overly simplistic method of artificially introducing variability such as randomly choosing a pronunciation.

In total, the VoxForgeDictionary covers 7035 of the 8610 remaining types in the data, leaving 1575 of the types untranscribed. We transcribe these words manually, using a simple pre-processing heuristic to aid the process.

2.1.3 Heuristically constructing pronunciations for unknown words

Many of the unknown words are either forms of types that already are in the lexicon, e.g. possessives (*Elmo's*) or plurals (*Legos*), or compounds of two types that are both in the lexicon individually (*frenchtoast*, *teddybear*). We handle the former case by simple rules operating on the orthographic forms directly, looking for possible plural or possessive endings and then checking whether the orthographic form can be decomposed into a known base-form with the

[3]The former applies mostly to cases where an item is mentioned rather than used, e.g. "Does the baby say 'Wah wah'?"; the latter, for example, applies to 'bonk' which, in addition to its onomatopoeic use, also occurs as a verb in the corpus, including its preterite and participle. Our data includes the full list of filtered items as well as the scripts that perform the automatic steps of transcription from the original xml-data so that researchers can easily make their own decisions about which items to exclude.

[4]While this may seem like a lot of items to exclude, most of these are hapaxes like *bumpoopadoompadadooboom* or *doodleuhdoo*.

[5]The dictionary is available at `http://www.repository.voxforge1.org/downloads/SpeechCorpus/Trunk/Lexicon/VoxForge.tgz`

Name	#Utt	#Tok	#Type	Avg. Utt. Len.	Avg. Tok. Len	Avg. Type Len.
Alex	8330	29423	1877	11.00	3.12	4.58
Violet	9024	39135	2343	13.43	3.10	4.68
William	10697	45689	2061	13.01	3.05	4.59
Ethan	18020	75564	2999	13.11	3.13	4.69
Lily	20641	94696	3946	14.77	3.22	4.96
Naima	27377	141990	4579	16.51	3.18	5.05

Table 1: Statistics about the different sub-corpora.

suffix added. In this case, we add the corresponding morph according to the rules of English phonology. To identify potential compounds, we try to decompose words into a prefix *p* and a maximal suffix *s* such that both *p* and *s* are known forms.

Taken together, our heuristic detects 924 cases which we then manually correct for mistakes. An alternative way of constructing pronunciations is to use letter-to-sound rules, something we plan to experiment with in future work.

2.1.4 Manual transcription

The remaining 651 word types are labelled manually, using where available the form-annotation in the XML files as guide-line.[7] Finally, we also manually inspect the forms generated by the automatic steps and correct mistakes.

2.2 Statistics

The final corpus comprises a total of 94,089 phonemically transcribed utterances and consists of six distinct sub-corpora, each corresponding to the CDS directed at one of the six children. Each sub-corpus is, in turn, subdivided into individual files corresponding to the age of the child at which recording took place, ranging from 11 up to 22 months. Both within these individual files and within the overall corpus, the order of the CDS utterances corresponds to the order in which these utterances were actually made, making them suitable for studies that look at changes over time.

Table 1 gives summary statistics over the full amount of data for each individual child. Looking at total number of utterances, we can broadly identify two groups: for Alex, Violet and William there are considerably less CDS utterances than for Ethan, Lily and Naima. This is presumably mostly due to the factors mentioned above. Yet, there also seem to be noticeable differences in terms of utterance-, token- and type-length. Although we will not do so in this paper, performing comparative evaluation of models across the children may lead to the discovery of interesting predictors of model performance and perhaps even actual language ability on behalf of the children.

For the rest of the paper, we will focus on the Naima part of the corpus and take a closer look at how the segmentation performance of different segmentation models changes as a function of the size of the input.

[7] While not always provided for caregiver utterances, some of them include phonetic markup for individual words, in particular if the words were names.

3 Bayesian Word Segmentation

The word segmentation models we study in this paper are Goldwater's Unigram and Bigram model (Goldwater, 2007; Goldwater et al., 2009) and Johnson (2008b)'s collocation-syllable Adaptor Grammar models. For the mathematical details of these models, we refer the reader to these original works.

All the models are Bayesian probabilistic models that define a generative process for the target of learning, in this case segmented utterances or sequences of words. This generative process is defined with the help of the Dirichlet Process (DP):[8] at an intuitive level, the DP can be used for word segmentation because it can bias models to identify compact ways to represent the observed unsegmented utterances, trading off the number of both tokens and types used in an analysis of the data. This trade-off is a consequence of the way that probabilities are assigned to tokens under a DP model: the probability of hypothesizing a word token[9] depends on the number of times that its type has previously been hypothesized, and the probability of a full hypothesis or segmentation of the data is the product of the probabilities for all the tokens used in the segmentation. This tends to make solutions in which a small number of words is used relatively frequently yet not over-excessively (as would be the case if every individual segment were a type) the most probable which, in most cases, also leads to linguistically reasonable results. What differentiates the different models from one-another are the specific assumptions about *the nature of possible word types* and *the relationships between word tokens*. We will quickly elaborate on these points, thus introducing all models used in our experiments.

3.1 Assumptions about possible words

A naive assumption about possible words is that they can be any arbitrary sequence of segments. Thus, both *dog* and *qfx* would be equally good candidates for possible words a priori. While obviously not true of human languages (*bnik* isn't a possible English word), such a unigram phoneme model is embodied in the original Unigram and Bigram models (Goldwater et al., 2009) and has been shown to work reasonably well on the BRB Corpus.

An alternative and linguistically more adequate assumption is that a word must conform to (arguably universal) constraints of syllable structure: words aren't just sequences of segments but consist of one or more syllables, themselves structured entities that consist of an optional initial consonantal onset, an obligatory vocalic nucleus and an optional consonantal coda (Smolensky and Legendre, 2005). In fact, Norris et al. (1997) provided evidence for a constraint on possible words along these lines in human segmentation of unsegmented speech and Johnson (2008b) showed previously how incorporating this kind of 'prior knowledge' into word-segmentation models can lead to a considerable improvement in segmentation accuracy.

From a language acquisition point of view, there are also reasons to assume that syllables and sub-syllabic units are learned by infants in addition to entire words: there is strong evidence that even very young infants track probabilities defined over entire syllables (Saffran et al., 1996) and that infants are sensitive to the phonotactics of their language from early on (Jusczyk et al., 1993), leading us to look at models that learn both entire syllables and sub-syllabic units. In addition, many languages including English are more or less restrictive about the material allowed to occur word-initially and word-finally than word-internally, having led previous work

[8] Adaptor Grammars actually use the Pitman-Yor Process, a strict generalization of the DP. Here, we gloss over this detail.

[9] Or a token of another entity, e.g. a syllable or a multi-word expression, if the model incorporates these notions.

such as Johnson (2008b) to distinguish between word-internal and word-peripheral onsets and codas.[10] The models we discuss, then, incorporate all of these ideas, that is they learn sub-syllabic units that are distinguished as to whether they occur word-peripherally or internally as well as entire syllables. The Adaptor Grammar framework makes it very easy to implement these different models, and we refer the reader to Johnson (2008b) for a discussion of how this is done.[11]

3.2 Assumptions about relations between word tokens

The simplest assumption about the relation between words within an utterance is probably that there is none. For a probabilistic model, this leads to a Unigram assumption about words, i.e. that the probability of a sequence of words is simply the product of the probability of each individual word, irrespective of its specific context. This is the assumption embodied by Goldwater's original Unigram model and a lot of previous work on word segmentation (Brent, 1999; Venkataraman, 2001).

A more plausible assumption is that words in a sequence are predictive of each other, a simple version of which can be spelt out as a Bigram assumption about words that is employed by Goldwater's Bigram model.

Yet another way of modelling the relation between words has been proposed by Johnson (2008b), employing a hierarchical instead of a sequential notion of context. The *collocation* models assume that sentences are sequences of *phrases* that, themselves, are made up of individual words. Consequently, the model not only learns words but an additional kind of entity, entire chunks of words. Importantly and in contrast to the Unigram and Bigram models, these chunks are stored in addition to and not at the expense of the words that make them up — a collocation model can infer that *thedoggie* is a high-frequent unit that is made up of the distinct words *the* and *doggie*. Johnson's Adaptor Grammar framework makes it easy to assume multiple levels of such collocations: a collocation2-grammar, for example, learns, in addition to words and collocations composed of words, collocations that are themselves composed of collocations of words. In this paper, following Johnson and Goldwater (2009) we examine models that use up to three levels of collocations.

3.3 The different models

As the different kinds of assumptions about the internal structure of words and about the relationship between words are independent, we can freely combine them, yielding a total of 9 models.[12] We refer to the different models by names that indicate which assumptions they embody. Models that do not incorporate the syllable structure assumption are simply referred to by the relationship assumed between word tokens, i.e. *unigram*, *bigram*, *colloc*, *colloc2* and *colloc3*, the last two names referring to models assuming a total of 2 and 3 levels of collocations, respectively.

Except for the bigram model, each of these models can either use a 'naive' word-assumption

[10] For example, in English *str* is only valid as an onset word-initially, as in *string* or *strong*, and the consonant cluster *dths* in *widths* is restricted to the end of words.

[11] In fact, the sole difference between Johnson's models and our own is that his do not learn entire syllables.

[12] With the exception of the bigram model for which we know of no existing implementation that makes it possible to incorporate syllable structure. In principle, however, this model is a possibility and we hope to be able to study it in the future.

allowing arbitrary sequences of segments or the syllable-structure word-assumption which, in addition to constraining the space of possible words, enables the model to explicitly learn properties of the language's phonology. To distinguish these two cases, we suffix models that embody the latter assumption with *Syll*.

4 Experiments

We are interested in how the segmentation performance of the different models varies with the amount of input available to the models during learning. As human language learners tend to get better at their native language with longer exposure, one would expect adequate computational models to exhibit something similar, initially improving as more data is observed and, at some point (probably beyond the size of samples we usually can look at in practice), asymptotically approaching some upper bound.

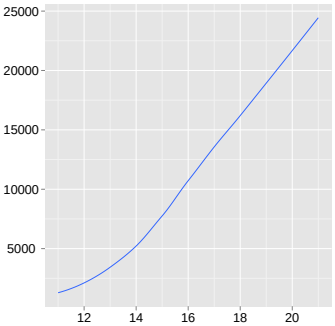

Figure 1: The months on the x-axis correspond to the different inputs, the y-axis gives the number of utterances in an input. The smallest input is month 11 with 973, the largest input month 21 with 24,327 utterances, approx 2.5 times the size of the BRB corpus.

The longitudinal data available in the Providence Corpus suggests a natural setup for studying this question by constructing inputs that consist of all CDS utterances directed at an individual child up to a certain point of time. For our experiments, we use the Naima section of the Providence Corpus and collect CDS utterances from when Naima was 11 months old through to when she was 21 months old to construct 11 differently sized inputs, each input consisting of all CDS utterances in the corpus up to and including a given month. We will refer to the different input sets by the last month from which it includes data and will use "language exposure" and "input size" exchangeably, a simplifying yet justified choice as is evident from figure 1 that shows how the size of the input grows over time and thus with language exposure.

We choose to evaluate on held-out data and construct the test-set by sampling 200 CDS utterances from the 22nd month of each of the six children's sub-corpus in the Providence Corpus. We propose this as a standard test corpus that can be used as a standard for any or all of the 6 children's data in the Providence Corpus. Our evaluation metric is token f-score, the harmonic mean between token precision (number of correct tokens identified by the model over the number of total tokens predicted by the model) and token recall (number of correct tokens identified by the model over the true number of tokens in the input) as a measure of segmentation accuracy. The segmentation on the held-out data is calculated after probabilistic inference has been performed on the input, thus implicitly defining a (probabilistic) lexicon according to which we sample a segmentation for each utterance in the test-set. Note that during this process, no novel words are added to the model's lexicon; in this sense, we evaluate the knowledge the learner has acquired after having had access to the input.

Our experimental procedure follows closely the one outlined in Johnson and Goldwater (2009). We use the current version of Mark Johnson's Adaptor Grammar implementation[13] to run

[13]Available at `http://web.science.mq.edu.au/~mjohnson/code/py-cfg-2012-08-16.tgz`.

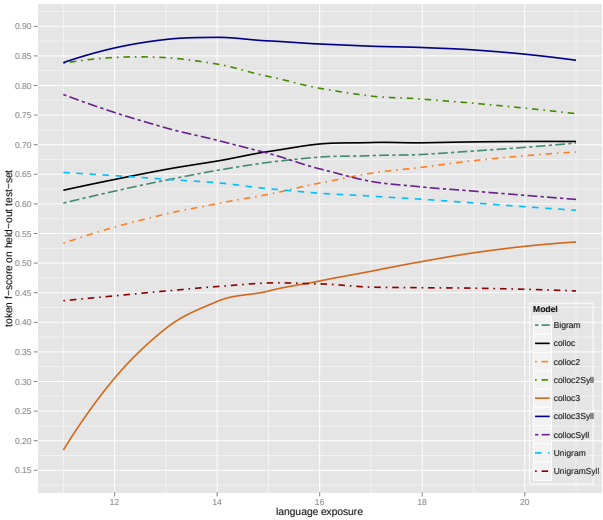

Figure 2: Word segmentation performance on the held-out test-set for the difference models, as a function of language exposure and consequently, size of the training set (see figure 1). The models incorporating syllable structure all exhibit some degree of performance decrease for larger inputs although the colloc3Syll consistently remains well above 80%. In contrast, the models without syllable structure exhibit an increase in performance over time although their segmentation accuracy is considerably worse than that of the best performing models with syllable-structures.

two Markov Chain Monte Carlo chains for each of the models for 1000 iterations, collecting sample analyses for the held-out test-set with a lag of 5 after a burn-in of 800 iterations and performing Minimum Bayes Risk decoding to get a single score for each condition at the end. For the Bigram model, the only model not expressible as an Adaptor Grammar, we use Sharon Goldwater's implementation and the experimental paradigm outlined in Goldwater (2007) and Goldwater et al. (2009), using simulated annealing for 20,000 iterations and evaluating on a single sample taken at the end. Figure 2 plots segmentation accuracy as measured by token f-score for different amounts of input size, with the size of the input growing from left to right.

Overall, we can see two broad patterns of behaviour across the different models. One group of models exhibits a degradation in performance for larger amounts of inputs, in particular the Unigram, the collocSyll and the colloc2Syll model. Neither the UnigramSyll nor the colloc3Syll model show a lot of variation although a small drop in performance for the last month as compared to their peak performance is noticeable for them as well. Another group consisting of the colloc, colloc2, colloc3 and Bigram models exhibits an increase in performance with amount of training data.

The colloc3Syll model clearly emerges as the most accurate with an accuracy of 87% at peak performance at around 14 months (4794 utterances) that drops to around 83% at month 21 (24,327 utterances). The second best model, the colloc2Syll model, peaks at around 85% at

month 13 and drops by 10% to about 75% at month 21, showing a clear decrease in accuracy. A third place is harder to assign. The collocSyll model shows the most dramatic drop in performance, from around 75% at month 11 (973 utterances) to just above 60% for month 21. In contrast, both the colloc and the Bigram model start around 60% at month 11 but, for month 21, reach around 70% so that there is no single model that comes in third for all amounts of input size. Incidentally, note how the behaviour of the Bigram and the colloc model is very similar, supporting Johnson (2008b)'s hypothesis that "the collocation word adaptor grammar can capture inter-word dependencies similar to those that improve the performance of Goldwater's bigram segmentation model."[14] The most dramatic performance improvement is seen for the colloc3 model which jumps from around 18% for month 11 to about 53% for month 21. Despite this, it is the second-worst model, loosing only to the UnigramSyll model which stays consistently below 50% accuracy with little variation.

To sum up, we observe two types of behaviour. The Unigram model and the models incorporating syllable structure and the notion of a multi-word phrase exhibit what we call "overlearning": they reach their peak performance for relatively small amounts of input and gradually get worse as the size of the input grows larger. This is much more pronounced for the collocSyll and the colloc2Syll than for the colloc3Syll model, with the latter remaining well above 80% accuracy even for the largest amount of input. Despite overlearning, the colloc3Syll and the colloc2Syll perform word segmentation the most accurate for all sizes of input. On the other hand, the models lacking the assumption of syllable structure do not exhibit overlearning, at least not on the amount of data we were able to test them.

5 Discussion

Why do the models we examine exhibit these two kinds of behaviour? We begin with a detailed explanation of the "overlearning", starting from an original observation going back to Goldwater (2007) who noticed that the Unigram model tends to identify undersegmented solutions where the predicted (incorrect) words often consist of several of the (correct) words. Her explanation for this is that "groups of words that frequently co-occur violate the unigram assumption in the model since they exhibit strong word-to-word dependencies", and that "[t]he only way the model can capture these dependencies is by assuming that these collocations are in fact words themselves." (Goldwater, 2007, p.72) Why is it, however, that these "misleading" co-occurrences occur in the data in the first place, and can this explanation be extended to account for the input-size effect we detected?

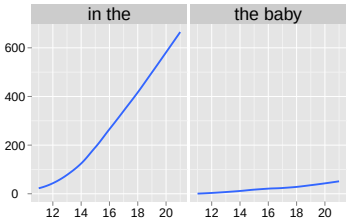

Figure 3: Frequency of a preposition+determiner pattern and determiner+noun pattern on the y-axis as a function of input size on the x-axis. Note the steep increase of frequency of *in the* and the much less dramatic increase for *the baby*.

We suspect that many of the "collocations" a model such as the Unigram model is susceptible to arise from principled regularities governing language: English syntax, for example, requires (most) prepositional phrases to begin with a preposition-determiner sequence and both preposi-

[14] Unlike Johnson (2008b) and Goldwater (2007), we did not hand-tune any of the parameters of the models which may partly explain why our scores for the Bigram model are slightly lower for the earlier months, in addition to the fact that we didn't use Minimum Bayes Risk decoding for the Bigram model.

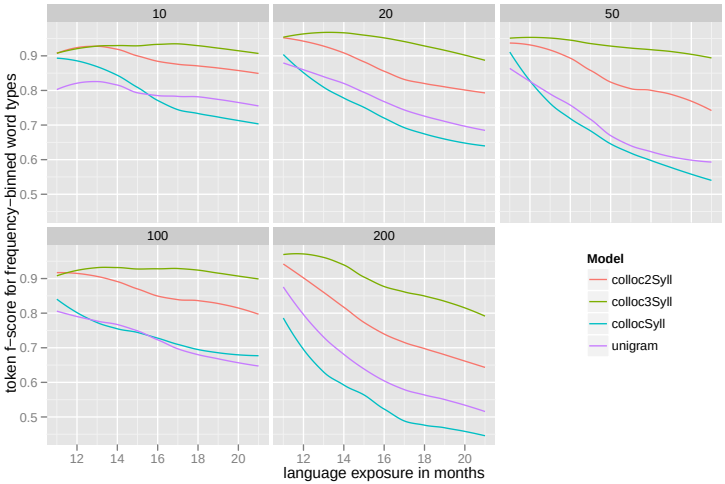

Figure 4: Token f-scores for word types of different frequencies in the test-set as a function of the size of the input. Note that the Unigram and the collocSyll model already show clear decreases in accuracy over time for types of frequency larger than 10 whereas the colloc3Syll model shows a relatively robust performance up to the highest-frequency bin of types with frequency larger than 200. The presence of the drop in performance shows that even the colloc3Syll model suffers from "overlearning" although this behaviour is much less pronounced than for the other models and only occurs dramatically for the highest-frequency types in the data.

tions and determiners are small closed classes, leading to a huge number of sequences such as *in the* in virtually any English text. Crucially, the occurrence of a sequence such as *in the* is largely independent of what is actually being talked about and the number of such occurrences can therefore be expected to grow with the amount of data considered. This is supported by figure 3 which plots the change in frequency of the preposition-determiner sequence *in the*, showing that the number of "misleading" co-occurrences of that kind does indeed increase for larger amounts of data. This leads to the prediction that the Unigram model will perform worse when trained on larger amounts of data, simply because the evidence for these kinds of spurious words that lead to undersegmentation errors grows with the input size. To our knowledge, we are the first to formulate this hypothesis and our experimental results strongly suggest that it is true. The drop in performance for the Unigram model is clear from figure 1: it reaches peak performance of around 65% when its input consists of a mere 973 utterances, and its segmentation accuracy steadily drops as it processes larger inputs down to around 58% for an input of 24,327 utterances.

More direct support for explaining the drop by the negative impact of the increasing frequency of patterns like the one in figure 3 comes from figure 4 that plots how well the model is able to identify word types of different frequencies in the test set as a function of input size. Note how for higher-frequency types, the Unigram model's performance decreases more dramatically than for low frequency types for larger amounts of input. To investigate whether this difference in

pattern	#test	month 11 (973 utterances)					month 21 (24,327 utterances)				
		#input	Unigram		colloc3Syll		#input	Unigram		colloc3Syll	
			% cor	% col	% cor	% col		% cor	% col	% cor	% col
in the	18	14	50%	50%	94%	0%	671	0%	89%	0%	100%
are you	19	14	100%	0%	100%	0%	536	0%	71%	0%	100%
on the	21	11	100%	0%	81%	0%	347	0%	86%	14%	86%
this is	9	5	100%	0%	100%	0%	196	0%	67%	56%	44%

the baby	4	0	100%	0%	100%	0%	80	0%	100%	100%	0%

Table 2: A qualitative look at how bigram-patterns of different frequency are handled by the Unigram and the colloc3Syll model at month 11 and month 21, respectively. The %cor and %col columns give the percentage of occurrences of a pattern in the test-set that were handled correctly or were misanalysed as constituting a two-word collocation. Note that %cor and %col need not add up to 100% as the models can also make other errors than simply undersegmeting. It is clear that at month 11, both the Unigram and the colloc3Syll model handle all the cases nearly perfectly; but unlike the Unigram model, the colloc3Syll model handles lower-frequency patterns at month 21 with increasing ease, making no mistake for a unit that occurs 80 times in its input such as *the baby* but still mis-analysing a pattern such as *in the*.

performance could actually be due to high-frequency items getting "absorbed" into larger units as we suggest following Goldwater (2007), in table 2 we perform a qualitative evaluation of a number of actual examples of patterns involving high-frequency that are themselves of different frequencies. As is clear, cases that are analysed correctly at month 11 are almost consistently misanalysed as a single word at month 21, showing that the "loss" of high-frequency items is a major reason for the overlearning.

Surprisingly, perhaps, the same kind of explanation seems to apply to the collocation-syllable models. While originally proposed by Johnson (2008b) to specifically address the problem of undersegmentation, looking at figure 4 indicates that collocation models do not solve the problem of high-frequency words completely, although it seems to get less problematic with the number of collocational levels the model has at its disposal. Looking at the kind of units learned by the collocation-models helps understand why that is: among the high-frequency collocations learned by both the collocSyll and the colloc2Syll model from the largest input is, for example, the two 'word' sequence *doyou remember*; this is a better solution than the Unigram model's *doyouremember* but it still involves the undersegmented collocation *do you*. While the colloc3Syll model analyses this specific case correctly as a three-word collocation *do you remember*, it fails to acquire the collocation *do you* on its own and prefers to use the "word" *doyou* in most other cases, showing that collocations do not solve the undersegmentation problem but only push it back a level, in line with figure 4: note that while the colloc3Syll model behaves relatively stable for word-types with frequencies smaller than 200, it also shows a marked drop for the high-frequency word types from around 95% at month 11 to just below 80% for month 21. Some concrete examples of patterns which the colloc3Syll model is and isn't able to handle correctly are given in table 2, alongside the performance of the Unigram model for these cases, showing how its ability to handle word-dependencies breaks for high-frequency patterns but handles patterns the Unigram model is unable to analyse correctly. After this discussion, the fact that even for collocation-models the undersegmentation problem gets worse for larger inputs shouldn't be too surprising. As pointed out above, many of the patterns leading to undersegmentation errors are due to syntactic regularities that, for example, require prepositions to be followed (in almost all cases) by articles. Figure 3 indicates that these kinds

of patterns grow continuously with the size of the input, suggesting that models that "merely" model co-occurrence statistics are bound to fail at some point. This may almost seem like a general problem for Bayesian probabilistic models of the kind discussed here that, in a sense, simply try to identify high-frequency patterns in the input. Yet this is not so. For one thing, the lack of detailed linguistic structure is not inherent to the Bayesian framework that is fully unrestricted as to what kind of structures a model is defined over. This much is clear from the ease with which syllable structure can be incorporated into the models. Secondly, even without additional linguistic structure the relative robustness of the colloc3Syll model shows that while not fully solving the problem of misleading co-occurrences, a sufficiently rich collocational structure goes a long way in alleviating the problem for input sizes that go well beyond 20,000 utterances. It suffices to handle most cases involving content words such as nouns, correctly learning for example that despite its (relatively) high frequency, *the baby* consists of two individual words. Figure 3 shows that for patterns like this, frequency grows much slower over time (although still too fast for a model lacking any ability to model larger-than-word-units such as the Unigram model), not too surprising considering that the occurrence of content words — unlike function words — is mainly dependent on what is actually being talked about and that conversation topics tend to change over time. This then suggests that a model like colloc3Syll will handle correctly these important cases for even considerably larger amounts of data, a clear desideratum for models of early language acquisition phenomena.

This leaves us to explain why the collocation models without syllable structure lead to an overall worse performance but seem to exhibit a positive relation between amount of input and segmentation accuracy. The key to this, we believe, lies again in considering the kinds of regularities the model is sensitive to. With no restriction on what an actual word may look like, high-frequency patterns of any kind — including individual segments and short n-gram like sequences of segments — can be employed by the models to explain the input they get. In particular for little input with overall few word tokens and, consequently, relatively few repetitions for each of the actual word types, the evidence for high-frequency non-words is extremely high, leading to over- rather than undersegmentation. To understand why this isn't happening for the Unigram model, recall that under the Unigram model, all tokens in a hypothesis are fully independent whereas the collocation and the Bigram model assume dependencies between tokens. Consequently, under the Unigram model a solution involving a large number of items is automatically discouraged because it can only work with marginal probabilities, whereas the other models without syllable structure can "abuse" their respective notions of context to capture dependencies not only between words but also between sub-word units. Ironically then, the oversegmentation behaviour is worst for models with a lot of additional structure such as the colloc3-model that, when combined with a syllable structure constraint, leads to the best performance. A quick glance at the kinds of units identified by it suggests why that is — at month 11, the most frequent "word" that is learned is *t* which is used in "collocations" like *t o*, *ge t* or, illustrating the problem very nicely, *j us t*. Crucially, the more input it has access to the stronger the evidence for larger (more word-like) units gets, leading to less undersegmentation at month 21 with a top-5 word list of *ing*, *you*, *z*, *the* and *to*. Yet, even for well over 20,000 utterances the colloc3 model prefers extremely short 'words' as it has another three levels of collocations that it can use to capture words; and it actually does learn collocations such as *ma mi*. The colloc2, colloc and the Bigram model are less extreme in their oversegmentation behaviour as they have fewer "levels" at their disposal, discouraging the excessive use of one-segment 'words' as in the colloc3 model more severely. In fact, as is suggested from both figure 2 and from inspecting their highest-frequency words at

month 21 that include "overlearned" units like *areyou* and *doyou*, the Bigram and the colloc model are starting to overlearn just like the syllable-structure models, as we would expect from basically every model ignorant of the linguistic regularities that can explain high-frequency patterns for sufficiently large amounts of data. In conclusion, we think this shows that the intuitively attractive behaviour of these models is an artefact of their strong preference for short units that, for small amounts of data, masks the overlearning at the expense of segmentation accuracy; in particular, the fact that models lacking syllable structure do not exhibit overlearning in our experiments should not be taken as evidence that they are more adequate than their overlearning relatives.

It is possible that the overlearning behavior we describe in this paper can be addressed by manually choosing appropriate values for the models' hyper-parameters, which control the models' Pitman-Yor Processes (PYPs). Goldwater (2007) observed that the segmentations proposed by the unigram and bigram models depend on the choice of hyper-parameters, and Johnson (2008b) observed a similar sensitivity to hyper-parameters in Adaptor Grammar models. However, the number of hyper-parameters is twice the number of PYPs in a model, and searching for hyper-parameter values that result in the most accurate segmentation is computationally very challenging. For this reason Johnson and Goldwater (2009) placed Beta and Gamma priors on the PYP a and b hyper-parameters respectively in their Adaptor Grammar models, and reported that sampling the hyper-parameters actually improved segmentation f-score as compared to the manually-specified settings they investigated. It is reasonable to expect that more realistic models of human language will be more complex, and therefore will have even more hyper-parameters, than the models investigated here. It is certainly conceivable that the hyper-parameters are innately fixed by universal grammar to values that result in good segmentations across different languages. But all else being equal, models which do not require hyper-parameters to be fixed to specific values should be preferred on general simplicity grounds over models that do require such prespecification. For this reason we chose to use Johnson and Goldwater's hyper-parameter sampler in the Adaptor Grammar models we studied here.

Conclusion and perspectives

We have presented a novel corpus of English CDS derived from the Providence Corpus for studying models of word segmentation. This corpus makes it possible to address a wider range of questions than is currently common, for example with respect to the study of developmental effects in incremental algorithms. We identified an interesting "overlearning" effect for state-of-the-art word segmentation models on large amounts of data that has so far gone unnoticed and proposed an explanation of this behaviour that highlights the importance of linguistic structure for Bayesian models; we have argued that the apparent lack of overlearning for linguistically less-sophisticated models is due to an undesirable preference for oversegmentation and shouldn't be mistaken for an advantage.

In future work, we want to further explore the impact of linguistic knowledge for Bayesian models of the kind discussed here; we suspect that giving the model the ability to model more of the regularities languages exhibit more appropriately, the overlearning behaviour we observed will become less severe. Also, we want to test the cross-linguistic usefulness of different kinds of constraints such as assuming (a certain kind of) syllable-structure. This is complicated by the fact that most current data-sets do not separate CDS directed at different children and children of different ages. We hope that our presentation of a data-set that fulfills these desiderata will lead to the creation of corpora like this for other languages as well.

ABSTRACT
In this work we address the challenge of augmenting *n*-gram language models according to prior linguistic intuitions. We argue that the family of hierarchical Pitman-Yor language models is an attractive vehicle through which to address the problem, and demonstrate the approach by proposing a model for German compounds. In our empirical evaluation the model outperforms a modified Kneser-Ney *n*-gram model in test set perplexity. When used as part of a translation system, the proposed language model matches the baseline BLEU score for English→German while improving the precision with which compounds are output. We find that an approximate inference technique inspired by the Bayesian interpretation of Kneser-Ney smoothing (Teh, 2006) offers a way to drastically reduce model training time with negligible impact on translation quality.

TITLE AND ABSTRACT IN AFRIKAANS

Bayes-modellering van saamgestelde woorde in Duits

Hierdie werk neem uitdagings rondom die uitbreiding van *n*-gramtaalmodelle volgens voorafgaande linguistieke intuïsie onder die loep. Ons voer aan dat die familie van hiërargiese Pitman-Yor taalmodelle 'n wenslike stuk gereedskap is om hierdie probleem mee aan te pak en formuleer 'n model van Duitse saamgestelde woorde om die benadering te demonstreer. Met behulp van 'n empiriese evaluering bevind ons dat die model in terme van toetsdataperpleksiteit beter vaar as die aangepaste Kneser-Ney *n*-grammodel. As onderdeel van 'n Engels→Duits-vertalingstelsel behaal die model in terme van die BLEU-metriek dieselfde vertaalafvoerkwaliteit as die kontrole stelsel en genereer saamgestelde woorde teen 'n hoër presisie. Verder stel ons vas dat 'n benaderde inferensietegniek, geïnspireer deur die Bayes-interpretasie van Kneser-Ney-gladstryking (Teh, 2006), gebruik kan word om die modelberamingtyd drasties te verminder sonder wesenlike impak op die vertaalafvoerkwaliteit.

1 Introduction

Statistical language modelling addresses the problem of assigning probabilities to sentences in natural languages. In an effective model, these probabilities function as statistical proxies for sentences' syntactic well-formedness and semantic plausibility. As such, language models (LMs) play a crucial role in machine translation (MT) and automatic speech recognition (ASR) systems, which need to distinguish well-formed output sentences from ill-formed ones.

To tackle the problem of assigning reasonable probabilities to an infinite space of possible sentences, two assumptions are commonly made: first, the closed vocabulary assumption, which states that sentences are sequences of words from a *finite* vocabulary $\mathscr{W}$, and second, a Markov assumption is made, which states that the probability of each word in a sentence is conditionally independent of all others, given the previous $n-1$ words of context. Relying on these assumptions, language modelling becomes the problem of estimating the conditional probabilities of $|\mathscr{W}|$ words in $|\mathscr{W}|^{n-1}$ contexts.

There are two problems with this approach that we address in this paper.[1] First, the closed vocabulary assumption is often unreasonable, in particular for languages that use productive compounding to create novel word types. We therefore focus on modelling German since it makes extensive use of productive compounding and gives us an opportunity to explore this problem in depth. Second, in a naïve n-gram parametrisation, words are modelled independently of each other. This is problematic since the number of parameters is far too large to estimate reliably from even the largest corpora, and it ignores our intuition that related word forms have related behaviour. We solve these problems with an n-gram language model based on the hierarchical Pitman-Yor process (HPYP): Our model relaxes the closed vocabulary assumption by incorporating productive compound formation in its generative story, while the hierarchical structure enables us to relax the naïve independence assumptions about the statistical behavior of related word forms.

In the next section, we address the German compound problem in further detail and use this to motivate the structure of our model (§3). We then discuss the inference problem (§4), and evaluate the model's performance in terms of held-out perplexity and on translation quality when used inside an English→German translation system (§5). We conclude by placing this work in the context of related approaches (§6) and addressing avenues for future work.

2 Compound Words

Our aim in this work is to develop a language model that accounts for the structure of compound words. Compounding is a process whereby words are formed by combining other words. In some languages (including German, Swedish, Dutch and Afrikaans), compounds are written as single orthographic units. NLP systems that rely on whitespace to demarcate their elementary modelling units, e.g. the "grams" in n-gram models, are thus prone to suffer from sparse data effects that can be attributed to compounds specifically. An account of compounds in terms of their components therefore holds the potential of improving the performance of such systems.

Examples of compounds

- A basic noun-noun compound:
  Auto + Unfall = Autounfall *(car crash)*

[1] Preliminary work on the approach we follow in this paper was previously reported on by Botha (2012). Here, we expand on the scale and depth of the empirical evaluation and investigate an additional inference technique.

- *Linking elements* can appear between components
  Küche + Tisch = Küchentisch *(kitchen table)*
- Components can undergo stemming
  Schule + Hof = Schulhof *(schoolyard)*
- Compounding is recursive
  (Geburt + Tag) + Kind = Geburtstag + Kind = Geburtstagskind *(birthday boy/girl)*
- Compounding extends beyond noun components
  Zwei-Euro-Münze *(two Euro coin)* Fahrzeug *(vehicle)*

A compound is said to consist of a *head* component and one or more *modifier components*, with optional *linking elements* between consecutive components (Goldsmith and Reutter, 1998). The linguistic intuition that we propose to exploit in our language model is that German compounds are overwhelmingly right-headed (Toman, 1992), i.e. the right-most component fully determines the word's morphosyntactic properties. For example, the "Bahn" in "Eisenbahn" (railway) identifies the word as singular feminine, which determines the requirements for its agreement with verbs, articles and adjectives.

A language model could therefore give a reasonable assessment of the syntactic fluency of a sequence of German words by ignoring the non-head components of compounds. For example, the sentence, "I'm going by train" can be rendered in German as either of the following:

- Ich fahre mit der Eisenbahn.
- Ich fahre mit der Bahn.

Collapsing all compounds to their heads and ignoring modifiers would decrease sparsity and allow more robust n-gram probabilities to be estimated from data. But such a strategy would not be probabilistically sound as a generative model of a corpus. Moreover, a model that ignores modifiers would assign the same probability value to "Eisenbahn" and the empirically much rarer "Bobbahn" (bobsled), which would be unsatisfactory in a task where the language model plays a disciminative role. The model needs to account for the non-head components in some way. We expect the identity and number of modifier components to be strongly correlated with the identity of the head. In particular, the conditional distributions of modifier given head will be sharply peaked. A simple approximation is thus to assume that, conditioned on the head, modifiers are generated by a reverse n-gram model:[2]

$$p(\text{eisenbahn} \mid \text{mit der}) \equiv p(\text{bahn} \mid \text{mit der}) \times p(\text{eisen} \mid \text{bahn}) \times p(\$ \mid \text{eisen})$$

The sentinel \$ indicates the word boundary and doubles as a control on the number of modifiers. In general, we will use this process as a *back-off* strategy, i.e., when the trigram "mit der Eisenbahn" is unobserved. Note that this is markedly different from linguistically naïve back-off models that would score the unobserved trigram "mit der Eisenbahn" by falling back on bigram or unigram estimates. In our model, we instead permit the model to back off to this decomposition before dropping valuable context information.

3 An n-gram Model with Compounding

In this section we aim to marry an n-gram model with the intuition of compound formation that we proposed before. We present an extension of the hierarchical Pitman-Yor language model

[2]The majority of compounds have two components and thus match this assumption well enough. Multipart compounds where the modifiers themselves are compounds may violate it.

Figure 1: Intuition for the proposed generative process of a compound word: The context generates the head component, which generates a modifier component, which in turn generates another modifier. (Literally, "with the cable car"; idiomatically, "by cable car")

(HPYLM) (Teh, 2006) that fulfils this aim. The particular properties of the Pitman-Yor process (PYP) (Pitman and Yor, 1997) that we exploit are its flexibility to specify arbitrary back-off distributions (making it easy to incorporate an additional model) and the fact that it generates distributions that adapt well to power-law behaviour, as is often observed in language.

We employ this HPYLM framework with its accompanying inference machinery rather than a seemingly obvious alternative of using two distinct word-level and compound-level n-gram models. The reasons are that our unified model can learn a subtle interpolation between those levels, obviating the need to introduce and tune an extraneous interpolation scheme between sub-models, while opening the door for future extensions, e.g. analysing compounds occuring in the n-gram history.

3.1 Hierarchical Pitman-Yor Language Model (HPYLM)

An n-gram model is an $(n-1)$-th order Markov model that approximates the joint probability of a sequence of words $\mathbf{w}$ as

$$p(\mathbf{w}) \approx \prod_{i=1}^{|\mathbf{w}|} p(w_i \mid w_{i-n+1}, \ldots, w_{i-1}), \tag{1}$$

where we occasionally abbreviate a context $[w_i, \ldots, w_j]$ as $\mathbf{u}$. In the HPYLM, the conditional distributions $p(w|\mathbf{u})$ are smoothed by placing PYP priors over them. The PYP is defined through its base distribution, and a *strength* (θ) and *discount* (d) hyperparameter that control its deviation away from its mean (which equals the base distribution).

The generative process for a word w in context $\mathbf{u}$ is:

$$\begin{aligned}
G_0 &= \text{Uniform}(|\mathscr{W}|) \\
G_\emptyset &\sim PY(d_0, \theta_0, G_0) \\
&\vdots \\
G_{\pi(\mathbf{u})} &\sim PY(d_{|\mathbf{u}|-1}, \theta_{|\mathbf{u}|-1}, G_{\pi\circ\pi(\mathbf{u})}) \\
G_{\mathbf{u}} &\sim PY(d_{|\mathbf{u}|}, \theta_{|\mathbf{u}|}, G_{\pi(\mathbf{u})}) \\
w &\sim G_{\mathbf{u}},
\end{aligned}$$

where $\pi(\mathbf{u})$ truncates the context $\mathbf{u}$ by dropping the left-most word in it. The hyperparameters are tied across all priors with the same context length $|\mathbf{u}|$. To explain this process in terms of the familiar trigram case, consider how the probability $p(w \mid u, v)$ comes to be. Let $\mathbf{u} = [u, v]$. $G_{[u,v]}$ is then the PYP-distributed distribution over w. The hierarchy arises by using as the base distribution for the prior of $G_{[u,v]}$ another PYP-distributed $G_{[v]}$, i.e. the distribution $p(w \mid v)$. The recursion bottoms out at the unigram distribution $G_\emptyset$, which is drawn from a PYP with base distribution equal to the uniform distribution over the vocabulary $\mathscr{W}$.

3.2 Hierarchical Pitman-Yor Language Model + Compounds (HPYLM+c)

We define a compound word $\tilde{w}$ as a sequence of components $[c_1, \ldots, c_z]$, plus a sentinel symbol \$ marking either the left or the right boundary of the word, depending on the direction of the model. To maintain generality over this choice of direction, let Λ be an index set over the positions, such that c_{Λ_1} always designates the head component.

Following the motivation in §2, we set up the model to generate the head component c_{Λ_1} conditioned on the word context $\mathbf{u}$, while the remaining components $\tilde{w} \setminus c_{\Lambda_1}$ are generated by some model F, independently of $\mathbf{u}$.

To encode this, we modify the HPYLM thus:

1. Replace the support with the reduced vocabulary $\mathscr{M}$, the set of unique elementary components c obtained when segmenting the items in $\mathscr{W}$. ($\mathscr{M}$ also includes items consisting of a single component to begin with.)
2. Add an additional level of conditional distributions $H_{\mathbf{u}}$ (with $|\mathbf{u}| = n-1$) where items from $\mathscr{M}$ combine to form the observed surface words.

The generative process changes as follows (see also Figure 2):

$$
\begin{aligned}
G_0 &= \text{Uniform}(|\mathscr{M}|) \\
G_\emptyset \ \ldots \ G_{\mathbf{u}} &\quad \text{(as before)} \\
H_{\mathbf{u}} &\sim PY(d_{|\mathbf{u}|}, \theta_{|\mathbf{u}|}, G_{\mathbf{u}} \times F) \\
\tilde{w} &\sim H_{\mathbf{u}}
\end{aligned}
$$

So the base distribution for the prior of the word n-gram distribution $H_{\mathbf{u}}$ is the product of a distribution $G_{\mathbf{u}}$ over compound heads, given the same context $\mathbf{u}$, and another (n'-gram) language model F over compound modifiers, conditioned on the head component.

Choosing F to be a bigram model ($n' = 2$) yields the following procedure for generating a word:

$$
\begin{aligned}
&c_{\Lambda_1} \sim G_{\mathbf{u}} \\
&\text{for } i = 2 \text{ to } z \\
&\qquad c_{\Lambda_i} \sim F(\cdot | c_{\Lambda_{i-1}})
\end{aligned}
$$

The linguistically motivated choice for conditioning in F is $\Lambda^{\text{ling}} = [z, z-1, \ldots, 1]$ such that c_{Λ_1} is the true head component; \$ is drawn from $F(\cdot|c_1)$ and marks the left word boundary.

In order to see if the correct linguistic intuition has any bearing on the model's extrinsic performance, we will also consider the reverse, supposing that the left-most component were actually more important in this task, and letting the remaining components be generated left-to-right. This is expressed by $\Lambda^{\text{inv}} = [1, \ldots, z]$, where \$ this time marks the right word boundary and is drawn from $F(\cdot|c_z)$.

Linking Elements In the preceding definition of compound segmentation, the linking elements do not constitute items in the vocabulary $\mathscr{M}$. Regarding linking elements as components in their own right would sacrifice important contextual information and disrupt the conditionals $F(\cdot|c_{\Lambda_{i-1}})$. That is, faced with the compound Küche·n·tisch, we want P(küche|tisch) in the model, but not P(küche|n).

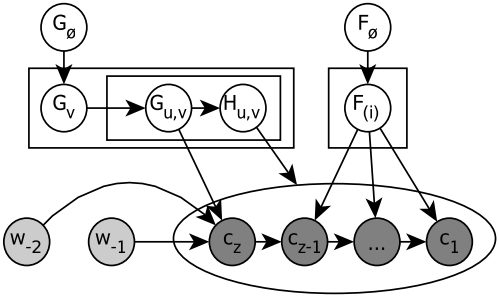

Figure 2: Plate diagram showing how a trigram version of HPYLM+c, using a bigram model F with condition scheme Λ^{ling} for modifiers, generates a word (the ellipse), consisting of head c_z and modifiers $c_1 \ldots c_{z-1}$. Here, w_{-2} and w_{-1} form the trigram context. We omit hyperparameters and their priors for clarity.

But linking elements must be accounted for to have a well-defined generative model. We follow the pragmatic option[3] of merging any linking elements onto the adjacent component – for Λ^{ling} merging happens onto the preceding component (e.g. P(küchen|tisch)), while for Λ^{inv} it is onto the succeeding one (e.g.P(ntisch|küche)). This keeps the 'head' component c_{Λ_1} intact.

4 Training

For ease of exposition we describe inference with reference to the trigram HPYLM+c model with a bigram HPYLM for F, but the general case should be clear.

The model is specified by the latent variables $\mathscr{L} = (G_{[\emptyset]}, G_{[v]}, G_{[u,v]}, H_{[u,v]}, F_{\emptyset}, F_c)$, where $u, v \in \mathscr{W}$, $c \in \mathscr{M}$, and hyperparameters $\Omega = (d_i, \theta_i, d'_j, \theta'_j, d''_2, \theta''_2)$, where $i = 0, 1, 2$, $j = 0, 1$, single primes designate the hyperparameters in F_{HPYLM} and double primes those of $H_{[u,v]}$. We can construct a collapsed Gibbs sampler by marginalising out the latent variables in $\mathscr{L}$, giving rise to a variant of the hierarchical Chinese Restaurant Process in which it is straightforward to do inference.

Chinese Restaurant Process A direct representation of a random variable G drawn from a PYP can be obtained from the stick-breaking construction (Pitman, 2002b). But the more indirect representation using the Chinese Restaurant Process (CRP) (Aldous, 1985; Pitman, 2002a) is more suitable here since it relates to distributions over items drawn from such a G. This fits the current setting, where words w are being drawn from a PYP-distributed G.

Imagine that a corpus is created in two phases: Firstly, a sequence of blank tokens x_i is instantiated, and in a second phase lexical identities w_i are assigned to these tokens, giving rise to the observed corpus. In the CRP metaphor , the sequence of tokens x_i are equated with a sequence of customers that enter a restaurant one-by-one to be seated at one of an infinite number of tables. When a customer sits at an unoccupied table k, they order a dish ϕ_k for the table, but customers joining an occupied table have to dine on the dish already served there. The dish ϕ_i that each customer eats is equated to the lexical identity (type) w_i of

[3]It is worth noting that for German the presence and identity of linking elements between c_i and c_{i+1} are in fact governed by the preceding component c_i (Goldsmith and Reutter, 1998).

the corresponding token, and the way in which tables and dishes are chosen gives rise to the characteristic properties of the CRP:

More formally, let $x_1, x_2, \ldots$ be draws from G, while T is the number of occupied tables, C the number of customers in the restaurant, and C_k the number of customers at the k-th table.

Conditioned on preceding customers $x_1, \ldots, x_{i-1}$ and their arrangement, the i-th customer sits at table $k = k'$ according to the following probabilities for the $T + 1$ choices:

$$\Pr(k = k' | \ldots) \propto \begin{cases} C_{k'} - d & \text{occupied table } k' \in [1, T] \\ \theta + dT & \text{unoccupied table } k' = T + 1 \end{cases} \tag{2}$$

Ordering a dish for a new table corresponds to drawing a value ϕ_k from the base distribution G_0, and it is admissible to serve the same kind of dish at multiple tables.

Some characteristic behaviour of the CRP can be observed easily from this description: 1) As more customers join a table, that table becomes a more likely choice for future customers too. 2) Regardless of how many customers there are, there is always a non-zero probability of joining an unoccupied table, and this probability also depends on the number of total tables.

The dish draws can be seen as backing off to the underlying base distribution G_0, an important consideration in the context of the hierarchical variant of the process explained shortly. Note that the strength and discount parameters control the extent to which new dishes are drawn, and thus the extent of reliance on the base distribution.

The predictive probability of a word w given a seating arrangement is given by

$$\Pr(w | \ldots) \propto C_w - dT_w + (\theta + dT)G_0(w), \tag{3}$$

where C_w is the number of customers of type w and T_w the number of tables serving dish w in the restaurant. In smoothing terminology, the first term can be interpreted as applying a discount of dT_w to the observed count C_w of w; the amount of discount therefore depends on the prevalence of the word (via T_w).

Hierarchical CRP When the prior of $G_{\mathbf{u}}$ has a base distribution $G_{\pi(\mathbf{u})}$ that is itself PYP-distributed, as in the HPYLM, the restaurant metaphor changes slightly. In general, each node in the hierarchy has an associated restaurant. Whenever a new table is opened in some restaurant R, another customer is spawned and sent to join the parent restaurant $\text{pa}(R)$. This induces a consistency constraint over the hierarchy: the number of tables T_w in restaurant R must equal the number of customers C_w in its parent $\text{pa}(R)$.

We take care to satisfy this constraint in our model where some restaurants have as base distribution a product of models. Here, when a new table serves a dish $\phi = \hat{w}$ in trigram restaurant $H_{[u,v]}$, a customer c_{Λ_1} joins the corresponding bigram restaurant $G_{[u,v]}$, *and* customers $c_{\Lambda_2}, \ldots, c_{\Lambda_z}, \$$ are sent to the restaurants for $F(\cdot|c_{\Lambda_1}), \ldots, F(\cdot|c_{\Lambda_z})$, respectively.

Sampling Although the CRP allows us to replace the priors with seating arrangements S, those seating arrangements are simply latent variables that need to be marginalised to compute the true posterior predictive probability of a word:

$$p(w|\mathscr{D}) = \int_{S,\Omega} p(w|S,\Omega)p(S,\Omega|\mathscr{D})\, dS\, d\Omega, \tag{4}$$

where $\mathcal{D}$ is the training data and, as before, Ω are the parameters. This integral can be approximated by averaging over m posterior samples (S, Ω) generated using Markov chain Monte Carlo methods. The simple form of the conditionals in the CRP allows us to do a Gibbs update whereby the table index k of a customer is resampled conditioned on all the other variables. Sampling a new seating arrangement S for the trigram HPYLM+c thus corresponds to visiting each customer in the restaurants for $H_{[u,v]}$, removing them while cascading as necessary to observe the consistency across the hierarchy, and seating them anew at some table k'.

In the absence of any strong intuitions about appropriate values for the hyperparameters, we place vague priors over them and use slice sampling[4] (Neal, 2003) to update their values during generation of the posterior samples: $d \sim \text{Beta}(1,1)$; $\theta \sim \text{Gamma}(10, 0.1)$

Lastly, we make the pragmatic approximation that $m = 1$, i.e. predictive probabilities are informed by a single sample[5] (S, Ω), taken after $B > 1$ iterations of burn-in.

Approximate Inference A common criticism of models like ours is that MCMC sampling increases training time unreasonably for an MT pipeline, despite the simplicity of Gibbs sampling.

To address this concern, we will evaluate the viability of using approximate inference in our model, inspired by the interpretation of original interpolated Kneser-Ney smoothing as approximate inference in the HPYLM (Teh, 2006; Goldwater et al., 2006). In each CRP, we constrain all the customers of a type to be seated at the same table, $T_w = 1 \; \forall w$. This changes the predictive probability of a word to

$$\Pr(w|\ldots) \propto C_w - d + (\theta + dT')G_0(w), \tag{5}$$

where T' is now the number of unique types in the restaurant. In the hierarchical model, this implies absolute discounting of the n-gram counts by an amount d.

Under this scheme, the calculation of all C_w and T' across the hierarchy is deterministic. We can therefore obtain the full seating arrangement S from a single pass through the training data. We update the hyperparameters as described in the previous section, although an alternative would be to tune them against perplexity on development data.

5 Experiments

In this section we report on experiments performed to gain insight into the behaviour of the proposed model. The first task we evaluate on is the model's ability to predict a previously unseen text. Our aim is to establish whether the model's account of compounds benefits it without hampering its global performance. We also investigate how the performance depends on the amount of context used when predicting tokens, and on the amount of training data used to estimate the model.

Secondly, we are interested in how the model interacts with a large-scale statistical machine translation system when translating from English to German. Compound words are known to be a challenging aspect of this task, and the aim is to see if specifically accounting for them in the language model can bias a decoder towards better translations. We did not modify other aspects of the translation system, thus it cannot hypothesise "new" compounds and will not benefit from our model's ability to score unseen compounds consisting of observed components.

[4] We employ Mark Johnson's implementation, http://www.cog.brown.edu/~mj/Software.htm

[5] Our preliminary experiments indicated that the posterior over the latent model structure is quite sharply peaked, so that a single sample constitutes a low-variance estimator of the posterior predictive distribution.

5.1 Methods

Data and Tools All data we used are from the WMT11 shared-task.[6] Standard data preprocessing steps comprised normalising punctuation, tokenising and lowercasing all words.

For language model training, we used the union of the news commentary data, Europarl and the news article corpus for 2011. Preprocessing and deduplication yielded a corpus of 59m running tokens, roughly a fifth of all the German monolingual data supplied in WMT11 when using the same preprocessing. No pruning was done on the n-gram counts, but we mapped training tokens to the "unknown" token if they do not appear in the target-side of the bitext (see below). The motivation is that the hypotheses to be scored against the language model during decoding are by definition constrained to this vocabulary.

Our test corpus for the monolingual task is the union of all the WMT11 development data for German (`news-test2008,9,10`, 7065 sentences).

For translation experiments, the preprocessed English-German bitext was filtered to exclude sentences longer than 50 tokens, resulting in 1.7 million parallel sentences; word alignments were inferred from this using the Berkeley Aligner (Liang et al., 2006) and used as a basis from which to extract a Hiero-style synchronous CFG (Chiang, 2007).

The weights of the linear translation models were tuned towards BLEU using `cdec`'s (Dyer et al., 2010) implementation of MERT (Och, 2003). For this, the development set `news-test2008` (2051 sentences) was used, while final BLEU scores are measured on the official test set `newstest2011` (3003 sentences, 171460 tokens), without detokenising or recasing hypotheses.

Compound segmentation For this evaluation, we used an *a priori* segmentation of compounds into parts to build our models. This means we assume a single, fixed analysis of a compound regardless of the context it occurs in, which is necessitated by the fact that our probabilistic model does not specify a step for choosing an analysis. To construct a segmentation dictionary, we ran a supervised[7] compound splitter (Dyer, 2009) on all the words[8] in the training vocabulary, retaining the one-best segmentation. In addition, word-internal hyphens were also taken as segmentation points. Finally, linking elements were merged onto components as discussed in §3.2. Any token that is split into more than one part by this procedure is regarded as a compound, and we find that the majority of compounds thus identified consist of one or two parts (Table 1b).

5.2 Compounds as n-grams

Our model is premised on the idea that better probability estimates can be obtained by analysing compounds into their components. To investigate this claim empirically, we trained a variety of 4-gram language models and compare them by how well they predict an unseen text consisting of N tokens. For each model q, we report measurements in terms of perplexity, $\text{PPL}=\exp\left(-1/N \sum_\tau \ln q(\tau)\right)$, calculated over all tokens τ in the text.

It should be noted that the domain of our model is a countably infinite set. According to the generative process of HPYLM+c (§3.2), there is no theoretical limit on the number of parts in a

[6] http://www.statmt.org/wmt11/

[7] We chose a supervised splitter as the focus of our evaluation is on the language model's subsequent use of the segmentation, not on the quality of the segmentation itself. Unsupervised methods could also be used with our model.

[8] We also included tokens having numerals and at least two letters, e.g. "CO2-handel" (carbon trade)

Table 1: Summary of training data and compound segmentation.

compound; there is always a non-zero probability of adding another modifier c from $\mathscr{M}$ to a partially formed compound. In this evaluation, we used the probabilities supplied by HPYLM+c without normalising over the finite vocabulary $\mathscr{W}$. Consequently, a comparison to baseline models that have a finite domain is somewhat biased in their favour.

Our main model of interest is HPYLM+c using the Λ^{ling} segmentation and a bigram model F_{HPYLM} over modifiers. To measure the importance of adhering to linguistic intuition, we also evaluate the variant using Λ^{inv}, other things equal. As baselines we used an interpolated, modified Kneser-Ney model (mKN) and an HPYLM. For the sampling-based models, we took one sample from the posterior after $B = 300$ iterations of burn-in.

We find that the main model achieves a slightly lower perplexity than HPYLM, which in turn beats the mKN baseline by 1.9% (Table 2a). The use of the linguistically implausible scheme Λ^{inv} has a noticeably detrimental effect on performance.

	Perplexity

(b) Test-set perplexity for different n-gram orders.

Table 2: Comparison of language models and effect of n-gram order.

For a more qualitative insight into the model performance, we did a further direct comparison of our main model and the mKN baseline by ranking test set compounds by the difference in probability value that each model assigns to the n-gram. The test compounds where the compound model does best (Table 3 top) are all words for which an analysis into a context-dependent head and modifiers should clearly be beneficial. For example, in scoring the phrases "wochen vor den präsidentschaftswahlen" (weeks before the presidential elections) and "tage vor den parlamentswahlen" (days before the parliamentary elections), the head "wahlen" is having a mutually reinforcing effect. In contrast, we find that the cases where the mKN baseline model does best (Table 3 bottom) feature various words that are not strictly speaking compounds, but largely artefacts of our segmentation method: e.g. mistakes such as "ging+rich" or "wissen+schaften", or greediness from splitting on hyphens, e.g. "ki-+moon". These are words where our compound model's smoothing is hurting performance, since it allocates some

probability mass toward observing other modifiers with the head, which in the case of these proper nouns will not happen. This is evidence of success on the part of our model's underlying mechanism, but demonstrates that more care should be taken with the particular segmentation method used.

5.3 Scaling

Here we consider the behaviour of our model under scaling along two dimensions: n-gram order and training data size.

Our model reduces data sparsity by generalising over different compounds that have the same head. But this happens at the maximal n-gram order, meaning the full surface form is not available in the lower-order conditional distributions. There may be cases where this amounts to "premature back-off" when the lower-order distributions are very informative for a particular surface form.

To see if this has an observable effect, we performed an additional experiment using orders $n = 2$ and $n = 3$. The results in Table 2b indicate that we maintain a lower perplexity than the baselines.

For $n = 2$ and $n = 3$, the sampler had not fully converged after 300 iterations. We suspect this is due to the higher entropy in the distributions governing the seating assignments: If $n = 2$, there should be more customers (and therefore more seating configurations) in the

average restaurant for context-length 2 than in the same restaurant if n is larger. This did not affect perplexity, which was stable when evaluating with different individual samples from the posterior around 300 iterations.

The other dimension of scaling is training data size. We drew random subsamples of different sizes from our training corpus for training further language models.

For small data sizes, the baseline models achieve a noticeably lower perplexity than our compound model. This is contrary to the effect we expected in light of the sparsity reduction our model brings. We suspect that this is primarily due to the lack of normalising the model over a finite vocabulary. For larger sizes, it is competitive against the baselines once more.

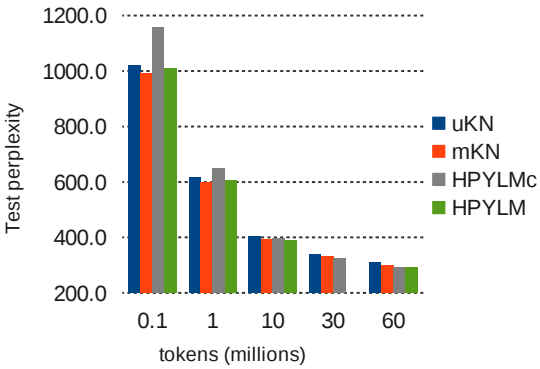

Figure 3: Test perplexity for different sizes of training data, keeping $n = 4$ fixed. uKN and mKN are original and modified Kneser-Ney, respectively, both using interpolation.

5.4 Effect on Translation

The performance of an n-gram language model in an intrinsic evaluation does not necessarily correlate with the effect it has when used as part of a translation system. We thus conducted a separate translation experiment, comparing the quality of the output produced by the translation system described in §5.1 when using different language models.

In terms of BLEU score, we do not find a meaningful difference between the various systems (Table 4a). The system using our main model matches the two baselines, a result that indicates our more expressive modelling is not sacrificing any performance in this task. This is an important outcome, as it means we avoid a common pitfall whereby a new model is proposed to target some specific phenomenon, does so successfully but then sacrifices performance globally. The linguistically implausible segmentation scheme again performs slightly worse.

When using the approximate inference scheme, denoted by `1tbl` in these results, we firstly find that language model training reduces to a trivial amount of time compared to the proper samplers; for `1tbl`, the posterior likelihood converged fully within 5 iterations, where an iteration comprises merely resampling the hyperparameters. By contrast, the posterior likelihood

	PPL	BLEU
mKN	299.9	13.9
HPYLM	294.1	13.9
F_{HPYLM}, Λ^{ling}	293.6	13.9
F_{HPYLM}, Λ^{inv}	305.5	13.7
F_{HPYLM}, Λ^{ling} `1tbl`	355.4	13.6

(a) BLEU over 3003 test sentences with single references. The standard deviation in BLEU score across the three independent runs varied between 0.1 and 0.3. For reference, we also show the perplexity of each model on the monolingual test set.

	P	R	F
mKN	25.4	17.1	20.5
HPYLM	24.3	**17.5**	20.4
F_{HPYLM}, Λ^{ling}	**27.5**	17.3	**21.3**
F_{HPYLM}, Λ^{inv}	23.7	17.2	19.9

(b) Precision, Recall and F-score for compounds in the translation output, relative to the reference set containing 2652 compounds. Each value is calculated across the union of hypotheses produced by decoding the test set with the weights obtained from the three independent runs.

Table 4: Translation results over three MERT runs, using 4-gram language models.

under proper sampling was still improving marginally after 300 iterations for the other models, where one iteration comprises hyperparameter resampling *and* a pass through all training tokens to resample their seating assignments in the CRP.

The `1tbl` model achieved a worse perplexity in the monolingual evaluation task, but with only a small negative effect on BLEU score compared to the baseline (Table 4a). This result suggests there is some leeway in the development of models in the HPYLM framework to explore in future work: model complexity can be pushed up by trading off predictive accuracy against training time.

Next, we turn to a more fine-grained look at the translation output. The BLEU metric is likely to miss small improvements in translation quality. Moreover, in our test corpus only 2652 of the 72661 reference tokens are compounds; a moderate improvement in generating them is unlikely to have a big impact on the BLEU.

To establish whether the model aids in the translation of compounds in particular, we measured the accuracy of hypotheses produced by the different translation systems against the reference translations. We use the standard metrics of precision (correct compounds as a fraction of all compounds output) and recall (correct compounds as a fraction of the compounds in the references).

The results in Table 4b show that using our model increases compound precision by 12% against the HPYLM baseline and 8% against the Kneser-Ney baseline (relative increases). The fact that recall remains stable proves that the gain in precision is not achieved simply by the system being more conservative about outputting compounds in the first place.

6 Related Work

Bilmes and Kirchhoff (2003) proposed a more general framework for n-gram language modelling, which can also be used for implementing sparsity reduction measures. Their Factored Language Model (FLM) views a word as a vector of features, such that a particular feature value is generated conditioned on some history of preceding feature values. This allows one to construct n-gram models with dependencies among sequences of PoS tags or semantic classes in addition to standard word-based dependencies. It should be possible to encode a model with structure comparable to ours in the FLM framework, but it does not lend itself naturally to

having a variable number of features depending on the predicted token in the way our model allows a variable number of parts in a compound.

Another common approach for addressing the sparsity effects of compounding (Koehn and Knight, 2003; Koehn et al., 2008; Stymne, 2009; Berton et al., 1996), and rich morphology (Habash and Sadat, 2006; Geutner, 1995), has been to use pre/post-processing with an otherwise unmodified translation system or speech recognition system. This approach views the existing machinery as adequate and shifts the focus to finding a more appropriate segmentation of words into tokens, i.e. compounds into parts or words into morphemes, thus achieving a vocabulary reduction. The downside of such a method is that training a standard n-gram language model on pre-segmented data introduces unwanted effects: in the case of German compounds, the split-off modifiers would take precedence in a split-off head's n-gram context, and during back-off the actual word-context information is discarded first. The problem is similar when modelling sequences of morphemes as n-grams, and earlier work in speech recognition has shown that taking steps against this effect can improve recognition accuracy (Ircing et al., 2001). Pre-processing also often requires heuristics to guard against over/under-segmentation, which do not generalise well to different settings or languages.

Our work is also subject to the whims of our compound segmentation method, but the model is more robust since it does retain the original surface form of the word – recall that the decomposition step amounts to interpolated back-off.

Baroni and Matiasek (2002) proposed basic models of German compounds for use in predictive text input, exploiting the same link between right-headedness and context as we have, although their focus was restricted to compounds with two components.

In terms of Bayesian modelling, the PYP has been found to be very useful in a variety of tasks, including word segmentation, speech recognition, domain adaption and unsupervised PoS tagging (Goldwater et al., 2006; Mochihashi et al., 2009; Huang and Renals, 2007; Neubig et al., 2010; Wood and Teh, 2009; Blunsom and Cohn, 2011). In all cases its power-law scaling and ease of extensibility via the base distribution allowed the formulation of interesting models that achieved competitive results.

7 Conclusion

We have demonstrated how an existing hierarchical Bayesian model can be used to build an n-gram language model that is informed by intuitions about the specific linguistic phenomenon of closed-form compounds. While our focus was on compounds, we argue that this approach can be useful for other phenomena, such as rich morphology more generally, where data sparsity creates smoothing problems for n-gram language models.

Our empirical results support the conclusions that the increased model expressiveness has a positive impact on the monolingual task of predicting unseen German text, outperforming a competitive Kneser-Ney baseline. When used as part of an English→German translation system, there was little effect on the BLEU metric, but the model was associated with an increase in the F-score for generating correct compounds during translation.

Future work will entail extending the translation system to hypothesise novel compounds, a situation where a productive language model should be vital for generating fluent translations. Further modelling work is therefore needed to handle novel compounds that occur in the n-gram history.

ABSTRACT
Lexical simplification is the task of replacing a word in a given context by an easier-to-understand synonym. Although a number of lexical simplification approaches have been developed in recent years, most of them have been applied to English, with recent work taking advantage of parallel monolingual datasets for training. Here we present LexSiS, a lexical simplification system for Spanish that does not require a parallel corpus, but instead relies on freely available resources, such as an on-line dictionary and the Web as a corpus. LexSiS uses three techniques for finding a suitable word substitute: a word vector model, word frequency, and word length. In experiments with human informants, we have verified that LexSiS performs better than a hard-to-beat baseline based on synonym frequency.

TITLE AND ABSTRACT IN SPANISH

¿Puede ser el Español más simple?
LexSiS: Simplificación Léxica en Español

La tarea de simplificación léxica consiste en sustituir una palabra en un contexto determinado por un sinónimo que sea más sencillo de comprender. Aunque en los últimos años han aparecido algunos sistemas para desempeñar esta tarea, la mayoría de ellos se han desarrollado para el inglés y hacen uso de corpus paralelos. En este artículo presentamos LexSiS, un sistema de simplificación léxica en español que utiliza recursos libremente disponibles tales como un diccionario en línea o la Web como corpus, sin la necesidad de acudir a la creación de corpus paralelos. LexSiS utiliza tres técnicas para encontrar un sustituto léxico más simple: un modelo vectorial basado en palabras, la frecuencia de las palabras y la longitud de la palabras. Una evaluación realizada con tres anotadores demuestra que para algunos conjuntos de datos LexSiS propone sinónimos más simples que el sinónimo más frecuente.

KEYWORDS: Lexical Simplification, Text Simplification, Textual Accessibility, Word Sense Disambiguation, Spanish.

1 Introduction

Automatic text simplification is an NLP task that has received growing attention in recent years (Chandrasekar et al., 1996; Carroll et al., 1998; Siddharthan, 2002; Aluísio et al., 2008; Zhu et al., 2010). Text simplification is the process of transforming a text into an equivalent which is easier to read and to understand than the original, preserving, in essence, the original content. This process may include the manipulation of several linguistic layers, and consists of sub-tasks such as syntactic simplification, lexical simplification, content reduction and the introduction of clarifications and definitions. Historically, text simplification started as a task mainly intended as a preprocessing stage in order to make other NLP tasks easier (Chandrasekar et al., 1996; Siddharthan, 2002). However, the task of simplifying a text also has a high potential to help people with various types of reading comprehension problems (Carroll et al., 1998; Aluísio and Gasperin, 2010). For example, lexical simplification by itself, without syntactic simplification, can be helpful for users with some cognitive conditions, such as aphasic readers or people with dyslexia (Hyönä and Olson, 1995). This second context in which text simplification is carried out is closely related to social initiatives which promote easy-to-read material, such as the Simple English section of the Wikipedia.[1] There are also various national and international organizations dedicated to the (mostly human) production of simple and simplified text.

Lexical simplification, an indispensable component of a text simplification system, aims at the substitution of words by simpler synonyms, where the evident question is: "What is a simpler synonym?". The lion's share of the work on lexical simplification has been carried out for English. In this paper, we present LexSiS, the first system for the lexical simplification of Spanish text, which proposes and evaluates a solution to the previous question. LexSiS is being developed in the context of the Simplext project (Saggion et al., 2011), which aims at improving text accessibility for people with cognitive impairments. Until now text simplification in Spanish has concentrated mainly on syntactic simplification (Bott and Saggion, 2012). Lexical and syntactic simplification are tasks which are very different in nature. Working with Spanish presents particular challenges, most notably dealing with the lack of large-scale resources which could be used for our purposes.

LexSiS uses (i) a word vector model to find possible substitutes for a target word and (ii) a simplicity computation procedure grounded on a corpus study and implemented as a function of word length and word frequency. LexSiS uses available resources such as the free thesaurus OpenThesaurus and a corpus of Spanish documents from the Web. The approach we take here serves to test how well relatively simple open domain resources can be used for lexical simplification. Since comparable resources can be found for many other languages, our approach is, in principle, language independent. As will be shown in this paper, by using contextual information and a well-grounded simplicity criterion, LexSiS is able to outperform a hard-to-beat frequency-based lexical replacement procedure.

Next section discusses related work on text simplification with particular emphasis on lexical simplification. Section 3 presents the analysis of a sample of original and simplified texts to design a word simplicity criteria. In Section 4 we present the resources we use for the development of LexSiS, while in Section 5 we describe our lexical simplification approach. We present the evaluation design in Section 6 and discuss the obtained results in Section 7. Finally, in Section 8 we summarize our findings and indicate possible ways to improve our results.

2 Related Work

Text simplification has by now become a well-established paradigm in NLP, combining a number of rather heterogeneous sub-tasks, such as syntactic simplification, content reduction, lexical simplification and the insertion of clarification material. In this paper, we are only interested in lexical simplification as one of the various aspects of text simplification. Lexical simplification requires, at least, two things: a way of finding synonyms (or, in some cases, hyperonyms), and a way of measuring lexical *complexity* (or simplicity, see Section 3). Note that applying word sense disambiguation can improve the accuracy of the simplification. Consider trying to simplify the word *hogar* in the following sentence: *La madera ardía en el hogar ('The wood was burning in the fireplace')*. The most frequent synonym of *hogar* is *casa ('house')*; however, choosing this word for simplification would produce the sentence *La madera ardía en la casa ('The wood was burning in the house')*, which does not preserve the meaning of the original sentence. Choosing the correct meaning of *hogar*, in this case *'fireplace'*, is important for lexical simplification.

Early approaches to lexical simplification (Carroll et al., 1998; Lal and Ruger, 2002; Burstein et al., 2007) often used WordNet in order to find appropriate word substitutions, in combination with word frequency as a measure of lexical simplicity. Bautista et al. (2011) use a dictionary of synonyms in combination with a simplicity criterion based on word length. De Belder et al. (2010) apply explicit word sense disambiguation, with a Latent Words Language Model, in order to tackle the problem that many of the target words to be substituted are polysemic.

More recently, the availability of the Simple English Wikipedia (SEW) (Coster and Kauchak, 2011b), in combination with the "ordinary" English Wikipedia (EW), made a new generation of text simplification approaches possible, which use primarily machine learning techniques (Zhu et al., 2010; Woodsend et al., 2010; Woodsend and Lapata, 2011b; Coster and Kauchak, 2011a; Wubben et al., 2012). This includes some new approaches to lexical simplification. Yatskar et al. (2010) use edit histories for the SEW and the combination of SEW and EW in order to create a set of lexical substitution rules. Biran et al. (2011) also use the SEW/EW combination (without the edit history of the SEW), in addition to the explicit sentence alignment between SEW and EW. They use WordNet as a filter for possible lexical substitution rules. Although they do not apply explicit word sense disambiguation, their approach is *context-aware*, since they use a cosine-measure of similarity between a lexical item and a given context, in order to filter out possibly harmful rule applications which would select word substitutes with the wrong word sense. Their work is also interesting because they use a Vector Space Model to capture the lexical semantics and, with that, their context preferences.

Finally, there is a recent tendency to use statistical machine translation techniques for text simplification (defined as a monolingual machine translation task). Coster and Kauchak (2011a) and Specia (2010), drawing on work by Caseli et al. (2009), use standard statistical machine translation machinery for text simplification. The former uses a dataset extracted from the SEW/EW combination, while the latter is noteworthy for two reasons: first, it is one of the few statistical approaches that targets a language different from English (namely Brazilian Portuguese); and second, it is able to achieve good results with a surprisingly small bi-data-set of only 4,483 sentences. Specia's work is closely related to the PorSimples project, described in Aluísio and Gasperin (2010). In this project a dedicated lexical simplification module was developed, and it uses a thesaurus and a lexical ontology for Portuguese. They use word frequency as a measure for simplicity, but apply no word sense disambiguation.

3 Corpus Analysis

As the basis for the development of LexSiS, we have conducted an empirical analysis of a small corpus of news articles in Spanish, the Simplext Corpus (Bott and Saggion, 2011). It consists of 200 news articles, 40 of which have been manually simplified. Original texts and their corresponding simplifications have been aligned at the sentence level, thus producing a parallel corpus of a total of 590 sentences (246 and 324 in the original and simplified sets respectively). All texts have been annotated using Freeling, including part-of-speech tagging, named entity recognition and parsing (Padró et al., 2010).

Our methodology, explained more in depth in Drndarevic and Saggion (2012), consists in observing lexical changes applied by trained human editors and preparing their computational implementation accordingly. In addition to that, we conduct quantitative analysis on the word level in order to compare frequency and length distributions in the sets of original and simplified texts. Earlier work on lexical substitution has largely concentrated on word frequency, with occasional interest for word length as well (Bautista et al., 2009). It has also been shown that lexical complexity correlates with word frequency: more frequent words present less cognitive effort for the reader (Rayner and Duffy, 1986). Our analysis is motivated by the desire to test the relevance of these factors in the text genre we treat and the possibility of their combined influence on the choice of the simplest out of a set of synonyms to replace a difficult input word.

We observe a high percentage of named entities (NE) and numerical expressions (NumExp) in our corpus, due to the fact that it is composed of news articles, which naturally abound in this kind of expressions. NEs and NumExps have been discarded from the frequency and length analysis because they are tagged as a whole by Freeling, and this presents us with two difficulties. First, some expressions, such as *30 millones de dólares ('30 million dolars')* or *Programa Conjunto de las Naciones Unidas sobre el VIH/sida ('Joint United Nations Programme on HIV/AIDS')*, are extremely long words (some exceed 40 characters in length) and are not found in the dictionary; thus, we cannot assign them a frequency index. Second, such expressions are not replaceable by synonyms, but require a different simplification approach.

We conduct word length and frequency analysis from two angles. First, we analyse the totality of the words in the parallel corpus. Second, we analyse all lexical units (including multi-word expressions, e.g. complex prepositions) that have been substituted with a simpler synonym. These pairs of lexical substitutions (O-S) have been included in the so-called Lexical Substitution Table (LST) and are used for evaluation purposes (see Section 6).

3.1 Word Length

Analysing the total of 10,507 words (6,595 and 3,912 in the original and simplified sets respectively), we have observed that the most prolific words in both sets are two character words, the majority of which are function words (97.61% in O and 88.97% in S). Two to seven-character words are more abundant in the S set, while longer words are slightly more common in the O set. The S set contains no words with more than 15 characters. Analysis of the pairs in the LST has given us similar results: almost 70% of simple words are shorter than their original counterparts.

On the whole, we can conclude that in S texts there is a tendency towards using shorter words of up to ten characters, with one to five-character words taking up 64.10% of the set and one to ten-character words accounting 95.54% of the content.

3.2 Word Frequency

To analyse the frequency, a dictionary based on the Referential Corpus of Contemporary Spanish (Corpus de Referencia del Español Actual, CREA)[2] has been compiled for the purposes of the Simplext project. Every word in the dictionary is assigned a frequency index (FI) from 1 to 6, where 1 represents the lowest frequency and 6 the highest. We use this resource for the corpus analysis because it allows easy categorisation of words according to their frequency and elegant presentation and interpretation of results. However, in Section 5 this method is abandoned and relative frequencies are calculated based on occurrences of given words in the training corpus, so as to ensure that words not found in the above mentioned dictionary are also covered.

In the parallel corpus, we have documented words with FI 3, 4, 5 and 6, as well as words not found in the dictionary. The latter are assigned FI 0 and termed *rare words*. This category consists of infrequent words such as *intransigencia* (*'intransigence'*), terms of foreign origin, like *e-book*, and a small number of multi-word expressions, such as *a lo largo de* (*'during'*). The latter are recognized as multi-word expressions by Freeling, but are not included in the dictionary as such. The ratio of these expressions with respect to total is rather small (1.08% in O and 0.59% in S), so it should not significantly influence the overall results, presented in Table 1.

Frequency index	Original	Simplified
Freq. 0	10,53%	4,71%
Freq. 3	1,36%	0,74%
Freq. 4	1,35%	1,00%
Freq. 5	6,68%	5,67%
Freq. 6	80,08%	87,88%

Table 1: The distribution of n-frequency words in original and simplified texts.

We observe that lower frequency words (FI 3 and FI 0) are around 50% more common in O texts than in S texts, while the latter are somewhat more saturated in highest frequency words. As a general conclusion we observe that simple texts (S set) make use of more frequent words from CREA than their original counterparts (O set).

In order to combine the factors of word length and frequency, we have additionally analysed the length of all the words in the category of *rare words*. We have found that rare words are largely (72.44% in O and 77.44% in S) made up of seven to nine-character words, followed by longer words of up to twenty characters in O texts (39.42%) and fourteen characters in S texts (29.88%).

We are, therefore, lead to believe that there is a degree of connection between the factors of word length and word frequency, and that these are to be combined when scores are assigned to synonym candidates. In Section 5.1 we propose criteria for determining word simplicity exploiting these findings.

4 Resources

As we already mentioned in Section 2, most attempts to resolve the problem of lexical simplification are concentrated on English and, in recent years, Simple English Wikipedia in combination with the "ordinary" English Wikipedia has become a valuable resource for the study of text

[2] `http://corpus.rae.es/creanet.html`

simplification in general, and lexical simplification in particular. For Spanish, like for most other languages, no comparably large parallel corpora are available.

Some approaches to lexical simplification make use of WordNet (Miller et al., 1990) in order to measure the semantic similarity between lexical items and to find an appropriate substitute. While Spanish is one of the languages represented in EuroWordNet (Vossen, 2004), its scope is much more modest. The Spanish part of EuroWordNet contains only 50,526 word meanings and 23,370 synsets, in comparison to 187,602 meanings and 187,602 synsets in the English WordNet 1.5.

4.1 Corpora

The most valuable resources for lexical simplification are comparable corpora which represent the "normal" and a simplified variant of the target language. Although the corpus described in Section 3 served us as a basis for the corpus study and provided us with gold standard examples for the evaluation presented in Section 6, it is not large enough to train a simplification model. We, therefore, made use of an 8M word corpus of Spanish text extracted from the Web to train the vector models in Section 4.3.

4.2 Thesaurus

We use the Spanish OpenThesaurus (version 2),[3] which is freely available under the GNU Lesser General Public License, for the use with OpenOffice.org. This thesaurus lists 21,831 target words (lemmas) and provides a list of word senses for each word. Each word sense is, in turn, a list of substitute words (and we shall refer to them as *substitution sets* hereafter). There is a total of 44,353 such word senses. The substitution candidate words may be contained in more than one of the substitution sets for a target word. The following is the Thesaurus entry for *mono*, which is ambiguous between the nouns *'ape'*, *'monkey'* and *'overall'*, as well as the adjective *'cute'*.

(a) mono|4
- |gorila|simio|antropoide
- |simio|chimpancé|mandril|mico|macaco
- |overol|traje de faena
- |llamativo|vistoso|atractivo|sugerente|provocativo|resultón|bonito

OpenThesaurus lists simple one-word and multi-word expressions, both as target and substitution units. In the current version of LexSiS, we only treat single-word units, but we plan to include the treatment of multi-word expressions in future versions. We counted 436 expressions of the kind, such as *arma blanca* (*'stabbing or cutting weapon'*) or *de esta forma* (*'in this manner'*). Some of those expressions are very frequent and are used as tag phrases. The treatment of multi-word expressions only requires a multi-word detection module as an additional resource.

4.3 Word Vector Model

In order to measure lexical similarity between words and contexts, we used a Word Vector Model (Salton et al., 1975). Word Vector Models are a good way of modelling lexical semantics

[3] `http://openthes-es.berlios.de`

(Turney and Pantel, 2010), since they are robust, conceptually simple and mathematically well defined. The 'meaning' of a word is represented as the contexts in which it can be found. A word vector can be extracted from contexts observed in a corpus, where the dimensions represent the words in the context, and the component values represent their frequencies. The context itself can be defined in different ways, such as an n-word window surrounding the target word. Whether two words are similar in meaning can be measured as the cosine distance between the two corresponding vectors. Moreover, vector models are sensitive to word senses. For example, vectors for word senses can be built as the sum of word vectors which share one meaning.

We trained this vector model on the 8M word corpus mentioned in 4.1. We lemmatized the corpus with FreeLing (Padró et al., 2010) and for each lemma type in the corpus we constructed a vector, which represents co-occurring lemmas in a 9-word (actually 9-lemma) window (4 lemmas to the left and to the right). The vector model has n dimensions, where n is the number of lemmata in the lexicon. The dimensions of each vector in the model (i.e. the vector corresponding to a target lemma) represent the lemmas found in the contexts, and the value for each component represents to number of times the corresponding lemma has been found in the 9-word context. In the same process, we also calculated the absolute and relative frequencies of all lemmas observed in this training corpus.

5 LexSiS Method

LexSiS tries to find the best substitution candidate (a word lemma) for every word which has an entry in the Spanish OpenThesaurus. The substitution operates in two steps: first the system tries to find the most appropriate substitution set for a given word, and then it tries to find the best substitution candidate within this set. Here the *best* candidate is defined as the simplest and most appropriate candidate word for the given context. As for the simplicity criterion, we apply a combination of word length and word frequency, and for the determination of appropriateness we perform a simple form of word sense disambiguation in combination with a filter that blocks words which do not seem to fit in the context.

In the first step, we check for each lemma if it has alternatives in OpenThesaurus. If this is the case, we extract a vector from the surrounding 9-word window, as described in Section 4.3. Since each word is a synonym to itself (and might actually be the simplest word among all alternatives), we include the original word lemma in the list of words that represent the word sense. We construct a common vector for each of the word senses listed in the thesaurus by adding all the vectors (resulting from Section 4.3) to the words listed in each word sense. Then, we select the word sense with the lowest cosine distance to the context vector. In the second step, we select the best candidate within the selected word sense, assigning a simplicity score and applying several thresholds in order to eliminate candidates which are either not much simpler or seem to differ too much from the context.

5.1 Simplicity

According to our discussion in Section 3, we calculate simplicity as a combination of word length and word frequency. The task of combining them, however, is not entirely trivial, considering the underlying distribution of lengths and frequencies. In both cases simplicity is clearly not linearly correlated to the observable values. We know that simplicity monotonically decreases with length and monotonically increases with frequency, but a linear combination of the two factors not necessarily behaves monotonically as well. What we need is a score for simplicity, such that for all possible combinations of word lengths and frequencies of two words, w_1 and

w_2, $score(w_1) > score(w_2)$ iff w_1 is simpler than w_2. For this reason, we try to approximate the correlation between simplicity and the observable values at least to some degree.

In the case of length, our corpus study showed that a word with length *wl* is simpler than a word with length $wl + 1$. But the degree to which it is simpler depends on the value of *wl*. The corresponding difference decreases with longer values for *wl*. For words with a very high *wl* value, a difference in simplicity between *wl* words and *wl* - 1 words is not perceived any more. In our corpus, we found that very long words (10 characters and longer) were always substituted with much shorter words with an average length difference of 4.35 characters. In medium length range (from 5 to 9 characters), the average difference was only 0.36 characters, and very short original words (4 characters or shorter) did not tend to be shortened in the simplified version at all. For this reason we use the following formula:[4]

$$score_{wl} = \begin{cases} \sqrt{wl - 4} & \text{if } wl \geq 5\,, \\ 0 & \text{otherwise.} \end{cases}$$

In the case of frequency, we make the standard assumption that word frequency is distributed according to Zipf's law (Zipf, 1935); therefore, simplicity must be similarly distributed (when we abstract away from the influence of word length). In order to get a score which associates simplicity to frequency in a way which comes closer to linearity, we calculate the simplicity score for frequency as the logarithm of the frequency count c_w for a given word:

$$score_{\text{freq}} = \log c_w$$

Now the combination of the two values is

$$score_{\text{simp}} = \alpha_1 score_{wl} + \alpha_2 score_{\text{freq}}$$

where α_1 and α_2 are weights. We determined values for α_1 and α_2 in the following way: we manually selected 100 good simplification candidates proposed by OpenThesaurus for given contexts. We only considered cases which were both indisputable synonyms and clearly perceived as being simpler than the original. Then we calculated the average difference between the scores for word length and word frequency between the the original lemma and the simplified lemma, and took these averaged differences as being the average contribution of length and frequency to the receivable *simplicity* of the lemma. This resulted in $\alpha_1 = -0.39$[5] and $\alpha_2 = 1.11$.

[4]The formula for $score_{wl}$ resulted in quite a stable average value for $score_{wl}(w_{\text{original}}) - score_{wl}(w_{\text{simplified}})$ for the different values of wl in the range of word lengths from 7 to 12, when tested on the gold standard (cf 6.3 below). For longer and shorter words this value was still over-proportionally high or low, respectively, but the difference is less pronounced than with alternative formulas we tried, and much smoother than the direct use of wl counts. In addition, 74% of all observed substitutions fell into that range.

[5]Note that word length is a penalizing factor, since longer words are generally less simple. For this reason, the value for α_1 is negative.

5.2 Thresholds

There are several cases in which we do not want to accept an alternative for a target word, even if it has a high simplicity score. First of all, we do not want to simplify frequent words, even if OpenThesaurus lists them. So we set a cutoff point for frequent words, such that LexSiS does not try to simplify words with a frequency higher than 1% (calculated on the training corpus in 4.3). We also discard substitutes where the difference in the simplicity score with respect to the original word is lower than 0.5, because such words can be expected not to be significantly simpler. We achieved this latter value through experimentation.

Many of the alternatives proposed by OpenThesaurus are in reality not acceptable substitutes. We try to filter out words that do not fit into the context by discarding all candidates whose word vector has a distance with a cosine inferior to 0.013, another value achieved through experimentation.

Finally, there are two cases in which the system does not propose a substitute. First, there are cases where none of the substitution candidates have low enough cosine distance to the context vector (with the threshold of 0.013). There are also cases where the highest scoring substitute is the same as the original lemma. In both cases the original word is preserved.

6 Evaluation

In this section we present the experimental set-up employed to evaluate LexSiS by comparing it with two baselines and a gold standard. The evaluation was conducted thoroughly, rating the degree of simplification and the preservation of meaning of the substitutions.

6.1 Baselines

We employ two baselines:

(a) Random: it replaces the target word with a synonym selected randomly from our resource.

(b) Frequency: it replaces a word with its most frequent synonym provided by the thesaurus, presumed to be the simplest, similar to Devlin and Unthank (2006).

6.2 Gold Standard

As the gold standard we used the synonym pairs composed by the manual lexical substitutions extracted from the corpus described in Section 3. Since current lexical simplification systems for English handle only one-word cases (Yatskar et al., 2010; Biran et al., 2011), only single lexical substitutions were taken intro consideration. For instance, the substitution of the word *pinacoteca (‘art gallery’)* by *museo (‘museum’)* in the following sentence:

(b) (O) El visitante puede contemplar los óleos y esculturas que se exponen en la PINACOTECA.
‘The visitor can appreciate the paintings and sculptures showed in the ART GALLERY.’
(S) El visitante puede contemplar los óleos y esculturas que se exponen en el MUSEO.
‘The visitor can appreciate the paintings and sculptures showed in the MUSEUM.’

With that restriction, we found a total of 26 lexical substitutions in the corpus. We discarded collocations and multi-word expressions, as well as single lexical substitutions which supposed a mayor transformation in the sentence structure. For instance, the word *pese a (‘despite’)*, substituted with *sin embargo (‘however’)*, has changed the structure of the sentence itself:

(c) (O) Amnistía subrayó que Manning se encuentra detenido en "custodia máxima", PESE A carecer de antecedentes por violencia o infracciones disciplinarias durante la detención, lo que significa que está atado de pies y manos durante todas las visitas y se le niega la oportunidad de trabajar y salir de su celda.
'Amnesty underlined that Manning is being held in "maximum custody", DESPITE having no history of violence or disciplinary offenses during detention, which means his hands and feet are tied during all visits and he is denied the opportunity to work and leave his cell.'
(S) Bradley Manning ha tenido un buen comportamiento en la cárcel. SIN EMBARGO, Bradley Manning está atado durante las visitas. Tampoco puede trabajar ni salir de su celda.
'Bradley Manning has exhibited good behavior in prison. HOWEVER, Bradley Manning is tied during visits. He cannot work or leave his cell.'

6.3 Evaluation Dataset

We have three different evaluation datasets.

(T-S/B) Target *vs.* **System and Baselines:** This dataset is composed of 50 unique target words, together with their synonyms generated by LexSiS and the baselines. To create this dataset, we first ran our system for lexical simplification through the original texts from the Spanish Simplext Corpus (Bott and Saggion, 2011). This gave us 739 automatic lexical substitutions. We randomly selected 50 sentences that included one lexical substitution. Subsequently, for each of the examples, we generated two baselines and inserted them in the sentences, obtaining a total of 200 sentences. We manually corrected the ungrammatical examples resulting from lexical substitution.

(T-G/S/B) Target *vs.* **Gold, System and Baselines:** This dataset is composed of the examples which were manually simplified in the gold standard and which were also simplified by our system (12 cases out of the 26 cases of single lexical substitution in the Simplext Corpus). For each of these examples, we also generated two baselines, obtaining a total or 48 sentences to evaluate.

(G-T) Gold *vs.* **Target:** This dataset is composed of the remaining lexical simplification examples of our gold standard (14 instances) and their target words. For these examples our system did not propose a simplified example.

We could set up more evaluation data to compare the system and the baselines. However, we considered 50 sentences (a total of 200 sentences for dataset T-S/B, and 276 different sentences if we consider all data sets) to be reasonable because: (i) It was feasible for the annotators to perform the task; and (ii) previous works in lexical simplification used slightly smaller data sets for evaluation - in Yatskar et al. (2010) they use a total of 200 simplification examples, and in Biran et al. (2011) 130 simplification examples are used. Below, we show two examples of a sentence with its original word (O) and the lexical substitution proposed by our system (S).

(d) (O) De la Iglesia merece este GALARDÓN.
'De la Iglesia deserves this AWARD.'
(S) De la Iglesia merece este PREMIO.
'De la Iglesia deserves this PRIZE.'

(e) (O) Cuenta con una AMPLIA oferta de títulos.
'It has a WIDE range of titles.'
(S) Cuenta con una GRAN oferta de títulos.
'It has a GREAT range of titles.'

6.4 Design

We created a multiple choice questionnaire presenting two sentences for each item. Each item contained one sentence with a simplification example and the same sentence with the target word. These sentences were presented in random order to the annotator (i.e., either as Target *vs.* LexSiS/Gold/Baseline or LexSiS/Gold/Baseline *vs.* Target). The labels for each pair of sentences in comparison with the other were: "simpler", "more complex", "equally simple or complex", "they do not have the same meaning", and "I do not know or I do not understand at least one of the sentences". In Table 2 we show an example of one target word and its corresponding substitutions presented in the sentences.

Type	Sentence
Target	Descubren en Valencia una nueva ESPECIE de pez prehistórico. *A new SPECIES of prehistoric fish is discovered in Valencia.*
LexSIS	Descubren en Valencia un nuevo TIPO de pez prehistórico. *A new TYPE of prehistoric fish is discovered in Valencia.*
Frequency Baseline	Descubren en Valencia un nuevo GRUPO de pez prehistórico. *A new GROUP of prehistoric fish is discovered in Valencia.*
Random Baseline	Descubren en Valencia un nuevo LINAJE de pez prehistórico. *A new LINEAGE of prehistoric fish is discovered in Valencia.*

Table 2: Example extracted from dataset (T-S/B) Target *vs.* LexSIS and Baselines.

6.5 Annotators

Three annotators with no previous annotation experience performed the tests using an on-line form. They were all Spanish native speakers, frequent readers and were not the authors of this paper. To measure the inter-annotator agreement of multiple annotators and multiple classes (five classes, one per label), we used the Fleiss' kappa measure (Fleiss, 1971). The three participants annotated all the instances of the three datasets, achieving a Fleiss' kappa score of 0.330. Hence, we can assume we have a fair agreement (Landis and Koch, 1977), comparable with other inter-annotator agreements in related literature (see Section 7).

7 Results and Discussion

In this section we present the results and discuss the performance of LexSiS. We calculate (in percentage) how well the meaning has been preserved, taking into consideration all the instances (Synonym column). The percentage of simpler, equal and more complex synonyms is calculated among the synonymous instances (Simpler Syn., Equal Syn. and Complex Syn. columns, respectively) and among all the instances, taking into consideration the global performance of LexSiS (Simpler Syn. Glob., Equal Syn. Glob. and Complex Syn. Glob. columns, respectively).[6]

System	Synonym (%)	Simpler Syn. (%)	Equal Syn. (%)	Complex Syn. (%)	Simpler Syn. Glob. (%)	Equal Syn. Glob. (%)	Complex Syn. Glob. (%)
Random	65.03	15.13	24.37	58.82	9.94	**16.02**	38.67
Frequency	66.12	**42.98**	19.01	**38.02**	28.42	12.57	**25.14**
LexSiS	**72.49**	40.88	**17.52**	41.61	**29.63**	12.70	30.16
Gold	97.44	71.05	17.11	11.84	69.23	16.67	11.54

Table 3: Evaluation of all the datasets.

[6]The sum of Simpler Syn. Glob., Equal Syn. Glob. and Complex Syn. Glob. columns equals the number of synonyms (Synonym column) and the sum of Simpler Syn., Equal Syn. and Complex Syn. columns equals 100.

In Table 3 we present the results for all the datasets. The percentage of meaning preservation is higher in LexSiS than in the baselines, and LexSiS offers simpler synonyms (29.63%) than the frequency baseline (28.42%). However, 30.16% of the lexical substitutions suggested by our system are found to be more complex by the annotators. One possible reason for this is that the texts used for this study were already simple from a lexical point of view. For instance, we found only 26 manual lexical substitutions in the Simplext corpus, and our system only offered a lexical substitute for 12 of these manual substitutions. Consequently, 53.84% of the manually substituted target words were not simplified by LexSiS, and 78.57% of these manual substitutions were found to be simpler synonyms by the annotators (see Table 4). Even though our gold standard is small, to the best of our knowledge, this is the only existing resource from which we could generate a gold standard for lexical simplification in Spanish.

System	Synonym (%)	Simpler Syn. (%)	Equal Syn. (%)	Complex Syn. (%)	Simpler Syn. Glob. (%)	Equal Syn. Glob. (%)	Complex Syn. Glob. (%)
Gold	100	78.57	16.67	4.76	78.57	16.67	4.76

Table 4: Evaluation of dataset (G-T): Gold *vs.* Target.

We performed an error analysis to try and discover why LexSiS did not account for the remaining instances from the gold standard, and we found five possible reasons: (1) the target word does not occur in the LexSiS dictionary; (2) the target word is already too frequent to be substituted by LexSiS; (3) the target word and its lexical substitution are the same; (4) the lexical substitution proposed by LexSiS has a very similar ranking to the target word, hence the substitution is not performed; and (5) the target word is discarded because its vectorial distance taking into account the original context is too large.

System	Synonym (%)	Simpler Syn. (%)	Equal Syn. (%)	Complex Syn. (%)	Simpler Syn. Glob. (%)	Equal Syn. Glob. (%)	Complex Syn. Glob. (%)
Random	**57.14**	4.76	42.86	47.62	2.86	25.71	28.57
Frequency	47.22	47.06	17.65	35.29	22.22	**8.33**	16.67
LexSiS	55.56	**65.00**	**15.00**	**20.00**	**36.11**	**8.33**	**11.11**
Gold	95.83	58.70	17.39	21.74	61.11	16.67	16.67

Table 5: Evaluation of dataset (T-G/S/B): Target *vs.* Gold, LexSiS and Baselines.

Among the instances from the gold standard not accounted for by LexSiS, our system presents more lexical substitutions synonymous with the target word than the baselines, and a greater amount of simpler synonyms (65.00%) than the frequency (47.06%) and random (4.76%) baselines (see results for dataset (T-G/S/B) in Table 5). We have found that the dataset (T-S/B) is the only case where the frequency baseline presents a higher percentage of suggesting simpler synonyms (31.29%) than LexSiS (27.33%). Nevertheless, LexSiS shows a higher meaning preservation percentage.

System	Synonym (%)	Simpler Syn. (%)	Equal Syn. (%)	Complex Syn. (%)	Simpler Syn. Glob. (%)	Equal Syn. Glob. (%)	Complex Syn. Glob. (%)
Random	66.00	18.18	20.20	60.61	12.08	**13.42**	40.27
Frequency	72.11	**43.40**	18.87	**37.74**	**31.29**	13.61	**27.21**
LexSiS	**76.00**	35.96	**18.42**	45.61	27.33	14.00	34.67

Table 6: Evaluation of dataset (T-S/B): Target *vs.* LexSiS and Baselines.

These results are consistent with the state of the art of lexical simplification for English. In SemEval-2012 shared task for lexical simplification, only one lexical simplification system

among nine systems presented a higher ranking (0.496) than the frequency baseline (0.471), according to a pairwise kappa metric (Specia et al., 2012).

Our results are comparable with the lexical simplification system for English presented in (Biran et al., 2011), whose frequency baseline for English target words (medium frequency) is very similar to ours (42.86%). The results of their system are higher for English and they make use of a comparable corpus. Our inter-annotator agreement rate (Fleiss' kappa score of 0.330) is also consistent with their pairwise inter-annotator agreement, where kappa score was between 0.35 and 0.53.

Our evaluation methodology includes five possible answers for each pair of instances, as in SIMPL method (Yatskar et al., 2010), although we present the annotators with the words in their original context. SIMPL reaches 66% precision for the 100 top pairs using a probabilistic model based on the edit history in simple Wikipedia.

Other methods, which include syntactic operations as well, approach lexical simplification as a monolingual machine translation problem and use machine translation measures to evaluate them (Zhu et al., 2010), together with human judges (Woodsend and Lapata, 2011a).

In summary, LexSiS is the first approach to lexical simplification in Spanish, a language where only syntactic simplification has been previously performed (Bott and Saggion, 2012). Our system uses free resources, such as a dictionary and the Web as corpus. LexSiS is based on the analysis of a small sample of data and it does not require a parallel corpus to function.

8 Conclusion and Future work

In the past few years, automatic text simplification has rapidly become an important technology for the information society, due to its potential application in information access and the benefits it may bring to people with special needs. One important aspect of text simplification is lexical simplification: the selection of simpler/easier substitutes for difficult words. Automatic lexical simplification has, in most cases, been applied to English datasets, with many recent approaches relying on the availability of large parallel simplified and non-simplified documents to train statistical methods.

In this paper we have presented LexSiS, the first implemented lexical simplification system for Spanish, which does not require a parallel corpus for its implementation. LexSiS, rather, uses available texts found on the Web and a freely available Thesaurus. LexSiS uses a word vector model to identify the correct sense of the word to be replaced, and then selects the simplest synonym using simplicity criteria based on word frequency and word length.

We have evaluated three aspects of LexSiS: (i) its ability to identify a correct synonym for the target to be simplified; (ii) its ability to provide a simpler word substitute; and (iii) its performance as a whole. We have compared LexSiS with two baselines, one of which is a hard-to-beat procedure based on word frequency.

For each of the datasets used in the evaluation, LexSiS shows a higher meaning preservation percentage, offering more synonymous lexical substitutions than the baseline. For the overall of the datasets, LexSiS proposes simpler synonyms than the frequency baseline.

We believe our research makes the following contributions: we present a well-grounded procedure for the simplification of Spanish text, which could possibly be a language independent method, due to its small-scale resources that can be found for many other languages. It repre-

sents the first computational implementation of a lexical simplification algorithm for Spanish. Finally, we use a well-designed and viable evaluation methodology for lexical simplification.

Based on the evaluation, we have found various aspects of the method which need to be taken into further consideration. First, we are facing the problem of out-of-dictionary words. One way to overcome this problem is by inducing possible word-substitutes with methods similar to the word vector model we use here, as well as larger datasets. Second, frequency computation in our procedure is not carried out considering word sense disambiguation, but by performing counts disregarding senses. It is possible that taking the word sense into consideration before computing its frequency could improve the results. Finally, in this work we only consider substitution of single lexical units – the identification of multi-word expressions and collocations, such as *poco a poco* (‘*little by little*’), substituted with its simpler synonym *gradualmente* (‘*gradually*’), will be addressed in future work.

Acknowledgments

We would like to thank Ricardo Baeza-Yates for his wise comments and Joan Codina for mathematical advice on the modeling of simplicity. We are also grateful for the annotators for their effort and patience: Toni Carbajo, Roberto Juan Carlini and Alfonso Rello. We also thank the anonymous reviewers for their constructive comments.

The research described in this paper arises from a Spanish research project called Simplext: An automatic system for text simplification (`http://www.simplext.es`). Simplext is led by Technosite and partially funded by the Ministry of Industry, Tourism and Trade of the Government of Spain, by means of the National Plan of Scientific Research, Development and Technological Innovation (I+D+i), within strategic Action of Telecommunications and Information Society (Avanza Competitiveness, with file number TSI-020302-2010-84). We are grateful to fellowship RYC-2009-04291 from Programa Ramón y Cajal 2009, Ministerio de Economía y Competitividad, Secretaría de Estado de Investigación, Desarrollo e Innovación, Spain and to the doctoral fellowship FI-DGR by Generalitat de Catalunya.

Abstract

The emergence of dialogue on social medial neccessitates the development of new dialogue processing models. We argue that to address coherence and to infer the implicatures of social dialogue it is vital to understand the social aspirations of the dialogue participants. One key aspect of understanding social dialogue is to understand the intentions and goals of participants. In this paper, we present 11 social acts that capture a broad number of social intentions and goals. We define social acts as pragmatic speech acts designed to give insight into the socio-cognitive processes that individuals unconsciously go through when communicating in dialogue. Identification of the social acts is done using a combination of a generative model in which utterances are generated from gappy patterns, which define a given social act, and a series of binary classifiers. Our experimentation shows that we can capture these social acts with an overall F-measure of 50.4%.

Keywords: dialogue, social actions, online communication, speech acts, social goals, social implicature.

Proceedings of COLING 2012: Technical Papers, pages 375–390,
COLING 2012, Mumbai, December 2012.

1 Introduction

Traditional approaches to dialogue processing have been primarily focused on task-based (Grosz, 1978; Traum and Hinkelman, 1992) dialogue. In addition, the recognition of speech acts has proved useful for identifying the structure of the dialogue which takes place in formal meetings (Shriberg et al., 2004) where the dialogue is often a function of the job or position of the participants. Theories of the coherence of discourse and discourse relations (Barzilay and Lapata, 2005; Byron and Stent, 1998; Hobbs, 1979, 1985; Mann and Thompson, 1988; Marcu and Echihabi, 2002) have proved useful for the semantic interpretation of discourse. However, in the world of Twitter, Facebook, and other social media where people voluntarily join in the conversation, dialogue is often focused on the social engagements between participants. These *social dialogues* are often not driven by a common group task, goal or purpose, but by the social aspirations of the participants. As an example let us examine the following excerpt of dialogue from a political debate forum:

> **A)** Seriously, how can anybody still support this president's economic policies? How can HE just continue to do the same things and why can't HE take responsibility for the lousy economy???
>
> **B)** Not to worry, last time we had a democrat president that was this bad, we had a huge victory!
>
> **C)** Being neither a Republican or Democrat I wonder if a Republican administration would have done any better? We know McCain's proposed tax and spending policies during the 2008 election would have led to even larger deficits than what Obama was proposing at the time. Not to mention the bailouts and TARP of Bush.
>
> **D)**What about the showing that when Obama took office, the economy was spiraling down with -9% real rate, losing 700,000+ jobs a month, skyrocketing unemployment, and the stock markets were crashing in the worst recession in 80 years. Not to mention the destruction of the housing market. Oh yeah and we were headed straight for a depression.

In the example shown above, the participants do not form a unified group working toward a common goal or task, but are instead splintered into subgroups which have their own agenda. The dialogue only progresses and stays coherent because the participants wish to further their own goals, e.g. further their bond with others in their subgroup, demonstrate their opposition to other groups, and influence the undecided. These social goals represent an individual's task in a task-oriented dialogue. Individuals construct a plan to accomplish their task and carry out their plan through social actions.

In order to address the coherence and to infer social implicatures from social dialogue it is vital to determine the social intentions and goals of the dialogue participants. The representation of social dialogue plays an important role in facilitating the inference of social intentions and goals. We believe the seminal work on attentions, intentions and the structure of discourse by Grosz and Sidner (1986) is best suited for the inference of social goals. A central component of this approach is the intentional structure, which takes into account the purpose of discourse segments. In social dialogue the purpose of a discourse segment is to further the social goal of the dialogue participants. Thus, by understanding the discourse segments, social goals can be inferred.

A straightforward approach to using Grosz and Sidner's theory for inferring social implicatures is to use the prevailing methods in dialogue processing. Topic modeling, such as Blei et al. (2003), can be used for identification of linguistic structure where topic shifts (Cassell et al., 2001) break the larger dialogue into dialogue segments. Dialogue acts (Allen and

Core, 1997; Stolcke et al., 1998; Bunt et al., 2010), which inform the intentions of dialogue, can be employed to infer the social goals of the participants. The attentional state can be captured using local coherence (Barzilay and Lapata, 2005; Byron and Stent, 1998). The social implicatures of the dialogue can then be inferred through the intentional structure, i.e. the social intentions and goals, and the attentional state, i.e. the focus of the dialogue and its participants.

However, our early experimentation revealed that this straightforward approach of using Grosz and Sidner's framework with prevailing dialogue processing techniques fails to capture the complexities of human social interactions and is incapable of reliably inferring the social implicatures of dialogue. The primary factor for this failure is that traditional dialogue acts are not capable of capturing the nuances of the social intentions and goals of the dialogue participants. Instead of focusing solely on the dialogue, we must also focus on the dialogue participants and how their social aspirations constrain their dialogue. Thus, we must look at the *social intentional structure* of dialogue which models the social intentions and goals of the dialogue participants and how the participants perceive the social intentions of others. The question then becomes: *How can the social intentional structure be captured?*

We propose to use *social acts* for inferring the social intentions and goals of dialogue participants which act to define the social intentional structure of the dialogue. Social acts capture the complex social actions individuals signal through their utterances. While most dialogue acts have some social overtones, they fail to adequately interpret the speaker's social goals. In contrast, the definitions of social acts are specifically designed to take into account participants' social cognition which constrains their dialogue facilitating the inference of social intentions and goals from their communication. We identify a set of 11 social acts, listed in section 3, that capture a variety of social goals and intentions. These social acts come from literature in the fields of psychology and organizational behavior and are motivated by work in dialogue understanding.

As with work in dialogue acts, we identify social acts at the utterance level. We employ a generative model for discovering gappy patterns which capture generalized cue phrases for each of the social acts. A gappy pattern consists of one or more words in between which there can exist gaps, or wildcards, which match any word. Each gap has an associated width which determines how many words the gap can match. The gappy patterns are used as features in a binary classifier. Each social act is associated with a classifier which determines if the social act is manifested or not in an utterance.

2 Related Work

Research understanding the intentionality of dialogue and dialogue has a long history. Some of the earliest work in dialogue processing is on speech acts. Speech acts are actions performed by individuals when making an utterance. Austin (1962) formalized the concept of speech acts by separating them into three classes: (1) *locutionary*, (2) *illocutionary*, and (3) *perlocutionary*. Much of the work in speech acts has been focused on illocutionary acts due to the work of Searle (1969).

Dialogue acts are specialized speech acts which include the internal structure, such as grounding and adjacency pairs, of a dialogue. There are a number of schemes for coding dialogue acts, such as DAMSL (Allen and Core, 1997), VERBMOBIL (Jekat et al., 1995), and DIT++ (Bunt et al., 2010). The DAMSL coding scheme defines dialogue acts that are

forward looking, which are extensions of speech acts, and which are backward looking, which relate the utterance to previous utterances. Frameworks like DIT++ have extended the typical coverage of dialogue acts to encompass a boarder set of acts, such as social obligations. However, when dialogue act schemes incorporate socially motivated acts often they do not fully take into account the multitude of purposes, social intentions, and ultimately the social implicatures of these acts. For example, in the statement "get me a cup of coffee", speech acts would focus on identifying the set of actions that would result from the utterance - presumably the target of the utterance physically going to get a cup of coffe for the speaker. In DIT++ the example utterance would most likely be labeled as "Instruct" which is void of any social implicatures resulting from the instruction. In contrast, social acts reflect the social intention of an utterance focusing on the social implicature of the statement, which in the case of the example utterance is that the speaker is indicating their power over the target.

A vast amount of research has been focused on the coherence of dialogue(Barzilay and Lapata, 2005; Byron and Stent, 1998; Hobbs, 1979; Mann and Thompson, 1988). Mann and Thompson Mann and Thompson (1988) introduce Rhetorical Structure Theory (RST), which was originally developed during the study of automatic text generation. They posit that the coherence of a text is attributed to the rhetorical relations between non-overlapping texts called the nucleus and satellite. The definition of the relations are not morphological or syntactic, but instead are focused on function and semantics. Discourse Representation Theory (DRT) (Kamp, 1984) provides a framework for the semantic understanding of discourse. DRT models the cognitive state of the reader, or hearer, of the discourse using discourse representation structures which convert the discourse into a logical form made up of referents and conditions. In social dialogue we must model and understand the speaker's cognitive state, which informs their social intentions and constrains their actions facilitating the progression and coherence of the dialogue.

Grosz and Sidner (1986) posit a structural approach to dialogue understanding where dialogue is broken into three constituents: *linguistic structure*, *intentional structure*, and *attentional state*. The linguistic structure encompasses how utterances combine together to form larger segments of dialogue. The intentional structure is defined using a single dialogue purpose and multiple dialogue segment purposes. The dialogue purpose is the overarching motivation for the dialogue. For social dialogue, the dialogue purpose should infer the social implicatures of the dialogue. Dialogue segment purposes are sub-components of the larger dialogue purpose and define the intention of a single dialogue segment. In social dialogue, one would expect the dialogue segment purpose to relate to the social intentions of the participants. The final structural component, the attentional state is a property of the dialogue and acts to keep track of the current focus of the dialogue. When dealing with social dialogue the attentional state is influenced by the participants and their social intentions.

The inference of social implicatures and identification of social goals through the use specialized social acts has been the focus of recent research. Bramsen et al. (2011) examined how individuals change their language usage depending on the status of the individual with whom they are communicating. In particular, they examine the use of *upspeak* and *downspeak* for signaling power relationships where *upspeak* is a sign that an individual is communicating with someone of higher status and *downspeak* is a sign that an individual is communicating with someone of lesser power. Danescu-Niculescu-Mizil et al. (2012) exam-

ined the use of coordination, often referred to as mimicry, for inferring power relationships. They showed that individuals are more likely to coordinate with individuals of higher status, i.e. those who have more power, than those with lower or equal status. Bracewell et al. (2011) examined a number of social acts for inferring whether two dialogue participants have a collegial relationship.

Other research has focused on the annotation of social acts. Tomlinson et al. (2012) examined the manifestation of a set of social acts in Arabic for inferring pursuits of power by participants. Bracewell et al. (2012) created an annotated corpus of *collegial* and *adversarial* social actions. Bender et al. (2011) created an annotated corpus of social acts relating to *authority claims* and *alignment moves* for determining authority and influence.

Related work is also found in the methods for identifying dialogue acts. Petukhova and Bunt (2011) examined using Bayes Net and Ripper for classification of high level dialogue acts in the DIT++ schema. They reported F-measures ranging from 62% to 95.1% for the AMI meeting corpus. Webb and Ferguson (2010) introduced an automated method for the extraction of cue phrases for identification of dialogue acts. They obtained an identification accuracy of almost 81% on the switchboard corpus when using cue phrases extracted from a portion of the switchboard corpus and an accuracy of almost 71% when using cue phrases extracted from the ICSI-MRDA corpus. Our approach combines the use of cue phrases and classification. We first extract cue phrases in the form of gappy patterns using a generative model. Then the cue phrases are used in a binary classifier which determines if an utterance is a manifestation of the associated social act.

3 Social Acts

Social interaction is one of the primary reasons for dialogue. Even predominantly task oriented dialogue (e.g. "let's go to the movies") has many possible social implications. The most apparent is the expression of a desire to establish or reaffirm a bond between the individuals. In order to reliably infer these social implications, the social intentions and goals for the dialogue participants must be taken into account.

We label the dialogue segment purpose, or the social intentions of an utterance, as social act. Social acts are pragmatic speech acts that signal a dialogue participant's social intentions. There are a number of social goals which a participant may have, including (1) maintaining an existing role, such as being an authority (Mayfield and Rose, 2011), in power (Bramsen et al., 2011), or collegial (Kim and Galstyan, 2010; Bracewell et al., 2011); (2) gaining a new role, such as by pursuing power (Tomlinson et al., 2012); or (3) maintaining or altering the role or status of another individual in the dialogue. Social acts can be signaled by a variety of cue phrases as well as through a dialogue participant's observation or violation of social norms, or expectations of socially appropriate responses.

The set of acts presented in this section have been derived from work in psychology on power, status, and leadership (Anderson et al., 2001; French and Raven, 1959; Keltner et al., 2008; Owens and Sutton, 2001; Smith and Galinsky, 2010), as well as on conflict and cooperation (Brewer and Gardner, 1996; Deutsch, 2011; Jehn and Mannix, 2001). This set of social acts was designed to have broad coverage, but is not to be taken as an exclusive set. Figure 2 gives an example of a dialogue marked with the social acts.

Agreement can act as an affordance to an individual or as a means to establish solidarity between individuals. Likewise disagreement can act as a way of undermining or challenging

Agreement	Statements that a group member makes to indicate that he/she shares the same view about something another member has said or done.
Challenge Credibility	Attempts to discredit or raise doubt about another group member's qualifications or abilities.
Disagreement	Statements a group member makes to indicate that he/she does not share the same view about something another member has said or done.
Disrespect	Inappropriate statements that a group member makes to insult another member of the group.
Establish Credibility	Statements that a speaker makes to demonstrate his/her knowledge or personal experience in order to make him/herself look better in the eyes of the group.
Managerial Influence	Statements that a speaker makes to control the discussion with the goal of increasing sway over the group.
Mediation	Attempts made by a group member to resolve a conflict occurring between other group members.
Relationship Conflict	Personal, heated disagreement between individuals.
Solidarity	Statements that a group member makes to strengthen the group's sense of community and unity.
Supportive Behavior	Statements of personal support that one group member makes toward another.
Task Conflict	Disagreement over the manner in which a task is performed or over the outcome of the task.

Figure 1: The set of eleven social acts.

credibility. However, because of the special status of agreement and disagreement we consider them as two separate social acts.

Agreement can be manifested through simple phrases, such as "I agree", through negations of disagreement, such as "I am not disagreeing with you", and through more complex phrases, such as "What Adam says is in principle correct." Similarly, disagreement is manifested through simple "I disagree" phrases as well as negations of agreement, such as "I definitely do not agree with what you said."

Challenging credibility can be used by an individual to lower the status of other group members (Owens and Sutton, 2001). These challenges can be in demands to prove credibility, such as "prove your lies" and aggressive accusing questions, such as "what does that have to do with what we are talking about?". Challenging credibility can also occur through gossip, such as "X doesn't know what he is talking about". This tactic can be used by group members to moderate the power of a leader who has overstepped their boundaries (Keltner et al., 2008).

Disrespected individuals often feel they have been unjustly treated due to the disrespectful action, causing a social imbalance between them and the perpetrator (Miller, 2001). This social imbalance causes a power differential between the two individuals, thus giving the perpetrator power over the individual. Examples of disrespect include "You are a gigantic hypocrite you know that?" and "Do you speak English well?"

Establishing credibility reflects an attempt by an individual to demonstrate their credibility and fitness for leadership (Keltner et al., 2008). Evidence for establishment of credibility manifests itself in many different ways. The most common in our data set is an explicit mention of the individual's credentials, such as "I am a physicist". Alternatively a person can demonstrate their credibility by providing the group with cited information, such as

A) Propose that this page be moved to East Timor Defence Force as this is the closest translation of Forças de Defesa de Timor Leste [*Managerial Influence*]. **I have worked in Timor Leste as a government advisor, including with FDTL, and have never heard anybody ever refer to the FDTL as Military of East Timor** [*Establish Credibility*].

B) As I understand it, 'East Timor Defence Force' is considered outdated [*Managerial Influence*]. **While it was commonly used when the force was established, almost all english-language publications now use 'F-FDTL'.** [*Managerial Influence*] 'Military of East Timor' is a generic name, and **I agree that it's rarely used and not a great title.** [*Agreement*] **I'd prefer 'Timor Leste Defence Force' as this seems to be the direct translation, but this would be inconsistent with the other Wikipedia articles on the country.** [*Managerial Influence*] **Should we be bold and move this article to 'Timor Leste Defence Force'?** [*Establish Solidarity*]

A) I so totally agree with you. [*Agreement*] **'Timor Leste Defence Force' is it.** [*Agreement*] **The only reason I did not propose that was the failure to change the country page from East Timor to Timor Leste, a decision that I feel was extremely discourteous of Wikipedia considering the government's specific request that it be referred to as Timor Leste.** [*Managerial Influence*] **If you have worked there you will know that everybody uses 'Timor Leste', even the ADF but the Australian DFAT uses East Timor although the more enlightened Kiwi embassy call it TL.** [*Establish Credibility*] **I suggest we leave it for 48 hours to see if anyone has any strong feelings and then change it to ' Timor Leste Defence Force' with diverts from F-FDTL and FDTL.** [*Managerial Influence*]

Figure 2: Social acts tagged for an excerpt of a discussion taken from a Wikipedia Talk page.

"Article 10.5 paragraph 3 says...". Finally an individual can justify their opinion through the use of logic or citation of personally relevant anecdotes.

Managerial influence is used by individuals to signal that they are a leader. Examples of managerial influence include "Can we focus the discussion" and "Are we still trying to find out where the scholarly consensus is on the matter of Lukan authorship?" Figure 2 has a number of examples of managerial influence, such as A proposing to move the page and B giving factual reasons why "Military of East Timor" is an incorrect name for the page.

A person in power often acts as a mediator for disputes between other group members. Mediation itself is an attempt to resolve a conflict occurring between other group members. Individuals performing mediation may already be in position of power. Examples of mediation include "You really need to back off and take a deep breath" and "Let's just all keep calm, yes?"

Relationship conflict is a personal, heated disagreement between individuals (Jehn and Mannix, 2001). Individuals exhibiting relationship conflict are being adversarial. Examples of relationship conflict include "your arrogant blathering" and "I consider it offensive for you to assert that i insist on turning every interaction into a personality conflict.'

Further, language indicative of a desire for group solidarity encapsulates the establishment and maintenance of shared group membership. Group membership can be expressed at either the relational level (e.g. Father, co-worker, etc.) or the collective level (e.g. single mothers) (Brewer and Gardner, 1996). Language indicative of a desire for group solidarity demonstrates that an individual identifies with the group, an important characteristic of leaders (Keltner et al., 2008) and cooperators (Deutsch, 2011). This solidarity can be expressed explicitly (e.g. "We're all in this together"), covertly (e.g. as through the use of inclusive first-person pronouns), or through unconscious actions and linguistic cues, such as the use of in-group jargon, certain syntactic constructions, and mimicry.

Supportive behavior, or cooperation towards a common goal, is an example of collegiality. This type of behavior lies at the center of group dynamics. Cooperation is correlated with both overall group performance and managerial ratings of group effectiveness (Campion et al., 1996). Evidence for cooperation manifests itself in many different ways. Classically, there is the notion of cooperation on a physical task (e.g. one person helping another lift a heavy weight), or cooperation through social support (e.g. Mary says, "John's decision is excellent").

There are also more subtle, unconscious examples of cooperation between individuals, which can demonstrate a certain degree of collegiality between the individuals. One example is cooperation for the effective use of language and the building of dialogue (Garrod and Pickering, 2004). Dialogue is a complicated interaction that requires commitment from both parties. In order to maintain a stable conversation, participants must be willing to expend cognitive effort to listen, understand, and form a relevant response that advances the dialogue. The degree to which participants are able to maintain a cohesive dialogue should be reflected in the collegiality of the participants. If one participant is not cooperating, the dialogue will not progress.

Task conflict often arises during power struggles in a group where one individual is attempting to overtake the position of another (Jehn and Mannix, 2001). It is defined as disagreement over the manner in which a task is performed or over the outcome of the task. Task conflict can be manifested by actions performed to undo or challenge other's work toward a task, such as "I reverted your all your changes." Additionally, it may manifest itself as taking sides or stating positions around a conflict, such as "So yes, I will not be editing but I will be monitoring to see if some other naive soul wishes to and try to support them (and revert the vandalism that happens from time to time)."

4 A Generative Model for Identifying Social Acts

A system for the recognition of intentions and goals is the foundation for the understanding of social implicatures in social dialogue. Here we present a generative model for identifying social acts at the utterance level. The model generates utterances exhibiting a social act as a series of gappy patterns. A gappy pattern consists of one or more words in between which there can be gaps, or wildcards, which match any contiguous sequence of non-whitespace characters. Associated with the gap is a width, which determines how many words the gap can match. An example of a gappy pattern with a gap width of one extracted for a three utterances is shown in Figure 3.

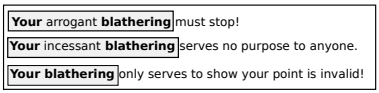

Figure 3: An example of a gappy pattern consisting of a single gap which can capture zero or one words and three utterances for which the pattern matches.

The generative model we employ is a modified version of the model introduced by Gimpel and Smith (2011) for machine translation. The main difference is that our model is supervised whereas Gimpel and Smith's model is unsupervised. The supervision in our

model helps to guide the generative process in discovering gappy patterns related to a specific social act.

We assume that we are given a set of utterances $u_{1:k}$ where each utterance is made up of n-words, $w_{1:n}$, and a set of labels $l_{1:k}$ such that label l_i is associated with utterance u_i. Following the terminology of Gimpel and Smith (2011), gappy patterns are represented over the words in the utterances as a color where each word in the utterance has a color assignment, i.e. there is a vector of color assignments $c_{i:n}$ for each utterance. A color C_j is a set made up of the c_i color-word associations such that $C_j = i : c_i = j$. A pattern is built from each color C_j by concatenating the words assigned to the color from left to write inserting gaps between non-adjacent words.

The generative story for a single utterance entails sampling the following:

1. The number of words, n, in an utterance as a $Poisson$ distribution with parameter β.
2. The number of unique colors in an utterance given a $Uniform$ distribution.
3. The color c_i for each word w_i in the utterance as a $Uniform$ distribution.
4. The probability of the pattern associated with each color C_j for utterances with label l as a $Multinominal$ with parameter μ.

Thus, to generate patterns we must calculate the probability of generating an utterance of length n, with m colors, label l, and color assignments $c_{1:n}$ as:

$$p(w_{1:n}, c_{1:n}, m|\beta, \mu) = \frac{1}{Z}(\frac{\beta^n}{n!}e^{-\beta})(\frac{1}{n})(\frac{1}{m})^n \prod_{j=1}^{m} p_\mu(\pi(C_j) \mid l)$$

where Z is a normalization factor.

The multinomial distribution, p_μ, is modeled using a Dirichlet process. A Dirichlet process can be treated as a probability distribution over random distributions which facilitates an unbounded set of parameters $\mu \sim DP(\alpha, P_0)$, where α is the concentration parameter and P_0 is the base distribution. The base distribution is made up of: (1) a $Poisson$ distribution with parameter υ over the number of words in the utterance; (2) a uniform distribution for each word; (3) a uniform distribution over the number of gaps given the number of words; and (4) a uniform distribution over the arrangement of gaps given the number of gaps and words.

Gibbs sampling is used to sample the posterior distribution $p(\{c^{(i)}, m^{(i)}\}_{i=1}^{U} \mid \{w^{(i)}\}_{i=1}^{U}, \upsilon, \alpha)$, where U is the total number of utterances. Gibbs sampling is a form of Markov Chain Monte Carlo (MCMC), which is used to obtain a sequence of random samples from a joint probability distribution of two or more random variables. In particular, Gibbs sampling is used when direct sampling is prohibitive. The Gibbs sampler makes repeated iterations. During each of the iterations it samples a new color for each of the color assignments (c_i). A new color is assigned to c_i by first removing the current color and then choosing from either one the other m colors in the utterance or a creating a new color. The probability of choosing a new color is proportional to:

$$\frac{N_{\pi(\{i\})} + \alpha P_0(\pi(\{i\}) \mid l)}{N + \alpha}$$

where $N_{\pi(\{i\})}$ is the count of pattern π over all utterances with label l and N is the total count of all the patterns. The probability of assigning an existing color j to c_i is proportional to:

$$\frac{N_{\pi(C_j \cup \{i\})} + \alpha P_0(\pi(C_j \cup \{i\}) \mid l)}{N_{\pi(C_j)} + \alpha P_0(\pi(C_j) \mid l)}$$

where $C_j \cup \{i\}$ states that c_i is being added to C_j.

After discovering gappy patterns using the described generative model, we build a binary classifier for each of the social acts we wish to identify. In particular, we use a logistic regression classifier to the learn a set of weights for each of the gappy patterns, which denotes the discriminatory ability of the pattern in identifying the social act. A social act is manifested in an utterance when $H(z) = 1$, where $H(z)$ is calculated as:

$$H(z) = \begin{cases} 1, & \frac{1}{1+e^{-z}} > 0.5 \\ 0, & \frac{1}{1+e^{-z}} \leq 0.5 \end{cases}$$

where $z = \sum_{i=1}^{m} w_i * \phi(\pi_i, w_{i:n})$ and ϕ returns 1 if pattern π_i is present in the utterance made up of words $w_{1:n}$. An utterance is then assigned all social acts whose accompanying classifier results in an $H(z) = 1$.

5 Data Collection & Annotation

We constructed a corpus of 215 social dialogues extracted from English Wikipedia talk pages, public forums, and chat transcripts. A total of 21,067 utterances were extracted from the social dialogues. On average each utterance contained 18.7 words.

A web-based interface was constructed for annotation. The interface listed for a single social dialogue all of the utterances in the order in which they appeared in the dialogue along with speaker information. Social acts were annotated by through the use a drop-down list and allowed for an arbitrary number of social acts to be assigned to an utterance.

Each utterance was annotated by two annotators, who were trained linguists, as either being a manifestation or not of one or more of the eleven social acts described in section 3. In total, 8,149 (38.7%) of the total utterances had at least one of the eleven social acts annotated. On average each utterance was assigned with 0.98 social acts.

We first looked at the inter-annotator agreement for if an utterance exhibited any social act or not. The results are listed in Table 1. The micro-averaged mutual F-Measure was 94.0% which broke down as 84.0% F-Measure for "exhibited" and a 94.0% F-Measure for "Not Exhibited." The results show that expert annotators can reliably determine the presence or absence of social actions in utterances.

Next, we examined the inter-annotator agreement rate for each of the individual social acts. Table 2 shows the number of utterances annotated for each social act, the Cohen's kappa (Cohen, 1960), and the mutual F-measure.

As seen in table 2, the kappa values range from 0.13 to 0.53. In contrast, the kappa values for dialogue acts have been reported as high as 0.76 for ANSWER and as low as 0.15 for COMMITTING-SPEAKER-FUTURE-ACTION (Allen and Core, 1997). More recent work in dialogue act annotation has been performed by Geertzen and Bunt (2006) who report kappa

	F-Measure
Exhibited	84.0%
Not Exhibited	94.0%
micro-Averaged	94.0%
macro-Averaged	89.0%

Table 1: The mutual F-Measure for an utterance exhibiting or not exhibiting any social act.

	# Annotated	Kappa	F-Measure
Agreement	295	0.38	0.76
Challenge Credibility	1,113	0.36	0.33
Disagreement	434	0.46	0.71
Disrespect	367	0.24	0.54
Establish Credibility	364	0.53	0.45
Managerial Influence	2,486	0.23	0.16
Mediation	167	0.26	0.52
Relationship Conflict	399	0.13	0.21
Solidarity	100	0.52	0.42
Supportive Behavior	269	0.36	0.68
Task Conflict	2,802	0.35	0.31

Table 2: The number of annotations and kappa per social act.

values between 0.21 and 1.0 for the top level of a hierarchical dialogue act scheme (Bunt et al., 2010). However, they only calculated kappa for utterances in which both annotators had assigned a dialogue act, i.e. utterances where only one annotator assigned a dialogue act were ignored. In contrast, we calculated our kappa values for all utterances where at least one annotator assigned a social act.

Other work in social acts have seen kappa values in a similar range, such as the Bender et al. (2011) who report kappa values from 0.13 to 0.63. Given the complexities presented by annotating the social intentions of dialogue participants, we believe that the kappa values reported here are acceptable given the accompanying F-Measures.

6 Experimental Results

The utterances in the corpus were labeled with a social act if it was assigned by either of the annotators. The reason for this was two-fold: (1) The definitions of the social acts can be interpreted differently depending on internal thresholding (e.g. how hostile does a remark need to be in order to be classified as a Relationship Conflict?) and no interpretation is truly incorrect. (2) Given the sparsity of annotation for some of the social acts (e.g. Solidarity only having 100 total annotations) made it necessary to include any instance. Experiments were then performed using a standard 80/10/10 split where 80% of the data was used for training, 10% for development, and 10% for testing. We examined an n-gram based approach for comparison to the gappy patterns.

For the gappy pattern method, we constrained the gap width to 2, meaning that the maximum number of words a gap can consume was two. In addition, the sampling process was ran for 1,000 iterations with a burn-in of 50 iterations. A minimum probability of

70% was needed to initiate a new color and a minimum probability of 40% was needed to propagate a color. These parameters were tuned using the development set.

The N-gram based method is a simplification of the gappy pattern method, i.e. it is patterns without gaps. First, n-grams were extracted from the annotated data. Second, the n-grams were pruned using information gain where the exact number of features retained was determined using the development set. Finally, the remaining n-grams were used as binary features in an Support Vector Machine (SVM) classifier with a linear kernel. SVMs are frequently used in text classification and have been shown to give good results for dialogue acts (Hu et al., 2009). We examined using unigrams (1-gram) and unigrams and bigrams (1+2-grams). Other size bigrams were tried as well as incorporating part-of-speech, but resulted in extremely poor performance.

	Precision	Recall	F-Measure
Gappy	49.5%	51.3%	50.4%
1-gram	43.8%	43.2%	43.5%
1+2-grams	38.4%	37.8%	38.1%

Table 3: Micro averaged precision, recall, and F-measure for identifying the 11 social acts using an 80/20 split.

Table 3 lists the micro-averaged precision, recall, and F-measure for the identification of the 11 social acts. As can be seen in the table, the gappy-pattern based approach had an increase of 6.9% in F-Measure over the best n-gram approach (1-gram). This included an increase in precision of 5.7% and in recall of 8.1%. The unigram and bigram (1+2-grams) based method performed the worst, mostly due to the size of data. In contrast, the gappy pattern approach was able to learn a mix of patterns of varying lengths and gaps (up to 2) that were able to separate the social acts. Figure 4 shows example patterns for each of the social acts that were discovered by the generative model and then weighted as a positive indicator by logistic regression.

Conclusion

In this work we have begun a process of revisiting classical theories of dialogue coherence and understanding. Our initial efforts have been to show how the social intentions behind dialogue segments can be understood. Understanding the social goals of individuals is critical to properly parsing dialogue in a modern age of social media. We introduced a set of social acts designed to capture the social intentions of dialogue participants. Our results show that social acts can be reliably understood by annotators and that a novel method for detecting speech acts, based on a generative method for identifying gappy patterns, can achieve results consistent with work in recognizing dialogue acts.

This work creates a foundation for building models of the higher level intentional structure of social dialogue and attention. The intentional structure around the social acts could provide valuable insight into the social goals of a dialogue and the dialogue participants. It is also critical that future work addresses the way in which social attention is modulated within a coherent dialogue.

Robust, lexicalized native language identification

Julian BROOKE *Graeme HIRST*
University of Toronto, Department of Computer Science, Toronto, Canada
jbrooke@cs.toronto.edu, gh@cs.toronto.edu

ABSTRACT
Previous approaches to the task of native language identification (Koppel et al., 2005) have been limited to small, within-corpus evaluations. Because these are restrictive and unreliable, we apply cross-corpus evaluation to the task. We demonstrate the efficacy of lexical features, which had previously been avoided due to the within-corpus topic confounds, and provide a detailed evaluation of various options, including a simple bias adaptation technique and a number of classifier algorithms. Using a new web corpus as a training set, we reach high classification accuracy for a 7-language task, performance which is robust across two independent test sets. Although we show that even higher accuracy is possible using cross-validation, we present strong evidence calling into question the validity of cross-validation evaluation using the standard dataset.

KEYWORDS: Native language identification, text classification, evaluation.

Proceedings of COLING 2012: Technical Papers, pages 391–408,
COLING 2012, Mumbai, December 2012.

1 Introduction

Native language identification (Koppel et al., 2005) is a task in which features of the second language (L2) texts written by non-native speakers of various different native language (L1) backgrounds are used to identify those backgrounds. One potential application is as a facet of author profiling, which can be used to identify those who misrepresent themselves online (Fette et al., 2007). Another is as a preprocessing step to language learner error correction (Leacock et al., 2010): for example, Rozovskaya and Roth (2011) use L1-specific information to improve their preposition-correction system, and recent work in collocation correction relies on the specific forms present in the writer's native language (Chang et al., 2008; Dahlmeier and Ng, 2011).

As a distinct task in computational linguistics, native language identification has been reasonably well-addressed (Koppel et al., 2005; Tsur and Rappoport, 2007; Wong and Dras, 2009), and in fact there has been a flurry of recent activity (Kochmar, 2011; Golcher and Reznicek, 2011; Wong and Dras, 2011; Brooke and Hirst, 2011; Wong et al., 2012). Though a wide range of feature types has been explored—with conflicting results—the evaluation of these feature sets has been fairly uniform: training and testing in one of several small corpora of learner essays (Granger et al., 2009; Yannakoudakis et al., 2011; Lüdeling et al., 2008), which are unfortunately quite expensive to collect. A notable problem with these corpora with respect to native language identification, however, is a clear interaction between native language and essay topic. Generally speaking, the solution in previous work has been to avoid the use of lexical features that might carry topical information, limiting feature sets to syntactic and phonological phenomena. There are two reasons to be critical of this approach. First, there are almost certainly kinds of language transfer (Odlin, 1989), i.e. transfer related to lexical choice, that are being overlooked. Second, and more troubling, is that avoiding the lexicon is not fully effective as a means of countering the effects of topic: some recent work indicates that variation in topic also has significant influence on non-lexical features (Golcher and Reznicek, 2011; Brooke and Hirst, 2011), calling into question the reliability of previous results that assume otherwise.

The approach we present here resolves this tension by requiring training and test sets that are independently sampled. Although corpora may have some form of confounding variation that may artificially inflate or (in some cases) lower performance relative to other samples from the same corpus, any variation that is consistent across very distinct corpora is likely to be a true indicator of L1. Although we test on the typical essay corpora used by other researchers, we train on a very different dataset, a large but messy corpus of journal entries scraped from a language learner website. Without the distraction of (irrelevant) topic bias, we can test the efficacy of lexical features, including *n*-grams and dependencies. We also test a number of options at the level of the classifier, most notably a multiclass support vector machine (SVM) decision-tree classifier that leverages the genetic relationships among languages, and a simple but elegant method for adapting an SVM classifier to the test corpus without integrating the confounding variation found there. Our best classifier with lexical and syntactic features provides results that compare well with previously-reported single-corpus performance; we also present, however, evidence that calls into question the validity of these previous results, showing that topic bias within the corpus is having a major effect and that indeed the performance of models built in the topic-biased ICLE corpus is not robust, regardless of the features chosen.

2 Related Work

The earliest focused work on native language detection was by Koppel et al. (2005). They classified texts from the International Corpus of Learner English (ICLE) into one of five (European) native language backgrounds using support vector machines. They described their feature set as stylistic; features included the frequency of function words, rare POS bigrams, letter *n*-grams, and spelling errors. They reported a performance of just over 80% on the task using the full feature set.

Other work on the ICLE includes that of Tsur and Rappoport (2007), who were concerned with identifying phonological language transfer; they focused on the construction of character *n*-gram models, reporting 66% accuracy with just these sub-word features, with only a small drop in performance when the dominant topic words in each sub-corpus (as identified using *tf-idf*) were removed. Wong and Dras (2009) investigated particular types of syntactic error: subject-verb disagreement, noun-number disagreement, and determiner problems, relating the appearance of these errors to the features of relevant L1s. However, they reported that these features do not help with classification, and they also note that character *n*-grams, though effective on their own, are not particularly useful in combination with other features. In follow-up work, Wong and Dras (2011) attained the best results to date, 80% performance on a 7-language task, by including syntactic production rules. Recent work by Wong et al. (2012) and Swanson and Charniak (2012) has explored the use of statistical grammatical induction techniques—Adaptor Grammars in the former case, Tree Substitution Grammars in the latter—to select better syntatic features for classification.

The work of Kochmar (2011) is distinct from those above in a number of ways: she used a different corpus of essays, derived from the Cambridge Learner Corpus[1], and concentrated on pairwise (SVM) classification within two European language sub-families. An exhaustive feature analysis indicated that character *n*-gram frequency is the most useful feature type for her task; unlike Wong and Dras (2011), syntactic production rules provided little benefit. With respect to lexical features, Kochmar presented some results using word *n*-grams, but regarded them as attributable to topic bias in the corpus. Error-type features (e.g. spelling, missing determiner) as provided by the corpus annotation offered little improvement over the high performance offered by the distributional features (e.g. POS/character *n*-grams).

Golcher and Reznicek (2011) used a string-distance metric to identify the native language of German learners in the Falko corpus (Lüdeling et al., 2008), and contrasted this with a topic classification task in the same corpus. Even after taking steps to mitigate topic bias (removing the influence of the words in the title), the usefulness of the three feature types that they investigated (word token, word lemma, and POS) was remarkably similar across the two tasks, with the word features dominating in both cases. Surprisingly, the effect of POS was higher in topic classification than it is on L1-classification. Earlier work of ours (Brooke and Hirst, 2011) also tested the confounding effect of topic in the context of native language identification. To motivate the use of new corpora for future research, we segregated a portion of the ICLE by topic and found that all the core features used by Koppel et al. for L1-identification showed significant drops in performance when topic-segregated 2-fold cross-validation is compared to standard (randomized) 2-fold cross-validation. This was particularly true of character *n*-grams.

[1] http://www.cup.cam.ac.uk/gb/elt/catalogue/subject/custom/item3646603/Cambridge-International-Corpus-Cambridge-Learner-Corpus

Finally, we note that native language identification has also been included as an element of larger author profiling studies (Estival et al., 2007; Garera and Yarowsky, 2009). A closely related task is the identification of translated texts and/or their language of origin (Baroni and Bernardini, 2006; van Halteren, 2008; Koppel and Ordan, 2011), though the tasks are distinct because the learners included in native language identification studies are usually at a level of linguistic proficiency below that of a professional translator (who in any case may be writing in his or her L1, rather than an L2) and are not operating under the requirement of faithfulness to some original text. Distinguishing whether or not a text is non-native (Tomokiyo and Jones, 2001) is also a related task, but most work in the area of L1 identification, including ours, assumes that we already know that a text was produced by a non-native speaker.

3 Corpora

Our training corpus is a set of 154,702 English journal entries collected from the Lang-8 language learner website.[2] In all, 65 L1s are represented, but only 14 languages have more than 1000 entries, with Asian languages being overrepresented (the website is based in Japan). Users may write whatever they want in their journal, and there are a variety of text types (some learners post assignments or translation questions, for instance), though the majority can be described as short personal narratives. The English proficiency of these learners varies widely; other users of the site can comment on journal entries and offer suggestions to improve the text. In the corpus, the entries are tagged for username, title, native language (which is provided by the user when they register), and date and time of posting. The average length of an entry is about 150 word tokens after our pre-processing, which strips HTML tags and non-ASCII characters prior to parsing—words with non-ASCII characters are ultimately disregarded during feature selection. Since these texts are relatively short compared to our test sets, for our purposes here we append consecutive short texts of writers with the same L1 (often the same author) until they are at least 250 tokens in length, which results in an average length of 431 tokens.

The International Corpus of Learner English (Granger et al., 2009), or ICLE, is a set of 6085 non-native speaker essays collected from university students at institutions around the world; v2.0 represents includes 16 L1 backgrounds, mostly European. Other variables tagged in the corpus are topic, genre (argumentative or literary), setting (timed writing or not), age, gender, and educational institution, all of which vary in unpredictable ways throughout the corpus. As already mentioned, a major problem with the ICLE is topic variation, which is both unnaturally strong and often arbitrary; for practical reasons, the different parts of the corpus were collected by EFL instructors in different countries, who chose a small, often fairly distinct set of topics for their students (of a particular L1 background) to write about. To investigate the proficiency level of students, the creators tested a sample of each native language for English level using the *Common European Framework* (CEF), showing that while learners in the corpus are generally at least of intermediate proficiency, the percentage of advanced learners is very different for different L1 backgrounds, another potential confound. The average text length in the ICLE is 617 words.

Our third learner corpus is a small sample of the First Certificate in English (FCE) portion of the Cambridge Learner Corpus, which has recently been released for the purposes of

[2]The URL is http://lang-8.com. We do not have permission to distribute the corpus directly; following Sharoff (2006), we will release a list of web URLs and software which can be used to recreate the corpus.

L1	Corpus		
	Lang-8	ICLE	FCE
Japanese	59156	366	81
Chinese	38044	982	66
French	1414	347	146
Spanish	3080	251	200
Italian	1072	392	76
Polish	1549	365	76
Russian	7159	276	83

Table 1: Number of texts in learner corpora, by L1.

essay scoring evaluation (Yannakoudakis et al., 2011); 16 different L1 backgrounds are represented. Each of the 1244 texts consists of two short answers in the form of a letter, a report, an article, or a short story, each tagged with the score provided by a trained examiner. The texts are also marked for specific usage errors, though we stripped this information in our pre-processing step. The average length of the texts in the FCE corpus is 428 words, or about 200 words less than the ICLE.

For this study, we selected the seven languages which had sufficient numbers in all three corpora, i.e. at least 1000 texts in the Lang-8 corpus, 200 texts in the ICLE, and 50 texts in the FCE. Table 1 shows, for each L1, the number of texts present in each corpus. For testing in the ICLE, we use 200 from each set, and a separate set of 50 per L1 is used for our bias adaptation method. For testing in the FCE, we use 50 texts, and 15 texts for bias adaptation.

4 Classifier Experiments

We split our main experiments into two parts. In our initial investigation, we found that using the full set of feature types, to be described later in Section 5, provided near-optimal results. Given that exploring the exhaustive set of combinations is not feasible in this space, we elect to first take the full feature set as fixed and turn our attention to higher-level classifier options, establishing the best among those options before we proceed with a feature analysis.

4.1 Classifier Options

Our experiments included testing the following options:

Balanced training (bal) vs. cost weight (cost) Statistical classifiers generally depend on having similar class distributions in training and testing sets, an assumption which is violated here. There are two simple ways to handle this problem: either balancing the training sets by discarding extra training data, or training the classifier with using different cost weights for different classes, promoting classification of rarer classes to the level expected in the (balanced) test data. We use the cost weight equation from Morik et al. (1999).

Binary (bin) vs. frequency (freq) features Previous work has mostly used normalized frequency rather than binary occurrence in a text as the feature value used for classification; Wong and Dras (2011) are an exception, but they do not justify that choice.

SVM vs. MaxEnt classifier Support vector machines were a popular option in previous work, but Wong and Dras (2011) report better performance with a Maximum Entropy (MaxEnt) classifier. A full discussion of these two machine learning methods is omitted here, though we note that (pairwise) SVMs are generally conceptualized as a hyperplane which maximizes the margin between classes in the feature space, while MaxEnt is a multinomial logistic model built by constrained maximization of the probability of the training data. For SVM classification (see below), we use LIBLINEAR (Fan et al., 2008), which is optimized for linear kernel classification of large datasets; except as explicitly mentioned below, we present results using default parameter settings (which were found to give good results). Feature vectors are normalized to the unit circle (Graf and Borer, 2001). For MaxEnt we follow Wong and Dras (2011) in using MegaM.[3]

Regularization parameters In the context of building a robust classifier for cross-corpus classification, the regularization of the model (Alpaydin, 2010), i.e. the degree to which the classifier increases in complexity to fit the training data, is of obvious relevance. For SVMs, the key parameter is C, which controls the penalty for misclassified examples in the training set: a large value of C means these errors have a higher influence on the objective function, promoting more complex models that minimize error but may result in overfitting. For the MaxEnt classifier, the λ parameter controls the influence of a Gaussian prior on the feature weights: low values of λ correspond to an imprecise prior, allowing the feature weights to fit the data. We tuned the corresponding parameter for each classifier configuration using 7-class task performance in the development set for each test corpus.[4]

Multiclass SVM type While MaxEnt has a natural multiclass interpretation, an SVM decision plane is appropriate only for binary choice. A standard approach to multiclass SVM is to combine multiple pairwise SVM classifiers (Hsu and Lin, 2002). Two general options in this vein are *one vs. one* (1v1), where $n(n-1)/2$ individual classifiers (for n classes), each trained on one pair of classes, are combined, and *one vs. all* (1va), where n classifiers are trained by separating one class from all the others. The winner of 1va is obviously the class with the highest margin (distance from the decision plane), but for 1v1 it is typically the class which is chosen by the most classifiers (ties are broken in favor of the highest margins). A third, novel option is made possible by the genetic relationships among languages in our test set: an SVM binary decision tree (tree), presented in figure 1.[5] Note that tree classifiers have a significant performance advantage over both 1va and 1v1 classifiers with respect to the number of classifiers required ($n-1$), and an advantage over the 1va classifiers with respect to the average size of the training sets used to build those classifiers. Finally, Crammer and Singer (2002) have proposed a multiclass SVM classifier based on class prototypes (pro) rather than hyperplane boundaries, and we also test this option (as implemented in LIBLINEAR).

Bias adaption, pairwise (adS) Since there are significant differences in the genre, domain, and quality of texts across our training and test corpora, some form of domain adaption (Daumé and Marcu, 2006; Bruzzone and Marconcini, 2010) would almost certainly be

[3] http://www.cs.utah.edu/~hal/megam/

[4] Since the C parameter is selected once for each configuration based on the 7-class task, some results that we would otherwise expect to be equivalent, e.g. the 2-class SVM classifers, actually vary slightly.

[5] There is some controversy in the literature about the genetic relationship amongst Romance languages; see the discussion by Kochmar (2011).

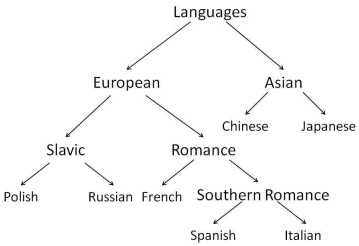

Figure 1: Binary decision tree for SVM experiments

helpful. However, even unsupervised forms of transfer learning (Pan and Yang, 2010) are likely to take advantage of those confounding factors that prompted us to reject within-corpus evaluation; we believe that any change to the feature weights based on samples from the same corpus that our test set is drawn from is ultimately self-defeating in this context. However, there is one key parameter to these that is not a feature weight: the bias. In pairwise SVM, changing the bias slides the hyperplane, changing only the total number of positive (or negative) features required to make a classification, not the individual influence of a particular feature (i.e. the sign of a feature weight). With respect to its effect (changing the balance of classes), it is closely related to our cost factor option above; however, whereas the cost factor is a parameter used during training, we shift the bias using our own iterative process after the model is built, using a sample from the same corpus as the test set (a development set).[6] Our algorithm is as follows: we first initialize our step size to the absolute value of the original bias, and then we iteratively modify the bias, adding or subtracting the present step size such that we are moving in the direction of a distribution where the ratio of classes predicted in our development set is the same as in the final test set, reclassifying the data after each step.[7] If we overshoot the desired ratio, we halve the step size, and continue until we reach the desired ratio or the predicted ratio does not change for 10 iterations. We do this separately for each test set with the corresponding development set.

Bias adaption, multi (adM) The MaxEnt and SVM prototype classifiers also have bias terms that can be optimized, but unlike the pairwise classifiers they cannot be dealt with one at a time; optimizing the bias for one class will affect the others in unpredictable ways. We proceed with the same basic algorithm as the pairwise classifier, but we do this for all bias terms simultaneously, i.e. all biases are adjusted in a single step. Each bias has a separate step size, and the optimization ends when the entire distribution is correct or nothing has changed in 10 iterations. We also implemented this for SVM 1va, i.e. interpreting it as a single multiclass classifier rather than a set of pairwise classifiers.

[6]Admittedly, we could accomplish this with additional parameter tuning, but there are both practical and principled reasons for doing it this way: it is much faster to modify the biases directly rather than retraining the model, and, more importantly, we want to preserve the original feature weights; we require that they do not reflect exposure to the confounds of the testing corpus in any way.

[7]This requires knowledge of that distribution. However, it is otherwise unsupervised in that we are only concerned with the distribution of predictions: we do not use the true class values except to create the appropriate subsets for the SVM 1v1 and SVM tree classifiers.

Table 2: Native language classification accuracy (%) for varying classifier options. Bold indicates best result in column, italics indicates difference from the pivot classifier (11).

4.2 Results

Table 2 shows the results of our experiments. In addition to the full 7-language task accuracy (the 'All' columns), we also present results classifying the two major subgroups; note that these are distinct tasks, e.g. for European it is the accuracy of a 5-language task, not the accuracy of the classification of those 5 languages within the 7-language task (see Figure 1 for our language classification schema). However, in our discussion, we focus on results for the full 7-language task. The upper part of Table 2 includes various key classifier options, ordered by their 7-way ICLE accuracy, while the bottom includes other options; the best classifier (11) is used as a pivot between the two.[8] The aspect(s) of the configuration that are different from the pivot are in italics, and the best results in each column are in bold. For each classifier, we report the results using the best C or λ values from an initial series of runs using the development set.

Unsurprisingly, we see better results when we use all the data at our disposal (11), rather than forcing balanced test cases (12). This result is useful, though, because it indicates that our consistently high performance in distinguishing Chinese and Japanese elsewhere in Table 2 is a result of that extra data, and not other factors, i.e. the fact that unlike our other language groupings, Chinese and Japanese do not belong to a single genetic language family (Comrie, 1987). Also clear is the preference for binary (11) rather than frequency-based (13) feature values: one possible explanation is that, in these relatively short texts, there is high variability in normalized frequencies, and a simpler metric, by having less variability, is easier for the classifier to leverage. In general, slightly less regularization (high C, low λ) values were preferred, though most were reasonably close to the default values; tuning made little difference, particularly for the SVM classifiers.

[8] The effects of the options in each of the two parts of the table are fairly independent, so for simplicity of presentation we test them separately.

Between the two main classifier types, the MaxEnt classifier was, with the appropriate choice of λ (5), the best performing classifier in the ICLE when no bias adaption was used; it was, however, worse than almost all of our SVM options in the main 7-language classification task when bias tuning was allowed (7). This does not appear to be a failure of the adaption algorithm, but rather a real distinction between the two classifiers: our experience is that the SVM classifiers are less robust, i.e. more prone to errors when training and test sets differ significantly, but they can be easily recalibrated for optimal performance with a relatively small amount of information. Here, we show that changing the bias alone is enough for major gains across all the SVM types (6,8–11), results which are statistically significant.

Our novel binary tree classifier (2,6) is competitive but ultimately performs poorly compared than other options, suggesting that the simplicity of the classifier does come with a trade-off in performance. The 1va classifiers (3,9,11) are consistently better than 1v1 (1,8), while the performance of the prototype-based SVM (4,10) is nearly indistinguishable from 1va. This is somewhat surprising, since we might expect a 1v1 or prototype approach to be able to better deal with the commonalities and differences among languages than the 1va, which lumps diverse languages into a single 'other' category. With respect to the 1va classifier, it does not seem to matter much whether pairwise (9) or single classifier (11) bias tuning is used; the latter gave us the best 7-class performance in the ICLE (and we use it as our best classifier), but the former gave slightly better performance in the FCE. In the ICLE, the difference between the best bias-adapted 1va classifier and the 1v1, tree, and MaxEnt classifiers is statistically significant (χ^2 test, $p < 0.001$).

5 Feature Analysis

5.1 Features

Our model includes the following feature types:

Function words A common feature in stylistic analysis. Our list of 416 common English words comes from the LIWC (Pennebaker et al., 2001).

Character n-grams (unigrams, bigrams, and trigrams) For bigrams and trigrams, the beginning and end of a word are treated as special characters.

Word n-grams (unigrams and bigrams) Note that word n-grams are a superset of function words. Punctuation is included.

POS n-grams (unigrams, bigrams, and trigrams) POS tagging is provided by the Stanford Parser V1.6.9 (Klein and Manning, 2003), also used by Wong and Dras (2011).

POS/function mixture n-grams (bigrams and trigrams) Wong et al. (2012) report better results with POS n-grams that retain the identity of individual function words rather than using their part of speech.

CFG productions Context-free grammar production rules, as provided by the Stanford parser. Lexical production rules are not included.

Dependencies Dependencies consist of two lexical items and the syntactic relationship between them. Also produced by the Stanford parser (de Marneffe et al., 2006).

Features	Asian		European		All

Table 3: Native language classification accuracy (%), by feature set. Bold indicates best result in column.

Syntactic Features POS *n*-grams, POS/function mixture *n*-grams, and CFG productions.

Lexical Features Word *n*-grams and dependencies.

Proper Nouns Not actually a separate feature, proper nouns are included by default in character and word *n*-grams as well as dependencies. They are obviously relevant to the task, but there are applications (e.g. forensic profiling) where they might not be appropriate, since they do not directly indicate language transfer from the L1 but rather reflect real-world correlations between native language and country of residence, etc. Here, we report results with all proper nouns excluded from consideration for all relevant features.

Feature Selection Wong and Dras (2011) tested feature selection based on information gain, but it provided no improvement in performance. For practical reasons, we have included by default a simple frequency-based feature selection; only features that appear in 5 different texts in the training set are included. Even with this restriction, our feature set has almost 800,000 features. Here, we test the effect of a higher frequency cutoff (at 20), and limiting our set to features with positive information gain.

5.2 Analysis

Again, we focus on the results of the full 7-language task (the 'All' columns). Clearly, all the feature types can be used to distinguish native language: each of the results in Table 3 is well above a chance baseline, though function words (1) and character *n*-grams (2) give a fairly modest performance individually. Compared to these, production (5) rules are markedly more useful, a result which is compatible with the conclusions of Wong and

Dras (2011). Nonetheless POS (3) and in particular mixed POS/function words *n*-grams (4) offer even better performance, despite being somewhat simpler. Compared to the latter of these, the usefulness of lexical dependencies (6) is muted, and shows a very inconsistent performance across the two test sets. Word *n*-grams (7), however, alone account for almost all of the accuracy we see when all features are combined.

Adding the POS features and CFG productions (8) generally boosts performance, suggesting that the syntactic features may not be entirely redundant, while the combination of the lexical features also provides a small improvement in the 7-language ICLE task, though the FCE is worse (9). Further adding the syntactic features to the lexical features increases performance for most of the tasks (10), while including character *n*-grams tends to degrade performance (11). Finally, we exhaustively tested feature combinations and found that the best performing for the 7-language task used only the two best individual feature types, POS/function word mixtures and lexical *n*-grams, though the differences among all the options containing lexical *n*-grams are not statistically significant (12).

When we remove proper nouns (13), there is a modest drop in performance, indicating that they had some positive role in the classification, but the benefits of using lexical features goes well beyond proper nouns. Additional frequency-based feature selection (14) has a small, mostly negative effect, as does restricting features to those with positive information gain (15). In general, we see no evidence that a simpler model is preferred in this case, though if speed is a concern one can be used without too much loss.

We also looked briefly at the individual lexical features that were useful based on their information gain in the training set. One thing that was immediately evident is that some common, entirely correct English words and expressions were extremely helpful for distinguishing native languages. For example, the phrase *decide to* was ranked high: we note that in at least one language in our set (French), a closely analogous cognate construction *decider de* exists, whereas another language, Chinese, has no analogous construction, since the verb that most closely means *decide to* (*jueding*) is phonetically dissimilar, has no element corresponding to *to*, is more common as a noun, and in fact is pragmatically associated only with major decisions, often in a legal context (closer to the English *make a decision to*). By default, learners will prefer forms that correspond to those from their L1 (Odlin, 1989), and lexical features are key to identifying this kind of language transfer.

6 ICLE-training Experiments

One of the primary motivations for our cross-corpus approach to NLI is the confounding variation found in the ICLE corpus. In this section, we turn to using the ICLE as a training corpus in order to highlight these problems, particularly those relevant to 'stylistic' features, which have been thought of as immune to these effects. The first experiment, the results of which are presented in Table 4, consists of two types of 2-fold cross-validation in the ICLE corpus: the first is standard, randomized cross-validation, while in the second, the two folds (of 700 texts each) are segregated by essay prompt; essays based on a given prompt are in one fold or the other.[9] For this we use the 1va classifier without any bias adaption, which is unnecessary in the case of cross-validation.

Within the ICLE, we see in the 'Difference' column of Table 4 the consistent effects of essay

[9]This experiment is possible only in the ICLE, since titles in the Lang-8 are freely chosen by each writer, and there is little variety of prompts in the FCE.

Features	Random	Segregated	Difference
Chance baseline	14.3	14.3	–
(1) Function words	58.0	46.7	−11.3
(2) Character *n*-grams	51.2	48.2	−3.0
(3) POS *n*-grams	83.3	72.2	−11.1
(4) POS/function *n*-grams	87.6	79.2	−10.4
(5) CFG productions	86.1	79.7	−6.4
(6) Dependencies	89.1	77.1	−12.0
(7) Word *n*-grams	94.3	81.3	−13.0
(8) All (1–7)	90.4	81.6	−8.8

Table 4: ICLE within-corpus experiment classification accuracy (%), by feature set.

prompt on classification, across all kinds of features. The effects on lexical features (6,7) are, not surprisingly, most pronounced, but other popular features are also implicated to varying degrees. The effectiveness of various features under both conditions roughly mirrors the results in the previous section, though there are a few notable exceptions: for instance, production rules (5) were more useful here than in the Lang-8 trained cross-corpus experiments; this is interesting since many of the most recent results in the ICLE (Wong and Dras, 2011; Swanson and Charniak, 2012) make use of these grammatical features. Surprisingly, character *n*-grams were the least affected, a contrast from our earlier work on ICLE topic bias (Brooke and Hirst, 2011), though there remains little doubt that they are inferior features for this task. Lexical *n*-grams are ultimately the most preferred feature (7), even when topic effects are partially[10] controlled for.

We also present cross-corpus experiments with the FCE and a language-balanced 150-text portion of the Lang-8 corpus as test sets. As with our training set, this test set consists of combined texts, this time with a minimum length of 500, making the texts of comparable length to those in the ICLE. We create another set of 50 texts for bias adaption. In the latter experiment, we also include a special set of features: the POS/function mixture 5-grams which were selected by the adaptor grammars of Wong et al. (2012), providing superior performance over exhaustive enumerations. Since these features were derived from the ICLE, they could not be defensibly used in other experiments (i.e. with the ICLE as a test set), but we can test their usefulness here. Since the original experiment involved cross-validation, there are in fact 5 different sets; our set consists of the union of these sets.[11]

The cross-corpus results in Table 5 are strikingly lower than the within-ICLE results. They also compare poorly to our earlier cross-corpus results in this paper. Part of this difference is, of course, the effect of the much-larger Lang-8 dataset, though the balanced result in Table 2 (12), uses a very similar amount of data (as measured in tokens) from the Lang-8 but attains a much better FCE classification accuracy (roughly 20% better). The POS/function mixture

[10]There are more pervasive topic and genre effects that segregating by prompt does not resolve. For instance, a large number of the Japanese texts are personal narratives, each with a different title, while in the Russian texts there is a particular focus on the literature of various authors, and in the Chinese texts there is a discussion of the advantages or disadvantages associated with certain government policies.

[11]We originally intended to take the intersection, but in fact the intersection of the feature sets is empty; no single feature was useful in every fold.

Features	Lang-8	FCE
Chance baseline	14.3	14.3
(1) Function words	27.6	20.0
(2) Character *n*-grams	29.7	24.0
(3) POS *n*-grams	37.0	32.8
(4) POS/function *n*-grams	40.2	33.4
(5) CFG productions	32.5	31.4
(6) Dependencies	30.7	25.1
(7) Word *n*-grams	50.8	35.7
(8) All (1–7)	46.8	39.1
(9) Adaptor grammar *n*-grams	40.9	30.8

Table 5: ICLE-training cross-corpus classification accuracy (%), by feature set.

features (9) derived using adaptor grammars do reasonably well, but are only marginally better than exhaustive mixture features (4) in the Lang-8 test set, and are markedly worse than a number of other features in the FCE. Again, lexical *n*-grams (7) are obviously the best individual feature type.

7 Discussion

The results in the previous section highlight the problematic nature of within-corpus evaluation in general, and the inadequacy of the ICLE as a training corpus in particular. It is unclear to what extent previous results on this task are influenced by these effects, but we believe there is at least reason to be skeptical of some of the conclusions. In particular, sophisticated feature selection techniques which have been the focus of recent work may result in models which perform better in the ICLE, but which have little or no benefit beyond that particular corpus. We believe more attention should be paid to the overall validity of NLI experiments, rather than to specific technical approaches. One interesting open question is whether features such as proper nouns, which are of obvious but somewhat trivial benefit, should be excluded. Certainly, we would argue that lexical features in general are far too important to the task to simply be discarded; our experiments here suggest that their usefulness goes well beyond proper nouns and is not simply a reflection of topic.

Though higher performance is clearly possible using cross-validation, our Lang-8 trained model does reasonably well in both our testing corpora; the results are fairly consistent, and the difference can be attributed to the smaller size of the FCE texts. It is clear that factors such as the choice of classifier and the size of the dataset play some role, though the most obvious improvement came from the use of our bias adaptation technique, which uses a small amount of data from a test corpus to improve the model; this was particularly effective for SVMs. Importantly, this method keeps the feature weights constant, a necessary precondition when the testing corpus has known arbitrary biases. Given the variation in text size, genres, and learner proficiency, some kind of adaption is clearly necessary to get competitive results, though our experiments using it with the ICLE as training data suggest the method cannot overcome a problematic training set.

We note that our still sizable error rate on this task may in fact be due to a learner proficiency effect; on inspection, one of the authors (a native speaker of English) found that some of

the European texts were nearly indistinguishable from native writing. As suggested by the statistics provided in the ICLE manual (Granger et al., 2009), many of these learners are highly proficient, and thus they might have completely integrated the norms of their L2, making them legitimately indistinguishable. We also tested the correlation between essay scores in the FCE and our classification accuracy, and found a small negative correlation, suggesting that those who scored better were harder to classify; text length, though, was a confounding factor, since longer texts got better scores and are also easier to classify. Finally, we also noticed that French was the most consistently misclassified language, by a significant margin; this could be due, in part, to the historical connection between French and English that makes French L1 transfer somewhat less distinct, whereas distant languages like Chinese and Japanese are easy discerned, an effect we saw even when the training sets were balanced. In general, we think the relationship between proficiency, distances between languages, and L1 classification merits further study.

One important strength of the current work is the training dataset, which, unlike many learner corpora resources, is fully accessible via the web (and growing!). The coverage of European languages is poor, however, and since large amounts of data are necessary to fully leverage the potential of lexical features, one future direction would be to look for even more inexpensive ways of finding learner texts, perhaps by collecting English texts that appear on otherwise non-English websites. Armed with larger datasets, we would like to move beyond classification of a handful of L1s, moving towards a system that can identify influence from a full range of common L1 backgrounds.

8 Conclusion

In this paper, we have demonstrated the feasibility of a cross-corpus approach to the development of native language identification systems, sidestepping the problem of within-corpus confounds to test the efficacy of relevant options. The most striking result is the dominance of shallow lexical features in our best classifier, even in comparison to high-performing, sophisticated feature types such as syntactic productions; also important is some degree of domain adaption, and we present a simple but highly effective method. We have also highlighted the not-insignificant role that other choices play in the classifier performance; for instance, the *one vs. all* classifier, which has been somewhat maligned in SVM multiclass comparisons (Hsu and Lin, 2002; Duan and Keerthi, 2005), provides the best performance in both test corpora when our simple bias adaption method is applied. We have also presented new evidence that within-corpus evaluations techniques are problematic, and that the validity of results that use the ICLE in this manner need to be re-evaluated.

ABSTRACT
A problem that crops up repeatedly in shallow and deep syntactic parsing approaches to South Asian languages like Urdu/Hindi is the proper treatment of complex predications. Problems for the NLP of complex predications are posed by their productiveness and the ill understood nature of the range of their combinatorial possibilities. This paper presents an investigation into whether fine-grained information about the distributional properties of nouns in N+V CPs can be identified by the comparatively simple process of extracting bigrams from a large "raw" corpus of Urdu. In gathering the relevant properties, we were aided by visual analytics in that we coupled our computational data analysis with interactive visual components in the analysis of the large data sets. The visualization component proved to be an essential part of our data analysis, particular for the easy visual identification of outliers and false positives. Another essential component turned out to be our language-particular knowledge and access to existing language-particular resources. Overall, we were indeed able to identify high frequency N-V complex predications as well as pick out combinations we had not been aware of before. However, a manual inspection of our results also pointed to a problem of data sparsity, despite the use of a large corpus.

KEYWORDS: Urdu, complex predicates, visualization, bigrams, corpus.

1 Introduction

A problem that crops up repeatedly in shallow and deep syntactic parsing approaches to South Asian languages like Urdu/Hindi[1] is the proper treatment of complex predications. Whereas verbal expressions in European languages are mostly realized with a single predicate (e.g. 'to remember'), South Asian languages tend to use combinations of more than one element to express an action (e.g., memory+do = 'remember'). In Urdu, only about 700 simple verbs exist (Humayoun 2006) — the remaining verbal inventory consists of complex predications. Complex predicates (CPs) are encountered frequently in general language use, as well as in newspaper corpora. Thus, any NLP application, whether shallow or deep, whether its goal be parsing, generation, question-answering or the construction of lexical resources like WordNet (cf. Bhattacharyya 2010), encounters complex predication sooner rather than later.

While the productive capability as well as constraints on V+V combinations are now comparatively well understood from a theoretical point of view (e.g, see Hook 1974; Butt 1995, 2010 and references therein), the constraints governing N+V, ADJ+V as well as P+V combinations are less well understood (the standard reference for N+V is Mohanan 1994, there is no standard reference for the other types). This is despite the fact that these latter three are very productive. Indeed, very little is known overall about P+V combinations (with Raza 2011 providing a first description), but as our results show, they do occur in newspaper corpora (section 5).

With respect to NLP applications the frequency and productivity of complex predications means that it is not possible to construct a static list of N/ADJ/P+V combinations, rather, there must be a way in which one can dynamically predict which kinds of combinations are possible and which should be impossible. In a recent paper, Ahmed and Butt (2011) propose that the combinatory possibilities of N+V combinations are in part governed by the lexical semantic compatibility of the noun with the verb. They propose an initial classification based on a small corpus study. If they are right, then lexical resources such as WordNet or lexica used in deep grammars could be augmented with semantic specifications or feature information that can then be used to determine dynamically whether a given N+V combination is licit or not.

For this paper, we took Ahmed and Butt (2011) as a point of departure and explored whether we could confirm and perhaps extend their results with respect to a larger corpus study. Given that to date no high-quality annotated large-scale corpus for Urdu exists,[2] we decided to experiment with a large-scale 7.9 million newspaper corpus of Urdu we have collected.

The idea was to take advantage of statistical methods and proceed per standard methods currently embraced in the field. That is, use an available corpus that should in principle be large enough to adequately reflect language use and to extract bigrams from this corpus in order to identify patterns in N+V combinations and to use our knowledge of the extracted patterns in further NLP applications.

In pursuing this experiment, we were indeed able to adduce new information about combinatory possibilities in CPs (section 5). However, our experiment also provides a cautionary tale with respect to diving into a corpus "blindly", i.e, assuming that mere statistical analysis will provide good enough results and any noise due to language particular considerations will simply wash out if the corpus is large enough. Some of the difficulties we encountered had to do with the

[1] Urdu is an Indo-Aryan language spoken primarily in Pakistan and parts of India, as well as in the South Asian diaspora. It is structurally almost identical to Hindi, although the orthographies differ considerably.

[2] However, some data is becoming available via the Hindi-Urdu Treebank (Bhatt et al., 2009) and a large-scale, balanced corpus for Urdu will be released soon (Urooj et al., 2012).

non-standardized nature of Urdu orthography, some with the structure of Urdu (section 3) and some with the complex nature of the data (section 4).[3]

With respect to the complex interrelationships between our data, we were able to achieve significant improvement by using novel methods coming from the field of *visual analytics* (Card et al., 1999; Thomas and Cook, 2005; Keim et al., 2008, 2010). Instead of trying to make sense of bare numbers, we used a visualization tool that maps figures to colors and therefore makes the statistical analysis immediately accessible via easy to process visual means. The visualization allowed us to assess our complex data "at-a-glance", to take corrective measures and to generate new hypotheses as to CP formation and the validation of existing hypotheses.[4]

The paper is organized as follows: section 2 presents relevant background information with respect to the linguistic phenomenon of CPs in section 2.1, followed by related work in section 2.2. Sections 3 and 4 present the details of our study. We describe the steps with respect to the corpus preparation and bigram extraction (section 3.1), the statistical basis for the collocation analysis (section 3.2), the clustering performed on N+V bigrams (section 3.3) and the visualization used (section 4). We also reflect on the depth of the language particular knowledge that was necessary and discuss our results in section 5. We were not in fact able to achieve our initial goal of confirming or extending Ahmed and Butt's original hypothesis. This turns out to be due to data sparsity, even with a 7.9 million token corpus. However, we were able to identify previously unreported information about highly productive combinations and gain further structural insights into the language, particularly due to our use of novel methods coming from the field of visual analytics.

2 Motivation and Background

2.1 Urdu and complex predicates

As already mentioned, an important means of expressing verbal concepts in Urdu is the usage of CPs. There is not one single way of forming CPs, rather there are several different kinds of V+V CPs, different kinds of ADJ+V combinations and different classes of N+V CPs (Butt, 1995; Mohanan, 1994). A discussion of the various combinatory possibilities and types of classes identified so far would lead us too far afield, but see Ahmed et al. (2012) for some examples of each type. Moreover, CPs are highly productive with respect to their combinatorial possibilities and can also be stacked on top of one another. This means that the compilation of a static list of possible combinations of different types of CPs is not feasible as it does not solve the challenges inherent in capturing the syntactic combinatory possibilities and the semantic interpretability via computational means — simply searching a corpus for all possible (and potentially infinitely many) combinations cannot do justice to the dynamic and manifold combinatory possibilities.

For the purpose of this paper, we decided to focus on N+V CPs, i.e., CPs which are formed by combining a noun and a verb. The verb is generally called a *light verb* (Mohanan, 1994), as the noun provides the main predicational content, while the verb specifies additional information

[3] In light of these difficulties, one reviewer encouraged us to explore the possibility of using treebanks. However, the existing definitive treebank for Urdu/Hindi does not do well with annotating complex predicates, merely noting that several bits of a clause are "part-ofs" another word or constituent (Bhatt et al., 2009). This part-of relation is not confined to CPs and when it does indicate a CP, it does not specify what kind. Treebanks which aim to do better in this respect are in the process of being built (Hautli et al., 2012; Ahmed et al., 2012). Indeed, the work reported on here was partly motivated by our on-going treebank effort.

[4] The visualization tool we used was designed by Christian Rohrdantz as part of an on-going cooperation. We would also like to thank him for a very useful discussion of the material in this paper.

about the action/event, like whether the action was agentive or telic. On the morphosyntactic side, the light verb determines the case marking on the subject, controls agreement patterns and provides information about tense and aspect. Some standard examples are in (1).[5]

(1) a. لڑکی نے کہانی یاد کی

laṛki=ne kəhani yad k-i
girl.F.Sg=Erg story.F.Sg.Nom memory.F.Sg.Nom do-Perf.F.Sg
'The girl remembered a/the story.' (lit.: 'The girl did memory of the story.')

b. لڑکی کو کہانی یاد ہے

laṛki=ko kəhani yad hɛ
girl.F.Sg=Dat story.F.Sg.Nom memory.F.Sg.Nom be.Pres.3P.Sg
'The girl remembers/knows a/the story.' (lit.: 'Memory of the story is at the girl.')

c. لڑکی کو کہانی یاد ہوی

laṛki=ko kəhani yad hu-i
girl.F.Sg=Dat story.F.Sg.Nom memory.F.Sg.Nom be.Part-Perf.F.Sg
'The girl came to remember a/the story.'
(lit.: 'Memory of the story became to be at the girl.')

In all of the examples in (1), it is evident that the noun and the verb form a single predicational element. The object *kəhani* 'story' is thematically licensed by the noun *yad* 'memory', but it is not realized as a genitive, as would be typical for arguments of nouns (and as in the English literal translations). Rather, *kəhani* 'story' functions as the syntactic object of the joint predication (see Mohanan 1994 for details on the argument structure and agreement patterns).

Mohanan (1994) already identified two subclasses of N+V CPs: one in which the light verb agrees with the noun (and, confusingly, the noun is both a syntactic object and a part of the verbal predication) and one in which the verb does not agree with the noun (and instead agrees with some other NP in the clause; (1) is of the non-agreeing type). Ahmed and Butt (2011) propose three further classes that cut across this morphosyntactic distinction. Their classification is based on the observation that while about five different verbs can function as light verbs in N+V CPs, not all nouns are necessarily compatible with each of these verbs.

The examples in (1) represent just one class of N+V CPs. This class is compatible with all of the possible light verbs and is identified as a smallish class in Ahmed and Butt (2011). (1) shows the combination with three of these. In (1a) the noun *yad* 'memory' is combined with the light verb *kər* 'do'. In this case the subject must be ergative and the overall reading is one of an agentive, deliberate remembering. In (1b), in contrast, *laṛki* 'girl' is already taken to be in the state of remembering the story. The difference between (1b) and (1c) is one of stative vs. eventive, so that in (1b), *laṛki* 'girl' is already taken to be in the state of remembering the story (and not actively entering a state of remembering the story). In (1c) the light verb is the participial form of *ho* 'be' and essentially means 'become'.

Table 1 summarizes the results presented in Ahmed and Butt (2011). Class A refers to examples as in (1) and this type seems to encompass what is known as *psych-predications*, i.e, actions of remembering, thinking, feeling, etc. However, not all nouns are as versatile as *yad* 'memory'.

[5]The Urdu script, which is also provided in (1), is based on the Arabic script and is written from right to left.

One type, Class B in Table 1, does not allow the subject to be non-agentive. That is, it does not allow combinations with those light verbs that require a dative subject, cf. (1b–c). This pattern is illustrated with an example in (2) and this class was identified as by far the largest class in Ahmed and Butt (2011).

	Light Verb			
N+V Type	kar 'do'	hɛ 'be'	hU- 'become'	**Analyis**
CLASS A	+	+	+	psych-predications
CLASS B	+	−	+	only agentive
CLASS C	+	+	−	do not allow subject to be an undergoer

Table 1: Classes of nouns identified by Ahmed and Butt (2011)

(2) a. بلال نے مکان تمیر کیا
bɪlal=ne mɑkan tɑmir ki-ya
Bilal.M.Sg=Erg house.M.Sg.Nom construction.F.Sg do-Perf.M.Sg
'Bilal built a/the house.'

b. بلال کو مکان تمیر ہ/ہوا
*bɪlal=ko mɑkan tɑmir hɛ/hu-a
Bilal.M.Sg=Dat house.M.Sg.Nom construction.F.Sg be.Pres.3.Sg/be.Part-Perf.M.Sg
'Bilal built a/the house.'

The third class allows dative subjects in principle, but not when they are the undergoer of the action (cf. (1c)). An example with the noun *ɪntɪzar* 'wait' is given in (3). Other nouns that pattern similarly are *taslim* 'acceptance' and *bɑrdaʃt* 'tolerance'. This was again identified as a fairly small class in Ahmed and Butt (2011).

(3) a. بلال نے نادیا کا انتزار کیا
bɪlal=ne nadya=ka ɪntɪzar ki-ya
Bilal.M.Sg=Erg Nadya.F.Sg=Gen.M.Sg wait.M.Sg do-Perf.M.Sg
'Bilal waited for Nadya.'

b. بلال کو نادیا کا انتزار ہ/ہوا
bɪlal=ko nadya=ka ɪntɪzar hɛ/*hu-a
Bilal.M.Sg=Dat Nadya.F.Sg=Gen.M.Sg wait.M.Sg be.Pres.3.Sg
'Bilal is waiting/*waited for Nadya.'

As already mentioned, while the classes identified by Ahmed and Butt (2011) seem promising, the corpus work was done manually and was limited to a total of 45 nouns. The goal of our experiment was to expand the search space by using automatized methods, to thus extract information about a significant number of nouns and to be able to confirm, expand or revise Ahmed and Butt's proposal. In particular, understanding the semantic constraints on N+V CP formation in more detail would be welcome for further NLP applications.

2.2 Related work

Most related work on South Asian languages with the focus on an automatic extraction of complex predicates has been done for Hindi (Mukerjee et al., 2006; Chakrabarti et al., 2008; Sinha, 2009) and Bengali (Das et al., 2010; Chakraborty and Bandyopadhyay, 2010), with the predominant aim of identifying and extracting CPs from corpora or treebanks. Mukerjee et al. (2006) identify Hindi CPs based on the statistical correspondence between English verbs and Hindi multiword expressions (MWEs), using the parallel EMILLE corpus in a sentence-aligned version. The assumption here is that a verb in English will project onto a CP MWE in Hindi most of the times.[6] Bhattacharyya (2010), in presenting a WordNet for Hindi, lists the ∼100 most frequently occurring CPs. This is welcome information to be included in a WordNet. However, this static list ultimately does not do justice to either the overall productivity of CPs, nor does it provide details as to their syntactic/semantic patterning.

This paper has different aims than previous work in that we are not interested in merely identifying CP constructions in a large corpus, but are trying to understand more about their syntactic and semantic properties. To this end, we follow the classic assumption of Levin (1993) that semantic predicational classes can be identified on the basis of a study of the syntactic contexts the predicates occur in (cf. also Schulte im Walde 2009; Raza 2011).

3 Methodology

In this section, we describe the methodology used for harvesting CP candidates from a raw Urdu text corpus and for identifying classes among the candidate CPs via a simple bigram analysis in conjunction with techniques from visual analytics. We also discuss the problems we discovered to be associated with working with an unannotated "raw" corpus for a language like Urdu. Our overall results make a strong case for the prioritization of (mainly manual) high quality resource building — it seems that significant progress with entirely shallow methods cannot be achieved unless high quality, linguistically informed resources can be drawn upon.

3.1 Corpus

A prerequisite for our experiment is access to a large corpus for Urdu. No large corpus for Urdu (annotated or not) is publicly available to date (but see Urooj et al. 2012). We therefore decided to use a 7.9 million word corpus we have been harvesting from the BBC Urdu website[7] for a number of months. The corpus consists of news articles on various different topics, e.g., entertainment, multimedia, science, sports. These articles were automatically collected and parsed into raw text using the Perl HTML module.[8] Inspection of the corpus showed that the BBC Urdu script encoding is particularly clean and systematic in comparison to other Urdu newspaper sites. We therefore did not clean or preprocess the corpus with respect to punctuation, orthography or other normalization issues.

[6] One reviewer wonders whether we could not have used comparable/parallel data from Wikipedia to help us in identifying semantic classes among nouns. This is a potential line of avenue to pursue, but one that is not taken on lightly. Take the pair English-Urdu, for example. Most of the simple verbal predications do correspond to some kind of complex predication in Urdu, but different kinds, none of which are well understood. In addition, English also contains N-V constructions such as *take a bath* whose collocational properties are not very well understood either. It is unclear whether looking at two sets of data for which the collocational constraints within each set of data is not well understood will be able to yield useful results (or results that could not have been achieved manually with less effort).

[7] http://www.bbc.co.uk/urdu/

[8] http://search.cpan.org/dist/HTML-Parser/Parser.pm

3.2 Bigram Collocation Extraction

As a first pass, we went through the corpus and extracted all the bigrams containing the four verbs *kɑr* 'do', *ho* 'be', *hu-* 'become' and *rɑkʰ* 'put'. We decided to extend our set of light verbs beyond the ones used in Ahmed and Butt (2011) by including *rɑkʰ* 'put' in the hopes of arriving at a finer-grained picture of the distribution of the nouns in N+V CPs. We thus looked for all instances of these verbs (in all of their conjugated forms) and extracted them plus any word immediately preceding them. These bigrams were stored and their frequency was recorded. This procedure yielded four initial lists of bigrams, one for each of the four verbs *kɑr* 'to do', *ho* 'to be', *hu* 'to become' and *rɑkʰ* 'to put'.

A manual inspection of these lists revealed that while we were finding N+V CPs of the type we were looking for, most of the highly frequent bigrams were either junk or not the kinds of combinations we were trying to find. We also had an issue with low frequency in that many bigrams were recorded just once or twice. Since Urdu allows quite a bit of scrambling and also allows the nouns to be scrambled away from the light verbs, it was clear from the outset that we would not necessarily net all of the instances of N+V CPs that occur in the corpus. However, we were not prepared for the amount of false hits we did get.

Closer inspection of the bigram lists revealed that many of the false hits were due to certain case markers, conjunctions and pronouns, which all occur frequently before our set of verbs. This is actually to be expected, given the structure of the language (see section 3.4 for discussion). Since our set of verbs is very versatile in that they can not only act as light verbs in N+V CPs, but also function as main verbs and as auxiliaries, many of our top bigrams turned out to be verb-verb combinations of one type or another. Although these are all valid bigrams, they are unwanted noise in the context of our investigation. Further errors were introduced by punctuation and tokenization or white-space issues (see section 3.4).

As a consequence, the initial bigram lists, which consisted of 16033 possible combinations, were pruned. For one, all bigrams which appeared less than 6 times in the corpus were removed. We assumed that most of them were tokenization errors and other machine processing lapses. We also removed all those bigrams which had a negative X^2 value (see below). This reduction left us with only around 4500 bigrams. In a second step, we constructed a list of stop words from various sources. For one, we removed any bigrams containing problematic closed class items such as case markers, conjunctions and pronouns. For another, we used a verb list containing all the conjugated forms of about 700 simple verbs in Urdu (15285 verb forms in total, from the verb conjugator in Raza 2011) in order to remove all those bigrams which we could identify as verb+verb combinations via this verb list.

After applying these steps, we were left with just 2154 candidate bigrams from the original 16033 bigram possibilities drawn from the raw corpus. These candidate bigrams still contained problematic items (see section 4), but identifying and removing them at this stage would have involved intense manual inspection and labor. We therefore decided to work with this list of bigrams for further analysis by different methods.

As a first analysis step, the association strength between the bigram members was computed using the Chi-Square (X^2) measure. This ensures that the more often one of our light verbs occurs with a certain word compared to all other words, the stronger the association is and the higher the bigram is ranked among the group of bigrams. The statistics were computed by

means of the UCS toolkit.[9] We decided to use the X^2 association measure to determine the positive or negative association between the words in the bigram for two reasons. First, papers using comparatively sized corpora have reported encouraging results for similar experiments (Ramisch et al., 2008; Kizito et al., 2009; Hautli and Sulger, 2011). Second, initial manual comparison between bigram lists ranked according to all measures implemented in the UCS toolkit revealed the most convincing results for the X^2 test. Based on the ranking, we reduced the list of bigrams and discarded all bigram instances with either a negative X^2 or a frequency below 6 (see above). A negative X^2 value indicates a negative word association, i.e. the bigram members do not occur together very often in comparison to their frequency in other bigrams.

At this point, we still had our four separate lists of bigrams for the verbs *kɑr* 'do', *ho* 'be', *hu-* 'become' and *rɑkʰ* 'put', but the lists are now of ranked bigrams. Manual inspection revealed that the top items in these lists now did contain N+V combinations of the type that Ahmed and Butt (2011) were looking at, among them also some of the nouns that were discussed in that paper. Our various steps of filtering and ranking thus did allow us to extract a list of strongly associated lexical items of the right type. The next step was to proceed to an analysis of our extracted data. Since our interest lay in the determination of possible classes of N+V CPs, we decided to run a clustering algorithm on our data.

3.3 Automatic clustering

Based on the filtered and ranked lists of bigrams from section 3.2, we investigated the occurrences of words with light verbs across the different types of bigram combinations, i.e. we combined the information of the four lists into one list recording the light verb behavior of every single word. That is, we had different classes of words: words occurring with all four light verbs or words with only *kɑr* 'do' and *ho* 'be', *hu-* 'become' and *rɑkʰ* 'put' or words occurring with various combinations of these verbs. Table 2 shows an exemplary matrix of four nouns (*hasıl* 'achievement', *alan* 'announcement', *bat* 'talk' and *ʃuru* 'beginning' in that order) and their relative frequency of co-occurrence with the four light verbs, i.e. out of all occurrences of noun 1 (*hasıl* 'achievement') with one of the four light verbs, the relative frequency of it occurring with *kɑr* 'do' is 0.771.

ID	Noun	Rel. freq. with *kɑr*	Rel. freq. with *ho*	Rel. freq. with *hu*	Rel. freq. with *rɑkʰ*
1	حاصل	0.771	0.222	0.007	0.000
2	اعلان	0.982	0.011	0.007	0.000
3	بات	0.853	0.147	0.000	0.000
4	شروع	0.530	0.384	0.086	0.000

Table 2: Relative frequencies of co-occurrence of nouns with light verbs

Note that although the motivation for our experiment stemmed from an interest in N+V CPs, our bigrams in fact contain all kinds of POS in combination with our set of four verbs. This is a direct and unavoidable consequence of using an untagged "raw" corpus.

Based on the pattern of relative co-occurrence with the four light verbs, the results were clustered automatically. This was done using a data mining platform developed at the University

[9] http://www.collocations.de; see Evert (2004) for documentation.

of Konstanz: KNIME.[10] We used a k-means clustering algorithm in order to assign each noun to a cluster. We found that a number of five clusters minimized the average distance between the nouns and the cluster centers. However, both the table of numbers as illustrated in Table 2 as well as the clusters were difficult to evaluate in this form. We therefore decided to experiment with visualization techniques as they are currently being pioneered in computational linguistics (e.g., Dörk et al. 2008; Collins 2010; Mayer et al. 2010). Before moving to a discussion of these techniques in section 4, we take a step back and consider the language particular knowledge we had to rely on so far.

3.4 Discussion: Language Particular Issues

As mentioned in section 3.2, our first pass at bigram extraction resulted in a large number of false hits. Upon some reflection on the structure of Urdu, this was only to be expected.

Urdu is a language which is not particularly morphologically complex (in comparison with Native American or Australian Aboriginal languages, for example), but it does use a significant amount of morphology. One unfortunate feature from the perspective of NLP is that the same material is used for several different purposes. For example, *-a*, *-i* and *-e* are morphemes used to mark gender and number on nouns, adjectives, verbs, participles as well as the genitive case. Additionally, there is significant homonymy with respect to frequently used words. For example, one that had a significant impact is the perfect masculine form of *kɑr* 'to do', *kɪya*, which is written the same way as the interrogative pronoun *kya* 'what'. Another example is the perfect feminine form *ki* of *kɑr* 'do', which is written the same way as the complementizer 'that' as well as the feminine singular form of the genitive case marker.

The genitive case marker in general posed a problem. It is structurally a clitic (Butt and King, 2004) and is written as a separate word in Urdu. Given that it is a genitive case marker, it is naturally found adjacent to nouns. For us this meant that we extracted many bigrams which turned out to be collocations of the feminine singular genitive marker and a noun. We therefore decided to remove all instances of bigrams with *ki*. This meant that we probably lost many "good" bigram candidates, but we did not see a way of filtering out the "bad" instances of the genitive while keeping the good instances of the perfect feminine singular of *kɑr* 'do'.

As already mentioned, our set of four verbs *kɑr* 'do', *ho* 'be', *hu-* 'become' and *rɑkʰ* 'put' can be employed as simple verbs in Urdu as well and 'do', 'be', and 'become' can also function as auxiliaries. This meant that our initial bigram extraction netted many V+V sequences in which an item of our set of four verbs occurred as an auxiliary after a main verb. We dealt with this by employing a list of verbs along with all of their inflections that was constructed as part of the work done by Raza (2011). Since this encompassed a total of 15285 verb forms, having access to this already existing resource was invaluable.

With respect to verb conjugation, we also naturally normalized over the bigrams we looked for. That is, we looked for a total of 238 different forms of our set of four verbs, but normalized the different inflected versions to just the stem form for purposes of bigram storage. This is necessary for the task at hand as the inflectional variability would cause a futile co-occurrence analysis. However, it also means that we lose some information with respect to being able to understand whether a given bigram was really associated with a genitive marker or the feminine singular form of 'do', for example.

[10] http://www.knime.org

Finally, our initial list of bigrams contained instances of words with punctuation attached to them. We naturally removed these; however, there are other problems arising with respect to the Urdu script that are not dealt with as easily. For one, there are several different ways of spelling certain words in Urdu. One preprocessing step that we could have done is to run a normalization module across the corpus. However, this also requires specialized knowledge about the language/orthography and this source of errors was not large enough for us to take this step. Similarly, our bigram counts contain instances of words which have not been spaced correctly. The Urdu script is such that each letter has joined and non-joined versions. The conditions governing when to use a joined vs. non-joined version of a letter are fairly complex.

For example, take the third noun (*bat*) from Table 2. The first "letter" is a combination of a 'b' and an 'a' (the joined forms), the second letter is the non-joined version of 't'. In order to differentiate between spaces within words and spaces between two words, two different types of spaces have been defined. One is a normal space, the other is zero-width non-joiner (HTML code: ‌). However, authors are not always consistent in their use, thus giving rise to errors in the corpus, which we again cannot deal with without adding time-consuming manual inspection coupled with deep language-particular knowledge to the process. These errors thus remain in the bigram list we use for the analysis detailed in the next section.

4 Analysis via Visualization

Visual Analytics is based on the tight coupling of algorithms for automatic data analysis and interactive visual components (Thomas and Cook, 2005; Keim et al., 2010). The idea is to exploit human perceptive abilities to support pattern detection (Card et al., 1999). This involves the mapping of data dimensions to eight *visual variables* (Bertin, 1983), namely *position* (two variables x and y), *size*, *value*, *texture*, *color*, *orientation* and *shape*. While some numerical data dimensions can be mapped directly to one visual variable, other data features may require complex layout algorithms that project a combination of multiple data dimensions to a combination of visual variables, e.g., to the combination of the two powerful positional variables x and y. Finally, a data analyst should be able to manipulate the visual display interactively for different perspectives on the data, following Shneiderman's Visual Information-Seeking mantra "Overview first, zoom and filter, then details on demand" (Shneiderman, 1996).

The purposes of visualizing data are manifold. On the one hand, visualizations can be used to achieve an overview of complex data sets. On the other hand, the visualization approach can serve as a starting point for interactively exploring data, ideally detecting hidden patterns. In addition, new hypotheses can be generated and existing hypotheses verified.

The visualization employed in this paper uses the visual variable *color* and encodes the relative frequency of occurrences with different light verbs. This relative frequency is mapped onto a linear saturation scale, i.e. the higher the relative frequency, the more saturated the color. Figure 1 shows a reference visualization on the top, where the saturation is exemplified with the relative frequencies of 0.25, 0.5, 0.75 and 1.0 in the columns from left to right. Below the reference visualization, the relative frequencies of the data in Table 2 are encoded visually. The left-most color column shows the relative frequencies with *kɑr* 'do', the next columns show the relative frequencies with the light verbs *ho* 'be', *hu* 'become' and *rɑkʰ* 'put', respectively. The lexical item on the left hand side is the transliterated version of the Urdu input in Table 2, using the transliterator of Bögel (2012), following the transliteration scheme by Malik et al. (2010).[11]

[11] Short vowels are not encoded in the Urdu script, the transliterator puts a default "*" in places where a short

Figure 1: Visualization of the relative frequencies in Table 2

The visualization tool allows for an interactive exploration of the data in that the human investigator can scroll through the list of visually encoded N+V combinations, with the possibility of zooming in to get a detailed view on a restricted set of nouns, as well as zooming out to see a greater number of combinations and their overall behavior. Mousing over a colored box reveals the relative frequency of the N+V CP.

4.1 Visual Analysis: Round 1

The best clustering result for the clustering method described in section 3.3 was obtained with a specification of five clusters. These are numbered 0–4. Cluster 4 is a large cluster of about 1100 words. This cluster contained just those sets of words which occured only or almost only with *ho* 'be'. A manual inspection of this cluster showed that all of these words were either errors, false hits containing inflected verbs or words like 'what' and 'how many' or items like 'small', 'teacher', 'market', 'tomorrow' (the vast majority). The last category are items that occur in run-of-the-mill copula contexts like 'He is a teacher.'. This class is of no interest to us as there are no useful combinatory constraints to be discovered. We therefore decided to discard this cluster from our bigram list in its entirety.

Cluster 3 contained a small set of words that occurred with *hu* 'become' 100% of the time. All of these were false hits and were discarded. Similarly, Cluster 1 was a comparatively small cluster that consisted of words occurring mainly with *rɑkʰ* 'put'. Manual inspection showed that all the words ocurring with *rɑkʰ* 'put' a 100% of the time were false hits: the words were all objects of the main verb 'put' and not CPs of any kind. Again, we culled our bigram list to remove this set.

The other two clusters are more of a mixed bag. Cluster 2 has very large number of items that occur only with *kɑr* 'do'. Figure 2 shows the top part of Cluster 2 on the left. This contains nouns already identified as belonging to the ones combining in the type of N-V CP we are interested in. However, this class contains desired results as well as false hits which cannot be separated from one another on a visual (or purely numerical basis). Culling down this cluster would involve intense manual labor, which we decided to forego.

Similarly, Cluster 0 contains desired results as well as false hits. Again, these are difficult to discern visually, though there are clearer subclusters because this cluster contains those words which occur with all the four light verbs (at different levels of frequency). In Figure 2 *hasil* 'achievement', *ʃuru* 'beginning', and *koʃɪʃ* 'struggle' are the kinds of nouns we are interested in. On the other hand, *xɑtɑm* 'finished' and *jari* 'continued' are adjectives.

vowel is expected. The ambiguous characters *vao* and *ye* (consonant or vowel) are represented with ⟨vao⟩ and ⟨ye⟩, respectively. In case of entries with '???', the automatic transliteration could not find an adequate transliteration — this can be due to typing errors or unusual vowel/consonant combinations of English loan words. We needed to use a transliterated version of our bigram lists as the visualization tool we used could not deal with UTF-8 input.

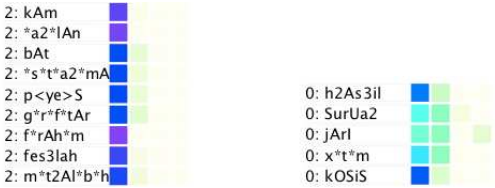

Figure 2: Visualization of the top of Cluster 2 (left) and Cluster 0 (right)

As part of our quick visual inspection, we also noted several types of unusual patterns found in the clusters, such as the ones illustrated in Figure 3 for the verb *ʊt̪ʰa* 'raise'. These often turned out to be false hits. The visualization thus allowed for a quick and easy identification of further errors. All unusual patterns that were identified as errors via this method of analysis were also removed from our bigram list. Detecting these types of errors would have been neigh impossible without an easily accessible visual representation.

Figure 3: Visually prominent pattern of a false hit

All in all, after the manual selection process, we were left with only 1090 instances of bigrams. This list still contains false hits, but removing these would take intensive manual labor. We therefore decided to rerun our automatic clustering algorithm on the (partially) cleaned data.

4.2 Visual Analysis: Round 2

The new clustering again yielded the best results with a specification of five clusters. The visualization shows that the cleaning and culling described in the previous section has had a positive effect, but that even the remaining 1090 bigrams still contain a good amount of false hits which would need to be culled on the basis of intense manual inspection. Nevertheless, the overall results are encouraging as different types of nouns are indeed being distributed over the different clusters.

As shown in Figure 4, Cluster 0 still contains *hasil* 'achievement' and *koʃɪʃ* 'struggle'. Items from the previous Cluster 2 also now appear here: *bat* 'talk', *ɪstemal* 'use' and *peʃ* 'presentation/happening'. On the other hand, *ʃuru* 'beginning', *xɑtɑm* 'finished' and *jari* 'continued' are now in Cluster 3, which mainly consists of adjectives, but also a few of the nouns we are interested in. While ADJ-V CPs were not the target of this paper, this cluster contains potentially useful information with respect to ADJ+V CPs.[12]

The same is true of Cluster 1: it consists of mainly adjectives, but there is a smattering of some of the nouns we are interested in as well as a number of spatial terms including postpositions.

Cluster 4 contains words which occur almost exclusively with *rɑkʰ* 'stay' and this set still does

[12]But note that Cluster 0 also contains adjectives, for instance *gɪrɪftar* 'arrested' in Figure 4.

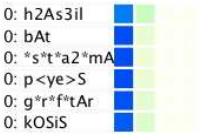

Figure 4: Visualization of the top of Cluster 0

not contain much that is of interest within the scope of this paper. On the other hand, Cluster 2 contains many nouns which occur in N-V CPs and indeed, contains many of the nouns that Ahmed and Butt (2011) identified as belonging to Class 2. A comparison of our results with that of Ahmed and Butt (2011) shows that while we did not find all of the nouns used in Ahmed and Butt, of the nouns that we did find most are Class B nouns (no dative subjects allowed). These are distributed over Clusters 0 and 2, while the Class A nouns (full range of light verb use) are found in Clusters 0, 1 and 3 (no Class C nouns were found in our study).

5 Results and Discussion

In this paper, we set out to see if we could find fine-grained information about the distributional properties of nouns in N+V CPs by extracting bigrams from a large "raw" corpus of Urdu. In addition to finding target instances of N+V combinations, our work has also resulted in lists of possible ADJ+V combinations and, in particular, the realization that P+V combinations are highly frequent. The prepositions involved are, for instance, 'front', 'back', 'on' and 'beside' and in combination with our set of verbs mean something like 'place on/beside/front/back' (with 'do' and 'put') or 'be/become on/beside/front/back' (with 'be' and 'become'). Given that these combinations are highly frequent, it is imperative that more be understood about P+V.

Unfortunately, this cannot be accomplished via our data because we actually have a problem with *data sparsity*. Manual inspection of some of the CPs we found showed that not all possible combinations of N/ADJ/P+V were in fact attested in the corpus. That is, our bigram lists will need to be complemented by manual native speaker work (traditional lexicography).[13]

We also find it remarkable that out of a corpus of 7.9 million words, we are at this point left with only 1090 bigrams (and are aware that a portion of these bigrams would still need to be culled as they represent errors or false hits). This problem of data sparsity could perhaps be ameliorated by using a different type of corpus, but we suspect that for our type of enterprise, data sparsity might be a problem regardless of how large or different a corpus is chosen — one cannot guarantee that all possible combinations will indeed be attested in any given corpus. On the other hand, one result that is very clear is that any word that occurred only in conjunction with *ho* 'be', *hu-* 'become' or *rak*^{h} 'put' was in fact not one that would occur in CPs. This means that one can exclude those words from candidate lists of nouns for N+V CPs in future work.

Our paper also makes contributions with respect to two methodological points. In order to be analyze our data more perspicuously, we experimented with new methods from *visual analytics*. This experimentation was successful as it allows for quick visual analysis of our data sets, which in turn also enables a non-labor-intensive way of further cleaning and culling our data. In

[13] One reviewer would like an indication of how many valid CPs we might have missed. Since we have no idea how many CPs were indeed contained in our corpus, we cannot say. And as N-V CPs are combinatorily dynamic, there are potentially infinitely many of these. All we can say is how many of the potentially infinitely many combinations we did find.

particular, the visual analysis allowed us to be able to quickly assimilate information about complex interrelationships in our data: which types of verbs does the word in question occur with with what level of frequency and how does this compare to other words in the list?

The visualization component proved to be an essential part of our data analysis. Another essential component turned out to be our language-particular knowledge and access to language-particular resources. The idea that we could work more or less "blindly" with a large corpus did not pan out. Rather, at every step we needed to be aware of language particular issues with respect to orthography, morphology and syntax. We could not have done our work without the use of a list of all the conjugated forms of 700 simple verbs (Raza, 2011) or a transliterator (Bögel, 2012) (needed to massage the input for the visualization component). We thus conclude that while we were partly successful in achieving what we set out to do, our work would have been able to be yield more precise results if we had access to standardized language-particular resources. On the other hand, our "blind" extraction of patterns yielded new insights into what kinds of CPs are highly frequent in newspaper corpora in addition to N+V CPs and which therefore need to be paid attention to with respect to NLP applications and the creation of language particular resources. This pertains in particular to P+V and ADJ+V combinations, about which not much is known either from a computational or from a theoretical perspective.

Native Language Identification Using Recurring N-grams – Investigating Abstraction and Domain Dependence

Serhiy BYKH *Detmar MEURERS*
Seminar für Sprachwissenschaft, Universität Tübingen
{sbykh,dm}@sfs.uni-tuebingen.de

ABSTRACT
Native Language Identification tackles the problem of determining the native language of an author based on a text the author has written in a second language. In this paper, we discuss the systematic use of recurring n-grams of any length as features for training a native language classifier. Starting with surface n-grams, we investigate two degrees of abstraction incorporating parts-of-speech. The approach outperforms previous work employing a comparable data setup, reaching 89.71% accuracy for a task with seven native languages using data from the International Corpus of Learner English (ICLE). We then investigate the claim by Brooke and Hirst (2011) that a content bias in ICLE seems to result in an easy classification by topic instead of by native language characteristics. We show that training our model on ICLE and testing it on three other, independently compiled learner corpora dealing with other topics still results in high accuracy classification.

TITLE AND ABSTRACT IN GERMAN

Muttersprachenerkennung mittels rekurrenter N-Gramme – Untersuchungen zur Abstraktion und Domänenabhängigkeit

Die Muttersprachenerkennung befasst sich mir der Erkennung der Muttersprache eines Autors auf der Basis eines Textes, der von diesem Autor in einer Zweitsprache verfasst worden ist. In der vorliegenden Arbeit diskutieren wir die systematische Verwendung rekurrenter N-Gramme aller Längen als Features für das Trainieren eines Muttersprachen-Klassifizierers. Beginnend mit oberflächenbasierten N-Grammen, untersuchen wir zwei Stufen der Abstraktion unter Verwendung von Wortarten. Unser Ansatz liefert eine Klassifikationsgenauigkeit von 89.71% für Texte aus dem International Corpus of Learner English (ICLE) mit sieben unterschiedlichen Muttersprachen und übertrifft somit die bisherigen Ergebnisse auf vergleichbaren Daten. Ferner untersuchen wir die Behauptung von Brooke und Hirst (2011), dass inhaltliche Aspekte des ICLE zu einer einfacheren Klassifikation der Texte nach dem Thema anstatt nach der Muttersprache führen könnten. Wir zeigen, dass ein auf ICLE Daten trainiertes Modell auch bei Tests auf drei unabhängig erstellten Lernerkorpora eine hohe Klassifikationsgenauigkeit ermöglicht.

1 Introduction

Inferring characteristics of an author by automatically analyzing that author's texts is a task that is increasingly drawing attention in recent years. Traits such as gender, age, level of education or native language are some of the properties targeted thus far (e.g., Koppel et al., 2005; Estival et al., 2007; Wong and Dras, 2009).

The work presented in this paper examines one particular characteristic, namely the author's *native language*, with the task being to infer it from a text written in a second language. So we explore the task of *Native Language Identification (NLI)*, which is of interest for a number of reasons. The impact of one's native language on a second language is studied in *Second Language Acquisition* (SLA) research, aimed at understanding how languages are acquired and how language works in general. Of particular relevance here is the notion of Transfer: *"Transfer is the influence resulting from similarities and differences between the target language and any other language that has been previously [...] acquired."* (Odlin, 1989, p. 27). Given the increasing availability of second language corpora with different native languages as well as powerful classification and evaluation techniques, it becomes viable to empirically explore and verify hypotheses regarding the existence and nature of L1 Transfer. Complementing the conceptual relevance for SLA, NLI also is of practical relevance for applications such as systems for profiling phishing emails (Estival et al., 2007) or in the context of learner modeling for intelligent language tutoring systems (Amaral and Meurers, 2008).

NLI started to attract interest less than ten years ago (Koppel et al., 2005), so the area still is quite young, with fundamental questions waiting to be addressed: Is the L1 Transfer effect strong and distinctive enough across domains to support an automatic classification with a reasonable degree of reliability for the typical available document lengths? Which language properties are the most appropriate ones to use as classifier features for the given task and can they reliably be identified? How well can a surface-based approach fare in the task and what is the effect of abstracting away, e.g., to distributional classes such as parts-of-speech (POS)?

In this paper, we consider the NLI task as a text classification problem with the different native languages as the classes. Inspired by the variation n-gram approach to corpus annotation error detection (Dickinson and Meurers, 2003, 2005; Boyd et al., 2008), we will follow a data-driven approach based on *recurring n-grams* as features in a machine learning setup capable of handling large feature spaces. The aim of our work is to contribute a piece to the overall puzzle to solve, starting with a particular take on surface features, recurring word-based n-grams of any size, and exploring the effect of incrementally introducing POS as abstractions. In the second part of the paper, we then explore the generalizability of our results across corpora.

2 Related Work

Koppel et al. (2005) used a subset of the first version of the *International Corpus of Learner English (ICLE)* (Granger et al., 2002) as data set. The ICLE corpus consists of essays written by non-native English speakers at a similar level of English proficiency, namely higher intermediate to advanced. Koppel et al. included texts for five native languages: Bulgarian, Czech, French, Russian and Spanish. Each native language was represented by 258 essays. They used a *Support Vector Machine* (SVM) as classifier and defined features based on the occurrence of function words, character-based n-grams, rare POS bi-grams as well as some error types (e.g., certain spelling errors). Testing was performed using 10-fold cross-validation. The best classification accuracy of 80.2% was obtained using all of the mentioned features combined.

Tsur and Rappoport (2007) replicated Koppel et al. (2005) and investigated the hypothesis that the choice of words in the second language is strongly influenced by the frequency of native language syllables. In support of their hypothesis, the authors report that an approximation using character bi-grams alone allows classification accuracy of about 66%. Since the corpus contains learner essays on several different topics, they also investigated whether the classification with such surface features is influenced by a content bias. Using a variant of the *Term Frequency - Inverted Document Frequency* content analysis metric, they conclude that if a content bias exists in the corpus, it only has a minor effect.

Estival et al. (2007) used a corpus of English emails as data incorporating three native languages, namely English, Arabic, Spanish, and considered a range of different demographic as well as psychometric traits including the native language for author profiling purposes. They used a wide range of features at different levels: character-based features such as frequency of punctuation marks, lexical features such as function words as well as POS, and some features at the structural level such as paragraph breaks. Using *Information Gain* as feature selection technique and *Random Forest* classification, they obtained an accuracy of 84.22%.

Wong and Dras (2009) used the second version of the ICLE corpus (Granger et al., 2009) as data and compiled a data set consisting of seven native languages, namely Bulgarian, Czech, French, Russian, Spanish, Chinese and Japanese, each represented by 70 essays for training and 25 essays for testing (plus 15 additional essays for development). On the one hand, they employed lexical features, such as function words, frequently used character-based uni-, bi-, tri-grams as well as rare and most frequently used POS bi- and tri-grams. On the other hand, they used three syntactic error types as features: misuse of determiners as well as subject-verb and noun-number disagreement. Using an SVM classifier they obtained an accuracy of 73.71%. Extrapolating to a larger training set, they argue that this result is consistent with the findings reported by Koppel et al. (2005). However, the syntactic features used in their study did not improve the results obtained by employing lexical features alone.

Wong and Dras (2011) extended their previous work by investigating more general syntactic features compiled on the basis of parse trees, namely horizontal slices as well as cross-sections of parse trees. These features were used along with the set of lexical ones of Wong and Dras (2009). Using the same data set as Wong and Dras (2009) and a *Maximum Entropy* classifier, they obtained a classification accuracy up to 81.71%, showing that incorporating more sophisticated syntactic features can improve the results.

Brooke and Hirst (2011) conducted several experiments employing two different corpora, namely the ICLE and the Lang-8. The second corpus was compiled by the authors themselves based on the data available on `http://lang-8.com`. This web site contains short personal journal entries of different kinds (personal narratives, requests for translations of particular phrases, etc.), which are posted by English learners in order to obtain feedback from native speakers. Compared to the ICLE corpus, there is a disproportionately high number of contributors from Eastern Asia, the level of English proficiency seems to be significantly lower, and little is known about the context of the writing for Lang-8 (e.g., there is no specification of time or resources used). To obtain texts from Lang-8 which are comparable in size to those in ICLE, Brooke and Hirst (2011) created texts consisting of multiple Lang-8 entries. In their computational approach, they use character, word, and POS-based uni- and bi-grams (excluding proper nouns in case of word-based n-grams) as well as some function words as features. Based on a dataset from ICLE and Lang-8 consisting of seven native languages, namely Chinese, Japanese, French,

Spanish, Italian, Polish and Russian, with each of them represented by 200 texts from each of the two corpora, they conducted experiments using an SVM classifier in a single-corpus evaluation (using 10-fold cross-validation) and a cross-corpus evaluation (training on the one corpus, testing on the other). The single-corpus evaluation on ICLE data yielded an accuracy of 93.8% using all the features together, yet only 25% when training and testing on the Lang-8 data. The results of cross-corpus evaluation were very low, at 15.7% to 22.9%. Based on these results, Brooke and Hirst (2011) argue that a strong content bias is present in ICLE, allowing an easy classification by topic instead of by native language. However, it remains unclear whether the poor Lang-8 results are not due to the properties of this specific corpus, which seems to be highly heterogeneous and incoherent, and whether the poor cross-corpus evaluation results are of general importance or due to the nature of the Lang-8 corpus. Brooke and Hirst then explore the usefulness of artificial learner corpora, which they compiled using machine translation of native language data. The results yield up to 67% in a setup with two native languages. Brooke and Hirst (2012) extend their previous work and show that using automatically translated word bi-grams in combination with a new L1 Transfer metric yields up to 48.3% in a setup with four native languages when tested on ICLE data. The accuracies are far below those reported previously, but the approach promises a low content bias.

3 Data

For our first, core study we use a subset of the *International Corpus of Learner English* (ICLE v. 2; Granger et al., 2009). The overall ICLE corpus consists of 6,085 essays written by English learners of 16 different native language backgrounds. They are at a similar level of English proficiency, namely higher intermediate to advanced and of about the same age. Following the setup of Wong and Dras (2009), we randomly select a set of essays from the same seven native languages – namely, Bulgarian, Czech, French, Russian, Spanish, Chinese, and Japanese – and we use the same data split with 70 essays for training and 25 essays for testing for each of the languages, resulting in a total of 490 essays for training and 175 for testing. As in Wong and Dras (2009), we only included essays between 500 and 1000 words in length. We tokenized the essays and removed all punctuation marks, special characters and capitalization. Thus each essay is represented as an array of lower-case words.

To get a better sense of how well our approach performs, we conducted ten experiments. We select the data for each of them randomly from the full set of ICLE essays within the mentioned length range. We thus are able to observe the variance of the results based on ten randomly selected samples from the overall corpus subset matching the described criteria. We first describe one of the ten experiments in detail and then turn to the overall ten experiments.

4 Features

Different from previous research, in this study we explore *recurring n-grams of all occurring lengths* as classifier features. By *recurring* we here mean all n-grams that occur in at least *two* different essays of the training set d (the test set is held out, i.e., not considered for determining the features). *Of all occurring lengths* means all recurring n-grams up to the maximum possible n value occurring in d, i.e., all n-grams with $1 \leq n \leq max_n(d)$.

On the one hand, we use recurring *word-based* n-grams directly, i.e., the surface forms. On the other hand, we explore two different classes of recurring *POS-based* n-grams as a generalization, based on a POS tagged version of the corpus using the PennTreebank tagset (Santorini, 1990). In sum, we define our features based on the following three classes of recurring n-grams:

Word-based n-grams (word n-grams): strings of words, i.e., the surface forms

- $n = 1$: *analyzing, attended, ...*
- $n = 2$: *aspect of, could only, ...*
- $n = 3$: *is capable of, the assumption that, ...*
- ...

POS-based n-grams (POS n-grams): *all words* are converted to the corresponding POS tags

- $n = 1$: *nnp, md, nns, vbd, ...*
- $n = 2$: *nns md, nn rbs, nn rbr, cc wdt, vbp jjr, vbp jjs, ...*
- $n = 3$: *cd wdt md, vbp nn md, dt rbr cc, nn jj in, ...*
- ...

Open-Class-POS-based n-grams (OCPOS n-grams)[1]**:** *nouns, verbs, adjectives* and *cardinal numbers* are converted to the corresponding POS tags

- $n = 1$: *far, vbz, much, jj, ...*
- $n = 2$: *nn whenever, jj well, jjs vbd, vbg each, nn always, ...*
- $n = 3$: *vbp currently jj, only to the, cd vbz jj, vb if there, ...*
- ...

We explore the whole range of n values as well as all possible $[1, n]$ intervals. Figure 1 depicts the counts of *different n-grams* for each n (for uni-grams, bi-grams, tri-grams, etc.) and Figure 2 for each $[1, n]$ interval (for uni-grams alone, uni-grams and bi-grams together, uni-grams, bi-grams and tri-grams together, etc.). There are large differences in terms of feature counts, depending on the particular n-gram class and the value of n used. The figures show that increasing the number of different POS tags leads to more possible different features (up to about 160,000 in our setup). The reason for that is the ability of POS to bridge some break points in the word sequences (i.e., places where different words occur, thus ending a recurrent surface n-gram) and hence to lead to more longer n-grams. Thus the n-grams including POS tags may also reach higher n values: For the word-based n-grams $max_n(d) = 29$, whereas POS-based n-grams reach $max_n(d) = 30$ in the training set used.

As expected, the feature counts fall rapidly as the n value passes a certain (n-gram class dependent) threshold (see Figure 1). Longer n-grams may potentially contain some specific information not contained in the shorter ones – they may capture, e.g., transliterations of native idioms (Milton and Chowdhury, 1994). So we do not discard any features a priori. The aim is to investigate up to which value of n the n-grams may be worth considering despite being rare.

We use binary feature vectors as classifier input, i.e., each essay is represented by a vector containing $\{0, 1\}$ values. If an essays contains a particular n-gram, then the corresponding value in the vector is 1, and 0 otherwise. Since the n-gram frequencies (especially in case of the longer ones) are rather low, we consider such a representation to be a reasonable simplification.

5 Tools

To extract all recurring n-grams, we implement a dynamic programming algorithm collecting all n-grams of length n based on the n-grams collected for $n-1$. The algorithm terminates once no n-grams for a given length can be found in the given data. To obtain the n-gram classes incorporating POS tags, we used the *OpenNLP* POS-tagger (`http://opennlp.apache.org`).

[1] Similar representations are also used by Baroni and Bernardini (2006) for the identification of "translationese".

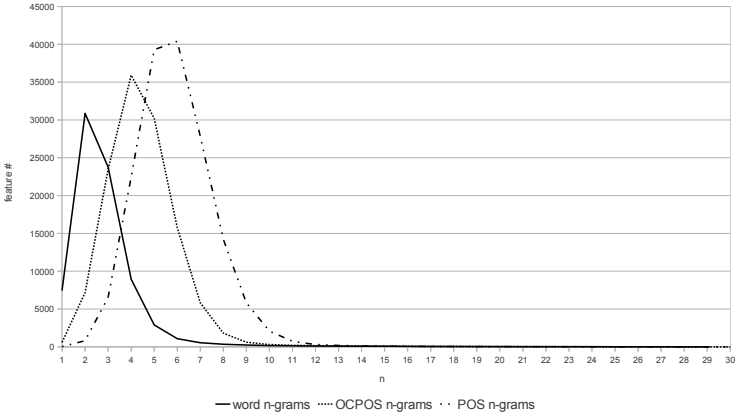

Figure 1: Feature counts for single n n-gram settings for the single ICLE sample

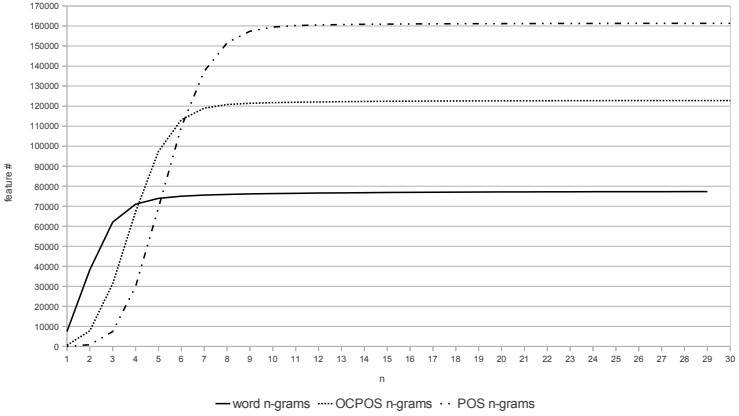

Figure 2: Feature counts for $[1, n]$ n-gram settings for the single ICLE sample

To choose the classifier to use, we conducted several preliminary tests employing different machine learning tools. We explored using *TiMBL* (Daelemans et al., 2007), which provides an implementation of the k-NN algorithm, incorporating a range of distance metrics. We then tested different Support Vector Machines (SVMs), which are well-known for their ability to handle large feature sets: *WEKA SMO* (Platt, 1998; Hall et al., 2009), *LIBSVM* (Chang and Lin, 2011), and *LIBLINEAR* (Fan et al., 2008). In our trials, the *LIBLINEAR* classifier yielded by far the best results and was in addition usually faster than the others as well. Hence, we employ the *LIBLINEAR* classifier in our study.

6 Results

The classification results for all feature settings are presented in Figures 3 and 4.

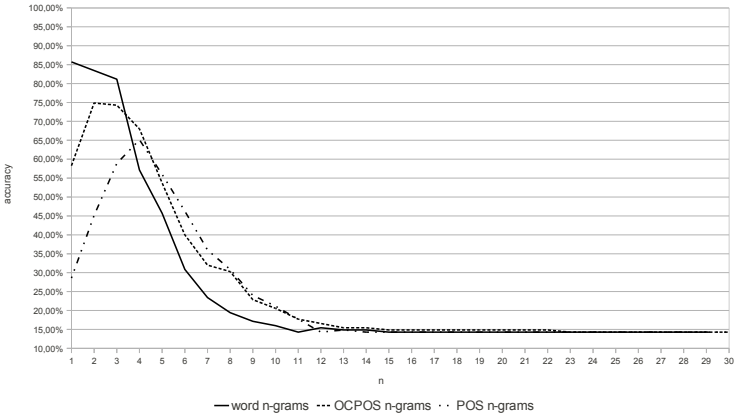

Figure 3: Results for single n n-gram settings for the single ICLE sample

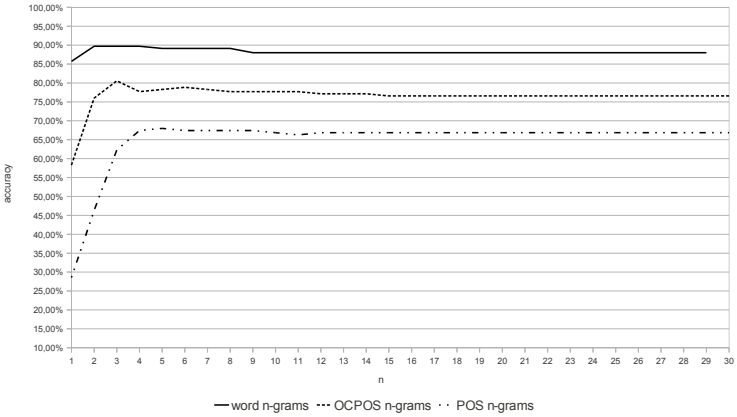

Figure 4: Results for $[1, n]$ n-gram settings for the single ICLE sample

Figure 3 shows the classification accuracy for all n values of the n-grams separately (i.e., for uni-grams, bi-grams, tri-grams, etc.), whereas Figure 4 depicts the classification accuracy for all $[1, n]$ intervals (i.e., for uni-grams alone, uni- and bi-grams together, uni-, bi-, tri-grams together, etc.). There are seven different native languages as classes, each represented by an equal number of essays, so 14.29% is the random baseline against which to interpret the results.

Best Accuracy Range The highest accuracy achieved by our recurring n-gram approach is 89,71% using word-based n-grams with intervals from $[1,2]$ to $[1,4]$. This is 16% higher than the best result reported by Wong and Dras (2009) and about 8% higher than that reported by Wong and Dras (2011) on a comparable data set. Brooke and Hirst (2011) reported a slightly better result, 93.8% for seven native languages, but as discussed in Section 2 they used more data and a different data split.

The confusion matrix in Table 1 shows the distribution of correctly classified as well as misclassified samples for each of the native languages. The performance on the different native languages is generally comparable; only the result for Russian is slightly below the others.

	BG	**CN**	**CZ**	**FR**	**JP**	**RU**	**SP**
BG	23	0	0	0	0	2	0
CN	0	24	0	0	1	0	0
CZ	0	0	23	1	0	1	0
FR	1	0	0	22	0	0	2
JP	0	0	1	0	24	0	0
RU	1	0	3	1	1	19	0
SP	1	1	0	1	0	0	22

Table 1: Confusion matrix for the best result for the single ICLE sample: 89,71%, word-based n-grams, $[1,2]$; BG: Bulgarian, CN: Chinese, CZ: Czech, FR: French, JP: Japanese, RU: Russian, SP: Spanish

However, there are clear differences in terms of accuracy between the n-gram classes utilized in this study. As mentioned above, the best result is obtained using pure surface forms, the word-based n-grams. The more different POS tags are incorporated, i.e., the bigger the step from the surface to the more general forms, the lower the accuracy. The information loss involved in the abstraction thus outweighs the broader applicability. The best results are presented in detail in Table 2.[2]

	n Intervals			**Single n**		
Features	$[1,n]$	**Accuracy**	**Feature #**	n	**Accuracy**	**Feature #**
word n-grams	2	89.71%	38,300	1	85.71%	7,446
OCPOS n-grams	3	80.57%	31,263	2	74.86%	7,176
POS n-grams	5	68.00%	69,139	4	65.14%	22,462

Table 2: Best results for the single ICLE sample

Table 2 shows that POS-based n-grams, i.e., features at the highest generalization level, yield about 13% lower accuracy than the Open-Class-POS-based n-grams, and the latter are performing about 9% worse than word-based n-grams. There is a gap of about 22% between the surface-based and the most generalized n-gram representation used in our study. However, even the most general POS-based n-grams still yield a result of 68%, which is reasonably high considering the baseline of 14.29%. The accuracy of 80.57% obtained using Open-Class-POS-based n-grams is in line with the best results published for a comparable data set.

[2] If more than one setting per feature class yields the same best accuracy, only the lowest n or $[1,n]$ interval is listed.

Different n Values Using intervals of n always leads to better results than using n-grams of a particular single n value alone (see Figures 3 and 4). One can also see that the more POS generalization is incorporated, the longer n-grams are needed to obtain the best results. In this study, the accuracy benefited from n-grams up to $n = 5$. Thus n-grams with $n > 3$, which are generally not considered in the related research, are not a priori useless.

The longer n-grams in the range of $6 \leq n \leq 10$ seem to be too sparse to improve on the accuracy obtained by intervals of shorter n-grams, at least in the data used in this study. There are a lot of different n-grams in that range, especially for n-grams with POS incorporated (see Figure 1), but the impact of lots of different features, with each occurring only in a few essays, seems to be very limited. Moreover, using them in intervals with n-grams of lower n values usually decreases the accuracy (see Figure 4). Thus they seem to introduce some noise into the feature set. However, increasing the size of the data set or incorporating more sophisticated generalizations may still allow such n-grams to become useful.

Finally, "very long" n-grams, i.e., n-grams with $n > 10$, usually encode a few, predetermined phrases, such as the wording of the topic the essay is about, or consist of some other copied passages. Hence, they are unlikely to be relevant for the given NLI task.

Reliability of the Findings Since the results described above are based on a single experiment, one may wonder, how generalizable those findings are. As mentioned in Section 3, we thus conducted nine further experiments. Summing up the results of the ten experiments, we computed the *mean accuracy* values along with the *Sample Standard Deviations (SSD)*. Given that the $max_n(d)$ value varies for the ten training sets, one cannot average over all n for all of the experiments. But as discussed in the previous paragraph, n-grams with $n > 10$ are unlikely to be useful for the purposes of the given task. Hence, we report the accuracy results for the $1 \leq n \leq 10$ range. Figure 5 shows the results for $[1, n]$. Overall, the means curves are very similar to the curves we presented in Figure 4.

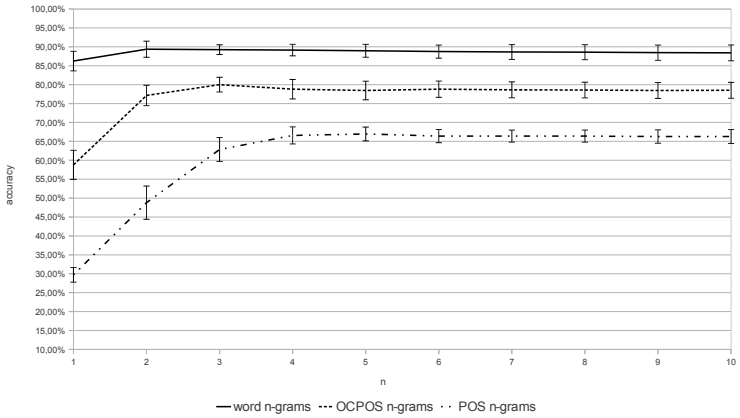

Figure 5: *Mean accuracy* and *SSD* for $[1, n]$ n-gram settings for the ten ICLE samples

The overall best outcomes are shown in Table 3. The best mean accuracy result of 89.37% is yielded by the same setting, namely by the word-based n-grams using the $[1, 2]$ interval.

	n **Intervals**			**Single** n		
Features	$[1, n]$	**Mean accuracy**	**SSD**	n	**Mean accuracy**	**SSD**
word n-grams	2	89.37%	2.12%	1	86.23%	2.59%
OCPOS n-grams	3	80.00%	1.94%	2	73.71%	2.68%
POS n-grams	5	66.97%	1.82%	4	60.91%	3.38%

Table 3: Best mean accuracy results for ten ICLE samples

This best mean accuracy over ten experiments is only 0.34% lower than the corresponding best result from the single experiment described in the *Best Accuracy Range* paragraph of the current section. The SSD with values around 2% for the best performing settings indicates that there is little variance among the experiments.

Discussion The ICLE contains essays from a range of topics, so one may wonder about the impact of the contents on the native language identification. Using only essays of the same topic would in principle be preferable, but it would significantly reduce the amount of data available. As mentioned in Section 2, Tsur and Rappoport (2007) argued that such a content bias is rather marginal for the subset of the ICLE they used. In contrast, the findings of Brooke and Hirst (2011) suggested a high topic bias in the ICLE data. In order to obtain more independence from the content of an essay, there is a clear need for some abstraction away from the surface encoding form and meaning together. Yet, the features in our study with the highest level of generalization and thus probably the lowest topic bias, recurring POS-based n-grams, provide results about 22% below those purely based on surface forms. A combination of surface and generalized forms may be a reasonable middle ground. In that light, the *Open-Class-POS-based n-grams* appear attractive since they replace many of the topic-specific meaning distinctions with POS-tags. They are less tied to the meaning than word-based n-grams, but still yield high accuracy with relatively low feature counts in the best performing n range. At the same time, Brooke and Hirst (2011) observe a comparable drop for word and POS-based features in cross-corpus evaluation with the Lang-8 corpus, and Golcher and Reznicek (2011, p. 31) show that POS n-grams still contain information relevant to topic classification for the German learner corpus FALKO. More research thus is needed to verify which features are sufficiently general and applicable across corpora. We address this issue in the next section.

7 Investigating the cross-corpus generalizability of the results

To address the question whether the models trained and evaluated on the ICLE corpus generalize to other learner corpora, we conducted a second set of experiments.

Data In this second study, we use four different learner corpora. Complementing the ICLE introduced above, we use the NOCE, USE and HKUST corpora compiled by independent research teams.

The *Non-Native Corpus of English / NOCE* (Díaz Negrillo, 2007, 2009) is an English learner corpus consisting of mainly argumentative essays on several topics written by Spanish native speakers. The data was collected at the University of Granada and the University of Jaén using texts by undergraduates pursuing an English degree. The corpus contains 1,022 essays.

The *Uppsala Student English Corpus / USE* (Axelsson, 2000, 2003) is a corpus of learner English consisting of texts written by Swedish students at the Department of English at Uppsala University. The texts contained in the corpus are essays written as part of the regular curriculum and cover several topics of different genres, e.g., argumentation, reflection, literature course assignment, etc. The corpus contains 1,489 essays. Since the essays from the other corpora used in this study are mostly argumentative, to obtain comparable data in terms of the text properties we use only the argumentative subset of the corpus (from the first term). This USE subcorpus consists of 344 essays.

The *Hong Kong University of Science and Technology English Examination Corpus / HKUST* (Milton and Chowdhury, 1994) is an English learner corpus containing texts written by Chinese native speakers. The version of the corpus we are using consists of 1,100 argumentative essays on different topics collected 1992 during the public matriculation examination, which is taken each year by students leaving secondary school. For the present work, we took a 8% random sample of the whole corpus, consisting of manually tagged 77 essays as described in Milton and Chowdhury (1994, p. 128).

As preprocessing, we removed all types of meta-information and annotation contained in the learner corpora (personal information about the author of the text such as the age or the native language, topic tags, error annotation, etc.) as well as all punctuation marks, special characters and capitalization, and we tokenized the essays. Hence, as in the first study each text is represented as an array of lower-case words.

Based on the data described above, we explore the NLI task using a setup with three native languages: Spanish, Swedish and Chinese. First, we compile *two separate test sets*. The first test set consists of randomly selected 70 essays per native language from ICLE. To compile the second test set, we randomly select 70 essays per native language correspondingly from HKUST and USE and 140 essays from the NOCE corpus. Since the NOCE essays tend to be shorter than the other ones, we merge the 140 essays pairwise to obtain 70 texts of a size comparable to the essay size from the other corpora. The texts on average contain 620 words. Second, we compile *ten separate training sets*. Each training set consists of randomly selected 140 essays per native language from the overall ICLE corpus (without the essays selected for the ICLE test). Thus we obtain ten separate training sets with 420 essays each, randomly selected from the ICLE corpus, and two separate test sets with 210 texts each, one compiled using ICLE alone and another compiled using NOCE, USE and HKUST.

This setup allows us to perform ten *single-corpus* evaluations (i.e., training and testing on the same corpus) on the ICLE data alone as well as ten *cross-corpus* evaluations (i.e., training on the one corpus and testing on another corpus) using ICLE data for training and NOCE, USE, HKUST data for testing. With ten separate ICLE training sets, we are able to build ten different classifier models and to observe the variance in the generalizability of the patterns learned on different ICLE subsets. We thus are able to observe the generalizability of the ICLE patterns to other corpora in direct comparison to ICLE itself.

Results Based on the ten different training sets, we conducted tests for each $[1, n]$ n-gram interval with $1 \leq n \leq 10$ using the two best performing n-gram classes (i.e., word- and OCPOS-based n-grams as features), and performed both a single-corpus evaluation and a cross-corpus evaluation. We thus obtained 400 separate accuracy values overall (10 training sets $\cdot$ 2 n-gram classes $\cdot$ 10 n-gram intervals $\cdot$ 2 evaluation types).

Figure 6 sums up the results by depicting the *mean accuracy* values on the two test sets obtained using ten different training sets for both n-gram classes and each of the ten n-gram intervals along with the random baseline. Since in this set of experiments there are three different native language classes, each represented by an equal number of essays, we obtain 33.33% as a random baseline against which to interpret the results.

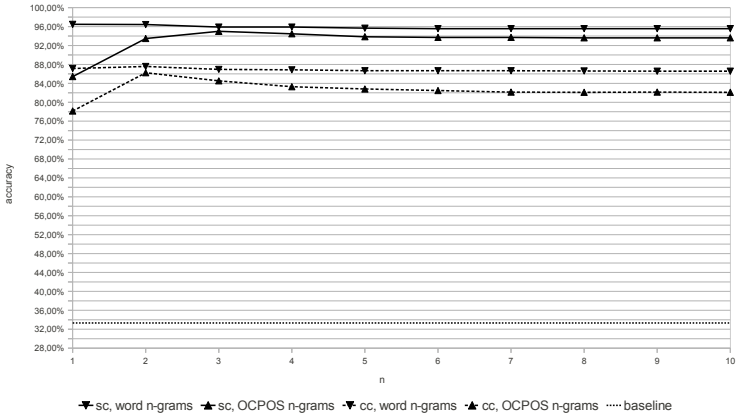

Figure 6: *Mean accuracy* for $[1, n]$ n-gram settings for the ten ICLE training sets (sc = single-corpus, cc = cross-corpus evaluation)

We left the SSD bars out of Figure 6 to keep it readable, but it naturally is interesting to consider the variance. Figure 7 shows the single- and cross-corpus accuracies for the word-based n-grams from Figure 6 together with the corresponding SSD. Figure 8 presents the same for the OCPOS-based n-grams. We see that in both figures the variance is low, with the cross-corpus evaluation showing slightly higher SSD values as expected.

Table 4 shows the best accuracies for both feature classes along with the corresponding SSD values obtained on the two different evaluation types as well as the corresponding n intervals. Though the best performing n-gram intervals differ for both feature classes on single-corpus evaluation, in the cross-corpus evaluation *recurrent bi-grams* perform best for both.

At the end of Section 6, we hypothesized that the more abstract OCPOS-based n-grams may perform better than the surface-near word-based ones in cross-corpus evaluation. However, the accuracies obtained using word-based n-grams are on average as good or better than the ones obtained using OCPOS-based n-grams (see Figure 6 and Table 4). Apparently people with different native language backgrounds make lexical choices which are indicative across a range of topics. A first qualitative analysis points to the use of predicates such as *get*, *take*, *choose*, *make use of*, *consider*, *be able to*, *understand*, or *suggest*. A precise characterization of the nature of this lexical material seems relevant to investigate in future work.

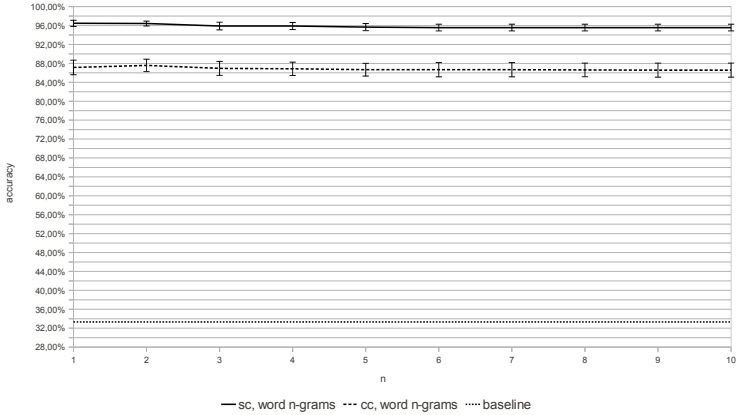

Figure 7: *Mean accuracy* and *SSD* for $[1, n]$ n-gram settings for the ten ICLE training sets, recurring *word-based n-grams* as features (sc = single-corpus, cc = cross-corpus evaluation)

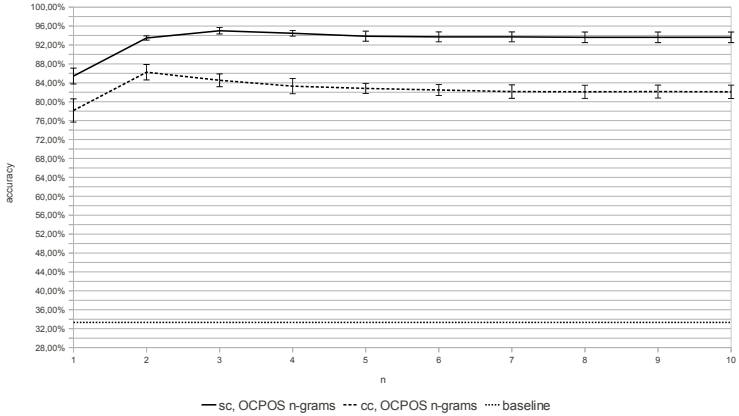

Figure 8: *Mean accuracy* and *SSD* for $[1, n]$ n-gram settings for the ten ICLE training sets, recurring *OCPOS-based n-grams* as features (sc = single-corpus, cc = cross-corpus evaluation)

Features	**Evaluation**	$[1, n]$	**Mean accuracy**	**SSD**
word n-grams	single-corpus	1	96.48%	0.64%
	cross-corpus	2	87.57%	1.32%
OCPOS n-grams	single-corpus	3	95.00%	0.68%
	cross-corpus	2	86.24%	1.63%

Table 4: Best results for ten ICLE training sets

Domain Dependence The experiments we ran with the NOCE, USE and HKUST corpora show far higher accuracies for the cross-corpus evaluation than what is reported by Brooke and Hirst (2011) for the Lang-8 corpus. In a setup with a random baseline of 14.2%, Brooke and Hirst (2011) report 70.1% – 93.8% (depending on the employed feature set) on single-corpus evaluation using ICLE, but only 15.7% – 17.0% for cross-corpus evaluation, training on ICLE and testing on Lang-8. In contrast, in a setup with a random baseline of 33.33% we obtained a best result of 95% – 96.48% (depending on the employed n-gram class) on single-corpus evaluation using ICLE, and 86.24% – 87.57% in a cross-corpus evaluation setup with training on ICLE and testing on NOCE/USE/HKUST (see Table 4 and Figure 6). Thus when using ICLE for training and another corpus instead of ICLE for testing, there is a drop of about 54% – 77% in Brooke and Hirst (2011) but only around 9% in our work. The dramatic drop Brooke and Hirst observed thus seems to be caused by some characteristic of the Lang-8 corpus and not by a general failure of the models learned on the ICLE corpus to generalize to other learner corpora.

The corpora we used for the cross-corpus evaluation were compiled by different research teams using their own essay topic lists. To investigate whether there still may be some topic overlap, we extracted the topics from our NOCE/USE/HKUST test set as well as from the ICLE training set yielding the best cross-corpus evaluation results. In both cases there were more than 100 different topics, and none of them matched between ICLE used for training and NOCE/USE/HKUST used for testing in the cross-corpus setup. Thus topic overlaps seem very unlikely to have notably skewed the results in our cross-corpus evaluation.

Conclusion

In this paper, we explored the task of *Native Language Identification (NLI)*. We derive three different classes of *recurring n-grams* as features, namely *word-*, *POS-* and *Open-Class-POS-based n-grams*. We use these features in a machine learning setup employing a Support Vector Machine (SVM) classifier on randomly selected data from the ICLE corpus incorporating seven different native languages. The best performing class are the word-based n-grams with an accuracy of 89.71%, which compares well to the 81.71% reported by Wong and Dras (2011) as the highest accuracy achieved thus far for a comparable data setup. To investigate the variance, we conducted nine further experiments based on random samples from ICLE. The mean accuracy values obtained from the overall ten experiments are very similar to those from the first experiment. The variance of the outcomes is moderate, with SSD being about 2% for the best performing settings. The bigger the step from the surface-based to more generalized features, the lower the accuracy. The recurring n-gram approach employing Open-Class-POS-based n-grams yields an accuracy of 80.57% and using POS-based n-grams we obtained 68%, which still is reasonably high considering the random baseline of 14.29% for this task.

We then investigated the claim in Brooke and Hirst (2011) that surface-based NLI classification models trained on the ICLE corpus do not generalize to other learner corpora. For this purpose we conducted a second set of experiments comparing *single-corpus* and *cross-corpus* results. In contrast to their cross-corpus findings using the Lang-8 corpus, our results show that the patterns learned on ICLE do generalize well to other learner corpora. More specifically, we showed that training on ICLE and testing on three independently collected corpora, NOCE, USE and HKUST, still yields reasonably high accuracy values of about 88% for a NLI classification task with three native languages. The low results for the Lang-8 corpus reported in Brooke and Hirst (2011) thus must have other reasons, possibly a lack of consistency in the Lang-8 pieces combined into documents, or the very different nature of the ICLE and the Lang-8 data.

ABSTRACT
Disambiguation to Wikipedia (D2W) is the task of linking mentions of concepts in text to their corresponding Wikipedia entries. Most previous work has focused on linking terms in formal texts (e.g. newswire) to Wikipedia. Linking terms in short informal texts (e.g. tweets) is difficult for systems and humans alike as they lack a rich disambiguation context. We first evaluate an existing Twitter dataset as well as the D2W task in general. We then test the effects of two tweet context expansion methods, based on tweet authorship and topic-based clustering, on a state-of-the-art D2W system and evaluate the results.

1 Introduction

Determining the correct meaning of each word in a natural language text is a prerequisite for proper understanding. Disambiguation to Wikipedia (D2W) (Mihalcea and Csomai, 2007), the process of linking each *concept mention* in a text to a *concept* referent (i.e. a Wikipedia page), is a framework that supports the word sense disambiguation (WSD) task[1]. For example, consider the sentence, "BP said Halliburton destroyed Gulf Spill evidence". A D2W system should break the text into concept mentions and return a unique identifier (an article title, in the case of Wikipedia) for each concept. The intended meaning of each concept mention can be inferred in terms of its surface form and its context.

Mention	**Wikipedia title**
BP	*BP*
said	*Press Release*
Halliburton	*Halliburton*
destroyed	*Spoliation of Evidence*
Gulf Spill	*Deepwater Horizon oil spill*
evidence	*Evidence*

Table 1: Desired D2W output

D2W may benefit both human end-users and natural language processing (NLP) systems. When a document is *Wikified* a reader can more easily grasp its contents as information about related topics is readily accessible[2]. From a system-to-system perspective, a disambiguated corpus has the meanings of many of its terms grounded in a structurally rich ontology, and indeed there is evidence that D2W output (Ratinov and Roth, 2012; Vitale et al., 2012) can improve NLP systems. Given a concept mention in a source text, and Wikipedia, D2W operates over a representation of the following:

1. the content of the text, and how its elements are related to the concept mention.
2. the content of Wikipedia, and how its concepts are related to one another.
3. how individual elements of the text are related to elements of Wikipedia.
4. a method for generating candidate concepts for the concept mention.

Each of these items may be represented using the output of Natural Language Processing (NLP) techniques applied to the source text and Wikipedia, and/or an analysis of built-in structure (e.g. TF-IDF, Information Extraction techniques, relationships between documents, structural features of Wikipedia such as links, info boxes, and categories). Most successful D2W applications enumerate potential concept referents for a given concept mention based on the anchor text of already existing links within Wikipedia, as well as information from *redirects* and *disambiguation pages*. Context is extracted from throughout the document where a target concept mention occurs, which is then compared against Wikipedia content to narrow the hypothesis space of potential concepts. The task is therefore more challenging when concept mentions occur in short texts containing informal language.

[1]We use “concept” in both the usual sense and to refer to a Wikipedia page about a concept.
[2]http://en.wikipedia.org/wiki/Wikipedia:Glossary#Wikify.

Over 300 million Twitter users generate over 400 million tweets (posts) daily[3] [4]. The microblogging genre presents unique challenges for NLP tasks. Twitter posts (tweets) are limited to 140 characters and informal language is often used. Contextual evidence is important for accurate D2W, but for tweets it is scattered among various knowledge sources.

In this work we explore ways in which the disambiguation context of concept mentions in tweets can be enhanced. The novel contributions of the paper are as follows. First, we provide a qualitative analysis of a hand-annotated data set (Meij et al., 2012) and infer some properties of the contextual evidence most likely sought by annotators. Two sources of additional context useful for disambiguation are identified: tweets from the same author, and topically related tweets. In addition, we evaluate the contribution of these additional context types to the performance of GLOW, a state-of-the-art D2W system (Ratinov et al., 2011).

2 Related work

The task of linking expressions to Wikipedia concepts has received increased attention over the past several years, as the linking of all concept mentions in a single text (Mihalcea and Csomai, 2007; Milne and Witten, 2008a,b; Kulkarni et al., 2009; He et al., 2011; Ratinov et al., 2011), the linking of a cluster of co-referent named entity mentions spread throughout different documents (Entity Linking) (McNamee and Dang, 2009; Ji et al., 2010, 2011; Zhang et al., 2011; Han and Sun, 2011; Han et al., 2011), or the linking of a whole tweet to a single concept (Genc et al., 2011). Most D2W work has been performed on newswire collections, and most work on tweets has been limited to a particular type of concept mention. For example, the Online Reputation Management Task (Amigó et al., 2010) focused on filtering tweets containing company name to extract only those tweets that were actually related to the company.

For an n-gram deemed a concept mention, most D2W systems define candidate target concepts as a subset of those that were ever linked to using the n-gram in question as anchor text, from within Wikipedia itself (though (Zhou et al., 2010) expanded this set using search engine click results). The relative frequency with which a given n-gram links to each target concept is referred to as its *commonness* distribution[5]. Disambiguation is then couched as re-ranking, computed based on similarity between the concept mention along with its surrounding context, and a candidate concept, The systems of (Ferragina and Scaiella, 2010; Ratinov et al., 2011; Milne and Witten, 2008a; Cucerzan, 2007; Han and Zhao, 2009) take into account the coherence of all concepts linked to in a given document, based on concept similarity. (Meij et al., 2012) created the hand-labeled dataset that we use in our work. Their best performing system based on random forests outperforms commonness accord, though it does not ensure any global coherence over the concepts assigned to a given tweet.

Some TAC-KBP Entity Linking (Ji et al., 2011) systems utilized all entities in the context of a given query, disambiguating all entities simultaneously using a graph-based re-ranking algorithm (Fernandez et al., 2010; Radford et al., 2010; Cucerzan, 2011; Guo et al., 2011; Han and Sun, 2011; Han et al., 2011) or a collaborative/ensemble ranking algorithm (Pennacchiotti and Pantel, 2009; Chen and Ji, 2011; Kozareva et al., 2011) to ensure global consistency. (McNamee et al., 2011) demonstrated that co-occurring named entities are particularly helpful

[3] http://blog.twitter.com/2011/08/your-world-more-connected.html as of August 2011.

[4] http://www.mediabistro.com/alltwitter/twitter400milliontweets_b23744 as of August 2012.

[5] For an n-gram m, concept $t \in T$, $COMMONNESS(m,t) = \frac{c(m \to t)}{\sum_{t' \in T} c(m \to t')}$, where $c(m \to t)$ denotes the number of times m serves as a hyperlink to the concept t.

for Cross-lingual Entity Linking (CLEL). None of the TAC-KBP systems performed full-document D2W to include concept mentions of different types, including non-entities.

For a given concept mention, all-concept D2W work we are aware of makes use of context that is part of or derived from its containing document, whereas we explore ways to obtain supporting context in the form of additional (tweet) documents.

3 Motivation

3.1 Analysis of human annotation task

Although there is a consensus that WSD is best suited for evaluation *in vivo* (i.e. as a component of another system), a reliable gold standard data set for *in vitro* evaluation is desirable, even if the output is not intended for a human end-user (Navigli, 2009). While annotation reliability depends in part on robust guidelines designed to maximize inter-annotator agreement (IAA), IAA tends to degrade as the sense repository becomes more fine-grained (Navigli, 2009), as is the case in D2W. On one hand, if a D2W task is limited to named entities, and the set of mentions to be linked is given in advance, agreement can be rather high – e.g. 91.53%, 87.5%, and 92.98% was observed for Person, Geo-political, and Organization type entities in the TAC2010 data (Ji et al., 2010) – in spite of a sense repository which is *a priori* quite vast. In contrast, the task of linking whichever concept mentions appear important in a corpus of very small documents should prove difficult, as it is more demanding in spite of a dearth of contextual evidence. A D2W task may be characterized along two dimensions: whether concept mentions to be disambiguated are given in advance, and whether the target domain of concepts consists of all of Wikipedia or from a limited subset (e.g. only named entities). We refer to the task of linking whichever concept mentions appear important to a (largely) unrestricted domain of concepts (i.e. all Wikipedia pages) as *open-ended concept linking*.

Annotating every word without regard to its syntactic or semantic category, or its prominence in the discourse, is probably unnecessary for any application (Navigli, 2009). The criteria for determining which concept mentions to annotate must be specified in terms of (1) the properties of the target domain of concepts, (2) whether a concept exists in the target domain, and (3) the extent to which a mention is deemed ambiguous. A concept mention can be said to lack a (Wikipedia) concept referent in two distinct ways: it may be deemed *unlinkable* because the string in question, in the context in question, does not refer to a *valid concept* (i.e. one that could, in principle, appear in Wikipedia). On the other hand, the mention may refer to a valid concept, but there is not yet a corresponding Wikipedia page (see (Lin et al., 2012) for further discussion). Similarly, a concept mention can qualify as ambiguous in two ways: it may obviously refer to some valid concept, but even if each candidate has a corresponding Wikipedia page, the intended concept may be impossible to determine; on the other hand, the (Wikipedia-independent) concept being referred to may be clear, but there may be more than one (Wikipedia) concept that constitutes a correct answer in accordance with the annotation guidelines (e.g. concepts for which article mergers have been suggested might be considered equivalent, for annotation purposes; also c.f. "Gators" and "Pine nut" in section 3.2 regarding taxonomic granularity). Concept mentions that unambiguously refer to a Wikipedia concept may still present difficulties. Specification of which concepts constitute valid targets must be done in terms of the property space of all concepts, which is arguably quite complex. In the case of D2W a concept's content derives not only from explicit (e.g. infobox, category, and link structure) but implicit (article text) facts, and may be difficult to separate from personal knowledge and experience with the (Wikipedia-independent) concept in

question. Such a separation potentially limits annotation richness but may reduce inconsistency across annotators. Furthermore, determining which mentions to annotate depends not only on the properties of potential target concepts but on the prominence of the mention in question in the context in which it occurs. Perhaps a concept mentioned in passing, which does not pertain to the main point, should not be annotated. Finally, a concept might be relevant to an entire tweet though not denoted by any word or phrase therein. For example, *2011 Tohoku earthquake and tsunami* is clearly related to the tweet, "my thoughts and prayers go out to the Japanese people". We are aware of no annotation schemes that account for all of these variables, and leave a more precise formulation to future work.

3.2 Information potentially used by annotators

Annotators use information from different sources when annotating a concept mention. When short and informal texts such as tweets are analyzed in isolation, identifying the context necessary to disambiguate the concept mentions therein is non-trivial. Informative context for a given concept mention might be derived from the mention alone, within the tweet, or within the authors other tweets. Information about the author in general, his or her interests, recent events in the author's life, , and world knowledge may be informative as well. We inferred that annotators made use of several different sources of information, often simultaneously, and that world knowledge is supplemented by information acquired from Wikipedia during annotation . We aim to determine what sort of additional tweet context might have provided for an improved disambiguation context[6]. In what follows we give examples in which annotators either (1) appeared to use, or (2) failed to take advantage of, a given type of contextual support, along with analysis. Table 2 illustrates cases in which it appears that annotators *have* taken advantage of the type of supporting context in question. First, "St. Patrick's Day" is unambiguous

Type	**Tweet text**	**Mention**
Mention Alone	Are you a college kid who likes drinking, dressing up, and making irish immigrants roll in their graves? Then St. Patrick's Day is for you!	St. Patrick's Day
Within Tweet	Slump is over! Way to ball out Jeff and Damian. Much needed win. Go Hawks!!	Hawks
Within Author's Tweets	Go Gators!!! A1: Sweet 16! What a good feeling. Keep it going... Go Gators!!!' A2: What's good everyone, catching up on these Tourney games and already see some upsets... March Madness! Go Gators!	Gators

Table 2: Context type used by annotators

regardless of context. That "Hawks" refers to a sports team is implied by "Slump" and the pattern "Go ... !", but "Hawks" also may refer to the teams *Fukuoka Softbank Hawks* or *Chicago Blackhawks*, in addition to the correct referent *Atlanta Hawks*. However, only the Atlanta Hawks have players named Jeff (Teague) and Damien (Wilkins), and knowing this requires either being a member of a subculture that possesses enough knowledge to make this distinction, or having searched for this information, which can be done with a Wikipedia search and very few clicks. That "Gators" refers to a sports team is implied by "Go ... !". Whether the mention can be reliably linked to *Florida Gators men's basketball* may depend on mentions in other tweets written by the same author. In the first supporting tweet, "Sweet 16" refers to *NCAA Men's*

[6]Note that in general by *disambiguation context* we mean all information that is applicable to the disambiguation task. Later in our description of GLOW 4.1 we take a narrower definition of this term.

Division I Basketball Championship as opposed to *Sweet Sixteen (birthday)*, as evidenced by the sports context; the situation is analogous for "March Madness" in the second supporting tweet. A candidate target like *Sweet Sixteen (KHSAA State Basketball Championship)*, a less prominent basketball tournament, is ruled out by the presence of "March Madness" and "Gators" (as both are associated with only the NCAA tournament). In addition, time of publication and author attributes provide ample evidence, independent of these supporting tweets: the tweet date was March 18th, during the NCAA Division I Men's Basketball Tournament, and the author played basketball at the University of Florida. Commonness alone would not suffice as "Gators" links most commonly to *Florida Gators*, the Wikipedia page about the University of Florida's athletics in general, which is not specific enough[7]. Some additional source of information is required to link to *Florida Gators men's basketball*. Table 3 illustrates annotation errors; presumably, annotators did not take advantage of the type of context in question.

Type	**Tweet text**	**Mention**
Mention Alone	So excited to announce I'll be singing "God Bless America" during the 7th Inning Stretch at the Detroit Tigers..	Detroit Tigers
Within Tweet	Making pesto! I had to soak my nuts for 3 hours	nuts
Within Author's Tweets	It was a pool report typo. Here is exact Rhodes quote: "this is not gonna be a couple of weeks. It will be a period of days." A1: At a WH briefing here in Santiago, NSA spox Rhodes came with a litany of pushback on idea WH didn't consult with Congress. A2: Rhodes singled out a Senate resolution that passed on March 1st which denounced Khaddafy's atrocities. WH says UN rez incorporates it	Rhodes
URL Content	Awesome post from wolfblitzercnn: Behind the scenes on Clinton's Mideast trip - URL - #cnn	Clinton

Table 3: Context type *not* used by annotators

"Detroit Tigers" is unambiguously associated with *Detroit Tigers*. The given annotation for "nuts" is *Nut (fruit)*, which is reasonable, but *Pine nut* is more appropriate as it is the nut ingredient used in pesto according to Wikipedia[8]. Ben Rhodes was the deputy National Security Advisor (NSA) to Barack Obama in March of 2011. This is not clear from the tweet text, but supporting tweets each provide evidence in favor of the target *Ben Rhodes (speechwriter)*. The American Political context indicates the target concept for "Clinton" is either *Bill Clinton* or *Hillary Rodham Clinton*. To inter that Hillary Clinton went on such a trip at the time of publication requires either American political knowledge or access to the URL in the tweet.

We observe that world knowledge, including what can quickly be obtained by looking through Wikipedia, helps annotation. Many such on-the-fly inferences would be difficult to make automatically, thus additional textual context is needed in order to generate a more comprehensive disambiguation context. We consider two methods for providing such content: (1) disambiguating mentions in the context of all tweets in the dataset by the same author, and (2) disambiguating mentions in the context of all tweets in the same cluster (section 4.2.1)[9].

[7]We base this judgement on the Gricean maxim of quantity: "Be as informative as required" (c.f. http://plato.stanford.edu/entries/implicature/). We leave an analysis in this vane to future work.

[8]Pesto may be made with other nuts, but according to the article *Pesto* this does not correspond with the classic recipe. The existence of multiple correct options for candidate targets at varying taxonomic levels makes evaluation more difficult because some arbitrary choices about what constitutes "close enough" or "specific enough" must be made.

[9]Other dimensions in terms of which tweets could be clustered to filter out noise include hashtags, timestamps and the mention/retweet structure for the tweet in question. Unfortunately Twitter API restrictions render these extensions slightly less accessible for older tweets.

4 System

4.1 Global coherence

Some D2W systems aim to maximize the *global coherence* of their output, i.e., the concepts linked to in a given *source document*. Essentially, some measure of relatedness among these concepts informs the selection process for a given concept mention. A relatedness metric based on the Wikipedia link structure can leverage the co-occurrence of concept mentions in a document to the extent that the relationships expressed therein are captured in the links between their referent concepts. Concept mentions in microblog messages often lack explicit supporting context, therefore systems and annotators alike must look elsewhere for disambiguation context. We hypothesize that with the right additional context, given the resulting enriched disambiguation context, a D2W system that relies on optimizing its output for global coherence should perform better. In our experiments we do this in two ways: to a given tweet, we (1) append additional tweets by the same author, and (2) append tweets based on a clustering algorithm. We constrain the term *disambiguation context* in what follows to a set of concepts, each deemed a candidate referent of any concept mention in the source document. This definition is analogous to that used in previous sections; world knowledge, including that gained by reading tweets and examining Wikipedia, is represented approximately, via the extension of the disambiguation context that results from augmenting tweets with related tweets to create multi-tweet documents.

Enforcing constraints can be potentially harmful. The system of (Milne and Witten, 2008a) performs poorly on the tweet dataset because it relies on unambiguous concept mentions for disambiguation, the guaranteed existence of which is implausible for the microblog genre (Meij et al., 2012). TAGME (Ferragina and Scaiella, 2010) begins with commonness but enforces global coherence through a "voting" scheme in which the score associated with an n-gram m and a target concept t is derived from the vote of each other n-gram m' in the tweet. The vote of m' is the average of the relatedness scores (Milne and Witten, 2008b) between each of its candidate concepts t' with t, weighted according to $COMMONNESS(m', t')$, and though links may be pruned, this system performs poorly on the tweet dataset as well (Meij et al., 2012). GLOW (Ratinov et al., 2011), on the other hand, optimizes for global coherence using two supervised classifiers, and is conducive to a balanced disambiguation context, neither prohibitively small, nor large and noisy. Their notion of disambiguation context consists of the top candidates returned by a *local model* (described below) that for a given concept mention takes into account surrounding textual context while remaining agnostic to candidate concepts for surrounding mentions. A *global model* finalizes linking choices so as to optimize global coherence of the output. We chose to use GLOW because of its state-of-the-art performance on benchmark D2W datasets and its focus on a balanced disambiguation context.

4.2 Pipeline

The pipeline consists of three phases: first a *tweet document* is generated, then the document is fed to the D2W system, and finally results are extracted from the D2W system output.

4.2.1 Tweet document creation

The first phase consists of grouping individual tweets into documents. We create tweet documents for each experimental case, as described in Table 4.

Case	Tweet document content
By file	Each document consists of a single tweet
By author	Each document consists of all tweets by a given author
By cluster	Each document consists of all tweets in the same cluster

Table 4: Description of experimental cases

All tweets are pre-processed such that URLs are removed, and the @ and # characters are removed from user mentions and hashtags respectively. Tweets in documents are ordered chronologically by publication date, and those labeled ambiguous or non-referential are omitted.

A number of well-known probabilistic topic modeling approaches such as Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003), have been explored to discover topics from a set of documents. However, due to the shortness and lack of context, these topic modeling approaches may not work well with tweets. To overcome this difficulty, we explicitly smooth the topic distributions of tweets by building linkages between tweets, weighted by cosine similarity in terms of TF-IDF. A random walk-based approach is used to propagate the topic distribution probabilities across the linkages:

$$\begin{aligned} \hat{P}(z_k|x_i) &= \sum_{x_j \in X} w_{ji} P(z_k|x_j), \\ P(z_k|x_i) &= (1-\lambda)P(z_k|x_i) + \lambda \frac{\hat{P}(z_k|x_i)}{\sum_i \hat{P}(z_k|x_i)} \end{aligned} \quad (1)$$

where $P(z_k|x_i)$ is the probability of topic z_k for tweet x_i, w_{ij} is the similarity between x_i and x_j, and λ is a parameter that controls the balance between the previous topic distribution $P(z_k|x_i)$ and propagated topic distribution. We utilize PLSA to initialize the topic distributions. We cluster tweets using this PLSA+Random Walk-based Propagation (PRP) method by assigning a tweet x_i to the topic z_k that maximizes $P(z_k|x_i)$.

4.2.2 GLOW: a D2W system

In the second phase we use GLOW (Ratinov et al., 2011), a D2W system that disambiguates terms by attempting to optimize the global coherence of its output. Given a document d consisting of mentions $M = \{m_1, \ldots, m_N\}$, the system output consists of an N-tuple of target concepts, $\Gamma =< t_1, \ldots, t_N >$, a subset of all available concepts $T = \{t_1, \ldots, t_{|T|}\}$. Formally, one element of T is a null concept $t_\emptyset$, such that linking m to $t_\emptyset$ is akin to not linking m at all. *Local* feature functions ϕ assign $< m, t >$ pairs a high score to the extent that the context surrounding m is similar to t, and are meant to measure the likelihood that m links to t irrespective of the concepts referred to by m's surrounding mentions. *Global* feature functions ψ assign a high score to Γ to the extent that its contents are coherent. Coherence is calculated on a pairwise basis. Each global feature is either the Pointwise mutual information (PMI) or normalized Google distance (NGD) of a pair of concepts in the set, calculated in terms of the sets of concepts that either (1) link to each concept in the pair, (2) are linked to from each concept in the pair, or (3) are in the intersection of the sets defined in (1) and (2), for each concept in the pair[10]. Thus, GLOW attempts to solve the following optimization problem for a given document d:

$$\Gamma^* = \arg\max_{\Gamma} [\sum_{i=1}^{N} \phi(m_i, t_i) + \psi(\Gamma)] \quad (2)$$

[10]See (Ratinov et al., 2011) for a detailed explanation including the adaptations of PMI and NGD used.

Where Γ^* is the optimal output. This problem is NP hard, so inter-concept relatedness is calculated pairwise to reduce complexity, reformulating the problem as:

$$\Gamma^* \approx \arg\max_{\Gamma} \sum_{i-1}^{N} [\phi(m_i, t_i)] + \sum_{t_j \in \Gamma'} [\psi(t_i, t_j)] \quad (3)$$

The optimization is performed in two stages. First, in the *ranker* stage, Γ^* is found but without allowing any mention to be linked to $t_\emptyset$. Next, in the *linker* stage, whether each mention's top candidate should be replaced by $t_\emptyset$ is determined. In the system output, mentions linked to $t_\emptyset$ have a negative linker score while others have a positive linker score.

4.2.3 Extracting output

For a given case, each tweet document d is fed to the D2W system separately, the output of which consists of mentions that were linked (including those ultimately linked to $t_\emptyset$ and their associated target concepts). Each mention is associated with a *linker score* - the confidence associated with the choice to link that term - while each of its candidate target concepts is associated with a *ranker score* - the confidence associated with that particular concept. Thus for each linked mention m_{di} we have its *result tuple*, $R(m_{di})$ which consists of a linker score and a list of k targets, ordered according to their ranker score.

$$R(m_{di}) = < ls(m_{di}), (< t^1_{m_{di}}, rs(t^1_{m_{di}}) >, \ldots, < t^k_{m_{di}}, rs(t^k_{m_{di}}) >) > \quad (4)$$

We abbreviate the first and second elements of $R(m_{di})$ as $R(m_{di})_{ls}$ and $R(m_{di})_{rs}$. The output for each set of surface-identical mentions in d is then aggregated into one result tuple as follows. For a surface string s_d associated with one or more mentions in d, the set of associated result tuples is denoted R_{s_d}. Then $R(s_d)$, the result tuple for s_d, is defined by:

$$R(s_d) = < max_{R(m_{di}) \in R_{s_d}} R(m_{di})_{ls}, \bigcup_{R(m_{di}) \in R_{s_d}} R(m_{di})_{rs} > \quad (5)$$

In other words for any surface string, we consider all target concepts and associated ranker scores, and associate the string with the highest linker score of any matching mention.

Output aggregation is informed by two parameters: *longest-n-gram*, a binary parameter indicating whether or not the "longest n-gram heuristic" is used (as opposed to "all terms"), and a *linker score threshold* λ. If the longest n-gram heuristic is used, then if both "Houston Rockets" and "Rockets" are disambiguated, for example, "Rockets" will be ignored. Finally, $R(s_d)$ will only be included in the final output if $R(s_d)_{ls} > \lambda$.

5 Data and scoring metric

In this section we describe the dataset, provide a critical evaluation, and explain how system output is evaluated.

5.1 Construction, content, and annotation

We use the dataset described in (Meij et al., 2012), which we refer to as *gold1*. A random sample of verified twitter accounts were selected, and up to their 20 most recent tweets were extracted. The original dataset had 562 tweets, but due to tweets having been deleted, the dataset consists of 502 tweets from 28 authors. Annotators used an interface enabling them to read and annotate tweets, searching Wikipedia as needed, and were instructed to, where

possible, indicate which concepts were "contained in, meant by, or relevant" to a particular tweet. Alternatively they were permitted to label tweets as ambiguous or as having referents outside of Wikipedia; 127 tweets were labeled as such and discarded[11]. The gold standard consists of the union of annotations from two annotators which amounts to 812 annotations (not including discarded tweets). URLs were removed entirely while mentions and hashtags were edited to remove leading @ and # characters respectively[12].

5.2 System false positives

Some system errors are the result of human annotation omissions (Meij et al., 2012) . There were 229 false positives when applying the GLOW to single tweets, using the longest n-gram heuristic, with the linker score threshold at -0.04. We looked at each one and rated it incorrect (110), partially correct (49), or correct (70). False positives deemed correct (FPDC) were labeled as follows: "@" (2), "#" (13), "lol" (5), "replace" (6), "new" (35), "equivalent" (9).

The *gold2* dataset is the result of adding all FPDC to *gold1*. For each FPDC type we provide representative system results followed by analysis. Table 5 gives some examples of each FPDC type, along with from the system output or *gold1*.

FPDC labeled *new* consist of a mention that annotators previously did not link and a target concept deemed correct. Table 5 gives three examples; "support", in this case, is an example of an analogous annotation in *gold1*. In the first a song was omitted in one tweet whereas in another a song was linked, and similarly so for the dates in the second example and its counterpart. In the third, a governmental acronym and an associated term are omitted, whereas in its counterpart they are annotated.

FPDC labeled *replace* consist of mentions that were originally annotated, but we believe the annotation provided by GLOW was significantly better. Table 5 contains three examples; "support", in this case, illustrates the change made by the system. In the first example some evidence was available in the tweet itself (though more conclusive evidence is available in the author's other tweets, as alluded to in section 3.2). In the second example note that *Grammy Nominees* is an album containing Grammy-nominated songs for a given year, but the URL in the tweet links to a page where only the album "Infinite Arms" can be purchased, revealing that the original annotation is incorrect (note that annotators did not have access to URLs in tweets). In the third the original annotation is too general. Note that the vast majority of false positives deemed *partially correct* are of this type.

FPDC labeled *eq* are instances where GLOW's target was deemed equivalent to the target in the original annotation. Table 5 lists three such examples followed by justification. FPDC labeled @ were user mentions that were not annotated, even though the user is identifiable and is prominent enough to have a Wikipedia page. FPDC labeled # were hash marked mentions that were not annotated. FPDC labeled *lol* were mentions expressing that the user laughed, e.g. "lol", "ROFL", "LMAO", etc. Annotating such mentions depends on whether we want to annotate actions the user indicates he or she performs in conjunction with the tweet.

[11] We acknowledge that ignoring non-referential tweets makes the task easier. Work that focuses on a system's ability to ignore irrelevant content is needed. Tweets were deemed ambiguous if annotators identified more than one correct answer, a case our system did not accommodate.

[12] @ and # characters were visible to human annotators, who were asked to ignore hash tagged terms unless their meaning is obvious; they were stripped during pre-processing. For further details and access to the dataset: http://ilps.science.uva.nl/resources/wsdm2012-adding-semantics-to-microblog-posts/ (Meij et al., 2012).

Note that these omissions and errors drawn from a subset of those mentions whose annotation was corrected by GLOW; however, other errors and omissions exist (e.g. when both humans and GLOW made mistakes). The purpose of this analysis is not to discredit the dataset. Classification of annotations or omissions as erroneous is highly subjective in that it depends on both the user's interpretation of the annotation guidelines, which in this case were rather open-ended, along with their own world knowledge. We believe the formation of guidelines and annotation methods that are more robust to such discrepancies is an important avenue of research.

6 Experiments

In this section we present and discuss experimental results. For each case we generate tweet documents (see section 4.2.1), each of which is fed to the D2W system, and final output is extracted from system output (see section 4.2.3). We calculate precision, recall, and MRR.

6.1 Evaluation metric

Output is evaluated against *gold1* and *gold2* (see section 5). Final output for a tweet document distinguishes identical mentions allowing each tweet to be associated with a list of targets.

Table of f-measures for different experimental parameters						
	By file		**By cluster**		**By author**	
	gold1	***gold2***	***gold1***	***gold2***	***gold1***	***gold2***
all terms	44.19%	51.00%	46.35%	51.82%	47.00%	52.56%
longest ngram	45.58%	52.79%	47.50%	53.13%	48.07%	53.92%
Link Threshold for F-Measures Shown Above						
	gold1	***gold2***	***gold1***	***gold2***	***gold1***	***gold2***
all terms	-0.2	-0.2	0	0.1	0.1	0
longest ngram	-0.4	-0.4	0	-0.2	0	-0.2
Cluster Size for F-Measures Shown Above						
	gold1	***gold2***	***gold1***	***gold2***	***gold1***	***gold2***
all terms	n/a	n/a	28	28	n/a	n/a
longest ngram	n/a	n/a	28	50	n/a	n/a

Table 6: Overview of different methods

Precision (P), recall (R), and F-measure (F1) are calculated on a by-tweet basis as follows:

$$P = \frac{\sum_i^{N_S} |T(x_i) \cap G(x_i)|}{N_S} \tag{6}$$

$$R = \frac{\sum_i^{N_G} |T(x_i) \cap G(x_i)|}{N_G} \tag{7}$$

$$F_1 = \frac{2PR}{P+R} \tag{8}$$

Where N_S is the number of $\langle m, t \rangle$ pairs in the system output, each x_i is a tweet, $T(x)$ contains the top target concept from each mention in tweet x, $G(x)$ contains each concept associated with x by an annotator, and N_G is the total number of gold standard annotations. Mean Reciprocal Rank (MRR) is calculated over all gold annotation tuples $\langle x, t \rangle \in G$ as follows:

$$MRR = \frac{1}{|G|} \sum_{i=1}^{|G|} \frac{1}{rank_i} \tag{9}$$

Where $rank_i$ is r if $< t_i^r, rs(t_i^r) >$ is in $R(s_d)_{rs}$, where t_i is the target of the ith gold annotation $< x_i, t_i >$, and d is the document that contains x_i. Otherwise, $1/rank_i = 0$.

6.2 Results

In order to investigate the most effective way to extend tweet context to improve D2W, we augmented single tweets using either the *by author* or *by cluster* methods (see Table 4)

For the case of single tweets, each tweet was input one at a time into GLOW. For cases where tweets were aggregated, a document containing the tweets, delimited by a line break and in chronological order by publication date, was input into GLOW.

Table 6 presents the results of applying these different methods to augment tweets. *By author* outperforms *by cluster*. Table 7 shows details for the top performing systems of each type. The systems that achieve the top Mean Reciprocal Rank (MRR), as well as MRR for the systems with the top F measure, are shown in Table 8.

The by file system performs the worst in each category. By author improves recall while by cluster improves precision. The Wilcoxon matched pairs signed rank text shows that improvement in f-measure from by file to by author method was significant ($p < .01$); improvement from by file

Statistics for top performing systems of each type							
System	**Correct**	**Missed**	**False Positives**	**Total Output**	**Precision**	**Recall**	**F1**
by file	307	505	228	535	0.5738	0.3781	0.4558
by author	318	494	193	511	0.6223	0.3916	0.4807
by cluster	309	503	180	489	0.6319	0.3805	0.4750

Table 7: Detailed results by system type using the optimal parameters for each

		MRR1		**MRR2**	
		Best Params	**Best F Params**	**Best Params**	**Best F Params**
by File	All terms	44.20%	41.62%	43.77%	41.29%
	Longest ngram	40.75%	39.70%	40.50%	39.53%
by Author	All terms	45.82%	42.27%	45.44%	42.03%
	Longest ngram	42.23%	40.21%	42.06%	40.05%
by Cluster	All terms	44.89%	41.86%	44.42%	41.56%
	Longest ngram	41.52%	39.35%	41.32%	39.25%

Table 8: Best MRR & MRR for parameters yielding best F1

to by cluster was significant as well ($p < .013$)[13]. The Adjusted Rand Index (ARI) is a measure of cluster similarity, corrected for chance. The ARI between the top author based and cluster based methods is low (.0128), indicating that there is very little overlap.

Detailed results for the highest performing systems are shown in Table 7. The differences in output moving from by file to by author systems consisted of 23 gains and 12 losses. Gains resulted for the following reasons: (i) because the top candidate was correct in both cases but in the by author case the linker score exceeded 0.0, but in the by file case it did not exceed -0.4; (ii) the top candidate was incorrect in the by file case but correct in the by author case; (iii) a surface-identical mention in another tweet either had a better linker score and/or it was linked to the correct target[14]. Some gains were deemed neutral (4) or bad (1), meaning that we deemed the change made incorrect, contrary to *gold1*. Examples of changes are illustrated in Table 9 and explained below. Losses were categorized in an analogous way.

Tweet	**By file**	**By author**	**Type**
Japan is one of NATOs global partners. On behalf of our Allies I want to extend our heartfelt condolences to those who have lost loved ones	Empire of Japan	Japan	Good change
Ejoying myself in Whistler!	Whistler, British Columbia	Whistler, British Columbia	Greater LS for identical mention
RT @kmoxnews: Section of I-55 Closed Until Monday: I-55 will be closed in both directions between Carondelet and the 4500 block of...	Carondelet, St. Louis	Carondelet, St. Louis	Context
Obama says he doesn't expect harmful levels of radiation to hit the U.S. ... public health experts say no precautionary measures needed	Ionizing radiation	Radiation	Neutral Change
Making pesto! I had to soak my nuts for 3 hours!	Pine nut	Nut (fruit)	Bad change

Table 9: Gains from by file to by author system

[13]We randomly split tweets into 17 groups, yielding 17 lists of annotations. We calculated F-measure for each group using both methods and the resulting F-measure pairs served as input to the test.

[14]Gains are determined with respect to the gold standard. The best by file and by author systems had linker score thresholds of -0.4 and 0.0, respectively.

The first change is due to additional supporting context in the author's other tweets, which include entities from modern politics (e.g. politician names and organizations). This additional context alleviates the noisy mention "Allies" which is strongly associated with *World War II* and hence *Empire of Japan*. In the second case the author had later mentioned "Whistler", a popular winter sports destination, near mentions of "slopes", "snowboarding", and "jet lag". In the third case, the author frequently mentions "St. Louis" in other tweets.

7 Conclusions and future work

D2W systems that attempt to maximize the global coherence of output have been successful in formal genres, but the required supporting concept mentions are hidden in the Twitter domain. Our approach to this apparent data sparsity is orthogonal to that taken by (Meij et al., 2012), who designed features in terms of individual n-grams and candidate concepts, rarely dependent on the entire tweet (5 out of 33), never attempting to achieve global coherence. We showed that for a given tweet, adding tweets based on both authorship and topical similarity provided GLOW sufficient information to enhance the disambiguation context for concept mentions therein, yielding statistically significant gains over the *by file* base.

We have provided a qualitative analysis of an existing hand-labeled dataset, which raised questions about both definition and evaluation of the D2W task, elucidating various sources of difficulty. In future work we plan to generate comprehensive annotation and evaluation guidelines for D2W. Second, it is clear that sometimes there is more than one appropriate target concept for a given concept mention. In some cases two concepts are equally plausible targets (*Devil* vs. *Satan* for the n-gram "the devil"), while in other cases returning a concept slightly higher up in the *is-a* taxonomic structure would plausibly still be useful for downstream applications (e.g. returning *Florida Gators* instead of the more accurate *Florida Gators men's basketball*, given only "go Gators!!"). We plan to explore principled criteria for Wikipedia concept equivalence that go beyond the provided redirects, as well as evaluation methods that do not penalize such "not so bad" deviation from human annotation. Finally, we plan to evaluate the effects of expanding tweet context based on Twitter-centric features such as the mention/retweet structure and hashtags, as well as websites linked to from within tweets.

On the Effectiveness of Using Sentence Compression Models for Query-Focused Multi-Document Summarization

ABSTRACT
This paper applies sentence compression models for the task of query-focused multi-document summarization in order to investigate if sentence compression improves the overall summarization performance. Both compression and summarization are considered as global optimization problems and solved using integer linear programming (ILP). Three different models are built depending on the order in which compression and summarization are performed: 1) *ComFirst* (where compression is performed first), 2) *SumFirst* (where important sentence extraction is performed first), and 3) *Combined* (where compression and extraction are performed jointly via optimizing a combined objective function). Sentence compression models include lexical, syntactic and semantic constraints while summarization models include relevance, redundancy and length constraints. A comprehensive set of query-related and importance-oriented measures are used to define the relevance constraint whereas four alternative redundancy constraints are employed based on different sentence similarity measures using a) cosine similarity, b) syntactic similarity, c) semantic similarity, and d) extended string subsequence kernel (ESSK). Empirical evaluation on the DUC benchmark datasets demonstrates that the overall summary quality can be improved significantly using global optimization with semantically motivated models.

KEYWORDS: Sentence compression, query-focused multi-document summarization, integer linear programming (ILP).

1 Introduction and Related Work

Text summarization is a good way to compress large amount of information into a concise form by selecting the most important information and discarding redundant information (Mani and Maybury, 1999). Query-focused multi-document summarization aims to create a summary from the available source documents that can answer the requested information need (Chali and Hasan, 2012). Extraction-based automatic summarization has been a common practice over the years for its simplicity (Edmundson, 1969; Kupiec et al., 1995; Carbonell and Goldstein, 1998; Lin, 2003; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011). Extraction of the most important sentences to form a summary can degrade the summary quality if there exists a longer sentence with partly relevant information to prevent inclusion of other important sentences (due to summary length constraint) (Martins and Smith, 2009). Sentence compression can be a good remedy for this problem where the task can be viewed as a single-sentence summarization (Jing, 2000; Clarke and Lapata, 2008). Sentence compression[1] aims to retain the most important information of a sentence in the shortest form whilst being grammatical at the same time (Knight and Marcu, 2000, 2002; Lin, 2003). Previous researches have shown that sentence compression can be used effectively in automatic summarization systems to produce more informative summaries by reducing the redundancy in the summary sentences (Jing, 2000; Knight and Marcu, 2002; Lin, 2003; Daumé III and Marcu, 2005; Zajic et al., 2007; Madnani et al., 2007; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011). However, most of these researches either focused on the task of single document summarization and generic summarization or did not consider global properties of the sentence compression problem (Clarke and Lapata, 2008). Due to the vast increase in both the amount of online data and the demand for access to different types of information in recent years, attention has shifted from single document and generic summarization[2] toward query-based multi-document summarization. On the other hand, sentence compression can achieve superior performance if it can be treated as an optimization problem and solved using integer linear programming (ILP) to infer globally optimal compressions (Gillick and Favre, 2009; Clarke and Lapata, 2008). ILP has recently attracted much attention in the natural language processing (NLP) community (Roth and Yih, 2004; Clarke and Lapata, 2008; Punyakanok et al., 2004; Riedel and Clarke, 2006; Denis and Baldridge, 2007). Gillick and Favre (2009) proposed to extend their ILP formulation for a concept-based model of summarization by incorporating additional constraints for sentence compression. However, to the best of our knowledge, there has not been a single research that deeply investigates the potential of using ILP-based sentence compression models for the task of query-focused multi-document summarization. In this paper, we accomplish this task by considering both compression and summarization as global optimization problems.

The sentence compression models used in the existing automatic summarization systems mostly exploit various lexical and syntactic properties of the sentences (Knight and Marcu, 2002; Mcdonald, 2006; Clarke and Lapata, 2008; Cohn and Lapata, 2008; Galanis and Androutsopoulos, 2010). A recent work has shown that discourse segmentation could be incorporated in a sentence compression system which can aid automatic summarization (Molina et al., 2011).

[1] Although most of the works on sentence compression are mainly related to the English language, researchers have also worked on sentence compression related to languages other than English (Molina et al., 2011; Filippova, 2010; Bouayad-Agha et al., 2006). Our work is applied to the English language. However, we believe that the proposed techniques can be applicable to other languages provided that the lexical, syntactical and semantic properties of the corresponding language are considered.

[2] A generic summary includes information which is central to the source documents whereas a query-oriented summary should formulate an answer to the user query (Goldstein et al., 1999).

Lin (2003) showed that pure syntactic-based compression does not improve a generic summarization system. A most recent work has shown that sentence compression can achieve better performance if semantic role information can be incorporated into the model (Yoshikawa et al., 2012). Inspired by their work, we recast their formulation as an ILP for sentence compression with semantic role constraints. We build three different ILP-based sentence compression models: 1) a bigram language model with lexical and syntactic constraints (derived from Clarke and Lapata (2008)), 2) the bigram language model with a topic signature modeling function (Lin and Hovy, 2000), and 3) the bigram language model with semantic role constraints (Yoshikawa et al., 2012). We choose to build them since the variation of these models were shown to achieve better results comparable to the state-of-the-art techniques (Clarke and Lapata, 2008; Yoshikawa et al., 2012). We perform a rigorous study to analyze the effectiveness of using these sentence compression models to generate query-focused summaries. For this study, we compose three different models depending on the order to perform sentence compression and extraction: 1) *ComFirst*, 2) *SumFirst*, and 3) *Combined*. The main motivation behind building these models is that we intend to study if the order of performing compression and extraction can affect the overall performance of the query-focused multi-document summarization. Martins and Smith (2009) argued that the two-step "pipeline" approaches such as *ComFirst* and *SumFirst* might often fail to select global optimal summaries.

Query-focused extractive multi-document summarization generally needs three essential criteria to be satisfied (McDonald, 2007): 1) Relevance: to contain informative sentences relevant to the given query, 2) Redundancy: to not contain multiple similar sentences, and 3) Length: should follow a fixed length constraint. We define a global optimization model that uses ILP to infer optimal summaries. The existing ILP formulations to the summarization task mostly rely on relevance and redundancy functions (such as word-level cosine similarity measure, word bigrams) that are primitive in nature (McDonald, 2007; Gillick and Favre, 2009; Martins and Smith, 2009). The major limitation of these approaches is that they do not consider the sequence of words (i.e. word ordering). They ignore the syntactic and semantic structure of the sentences and thus, cannot distinguish between "The police shot the gunman" and "The gunman shot the police". The researchers speculate that the better the relevance and redundancy functions could be, the more the solutions would be efficient (Gillick and Favre, 2009). In the proposed optimization framework, we incorporate a comprehensive set of query-related and importance-oriented measures to define the relevance function. We employ four alternative redundancy constraints based on different sentence similarity measures using a) cosine similarity, b) syntactic similarity, c) semantic similarity, and d) extended string subsequence kernel (ESSK). We propose the use of syntactic tree kernel (Moschitti and Basili, 2006), shallow semantic tree kernel (Moschitti et al., 2007), and a variation of the extended string subsequence kernel (ESSK) (Hirao et al., 2003) to accomplish the task. Our empirical evaluation on the DUC benchmark datasets demonstrate the effectiveness of applying sentence compression for the task of query-focused multi-document summarization. The results also show that the quality of the generated summaries vary based on the use of alternative redundancy constraints in the optimization framework.

2 ILP-based Sentence Compression Models

An ILP is a constrained optimization problem, where both the cost function and constraints are linear in a set of integer variables (McDonald, 2007; Clarke and Lapata, 2008). In this section we describe three ILP-based sentence compression models which we apply for the task of query-focused multi-document summarization. Our first model is a bigram language model

derived from the work of Knight and Marcu (2002); Clarke and Lapata (2008). Our second model is close in spirit rather different in content to Clarke and Lapata (2008). In this model, we combine the bigram language model with a corpus-based topic signature modeling approach of Lin and Hovy (2000). Our first two models include various lexical and syntactical constraints based on the work of Clarke and Lapata (2008). In the third model, we add a set of semantically motivated constraints into the bigram language model based on the work of Yoshikawa et al. (2012).

2.1 Bigram Language Model

According to Clarke and Lapata (2008), the sentence compression problem can be formally defined as follows. Let $S = w_1, w_2, \cdots, w_n$ is an original sentence in a document. To represent the words to be included in the compressed version of this sentence, we define a set of indicator variables δ_i that are set to 1 if i-th word is selected into the compression, and 0 otherwise. To make decisions based on word sequences (rather than individual words), we define additional indicator variables a_i (that are set to 1 if i-th word starts the compression, and 0 otherwise), b_i (that are set to 1 if i-th word ends the compression, and 0 otherwise), and c_{ij} (that are set to 1 if sequence w_i, w_j is present in the compression, and 0 otherwise). Now the inference task is solved by maximizing the following objective function (that includes the overall sum of the decision variables multiplied by their log-transformed corpus bigram probabilities) (Clarke and Lapata, 2008):

$$Maximize \sum_i a_i \cdot P(w_i|start) + \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} c_{ij} \cdot P(w_j|w_i) + \sum_i b_i \cdot P(end|w_i) \quad (1)$$

such that $\forall i, j \in \{1 \cdots n\}$:

$$\delta_i, a_i, b_i, c_{ij} \in \{0, 1\} \quad (2)$$

$$\sum_i a_i = 1 \quad (3)$$

$$\delta_j - a_j - \sum_{i=1}^{j} c_{ij} = 0 \quad (4)$$

$$\delta_i - \sum_{j=i+1}^{n} c_{ij} - b_i = 0 \quad (5)$$

$$\sum_i b_i = 1 \quad (6)$$

$$\sum_i \delta_i \geq l \quad (7)$$

$$\sum_{i:w_i \in verbs} \delta_i \geq 1 \quad (8)$$

$$\delta_i = 1 \quad (9)$$
$$\forall i : w_i \in personal\ pronouns$$

$$\delta_i = 0 \quad (10)$$
$$\forall i : w_i \in words\ in\ parentheses$$

$$\delta_i - \delta_j = 0 \quad (11)$$
$$\forall i, j : w_j \in possessive\ mods\ of\ w_i$$

The objective function in Equation 1 is maximized to find the optimal target compression where "start" and "end" denote w_0 and w_n, respectively. The above ILP formulation incorporates

various constraints. The first constraint states that the variables are binary. The later constraints are defined to disallow invalid bigram sequences in the compression. Constraint 3 states that exactly one word can start a compression. Constraint 4 and Constraint 5 are responsible to ensure correct bigram sequences, whereas Constraint 6 denotes that exactly one word can end the compression. On the other hand, Constraint 7 forces the compression to have at least l words. We add some additional constraints (Constraint 8 to Constraint 11) from Clarke and Lapata (2008) to ensure that the target compressions are lexically and syntactically acceptable. To accomplish this purpose, we use the Oak system[3] (Sekine, 2002) and the Charniak parser[4] (Charniak, 1999) to obtain information regarding parts-of-speech and grammatical relations in a sentence.

2.2 Topic Signature Model

We use a topic signature modeling approach (Lin and Hovy, 2000) to identify the important content words from the original source sentence. The important words are considered to have significantly greater probability of occurring in a given text compared to that in a large background corpus. We incorporate this importance score into the objective function of the bigram language model (Section 2.1) to ensure that the target compression prefers to keep important content words. We use a topic signature computation tool[5] for this purpose. The background corpus that is used in this tool contains 5000 documents from the English GigaWord Corpus. Our modified objective function becomes:

$$Maximize \sum_i \delta_i \cdot I(w_i) + \sum_i a_i \cdot P(w_i|start) + \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} c_{ij} \cdot P(w_j|w_i) + \sum_i b_i \cdot P(end|w_i) \quad (12)$$

where $I(w_i)$ denotes the importance score of the i-th word.

2.3 Bigram Language Model with Semantic Constraints

Yoshikawa et al. (2012) have proposed a set of formulas called Markov Logic Network (MLN) to build a semantically motivated sentence compression model and showed that their model achieves improved performance. We recast their formulas as constraints of our ILP model and incorporate them into the bigram language model. The main idea is to utilize the predicate-argument relations of a sentence and define constraints based on semantic roles to improve the weaknesses of the lexical and syntactical constraints. In this manner, we can ensure that the target compression contains meaningful information. For this purpose, we parse the source sentence semantically using a Semantic Role Labeling (SRL) system (Kingsbury and Palmer, 2002; Hacioglu et al., 2003), ASSERT[6]. When presented with a sentence, ASSERT performs a full syntactic analysis of the sentence, automatically identifies all the verb predicates in that sentence, extracts features for all constituents in the parse tree relative to the predicate, and identifies and tags the constituents with the appropriate semantic arguments. We add the following additional constraints as the semantic constraints to our bigram language model (Section 2.1):

$$\delta_i = 1 \quad (13)$$
$$\forall i : w_i \; is \; a \; predicate$$

[3] http://nlp.cs.nyu.edu/oak/
[4] Available at ftp://ftp.cs.brown.edu/pub/nlparser/
[5] Available at http://www.cis.upenn.edu/ lannie/topicS.html
[6] Available at http://cemantix.org/assert.html

$$\delta_i - \delta_j = 0 \quad (14)$$
$$\forall i, j : w_j \text{ is an argument of predicate } w_i$$

$$\delta_i = 1 \quad (15)$$
$$\forall i : w_i \in [ARG0...ARG5]$$

$$\delta_i = 0 \quad (16)$$
$$\forall i : w_i \in \text{optional arguments}$$

Here, Constraint 13 guarantees that if a word is a predicate, it is included in the compression. Constraint 14 states that if a predicate is in compression, then its argument is also kept in the compression. In Constraint 15, we define that if a word denotes any of the possible semantic roles (i.e. *[ARG0...ARG5]* which are called *mandatory arguments*), it is included in the compression. On the other hand, we use Constraint 16 to restrict the inclusion of optional arguments[7] in the compression.

3 ILP for Query-focused Multi-document Summarization

The query-focused multi-document summarization inference problem can be formulated in terms of ILP. To represent the sentences included in the summary we define a set of indicator variables α_i that are set to 1 if i-th sentence is selected into the summary, and 0 otherwise. Let $Rel(i)$ be the relevance function that returns the relevance score of the i-th sentence. The score of a summary is the sum of the relevance scores of the sentences present in the summary. The inference task is solved by maximizing the overall score of a summary:

$$Maximize \sum_i Rel(i) * \alpha_i$$

such that $\forall i, j$:

$$\alpha_i \in \{0, 1\} \quad (17)$$

$$Sim(i, j) * \left(\alpha_i + \alpha_j\right) \leq K \quad (18)$$

$$\sum_i Len(i) * \alpha_i \leq L \quad (19)$$

We incorporate three constraints into our formulation. The first constraint states that the variables are binary. The second constraint is the redundancy constraint that ensures that only one of the two similar sentences is chosen into the summary. $Sim(i, j)$ function returns a similarity score between the i-th and j-th sentences. Higher scores correspond to higher similarity between a pair of sentences. We assume a threshold K, that sets a tolerance limit to the acceptable similarity score between any two sentences. This value is empirically determined during experiments. The third constraint controls the length of the summary up to a maximum limit, L. $Len(i)$ denotes the length of the i-th sentence in words.

3.1 $Rel(i)$ Function

For each sentence, the $Rel(i)$ function returns a relevance score by combining a set of query-related and importance-oriented measures. The query-related measures calculate the similarity between each sentence and the given query while the importance-oriented measures denote the importance of a sentence in a given document (Chali and Hasan, 2012; Edmundson, 1969; Sekine and Nobata, 2001). For query-related measures, we consider n–gram overlap,

[7] There are some additional arguments or semantic roles that can be tagged by ASSERT. They are called *optional arguments* and they start with the prefix *ARGM*. These are defined by the annotation guidelines set in (Palmer et al., 2005).

longest common subsequence (LCS), weighted LCS, skip-bigram, exact word, synonym, hypernym/hyponym, gloss and basic elements (BE) overlap (Lin, 2004; Zhou et al., 2005) using WordNet (Fellbaum, 1998), and syntactic similarity (Collins and Duffy, 2001; Moschitti and Basili, 2006). To measure the importance of a sentence, we consider its position, length, similarity with topic title, and presence of certain named entities and cue words. The mean of these scores denote the relevance of a sentence.

3.1.1 Query-related Measures

n-gram Overlap n–gram overlap measures the overlapping word sequences between the candidate document sentence and the query sentence (Lin, 2004).

LCS Given two sequences S_1 *and* S_2, the longest common subsequence (LCS) of S_1 *and* S_2 is a common subsequence with maximum length. We use this feature to calculate the longest common subsequence between a candidate sentence and the query.

WLCS Weighted Longest Common Subsequence (WLCS) improves the basic LCS method by remembering the length of consecutive matches encountered so far. Given two sentences X and Y, the WLCS score of X and Y can be computed using the similar dynamic programming procedure as stated in Lin (2004).

Skip-Bigram Skip-bigram measures the overlap of skip-bigrams between a candidate sentence and a query sentence. Skip-bigram counts all in-order matching word pairs while LCS only counts one longest common subsequence.

Exact-word Overlap This is a measure that counts the number of words matching exactly between the candidate sentence and the query sentence.

Synonym Overlap This is the overlap between the list of synonyms of the content words (i.e. nouns, verbs and adjectives) extracted from the candidate sentence and *query related words*[8].

Hypernym/Hyponym Overlap This is the overlap between the list of hypernyms (up to depth 2 in WordNet's hierarchy) and hyponyms (depth 3) of the nouns extracted from the sentence in consideration and *query related words*.

Gloss Overlap This is the overlap between the list of content words that are extracted from the gloss definition of the nouns in the sentence in consideration and *query related words*.

Syntactic Feature The syntactic similarity between the *query* and the *sentence* is calculated using a similar procedure discussed in Section 3.2.2, which gives the similarity score based on syntactic structures.

Basic Element (BE) Overlap We extract BEs (Hovy et al., 2006) for the sentences (or query) by using the BE package distributed by ISI[9]. We compute the Likelihood Ratio (LR) for each BE according to Zhou et al. (2005). We sort the BEs based on LR scores to produce a BE-ranked list. The ranked list contains important BEs at the top which may or may not be relevant to the

[8]To establish the query related words, we took a query and created a set of related queries by replacing its content words by their first-sense synonyms using WordNet.

[9]BE website:http://www.isi.edu/ cyl/BE

complex question. We filter out the BEs that are not related to the query and get the BE overlap score.

3.1.2 Importance-oriented Measures

Position of Sentences Sentences that reside at the start and at the end of a document often tend to include the most valuable information. We manually inspected[10] the given document collection and found that the first and the last 3 sentences of a document often qualify to be considered for this feature. We assign the score 1 to them and 0 to the rest.

Length of Sentences Longer sentences contain more words and have a greater probability of containing valuable information. Therefore, a longer sentence has a better chance of inclusion in a summary[11]. We give the score 1 to a longer sentence and assign the score 0 otherwise. We manually investigated the document collection and set a threshold that a longer sentence should contain at least 11 words.

Title Match If we find a match such as exact word overlap, synonym overlap and hyponym overlap between the title and a sentence, we give it the score 1, otherwise 0.

Named Entity The score 1 is given to a sentence that contains a Named Entity class among: PERSON, LOCATION, ORGANIZATION, GPE (Geo-Political Entity), FACILITY, DATE, MONEY, PERCENT, TIME. We believe that the presence of a Named Entity increases the importance of a sentence. For example, the sentence *"Washington, D.C. is the capital of the United States"* has two named entities (i.e. locations) which denote that the sentence is important. We use the *OAK* System (Sekine, 2002), from New York University for Named Entity recognition.

Cue Word Match The probable relevance of a sentence is affected by the presence of pragmatic words such as "significant", "impossible", "in conclusion", "finally" etc. We use a cue word list of 228 words. We give the score 1 to a sentence having any of the cue words and 0 otherwise.

3.2 $Sim(i, j)$ Function

We employ four alternative redundancy constraints based on different sentence similarity functions (i.e. $Sim(i, j)$) using a) cosine similarity, b) syntactic similarity, c) semantic similarity, and d) extended string subsequence kernel (ESSK).

3.2.1 Cosine Similarity Measure (COS)

The cosine similarity between the respective pair of sentences can be calculated by representing each sentence as a vector of term specific weights (Erkan and Radev, 2004). The term specific weights in the sentence vectors are products of local and global parameters. This is known as term frequency-inverse document frequency (tf-idf) model. The weight vector for a sentence s is $\vec{v_s} = [w_{1,s}, w_{2,s}, \ldots, w_{N,s}]^T$, where,

$$w_{t,s} = tf_t \times \log \frac{|S|}{|\{t \in s\}|}$$

[10] We randomly investigated few newspaper articles and observed that sentences that reside at the start and at the end of a document often tend to include the most valuable information. The "Position of sentences" feature could be tuned to fit other genres of texts as well.

[11] The "Length of sentences" feature was exploited for summarization by extraction in general, which was our motivation to apply different compression models for the task.

Here, tf_t is the term frequency (*tf*) of the term t in a sentence s (a local parameter). $\log \frac{|S|}{|\{t \in s\}|}$ is the inverse document frequency (idf) (a global parameter). $|S|$ is the total number of sentences in the corpus, and $|\{t \in s\}|$ is the number of sentences containing the term t.

3.2.2 Syntactic Similarity Measure (SYN)

Pasca and Harabagiu (2001) demonstrated that with the syntactic form one can see which words depend on other words. Syntactic features have been used successfully so far in *question answering* (Zhang and Lee, 2003; Moschitti et al., 2007; Moschitti and Basili, 2006). Inspired by the potential significance of using syntactic measures for finding similar texts, we get a strong motivation to use it as a redundancy measure in our optimization framework. The first step to calculate the syntactic similarity between two sentences is to parse the corresponding sentences into syntactic trees using the Charniak parser (Charniak, 1999). Once we build the syntactic trees, our next task is to measure the similarity between the trees. For this, every tree T is represented by an m dimensional vector $v(T) = \big(v_1(T), v_2(T), \cdots v_m(T)\big)$, where the i-th element $v_i(T)$ is the number of occurrences of the i-th tree fragment in tree T. The tree fragments of a tree are all of its sub-trees which include at least one production with the restriction that no production rules can be broken into incomplete parts. The tree kernel of two trees T_1 and T_2 is actually the inner product of $v(T_1)$ and $v(T_2)$ (Collins and Duffy, 2001):

$$TK(T_1, T_2) = v(T_1).v(T_2) \tag{20}$$

We define the indicator function $I_i(n)$ to be 1 if the sub-tree i is seen rooted at node n and 0 otherwise. It follows:

$$v_i(T_1) = \sum_{n_1 \in N_1} I_i(n_1)$$

$$v_i(T_2) = \sum_{n_2 \in N_2} I_i(n_2)$$

where, N_1 and N_2 are the set of nodes in T_1 and T_2 respectively. The *TK* (tree kernel) function gives the similarity score between a pair of sentences based on the syntactic structure.

3.2.3 Semantic Similarity Measure (SEM)

Shallow semantic representations can prevent the sparseness of deep structural approaches and the weakness of cosine similarity based models (Moschitti et al., 2007). As an example, PropBank (PB) (Kingsbury and Palmer, 2002) made it possible to design accurate automatic Semantic Role Labeling (SRL) systems (Hacioglu et al., 2003). Therefore, we get the feeling that an application of SRL as a redundancy measure might suit well, since the textual similarity between a pair of sentences relies on a deep understanding of the semantics of both. So, applying semantic similarity measurement as a $Sim(i, j)$ function is another noticeable contribution of this paper. To calculate the semantic similarity between two sentences, we first parse the corresponding sentences semantically using the Semantic Role Labeling (SRL) system, ASSERT. ASSERT is an automatic statistical semantic role tagger, that can annotate naturally occurring text with semantic arguments. We represent the annotated sentences using tree structures that are called semantic trees (ST). In the semantic tree, arguments are replaced with the most important word, often referred to as the semantic head. We look for noun, then verb, then adjective, then adverb to find the semantic head in the argument. If none of these is present, we take the first word of the argument as the semantic head. As in tree kernels (Section 3.2.2), common substructures cannot be composed by a node with only some of its

children as an effective ST representation would require, Moschitti et al. (2007) solved this problem by designing the Shallow Semantic Tree Kernel (SSTK) which allows to match portions of a ST. The SSTK function yields the similarity score between a pair of sentences based on their semantic structures.

3.2.4 Extended String Subsequence Kernel (ESSK)

The ESSK is a simple extension of the Word Sequence Kernel (WSK) (Cancedda et al., 2003) and String Subsequence Kernel (SSK) (Lodhi et al., 2002) that can incorporate semantic information with the use of word senses. In original ESSK, each "alphabet" in SSK is replaced by a disjunction of an "alphabet" and its alternative (word senses) (Hirao et al., 2003). Here, all possible senses of a word are used as the alternatives. However, in our ESSK formulation, we consider each word in a sentence as an "alphabet", and the alternative as its disambiguated sense found through a dictionary based disambiguation approach. We use WordNet to find the semantic relations among the words in a text. We calculate the similarity score $\mathrm{Sim}(T_i, U_j)$ using ESSK where T_i and U_j are the two sentences. Formally, ESSK is defined as follows[12]:

$$K_{essk}(T,U) = \sum_{m=1}^{d} \sum_{t_i \in T} \sum_{u_j \in U} K_m(t_i, u_j)$$

$$K_m(t_i,u_j) = \begin{cases} val(t_i,u_j) & \text{if } m=1 \\ K'_{m-1}(t_i,u_j) \cdot val(t_i,u_j) & \end{cases}$$

Here, $K'_m(t_i,u_j)$ is defined below. t_i and u_j are the nodes of T and U, respectively. The function $val(t,u)$ returns the number of attributes (i.e. words) common to the given nodes t and u.

$$K'_m(t_i,u_j) = \begin{cases} 0 & \text{if } j=1 \\ \lambda K'_m(t_i,u_{j-1}) + K''_m(t_i,u_{j-1}) & \end{cases}$$

Here λ is the decay parameter for the number of skipped words. We choose $\lambda = 0.5$ for this research. $K''_m(t_i,u_j)$ is defined as:

$$K''_m(t_i,u_j) = \begin{cases} 0 & \text{if } i=1 \\ \lambda K''_m(t_{i-1},u_j) + K_m(t_{i-1},u_j) & \end{cases}$$

Finally, the similarity measure is defined after normalization as below:

$$sim_{essk}(T,U) = \frac{K_{essk}(T,U)}{\sqrt{K_{essk}(T,T) K_{essk}(U,U)}}$$

4 Experiments

4.1 Task Description

We consider the query-focused multi-document summarization task defined in the Document Understanding Conference (DUC[13]), 2007. The task is: *"Given a complex question and a collection of relevant documents, the task is to synthesize a fluent, well-organized 250-word summary of the documents that answers the question(s) in the topic"*. We generate 250-word extract summaries for the topics of DUC-2007 using different combinations of sentence compression models (defined in Section 2) and alternative redundancy constraints (Section 3.2). DUC-2007 provided 45 document clusters each containing 25 news articles that came from the

[12]The formulae denotes a dynamic programming technique to compute the ESSK similarity score (Hirao et al., 2004) where d is the vector space dimension i.e. the number of all possible subsequences of up to length d.

[13]http://duc.nist.gov/

AQUAINT corpus, which is comprised of newswire articles from the Associated Press and New York Times (1998-2000) and Xinhua News Agency (1996-2000). As we intend to study if the order of performing compression and extraction can affect the overall performance of the query-focused multi-document summarization, we compose three different models depending on the order to perform sentence compression and extraction: **(1) ComFirst:** In this approach, document sentences are compressed first (using different models as described in Section 2) and then the most relevant compressions are selected to form the summaries (according to Section 3), **(2) SumFirst:** In this approach, we extract the most important sentences first from the source documents (according to Section 3) and then compress them (using different models as described in Section 2) to form the summaries, and **(3) Combined:** Here, we perform compression and extraction jointly by combining the objective functions of Section 2 and Section 3 according to Martins and Smith (2009). Then we optimize the combined objective function to select a small number of most important sentences (from the source documents) whose compressions should be used to form a summary.

4.2 Solving the ILPs

To solve the proposed ILP formulations, we use *lp_solve*[14], a widely used Integer Linear Programming solver that implements Branch-and-Bound algorithm. For summarization, we solve an ILP for each topic in consideration and generate the corresponding query-focused summary. For a document cluster of average size (approximately 510 sentences), the solving process takes under 20 seconds on an Intel Pentium 4, 3.20 GHz desktop machine. For a larger document cluster (of size around 1000 sentences), it takes $90-120$ seconds to solve the ILP. For a smaller document set, the ILP is solved in a few seconds. For compression, we solve an ILP for each sentence in consideration. The solving process takes less than a second per sentence on average for all the compression models. For the joint extraction and compression model, we solve an ILP for each topic in consideration. The solving process is generally slower than solving the ILPs for only sentence extraction or compression as it takes $300-1200$ seconds depending on the document cluster size.

4.3 Evaluation Results and Discussion

4.3.1 Automatic Evaluation

The multiple "reference summaries" given by DUC-2007 are used in the evaluation of our summary content. We carried out the automatic evaluation of our summaries using the ROUGE (Lin, 2004) toolkit. Among different scores reported by ROUGE, unigram-based ROUGE score (ROUGE-1) has been shown to agree with human judgment most (Lin, 2003). We report the widely adopted important ROUGE metrics in the results: ROUGE-1 (unigram),and ROUGE-2 (bigram). The comparison between the systems in terms of their F-scores is given in Table 1. We also include the results of the official baseline systems, the best system (Pingali et al., 2007), and the average ROUGE scores of all the participating systems of DUC-2007. Baseline-1 returns all the leading sentences (up to 250 words) of the most recent document whereas baseline-2's main idea is to ignore the topic narrative while generating summaries using an HMM model[15].

The columns in Table 1 denote the use of alternative redundancy constraints in the optimization

framework whereas the rows stand for the use of different compression models[16]. From these results, we can clearly see the impact of using different sentence compression models on the overall summarization performance. In the **ComFirst** approach, we can see that the bigram model with semantic constraints outperforms all the other alternative models by a clear margin. We can also see the impact of different redundancy constraints on the overall performance. We observe that the use of semantic measure as the redundancy constraint yields the best performance. On the other hand, we see a clear improvement in almost all the scores when we follow the **SumFirst** approach. This phenomenon suggests that compressing the document sentences at the beginning often tend to reduce relevant information in the sentences for which we get lesser similarity matching when we calculate the relevance scores according to Section 3.1. In the **Combined** approach, we achieve better summarization performance than the other two approaches which denotes that the overall summary quality can be improved if a global optimization framework is utilized having a joint compression and extraction model. Again, we see that the bigram language model with semantic constraints along with the semantic redundancy constraint (used in the summarization model) yields the best performance. We also report the results of a *"No compression"* and a *"No redundancy"* baseline. Comparisons with these baselines also suggest that our bigram compression model with semantic constraints can improve the overall summarization performance if a **Combined** optimization framework is used in presence of **COS** or **SEM** redundancy constraints. These results also demonstrate that the absence of a redundancy constraint in the ILP framework for summarization really hurts the overall quality of the summaries. We also compare the scores of our model with the state-of-the-art systems of DUC-2007. From the results, we see that our semantically motivated models can mostly outperform the **DUC baselines** and the **AverageDUC** scores to show a clear improvement in the overall summarization performance while achieving a comparable performance with respect to the DUC-2007 best system. The differences between the models are computed

[16]The last few rows and columns are used to accommodate the scores of the baselines and the state-of-the-art systems.

to be statistically significant at $p < 0.05$ (using Student's t-test) except for the differences between **topicSig+SYN** and **bigram+SYN**, and **topicSig+ESSK** and **bigram+ESSK** in all the three approaches, between **topicSig+COS** and **bigram+COS** in the **Combined** approach, and between **"bigram+sem"+SEM** and **DUC Best System** in the **Combined** approach.

4.3.2 Manual Evaluation

One of the important demerits of using sentence compression models is that they can degrade the linguistic quality of a summary by showing poor compression performance. ROUGE is not reliable to some researchers as there might be some linguistically bad summaries that get state-of-the-art ROUGE scores (Sjöbergh, 2007). So, we conduct an extensive manual evaluation in order to analyze the effectiveness of our approaches. Two self reported native English-speaking university graduate students judge the summaries for linguistic quality and overall responsiveness according to the DUC-2007 evaluation guidelines[17]. The given linguistic quality score is an integer between 1 (very poor) and 5 (very good) and is guided by consideration of the following factors: 1. Grammaticality, 2. Non-redundancy, 3. Referential clarity, 4. Focus, and 5. Structure and Coherence. The responsiveness score is also an integer between 1 (very poor) and 5 (very good) and is based on the amount of information in the summary that helps to satisfy the information need. The carried out user evaluation was subjective in nature specially while judging referential clarity, focus, coherence and overall responsiveness of the summaries. The inter-annotator agreement of Cohen's $\kappa = 0.43$ (Cohen, 1960) was computed that denotes a moderate degree of agreement (Landis and Koch, 1977) between the raters. Table 2 presents the average linguistic quality and overall responsive scores of all the systems. From these results, we can see that the use of different sentence compression models has a negative impact on the overall linguistic quality of the summaries. The reason behind this is that our bigram compression models were less aware of the underlying context in a sentence and hence, some word deletions resulted a loss in focus and coherence of the overall summaries. However, we observe that the semantically motivated models are showing an improved summarization performance; also, their overall responsiveness scores are comparable to the state-of-the-art systems. This suggests that the manual evaluation results are corresponding well to the automatic evaluation results. Considering the work of Gillick and Favre (2009) for a relative comparison, we find that both our automatic and manual evaluation results are corresponding fairly well to their results obtained on the TAC[18]-2008 data. Their ILP model with additional constraints to include sentence compression achieved an improvement in ROUGE-2 score over the "no compression" alternative while having reductions in manual evaluation scores. We perform a statistical significance test on our manual evaluation results at $p < 0.05$ using Student's t-test. The differences between the models are statistically significant except for the differences between **topicSig+COS** and **bigram+COS**, and **topicSig+SYN** and **bigram+SYN** in all the three approaches. The manual evaluation results also demonstrate that the use of different redundancy constraints certainly affects the overall performance of the proposed optimization framework for summarization[19]. From these experiments we can conclude that the semantic similarity measure can be used effectively as the $Sim(i, j)$ function to improve the performance of the traditional cosine similarity based approaches. We plan to make our created resources available to the scientific community.

Conclusion and Future Work

We have analyzed the effectiveness of using different ILP-based sentence compression models for the task of query-focused multi-document summarization. Our empirical evaluation suggested that the semantically motivated sentence compression models can enhance the overall summarization performance in presence of the semantic redundancy constraint in the summarization model and this can be achieved irrespective of the compression and extraction order followed during the process. Our results also demonstrated that a combined optimization framework of compression and extraction can achieve better performance than the other two considered approaches effectively. We also found that the *SumFirst* approach shows superior performance to that of the *ComFirst* approach suggesting the fact that extracting the most important sentences before compression is a more effective way of summarization. We have also used different textual similarity measurement techniques as the redundancy constraints of the ILP-based summarization framework and performed an extensive experimental evaluation to show their impact on the overall summarization performance. Experimental results showed that the use of semantic similarity measure as the $Sim(i, j)$ function in the redundancy constraint yields the best performance. Overall, our global optimization frameworks showed promising performance with respect to the state-of-the-art systems. We look forward to apply our approach to other available datasets of DUC-2005 and DUC-2006. The findings should hold for these datasets as well as for other genres of datasets since we believe that our ILP-based compression and summarization models could be tuned to fit them. We also plan to use other automatic measures (Saggion et al., 2010; Pitler et al., 2010) to evaluate our approach.

ABSTRACT
We address the challenge of automatically generating questions from topics. We consider that each topic is associated with a body of texts containing useful information about the topic. Questions are generated by exploiting the named entity information and the predicate argument structures of the sentences present in the body of texts. To measure the importance of the generated questions, we use Latent Dirichlet Allocation (LDA) to identify the sub-topics (which are closely related to the original topic) in the given body of texts and apply the Extended String Subsequence Kernel (ESSK) to calculate their similarity with the questions. We also propose the use of syntactic tree kernels for computing the syntactic correctness of the questions. The questions are ranked by considering their importance (in the context of the given body of texts) and syntactic correctness. To the best of our knowledge, no other study has accomplished this task in our setting before. Experiments show that our approach can significantly outperform the state-of-the-art results.

KEYWORDS: Question generation, named entity information, predicate argument structures, latent dirichlet allocation (LDA), extended string subsequence kernel (ESSK), syntactic tree kernel.

1 Introduction

When a user is served with a ranked list of relevant documents by the standard document retrieval systems (i.e. search engines), his/her search task is usually not over (Chali et al., 2009b). The next step for him/her is to look into the documents themselves and search for the precise piece of information he/she was looking for. This method is time consuming, and a correct answer could easily be missed, by either an incorrect query resulting in missing documents or by careless reading. This is why, Question Answering (QA) has received immense attention from the information retrieval, information extraction, machine learning, and natural language processing communities (Kotov and Zhai, 2010). One of the main requirements of a QA system is that it must receive a well-formed question as input in order to come up with the best possible correct answer as output. Available studies revealed that humans are not very skilled in asking good questions about a topic of their interest. They are forgetful in nature which often restricts them to properly express whatever that is peeking in their mind. Therefore, they would benefit from automated Question Generation (QG) systems that can assist in meeting their inquiry needs (Olney et al., 2012; Ali et al., 2010; Kotov and Zhai, 2010; Rus and Graesser, 2009; Lauer et al., 1992; Graesser et al., 2001). Question asking and Question Generation are important components in advanced learning technologies such as intelligent tutoring systems, and inquiry-based environments (Graesser et al., 2001). A QG system would be useful for building better question asking facilities in intelligent tutoring systems. Another benefit of QG is that it can be a good tool to help improve the quality of the Question Answering (QA) systems (Graesser et al., 2001; Rus and Graesser, 2009).

The main motivation of this work is to generate all possible questions about a given topic. For example, given the topic *"Apple Inc. Logos"*, we can generate questions such as *"What is Apple Inc.?"*, *"Where is Apple Inc. located?"*, *"Who designed Apple's Logo?"* etc. We consider this task of automatically generating questions from topics and assume that each topic is associated with a body of texts having useful information about the topic. Our main goal is to generate fact-based questions[1] about a given topic from its associated content information. We generate questions by exploiting the named entity information and the predicate argument structures of the sentences (along with semantic roles) present in the given body of texts. The named entities and the semantic role labels are used to identify relevant parts of a sentence in order to form relevant questions over them. The importance of the generated questions is measured in two steps. In the first step, we identify whether the question is asking something about the topic or something that is very closely related to the topic. We call this the measure of *topic relevance*. For this purpose, we use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to identify the sub-topics (which are closely related to the original topic) in the given body of texts and apply the Extended String Subsequence Kernel (ESSK) (Hirao et al., 2003) to calculate their similarity with the questions. In the second step, we judge the syntactic correctness of each generated question. We apply the tree kernel functions (Collins and Duffy, 2001) and re-implement the syntactic tree kernel model according to Moschitti et al. (2007) for computing the syntactic similarity of each question with the associated content information. We rank the questions by considering their topic relevance and syntactic correctness scores. Experimental results show the effectiveness of our approach for automatically generating topical questions. The remainder of the paper is organized as follows. Section 2 describes the related work and motivation followed by Section 3 that presents the description of our QG system. Section 4 explains the experiments and shows evaluation results. We conclude the paper in the next section.

[1] We mainly focus on generating *Who, What, Where, Which, When, Why and How* questions in this research.

2 Related Work and Motivation

Recently, question generation has got immense attention from the researchers and hence, different methods have been proposed to accomplish the task in different relevant fields (Andrenucci and Sneiders, 2005). McGough et al. (2001) proposed an approach to build a web-based testing system with the facility of dynamic question generation. Wang et al. (2008) showed a method to automatically generate questions based on question templates (which are created from training on medical articles). Brown et al. (2005) described an approach to automatically generate questions to assess the user's vocabulary knowledge. To mimic the reader's self-questioning strategy during reading, Chen et al. (2009) developed a method to generate questions automatically from informational text. On the other hand, Agarwal et al. (2011) considered the question generation problem beyond sentence level and proposed an approach that uses discourse connectives to generate questions from a given text. Several other QG models have been proposed over the years that deal with transforming answers to questions and utilizing question generation as an intermediate step in the question answering process (Echihabi and Marcu, 2003; Hickl et al., 2005). There are some other researchers who have approached the task of generating questions for educational purposes (Mitkov and Ha, 2003; Heilman and Smith, 2010b).

The Natural Language Processing (NLP), Natural Language Generation (NLG), Intelligent Tutoring System, and Information Retrieval (IR) communities have currently identified the Text-to-Question generation task as promising candidates for shared tasks[2] (Rus and Graesser, 2009; Boyer and Piwek, 2010). In the Text-to-Question generation task, a QG system is given a text, and the goal is to generate a set of questions for which the text contains answers. The task of generating a question about a given text can be typically decomposed into three subtasks. First, given the source text, a content selection step is necessary to select a target to ask about, such as the desired answer. Second, given a target answer, an appropriate question type is selected, i.e., the form of question to ask is determined. Third, given the content, and question type, the actual question is constructed. Based on this principle, several approaches have been described in Boyer and Piwek (2010) that use named entity information, syntactic knowledge and semantic structures of the sentences to perform the task of generating questions from sentences and paragraphs (Heilman and Smith, 2010a; Mannem et al., 2010). Inspired by these works, we perform the task of topic to question generation using named entity information and semantic structures of the sentences. A task that is similar to ours is the task of keywords to question generation that has been addressed recently in Zheng et al. (2011). They propose a user model for jointly generating keywords and questions. However, their approach is based on generating question templates from existing questions which requires a large set of English questions as training data. In recent years, some other related researches have proposed the tasks of high quality question generation (Ignatova et al., 2008) and generating questions from queries (Lin, 2008). Fact-based question generation has been accomplished previously by Rus et al. (2007); Heilman and Smith (2010b). We also focus on generating fact-based questions in this research.

Besides grammaticality, an effective QG system should focus deeply on the importance of the generated questions (Vanderwende, 2008). This motivates the use of a question ranking module in a typical QG system. Over-generated questions can be ranked using different approaches such as statistical ranking methods, dependency parsing, identifying the presence of pronouns and

[2] http://www.questiongeneration.org/QGSTEC2010

named entities, and topic scoring (Heilman and Smith, 2010a; Mannem et al., 2010; McConnell et al., 2011). However, most of these automatic ranking approaches ignore the aspects of complex paraphrasing by not considering lexical semantic variations (e.g. synonymy) while measuring the importance of the questions. In our work, we use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to identify the sub-topics (which are closely related to the original topic) in the given body of texts. In recent years, LDA has become one of the most popular topic modeling techniques and has been shown to be effective in several text-related tasks such as document classification, information retrieval, and question answering (Misra et al., 2008; Wei and Croft, 2006; Celikyilmaz et al., 2010). Hirao et al. (2003) introduced ESSK considering all possible senses to each word to perform their summarization task. Their method is effective. However, the fact that they do not disambiguate word senses cannot be disregarded. In our task, we apply ESSK to calculate the similarity between important topics (discovered using LDA) and the generated questions in order to measure the importance of each question. We use disambiguated word senses for this purpose.

Syntactic information has been used successfully in *question answering* previously (Chali et al., 2009a, 2011; Zhang and Lee, 2003; Moschitti et al., 2007; Moschitti and Basili, 2006). Pasca and Harabagiu (2001) argued that with the syntactic form of a sentence one can see which words depend on other words. We also feel that there should be a similarity between the words which are dependent in the sentences present in the associated body of texts and the dependency between words of the generated question. This motivates us to propose the use of syntactic kernels in judging the syntactic correctness of the generated questions automatically.

The main goal of our work is to generate as many questions as possible related to the topic. We use NE information and the predicate argument structures of the sentences to accomplish this goal. Our approach is different from the setup in shared tasks (Rus and Graesser, 2009; Boyer and Piwek, 2010) as we generate a set of basic questions which are useful to add variety in the question space. A paragraph associated with each topic is used as the source of relevant information about the topic. We evaluate our systems in terms of topic relevance which is different from the prior works (Heilman and Smith, 2010a; Mannem et al., 2010). Syntactic correctness is also an important property of a good question. For this reason, we evaluate our system in terms of syntactic correctness as well. The proposed system will be useful to generate topic related questions from the associated content information which can be used to incorporate a "question suggestions for a certain topic" facility in the search systems. For example, if a user searches for some information related to a certain topic, the search system could generate all possible topic-relevant questions from a preexistent related body of texts to provide suggestions. Kotov and Zhai (2010) approached a similar task by proposing a technique to augment the standard ranked list presentation of search results with a question based interface to refine user given queries.

The major contributions of our work can be summarized as follows:

- We perform the task of topic to question generation which can help users in expressing their information needs. Questions are generated using a set of general-purpose rules based on named entity information and the predicate argument structures of the sentences (along with semantic roles) present in the associated body of texts.
- We use LDA to identify the sub-topics (which are closely related to the original topic) in the given body of texts and apply ESSK (with disambiguated word senses) to calculate

their similarity with the questions. This helps us to measure the importance of each question.

- We apply the tree kernel functions and re-implement the syntactic tree kernel model for computing the syntactic similarity of each question with the associated content information. In this way, we judge the syntactic correctness of each generated question automatically.
- The ESSK similarity scores and the syntactic similarity scores are used to rank the generated questions. In doing so, we show that the use of ESSK and syntactic kernels improve the relevance and the syntactic correctness of the top-ranked questions, respectively.
- We also run experiments by narrowing down the topic focus. Experiments with the topics about persons (biographical focus) reveal improvements in the overall results.

3 Topic to Question Generation

Our QG approach mainly builds on four steps. In the first step, complex sentences (from the given body of texts) related to a topic are simplified as it is easier to generate questions from simple sentences. In the next step, named entity information and predicate argument structures of the sentences are extracted and then, questions are generated using them. In the third step, LDA is used to identify important sub-topics from the given body of texts and then ESSK is applied to find their similarity with the generated questions. In the final step, syntactic tree kernel is employed and syntactic similarity between the generated questions and the sentences present in the body of texts determines the syntactic correctness of the questions. Questions are then ranked by considering the ESSK similarity scores and the syntactic similarity scores. We describe the overall procedure in the following subsections.

3.1 Sentence Simplification

Sentences may have complex grammatical structure with multiple embedded clauses. Therefore, we simplify the complex sentences with the intention to generate more accurate questions. We use the simplified factual statement extractor model[3] of Heilman and Smith (2010a). Their model extracts the simpler forms of the complex source sentence by altering lexical items, syntactic structure, and semantics and by removing phrase types such as leading conjunctions, sentence-level modifying phrases, and appositives. For example, given a complex sentence *s*, we get a corresponding simple sentence as follows:

Complex Sentence (s): Apple's first logo, designed by Jobs and Wayne, depicts Sir Isaac Newton sitting under an apple tree.

Simple Sentence: Apple's first logo is designed by Jobs and Wayne.

3.2 Named Entity (NE) Information and Semantic Role Labeling (SRL) for QG

We use the Illinois Named Entity Tagger[4], a state of the art NE tagger that tags a plain text with named entities (people, organizations, locations, miscellaneous) (Ratinov and Roth, 2009).

[3] Available at http://www.ark.cs.cmu.edu/mheilman/
[4] Available at http://cogcomp.cs.illinois.edu/

Once we tag the topic in consideration and its associated body of texts, we use some general purpose rules to create some basic questions even though the answer is not present in the body of texts. For example, "Apple Inc." is tagged as an organization, so we generate a question: "Where is Apple Inc. located?". The main motivation behind generating such questions is to add variety to the generated question space. Table 1 shows some example rules for basic questions generated in this work.

Tag	Example Question
person	Who is *person*?
organization	Where is *organization* located?
location	Where is *location*?
misc.	What do you know about *misc.*?

Table 1: Example basic question rules

Our next task is to generate specific questions from the sentences present in the given body of texts. For this purpose, we parse the sentences semantically using a Semantic Role Labeling (SRL) system (Kingsbury and Palmer, 2002; Hacioglu et al., 2003), ASSERT[5]. ASSERT is an automatic statistical semantic role tagger, that can annotate naturally occuring text with semantic arguments. When presented with a sentence, it performs a full syntactic analysis of the sentence, automatically identifies all the verb predicates in that sentence, extracts features for all constituents in the parse tree relative to the predicate, and identifies and tags the constituents with the appropriate semantic arguments. For example, the output of the SRL system for the sentence "Apple's first logo is designed by Jobs and Wayne." is: [ARG1 Apple 's first logo] is [TARGET designed] [ARG0 by Jobs and Wayne]. The output contains one verb (predicate) with its arguments (i.e. semantic roles). These arguments are used to generate specific questions from the sentences. For example, we can replace *[ARG1 ..]* with *What* and generate a question as: "What is designed by Jobs and Wayne?". Similarly, *[ARG0 ..]* can be replaced and the question: "Who designed Apple's first logo?" can be generated. The semantic roles *ARG0...ARG5* are called *mandatory arguments*. There are some additional arguments or semantic roles that can be tagged by ASSERT. They are called *optional arguments* and they start with the prefix *ARGM*. These are defined by the annotation guidelines set in (Palmer et al., 2005). A set of about 350 general purpose rules are used to transform the semantic-role labeled sentences into the questions. The rules were set up in a way that we could use the semantic role information to find the potential answer words in a sentence which would be replaced by suitable question words. In case of a mandatory argument, the choice of question word depends on the argument's named entity tag (e.g. "Who" for a person, "Where" for a location etc.). Table 2 shows how different semantic roles can be replaced by possible question words in order to generate a question.

3.3 Importance of Generated Questions

3.3.1 Latent Dirichlet Allocation (LDA)

To measure the importance of the generated questions, we use LDA (Blei et al., 2003) to identify the important sub-topics from the given body of texts. LDA is a probabilistic topic modeling technique where the main principle is to view each document as a mixture of various topics.

[5]Available at http://cemantix.org/assert.html

Arguments	Question Words
ARG0...ARG5	Who, Where, What, Which
ARGM-ADV	In what circumstances
ARGM-CAU	Why
ARGM-DIS	How
AGRM-EXT	To what extent
ARGM-LOC	Where
ARGM-MNR	How
ARGM-PNC	Why
ARGM-TMP	When

Table 2: Semantic roles with possible question words

Here each topic is a probability distribution over words. LDA assumes that documents are made up of words and word ordering is not important ("bag-of-words" assumption) (Misra et al., 2008). The main idea is to choose a distribution over topics while generating a new document. For each word in the new document, a topic is randomly chosen according to this distribution and a word is drawn from that topic. LDA uses a generative topic modeling approach to specify the following distribution over words within a document:

$$P(w_i) = \sum_{j=1}^{K} P(w_i|z_i = j)P(z_i = j) \tag{1}$$

where K is the number of topics, $P(w_i|z_i = j)$ is the probability of word w_i under topic j and $P(z_i = j)$ is the sampling probability of topic j for the i^{th} word. The multinomial distributions $\phi^{(j)} = P(w|z_i = j)$ and $\theta^{(d)} = P(z)$ are termed as topic-word distribution and document-topic distribution, respectively (Blei et al., 2003). A Dirichlet (α) prior is placed on θ and a Dirichlet (β) prior is set on ϕ to refine this basic model (Blei et al., 2003; Griffiths and Steyvers, 2002). Now the main goal is to estimate the two parameters: θ and ϕ. We apply this framework directly to solve our problem by considering each topic-related body of texts as a document. We use a GUI-based toolkit for topic modeling[6] that uses the popular MALLET (McCallum, 2002) toolkit for the back-end. The process starts by removing a list of "stop words" from the document and runs 200 iterations of Gibbs sampling (Geman and Geman, 1984) to estimate the parameters: θ and ϕ. From each body of texts, we discover K topics and choose the most frequent words from the most likely unigrams as the desired sub-topics. For example, from the associated body of texts of the topic *Apple Inc. Logos*, we get these sub-topics: *janoff, themes, logo, color, apple*.

3.3.2 Extended String Subsequence Kernel (ESSK)

Once we identify the sub-topics, we apply ESSK to measure their similarity with the generated questions. ESSK is the simple extension of the Word Sequence Kernel (WSK) (Cancedda et al., 2003) and String Subsequence Kernel (SSK) (Lodhi et al., 2002). WSK receives two sequences of words as input and maps each of them into a high-dimensional vector space. WSK's value is just the inner product of the two vectors. But, WSK disregards synonyms, hyponyms, and hypernyms. On the other hand, SSK measures the similarity between two sequences of

[6]Available at http://code.google.com/p/topic-modeling-tool/

"alphabets". In ESSK, each "alphabet" in SSK is replaced by a disjunction of an "alphabet" and its alternative (Hirao et al., 2003). In ESSK, each word in a sentence is considered an "alphabet", and the alternative is its all possible senses. However, our ESSK implementation considers the alternative of each word as its disambiguated sense. We use a dictionary based Word Sense Disambiguation (WSD) System assuming one sense per discourse. We use WordNet (Fellbaum, 1998) to find the semantic relations (such as repetition, synonym, hypernym and hyponym, holonym and meronym, and gloss) for all the words in a text. We assign a weight to each semantic relation and used all of them. Our WSD technique is decomposed into two steps: (1) building a representation of all possible senses of the words and (2) disambiguating the words based on the highest score. To be specific, each candidate word from the context is expanded to all of its senses. A disambiguation graph is constructed as the intermediate representation where the nodes denote word instances with their WordNet senses and the weighted edges (connecting the senses of two different words) represent semantic relations. This graph is exploited to perform the WSD. We sum the weights of all edges leaving the nodes under their different senses. The sense with the highest score is considered to be the most probable sense. In case of a tie between two or more senses, we select the sense that comes first in WordNet, since WordNet orders the senses of a word by decreasing order of their frequency.

ESSK is used to measure the similarity between all possible subsequences of the question words/senses and topic words/senses. We calculate the similarity score $\mathrm{Sim}(T_i, Q_j)$ using ESSK where T_i denotes a topic/sub-topic word sequence and Q_j stands for a generated question. Formally, ESSK is defined as follows[7]:

$$K_{essk}(T,Q) = \sum_{m=1}^{d} \sum_{t_i \in T} \sum_{q_j \in Q} K_m(t_i, q_j)$$

$$K_m(t_i, q_j) = \begin{cases} val(t_i, q_j) & \text{if } m = 1 \\ K'_{m-1}(t_i, q_j) \cdot val(t_i, q_j) & \end{cases}$$

Here, $K'_m(t_i, q_j)$ is defined below. t_i and q_j are nodes of T and Q, respectively. The function $val(t, q)$ returns the number of attributes common (i.e. the number of common words/senses) to the given nodes t and q.

$$K'_m(t_i, q_j) = \begin{cases} 0 & \text{if } j = 1 \\ \lambda K'_m(t_i, q_{j-1}) + K''_m(t_i, q_{j-1}) & \end{cases}$$

Here λ is the decay parameter for the number of skipped words. $K''_m(t_i, q_j)$ is defined as:

$$K''_m(t_i, q_j) = \begin{cases} 0 & \text{if } i = 1 \\ \lambda K''_m(t_{i-1}, q_j) + K_m(t_{i-1}, q_j) & \end{cases}$$

Finally, the similarity measure is defined after normalization as below:

$$sim_{essk}(T,Q) = \frac{K_{essk}(T,Q)}{\sqrt{K_{essk}(T,T) K_{essk}(Q,Q)}}$$

[7]The formulae denotes a dynamic programming technique to compute the ESSK similarity score where d is the vector space dimension i.e. the number of all possible subsequences of up to length d. More information about these formulae can be obtained from Hirao et al. (2003, 2004)

3.4 Judging Syntactic Correctness

The generated questions might be syntactically incorrect due to the process of automatic question generation. It is time consuming and a lot of human intervention is necessary to check for the syntactically incorrect questions manually. We strongly believe that a question should have a similar syntactic structure to a sentence from which it is generated. For example, the sentence "Apple's first logo is designed by Jobs and Wayne.", and the generated question "What is designed by Jobs and Wayne?" are syntactically similar. Hence, to judge the syntactic correctness of each generated question automatically, we apply the tree kernel functions and re-implement the syntactic tree kernel model for computing the syntactic similarity of each question with the associated content information. We first parse the sentences and the questions into syntactic trees using the Charniak parser[8] (Charniak, 1999). Then we calculate the similarity between the two corresponding trees using the *tree kernel* method (Collins and Duffy, 2001). We convert each parenthetic representation generated by the Charniak parser into its corresponding tree and give the trees as input to the tree kernel functions for measuring the syntactic similarity.

Each tree T is represented by an m dimensional vector $v(T) = \big(v_1(T), v_2(T), \cdots v_m(T)\big)$, where the i-th element $v_i(T)$ is the number of occurrences of the i-th tree fragment in tree T. The tree fragments of a tree are all of its sub-trees which include at least one production with the restriction that no production rules can be broken into incomplete parts. Figure 1 shows an example tree and a portion of its subtrees.

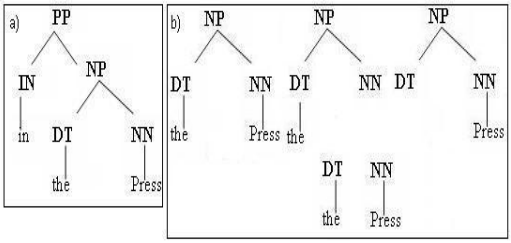

Figure 1: (a) An example tree (b) The sub-trees of the NP covering "the press".

Implicitly we enumerate all the possible tree fragments $1, 2, \cdots, m$. These fragments are the axis of this m-dimensional space. Note that this could be done only implicitly, since the number m is extremely large. Because of this, Collins and Duffy Collins and Duffy (2001) defined the tree kernel algorithm whose computational complexity does not depend on m. The tree kernel of two syntactic trees T_1 and T_2 is actually the inner product of $v(T_1)$ and $v(T_2)$:

$$TK(T_1, T_2) = v(T_1).v(T_2) \tag{2}$$

We define the indicator function $I_i(n)$ to be 1 if the sub-tree i is seen rooted at node n and 0 otherwise. It follows:

$$v_i(T_1) = \sum_{n_1 \in N_1} I_i(n_1)$$

[8] Available at ftp://ftp.cs.brown.edu/pub/nlparser/

$$v_i(T_2) = \sum_{n_2 \in N_2} I_i(n_2)$$

where, N_1 and N_2 are the set of nodes in T_1 and T_2 respectively. So, we can derive:

$$\begin{aligned} TK(T_1, T_2) &= v(T_1).v(T_2) \\ &= \sum_i v_i(T_1) v_i(T_2) \\ &= \sum_{n_1 \in N_1} \sum_{n_2 \in N_2} \sum_i I_i(n_1) I_i(n_2) \\ &= \sum_{n_1 \in N_1} \sum_{n_2 \in N_2} C(n_1, n_2) \end{aligned} \tag{3}$$

where, we define $C(n_1, n_2) = \sum_i I_i(n_1) I_i(n_2)$. Next, we note that $C(n_1, n_2)$ can be computed in polynomial time, due to the following recursive definition:

1. If the productions at n_1 and n_2 are different then $C(n_1, n_2) = 0$
2. If the productions at n_1 and n_2 are the same, and n_1 and n_2 are pre-terminals, then $C(n_1, n_2) = 1$
3. Else if the productions at n_1 and n_2 are not pre-terminals,

$$C(n_1, n_2) = \prod_{j=1}^{nc(n_1)} (1 + C(ch(n_1, j), ch(n_2, j))) \tag{4}$$

where, $nc(n_1)$ is the number of children of n_1 in the tree; because the productions at n_1 and n_2 are the same, we have $nc(n_1) = nc(n_2)$. The i-th child-node of n_1 is $ch(n_1, i)$.

Note that, the tree kernel (TK) function computes the number of common subtrees between two trees. Such subtrees are subject to the constraint that their nodes are taken with all or none of the children they have in the original tree. The *TK* (tree kernel) function gives the similarity score between each sentence in the given body of texts and the generated question based on the syntactic structure. Each sentence[9] contributes a score to the questions and then the questions are ranked by considering the average of similarity scores.

4 Experiments

4.1 System Description

We consider the task of automatically generating questions from topics where each topic is associated with a body of texts having a useful description about the topic. The proposed QG system ranks the questions by combining the topic relevance scores and the syntactic similarity scores of Section 3.3 and Section 3.4 using the formula as follows:

$$w * ESSK_{score} + (1 - w) * SYN_{score} \tag{5}$$

Here w is the importance parameter which holds the value in $[0, 1]$. We kept $w = 0.5$ to give equal importance[10] to topic relevance and syntactic correctness.

[9] We consider that a question is syntactically fluent as well as relevant to the topic if it has similar syntactic sub-trees as those of the most sentences in the body of texts.

[10] A syntactically incorrect question is not useful even if it is relevant to the topic. This motivated us to give equal

4.2 Corpus

To run our experiments, we use the dataset provided in the Question Generation Shared Task and Evaluation Challenge[11] (QGSTEC, 2010) for the task of question generation from paragraphs. This dataset consists of 60 paragraphs about 60 topics that were originally collected from several Wikipedia, OpenLearn, and Yahoo!Answers articles. The paragraphs contain around $5-7$ sentences for a total of $100-200$ tokens (including punctuation). This dataset includes a diversity of topics of general interest. We consider these topics and treat the paragraphs as their associated useful content information in order to generate a set of questions using our proposed QG approach. We use 10 topics and their associated paragraphs as the development data[12]. A total of 2186 questions are generated from the remaining 50 topics (test data) to be ranked.

4.3 Evaluation Setup

4.3.1 Methodology

We use a methodology derived from Boyer and Piwek (2010); Heilman and Smith (2010b) to evaluate the performance of our QG systems. Three native English-speaking university graduate students judge[13] the quality of the top-ranked 20% questions using two criteria: topic relevance and syntactic correctness. For topic relevance, the given score is an integer between 1 (very poor) and 5 (very good) and is guided by the consideration of the following aspects: 1. Semantic correctness (i.e. the question is meaningful and related to the topic), 2. Correctness of question type (i.e. a correct question word is used), and 3. Referential clarity (i.e. it is clearly possible to understand what the question refers to). For syntactic correctness, the assigned score is also an integer between 1 (very poor) and 5 (very good). Whether a question is grammatically correct or not is checked here. For each question, we calculate the average of the judges' scores.

4.3.2 Systems for Comparison

We report the performance of the following systems in order to do a meaningful comparison with our proposed QG system:

(1) Baseline1: This is our QG system without any question-ranking method applied to it. Here, we randomly select 20% questions and rate them.

(2) Baseline2: For our second baseline, we build a QG system using an alternative topic modeling approach. Here we use a topic signature model (instead of using LDA as discussed in Section 3.3.1) (Lin and Hovy, 2000) to identify the important sub-topics from the sentences present in the body of texts. The sub-topics are the important words in the context which are closely related to the topic and have significantly greater probability of occurring in the given text compared to that in a large background corpus. We use a topic signature computation tool[14] for this purpose. The background corpus that is used in this tool contains 5000 documents from the English GigaWord Corpus. For example, from the given body of texts of the topic *Apple Inc.*

importance to topic relevance and syntactic correctness. The parameter w can be tuned to investigate its impact on the system performance.

[11] http://www.questiongeneration.org/mediawiki

[12] We use this data to build necessary general purpose rules for our QG model.

[13] The inter-annotator agreement of Fleiss' $\kappa = 0.41, 0.45, 0.62$, and 0.33 are computed for the three judges for the results in Table 3 to Table 6, indicating moderate (for the first two tables), substantial and fair agreement (Landis and Koch, 1977) between the raters, respectively.

[14] Available at http://www.cis.upenn.edu/ lannie/topicS.html

Logos, we get these sub-topics: *jobs, logo, themes, rainbow, monochromatic*. Then we use the same steps of Section 3.3.2 and Section 3.4, and use equation 5 to combine the scores. We evaluate the top-ranked 20% questions and show the results.

(3) State-of-the-art: We choose a publicly available state-of-the-art QG system[15] to generate questions from the sentences in the body of texts. This system was shown to achieve good performance in generating fact-based questions about the content of a given article (Heilman and Smith, 2010b). Their method ranks the questions automatically using a logistic regression model. Given a paragraph as input, this system processes each sentence and generates a set of ranked questions for the entire paragraph. We evaluate the top-ranked 20% questions[16] and report the results.

4.3.3 Results and Discussion

Table 3 shows the average topic relevance and syntactic correctness scores for all the systems. From these results we can see that the *proposed QG* system improves the topic relevance and syntactic correctness scores over the *Baseline1* system by 61.86%, and 34.98%, respectively, and improves the topic relevance and syntactic correctness scores over the *Baseline2* system by 7.40%, and 7.57%, respectively. On the other hand, the *proposed QG* system improves the topic relevance and syntactic correctness scores over the *state-of-the-art* system by 3.88%, and 2.89%, respectively. From these results, we can clearly observe the effectiveness of our proposed QG system. The improvements in the results are statistically significant[17] ($p < 0.05$).

The main goal of this work was to generate as many questions as possible related to the topic. For this reason, we considered generating the basic questions. These questions were also useful to provide variety in the question space. We generated these questions using the NE information. As the performance of the NE-taggers were not that great, we had a few of these questions generated. In most cases, these questions were outranked by other important questions that included a combination of topics and sub-topics to show higher topic relevance score measured by ESSK. Therefore, they do not have a considerable impact on the evaluation statistics. We claim that the overall performance of our systems could be further improved if the accuracy of the NE-tagger and the semantic role labeler could be increased.

Systems	Topic Relevance	Syntactic Correctness
Baseline1 (No Ranking)	2.15	2.63
Baseline2 (Topic Signature)	3.24	3.30
State-of-the-art (Heilman and Smith, 2010b)	3.35	3.45
Proposed QG System	3.48	3.55

Table 3: Topic relevance and syntactic correctness scores

Acceptability Test In another evaluation setting, the three annotators judge the questions for their overall acceptability as a good question. If a question shows no deficiency in terms of the criteria considered for topic relevance and syntactic correctness, it is termed as *acceptable*. We evaluate the top 15% and top 30% questions separately for each QG system and report

[15] Available at http://www.ark.cs.cmu.edu/mheilman/questions/

[16] We ignore the yes-no questions for our task.

[17] We tested statistical significance using Student's t-test.

the results indicating the percentage of questions rated as acceptable in Table 4. The results indicate that the percentage of the questions rated acceptable is reduced when we evaluate more number of questions which proves the effectiveness of our QG system.

Systems	Top 15%	Top 30%
Baseline1 (No Ranking)	35.2	32.6
Baseline2 (Topic Signature)	45.9	33.8
State-of-the-art (Heilman and Smith, 2010b)	44.7	38.5
Proposed QG System	46.5	40.6

Table 4: Acceptability of the questions (in %)

Systems	Topic Relevance	Syntactic Correctness
Baseline1 (No Ranking)	3.20	3.54
Baseline2 (Topic Signature)	3.80	3.92
State-of-the-art (Heilman and Smith, 2010b)	4.01	4.15
Proposed QG System	4.12	4.25

Table 5: Topic relevance and syntactic correctness scores (narrowed focus)

Systems	Top 15%	Top 30%
Baseline1 (No Ranking)	41.3	37.1
Baseline2 (Topic Signature)	53.5	43.6
State-of-the-art (Heilman and Smith, 2010b)	57.5	43.2
Proposed QG System	58.4	44.5

Table 6: Acceptability of the questions in % (narrowed focus)

Narrowing Down the Focus We run further experiments by narrowing down the topic focus. We consider only the topics about persons (biographical focus). We choose 10 persons as our topics from the list of the 20th century's 100 most influential people, published in Time magazine in 1999 and obtained the paragraphs containing their biographical information from Wikipedia articles[18]. We generate a total of 390 questions from the considered 10 topics and rank them using different ranking schemes as discussed before. We evaluate the top 20% questions using the similar evaluation methodologies and report the results in Table 5. Again, we evaluate the top 15% and top 30% questions separately for each QG system and report the results indicating the percentage of questions rated as acceptable in Table 6. From these tables, we can clearly see the improvements in all the scores for all the QG approaches. This is reasonable because the accuracy of the NE tagger and the semantic role labeler is increased for the biographical data. These results further demonstrate that the proposed system is significantly better (at $p < 0.05$) than the other considered systems. We plan to make our created resources available to other researchers.

Systems	Top-ranked questions
Baseline2	Who presented Jobs with several different monochromatic themes for the bitten logo? What were conceived to make the logo more accessible? Who liked the logo?
State-of-the-art	Whose first logo depicts Sir Isaac Newton sitting under an apple tree? What depicts Sir Isaac Newton sitting under an apple tree? What did Janoff present Jobs with?
Proposed QG System	Who designed Apple's first logo? What was replaced by Rob Janoff 's "rainbow Apple"? What were conceived to make the logo more accessible?

Table 7: System output

4.3.4 An Input-Output Example

An input to our systems is for instance, the topic *"Apple Inc. Logos"* with the associated content information (body of texts): *"Apple's first logo, designed by Jobs and Wayne, depicts Sir Isaac Newton sitting under an apple tree. Almost immediately, though, this was replaced by Rob Janoff's "rainbow Apple", the now-familiar rainbow-colored silhouette of an apple with a bite taken out of it. Janoff presented Jobs with several different monochromatic themes for the "bitten" logo, and Jobs immediately took a liking to it. While Jobs liked the logo, he insisted it be in color to humanize the company. The Apple logo was designed with a bite so that it would be recognized as an apple rather than a cherry. The colored stripes were conceived to make the logo more accessible, and to represent the fact the monitor could reproduce images in color. In 1998, with the roll-out of the new iMac, Apple discontinued the rainbow theme and began to use monochromatic themes, nearly identical in shape to its previous rainbow incarnation."* The output of our systems is the ranked lists of questions. We show an example output in Table 7.

Conclusion and Future Work

In this paper, we have considered the task of automatically generating questions from topics where each topic is associated with a body of texts containing useful information. We have exploited the named entity and semantic role labeling information to accomplish the task. A key aspect of our approach is the use of LDA to automatically discover the hidden sub-topics from the sentences. We have proposed a method to rank the generated questions by considering: 1) sub-topical similarity determined using ESSK algorithm in combination with word sense disambiguation, and 2) syntactic similarity determined using the syntactic tree kernel based method. We have compared the proposed QG system with two baseline systems and one state-of-the-art system. The evaluation results have shown that the proposed QG system significantly outperforms all other considered systems as our system generated top-ranked questions are found to be better in topic-relevance and syntactic correctness than those of the other systems. We have conducted another experiment by narrowing down the topic focus. In this experiment, we have considered *persons* as topics. Our experiments have demonstrated the effectiveness of the proposed topic to question generation approach. We hope to carry on this ideas and develop further mechanisms to question generation based on the dependency features of the answers and answer finding (Li and Roth, 2006; Pinchak and Lin, 2006).

Adjective Deletion for Linguistic Steganography and Secret Sharing

Ching – Yun Chang[1] *Stephen Clark*[1]
(1) University of Cambridge, Computer Laboratory, 15 JJ Thomson Avenue, Cambridge, UK
Ching-Yun.Chang@cl.cam.ac.uk, Stephen.Clark@cl.cam.ac.uk

ABSTRACT
This paper describes two methods for checking the acceptability of adjective deletion in noun phrases. The first method uses the Google n-gram corpus to check the fluency of the remaining context after an adjective is removed. The second method trains an SVM model using n-gram counts and other measures to classify deletable and undeletable adjectives in context. Both methods are evaluated against human judgements of sentence naturalness. The application motivating our interest in adjective deletion is data hiding, in particular linguistic steganography. We demonstrate the proposed adjective deletion technique can be integrated into an existing stegosystem, and in addition we propose a novel secret sharing scheme based on adjective deletion.

KEYWORDS: linguistic steganography, adjective deletion.

Proceedings of COLING 2012: Technical Papers, pages 493–510,
COLING 2012, Mumbai, December 2012.

1 Introduction

Linguistic steganography is a form of covert communication in which information is embedded in a seemly innocent cover text so that the presence of the information is imperceptible to an outside observer (human or computer) (Fridrich, 2009). An ideal linguistic stegosystem should fulfil two fundamental requirements: *high imperceptibility* and *high payload capacity*. The former aims at imposing minimum embedding distortion to the cover text so that the resulting stegotext in which a message is camouflaged is inconspicuous. The latter aims at providing sufficient embedding capacity in order to achieve efficient information transmission. There is a trade-off between imperceptibility and payload, since any attempt to embed additional information via changes to the cover text increases the chance of introducing anomalies into the text and thus raising the suspicion of an observer (Chang and Clark, 2010a).

Another cryptographic method is secret sharing. Secret sharing (Blakley, 1979; Shamir, 1979) refers to methods for distributing a secret amongst a group of n people, each of whom is allocated a *share* of the secret. Individual shares are of no use on their own; only when any group of t (for *threshold*) or more shares are combined together can the secret be reconstructed. Such a system is called a (t, n)-threshold scheme. For example, a simple (3,3)-threshold scheme for a secret number s can be achieved by splitting s into three numerical shares s_1, s_2 and s_3 such that $s = s_1 + s_2 + s_3$. Note that there is no way to recover the secret number by only using one or two of the shares; all shares are required for effective recovery.

There are some proposed (t, n)-threshold schemes where $t \neq n$. For example, Shamir's scheme (Shamir, 1979) allows that any t out of n shares may be used to recover the secret. This scheme relies on the idea that it takes t points to define a polynomial of degree t-1 (e.g. it takes two points to define a straight line, three points to define a quadratic, four points to define a cubic curve). The method first randomly creates a polynomial of degree t-1 with the secret number as the first coefficient. Next each of the n people is given a distinct point on the curve. Therefore, any t out of the n people can fit a (t-1)th degree polynomial using their points, where the first coefficient is the secret. For example, any three of the five points (1, 1494), (2, 1942), (3, 2578), (4, 3402) and (5, 4414) can fit the polynomial of degree two $f(x) = 1234 + 166x + 94x^2$ and reveal the secret as 1234.[1] From the above two secret sharing schemes we can see that the share can be in different forms, such as numbers and points, depending on the methods used.

In this paper, we propose a novel (2, 2)-threshold secret sharing method where the shares are presented as two comparable texts, as explained in Section 8. The proposed method exploits the adjective deletion technique to embed secret bitstrings of 0s and 1s in two texts. These two texts can then be combined to reveal the secret bitstring; but neither text by itself can reveal the bitstring. Hence the proposed method is a novel combination of secret sharing and linguistic steganography. In addition, we demonstrate the adjective deletion technique can be integrated into an existing linguistic stegosystem (Chang and Clark, 2010a).

We have identified adjectives as a potentially large source of deletable words, in the sense that adjectives can often be removed without significantly affecting the meaning or naturalness of the resulting text. For example, "he spent only his *own* money" and "he spent only his money" express the same meaning. In the extreme case, there are adjective-noun pairs in which the adjective is somewhat redundant, for example *unfair prejudice*, *horrible crime* and *fragile glass*.

We explore the identification of redundant adjectives in context for the applications of linguistic

[1] http://en.wikipedia.org/wiki/Shamir's_Secret_Sharing.

steganography and secret sharing. In order to generate unsuspicious stegotext and textual shares after adjective deletion, we propose two checking methods using the Google n-gram corpus and an SVM to certify the naturalness of the generated sentences. The methods are evaluated using human judgements of naturalness. Note that the evaluation is based on the sentence-level naturalness rather than the coherence of the whole document. Modeling the document-level coherence of modified text would be useful but is outside the scope of our study. The resulting precision can be seen as an indirect measure of the imperceptibility of the stegosystem since quality deletions are less likely to be seen as suspicious by the observer, whereas the recall can be seen as an indirect measure of the payload since deletable adjectives are detected where possible and therefore as much information as possible is embedded.

There are various practical security issues in the application of linguistic steganography and secret sharing systems that we have chosen to ignore or simplify in order to focus on the underlying NLP technology. For example, we assume the adversary is a human acting passively rather than actively. In other words, we have ignored the possibility of computational steganalysis and steganographic attacks, such as detecting, extracting and destroying the hidden message (Fridrich, 2009).

2 Related Work

2.1 Linguistic Transformations for Steganography

Existing studies have exploited different linguistic transformations for the application of steganography, such as lexical substitution (Chapman and Davida, 1997; Bolshakov, 2004; Taskiran et al., 2006; Topkara et al., 2006c; Chang and Clark, 2010b), phrase paraphrasing (Chang and Clark, 2010a), sentence structure manipulations (Atallah et al., 2001a,b; Liu et al., 2005; Meral et al., 2007; Murphy, 2001; Murphy and Vogel, 2007b; Topkara et al., 2006b) and semantic transformations (Atallah et al., 2002; Vybornova and Macq, 2007). For details of the transformations mentioned above, readers can refer to our previous papers: Chang and Clark (2010a) and Chang and Clark (2010b).

Another group of studies aim to embed information into translated text. Stutsman et al. (2006) use multiple translation systems to provide alternative candidates for a sentence. The secret information is then embedded into the choice of translation. Another recent work proposed by Venugopal et al. (2011) introduces a watermark as a parameter in the machine translation algorithm and probabilistically identifies the watermarked translation. The motivation of watermarking machine translation outputs is to distinguish machine and human generated translations so a machine translation system is unlikely to learn from self-generated data.

These transformations often rely on sophisticated NLP tools and resources. For example, a lexical substitution-based stegosystem may require synonym dictionaries, POS taggers, word sense disambiguation tools and language models; a syntactic transformation-based stegosystem may require syntactic or semantic parsers and language generation tools. However, given the current state-of-the-art, such NLP techniques cannot guarantee the transformation's imperceptibility. Hence it is important to evaluate the security level of a stegosystem.

2.2 Stegosystem Evaluations

A stegosystem can be evaluated from two aspects: the security level and the embedding capacity. The security assessment methods used so far can be classified into two categories: automatic evaluation and human evaluation. Topkara et al. (2006b) and Topkara et al. (2006a) used

machine translation evaluation metrics BLEU and NIST, automatically measuring how close a stego sentence is to the original. Topkara et al. (2006b) admitted that machine translation evaluation metrics are not sufficient for evaluating stegosystems; for example, BLEU relies on word sequences in the stego sentence matching those in the cover sentence and thus is not suitable for evaluating transformations that change the word order significantly.

The other widely adopted evaluation method is based on human judgements. Meral et al. (2007), Kim (2008), Kim (2009) and Meral et al. (2009) asked subjects to edit stegotext for improving intelligibility and style. The fewer edit-hits a transformed text received, the higher the reported security level. Murphy and Vogel (2007b) and Murphy and Vogel (2007a) first asked subjects to rate the acceptability (in terms of plausibility, grammaticality and style) of the stego sentences on a seven-point scale. Then subjects were provided with the originals and asked to judge to what extent meaning was preserved on a seven-point scale. Chang and Clark (2010a) asked subjects to judge whether a paraphrased sentence is grammatical and whether the paraphrasing retains the meaning of the original.

The other aspect of the stegosystem evaluation is to calculate the amount of data capable of being embedded in a stego text, which can be quantified in terms of bits per language unit, for example per word or per sentence. Payload measurements can be theoretical or empirical. The theoretical payload measurement only depends on an encoding method and is independent of the quality of a stego text; whereas the empirical measurement takes the applicability of a linguistic transformation, namely the security of a stego text, into consideration and measures the payload capacity while a certain security level is achieved. Most of the payload rates reported in existing work are based on empirical measurements, with typical payload rates between 0.5 and 1.0 bits per sentence.

Not only the linguistic transformation and the encoding method, but also the choice of cover text can affect the security level and the payload capacity of a stegosystem. For example, if a newspaper article were chosen as the cover text, then any changes could be easily found in practice by comparing the stego text with the original article, which is likely to be readily available. In addition, an anomaly introduced by a linguistic transformation may be more noticeable in a newspaper article than in a blog article. In terms of payload capacity, a synonym substitution-based stegosystem may find more words that can be substituted in a fairy tale than in a medical paper since there are usually many terminologies in a medical paper which cannot be changed or even cannot be found in a standard dictionary. To the best of our knowledge, there is no study on the practical issue of using different types of cover text for the steganography application.

2.3 Sentence Compression

Sentence compression, text simplification and text summarisation usually involve removing unimportant words in a sentence in order to make the text more concise. For example, Knight and Marcu (2002), Cohn and Lapata (2008), Filippova and Strube (2008) and Zhu et al. (2010) have used the word deletion operation in their systems. However, to our knowledge, there is no work looking at redundant adjectives in text in particular. The proposed adjective deletion methods can be applied before and/or after a sentence compression system. Deleting unnecessary adjectives before can help the system focus on other content of a sentence. Deleting unnecessary adjectives after can generate an even more concise sentence.

Sentence	Those awaiting execution spent their *last* days alone .
Supertags before deletion	NP[nb]/N N/N N (S[dcl]\NP)/NP NP[nb]/N *N/N* N NP\NP .
Supertags after deletion	NP[nb]/N N/N N (S[dcl]\NP)/NP NP[nb]/N N N NP\NP .
Sentence	We met in UK *last* time .
Supertags before deletion	NP S[dcl]\NP ((S\NP)\(S\NP))/NP N *((S\NP)\(S\NP))/((S\NP)\(S\NP))* (S\NP)\(S\NP) .
Supertags after deletion	NP S[dcl]\NP ((S\NP)\(S\NP))/NP N/N N .

Table 1: Comparing supertags before and after adjective deletion

3 Deletable Adjective Classification

In order for an adjective deletion to be acceptable according to our method, we use two checks: grammaticality and naturalness checks. In order to prevent an ungrammatical adjective deletion, we use the syntactic filter proposed in Chang and Clark (2010a) to certify the deletion grammaticality. This is only a preliminary grammaticality check and does not guarantee sentence fluency. For generating the modified sentence, we also use Minnen et al. (2001)'s tools for correcting the form of an indefinite. For example, after deleting *alternative*, the phrase "**an** alternative choice" would be modified to "**a** choice". The original and modified sentences are then parsed using a wide-coverage CCG parser (Clark and Curran, 2007). After parsing, each lexical token is associated with a syntactic description, called a lexical category, or supertag. With the significant amount of information included in supertags, comparing two sequences of supertags is similar to comparing two syntax trees. Thus we require a deletion to retain the same sequence of supertags as that of the original sentence in order to ensure grammaticality. Table 1 shows two adjective deletion examples and their supertags,[2] where *last* is the target adjective. The first deletion case passes the grammaticality check since all the supertags remain the same after deleting *last*; while in the second example, both *UK* and *time*'s supertags are changed after the deletion and thus, this deletion fails the check. Note that all the experiment data used in this paper pass the syntax check.

3.1 N-gram Count Method

Inspired by Chang and Clark (2010b), which used the Google n-gram corpus to check the applicability of a synonym in context based on Bergsma et al. (2009), we use a similar method to calculate a score based on the n-gram counts before and after a potential deletion, as demonstrated in Table 2. The Google n-gram corpus[3] is a large publicly available collection of bi-grams to five-grams generated from approximately 1 trillion tokens of online text. Only n-grams appearing more than 40 times are kept in the corpus.

For the example in Table 2 we first extract contextual bi- to five-grams containing the target adjective *alternative* as well as that across the target position with *alternative* removed. The Google n-gram corpus is then consulted to obtain their frequency counts. We sum up all the logarithmic counts[4] for the original and modified cases. The reason for using the logarithm count is that lower-order n-grams usually have much larger counts than higher-order n-grams so taking the logarithm may prevent the sum being dominated by lower-order n-gram counts. Since before the deletion there are more n-grams extracted, we divide the sum by the number

[2]There is a parse error in the first sentence, but it does not affect the supertag comparison.
[3]Available from the LDC as LDC2006T13.
[4]log(0) and division by zero are taken to be zero.

There is always an *alternative* choice in a mental situation.	
N-grams before the deletion (log *freq*)	N-grams after the deletion (log *freq*)
an *alternative* (15.5)	a choice (15.2)
alternative choice (9.8)	always a choice (8.8)
always an *alternative* (7.9)	a choice in (11.3)
an *alternative* choice (9)	is always a choice (8.3)
alternative choice in (6.2)	always a choice in (5.5)
is always an *alternative* (7.4)	a choice in a (7.6)
always an *alternative* choice (0)	There is always a choice (7)
an *alternative* choice in (5.5)	is always a choice in (4.3)
alternative choice in a (0)	always a choice in a (0)
There is always an *alternative* (6)	a choice in a mental (0)
is always an *alternative* choice (0)	
always an *alternative* choice in (0)	
an *alternative* choice in a (0)	
alternative choice in a mental (0)	
$Count_{average}^{Before} = 4.8$	$Count_{average}^{After} = 6.8$
$Score = \frac{Count_{average}^{After}}{Count_{average}^{Before}} = 1.4$	

Table 2: An example of the Google n-gram count method

of extracted n-grams and call the derived average value the $Count_{average}$. Finally, we use a *Score* function which is equal to $\frac{Count_{average}^{After}}{Count_{average}^{Before}}$ to measure how much the $Count_{average}^{Before}$ changes after deleting the target word *alternative*. In this example the *Score* for deleting *alternative* in this context is equal to 1.4 and will be determined as acceptable by a threshold with value below 1.4.

3.2 SVM Method

Since some n-grams may be more informative than others when deciding whether an adjective can be deleted, we combine the n-gram counts and other measures described in Section 4 to train a classifier. We use the LIBSVM (Chang and Lin, 2011) implementation of support vector machines (SVMs) for classification. As suggested by Hsu et al. (2010), we scale feature values to the range [-1, +1], and use the default radial basis function (RBF) kernel. The two parameters of the RBF kernel, C and γ, are determined by using the model selection tool grid.py provided from LIBSVM. After the best (C, γ) is found using the training data, the whole training set is used again to train the final classifier. In order to observe the trade-off between precision and recall, we use the probability estimate feature in LIBSVM and train the SVM model to output probabilities so users can decide the security level by varying a probability threshold.

4 Features for the SVM

4.1 N-gram Counts

The first set of features consists of logarithmic contextual bi- to five-gram counts. Before the deletion, there are 14 contextual n-grams; after the deletion, there are 10 contextual n-grams as shown in Table 2. If a contextual window is not available, for example if a window spans beyond

the current sentence, the n-gram count is set to zero. For each contextual window we provide an additional boolean feature to indicate whether a window is available. The second set of features consists of 5 score values. The first score is the *Score* function described in Section 3.1. The second to the fifth scores are the scores calculated by only considering a specific window size n, where $n = 2$ to 5, using the same method as for the *Score* function. Again, each score is provided with an additional boolean feature to indicate whether the $Count^{Before}_{average}$ is equal to zero. There are a total of 58 features contributed from the n-gram counts.

4.2 Lexical Association Measures

In addition to n-gram features, we exploit some standard lexical association measures to determine the degree of association between an adjective and a noun. Pointwise Mutual Information (PMI) (Church and Hanks, 1990) is roughly a measure of how much one word tells us about the other. In order to calculate PMI, we need the joint frequency of the noun-adjective pair, the frequency of the noun modified by any adjective and the frequency of the adjective modifying any noun.

We collect (adjective, noun) pairs and their frequency counts from grammatical relations (GRs). The GRs we use are derived by parsing a Wikipedia dump (dated October 2007) with Clark and Curran (2007)'s CCG parser. We first consider GRs having the pattern (ncmod _ *noun adjective*) and extract the (*adjective*, *noun*) pair. Next we extract pairs that match patterns (xcomp _ be *adjective*) and (ncsubj be *noun* _) in a sentence. For instance, the GRs of the sentence "The car is red" are (det car_1 the_0) (xcomp _ be_2 red_3) and (ncsubj be_2 car_1 _), and since *car* and *red* match the two patterns, (*red*, *car*) is seen as an eligible pair for our database. A total of 63,896,006 adjective-noun pairs are extracted form the parsed Wikipedia corpus which includes 832,320 noun types and 792,914 adjective types.

We also use the log likelihood ratio (LLR), an alternative to PMI, which is reported to handle rare events better (Dunning, 1993). Again, the contingency table for computing LLR can be derived from the parsed Wikipedia corpus described above. In the study of collocation extraction, both high PMI and LLR values are treated as evidence that the collocation components occur together more often than by chance. In this paper, we use PMI and LLR as features in the SVM.

4.3 Noun and Adjective Entropy

Suppose we observe a noun N_1 as being modified by adjective J_1 five times, J_2 twice and J_3 three times. The modifier entropy of N_1 is $H(N_1) = -((0.5\,log\,0.5) + (0.2\,log\,0.2) + (0.3\,log\,0.3)) = 1.5$. Now suppose there is a noun N_2 modified by J_4 nine times and J_5 once. The modifier entropy of N_2 is $H(N_2) = -((0.9\,log\,0.9) + (0.1\,log\,0.1)) = 0.5$. Thus we can conclude that the modifier of N_1 is more unpredictable than that of N_2. Similarly, we calculate an adjective's argument entropy based on the entropy of the noun given a fixed adjective.

We also observe the modification frequency of a noun using the parsed Wikipedia corpus. From the corpus, we obtain the frequency of a noun being modified by any adjective (mod_{adj}), the frequency of a noun being modified by something other than an adjective (mod_{other}), and the frequency of a noun not being modified at all (mod_{non}). The modification entropy of a noun is defined as: $M(N) = -(p(mod_{adj})\,log\,p(mod_{adj}) + p(mod_{non})\,log\,p(mod_{non}))$. Note that $p(mod_{other})$ is not included in the definition of $M(N)$ since we want to focus on the adjectival modification of a noun. Modifier entropy, argument entropy, modification entropy plus the modification probabilities $p(mod_{adj})$, $p(mod_{other})$ and $p(mod_{non})$ are used as SVM features.

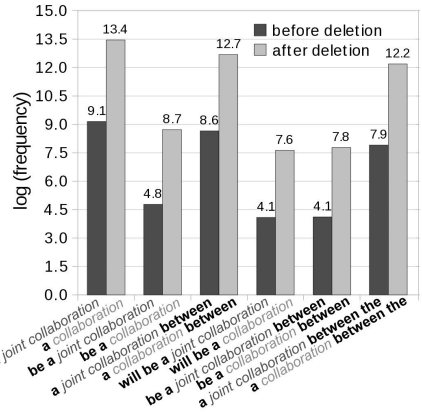

Figure 1: N-gram count distributions before and after deleting *joint*

4.4 Contextual α-Skew Divergence

We assume that if an adjective in a noun phrase is deletable, the noun should have a similar n-gram distribution to the original adjective-noun phrase across the various n-gram counts. Figure 1 shows the logarithmic n-gram counts of *joint collaboration* and *collaboration* being in the same context of the sentence "The task force will be a *joint collaboration* between the cities of Sterling Heights and Warren." In this example sentence, *joint* is determined as deletable. We can see that the counts have similar distributions before and after the deletion.

We use α-skew divergence (Lee, 1999) to calculate the n-gram distributional similarity between the original and the modified sentences. The α-skew divergence is a non-symmetric measure of the difference between two probability distributions P and Q. In our application, P is a probability vector containing normalised logarithmic counts derived from the contextual n-grams before removing the adjective, and Q is a probability vector obtained after deleting the adjective. The α-skew divergence measure is defined as:

$$S_\alpha(Q,P) = D(P\|\alpha{\cdot}Q + (1-\alpha){\cdot}P),$$

where $0 \leq \alpha \leq 1$ and D is the Kullback-Leibler divergence $D(P\|Q) = \sum_v P(v) log \frac{P(v)}{Q(v)}$. The α parameter is for avoiding the problem of zero probabilities, and in our system we use α=0.99. Under our assumption, a deletable adjective would have a smaller effect on the n-gram count distribution after deletion than an undeletable adjective and, therefore, a deletable adjective would have a smaller divergence value.

5 Data

5.1 Pilot Study Data

We first created a small dataset for a preliminary study. In order to experiment with redundant adjectives, we collected 90 sentences from the Internet, each of which contained an adjective-

noun pleonasm.[5] A pleonasm consists of two concepts (usually two words) that are mutually redundant: examples are *free gift*, *cold ice* or *final end*. In other words, pleonasms contain unnecessary words, and those words can be removed without affecting the meaning of the text.

Apart from positive data (deletable adjectives), we also need some negative data (undeletable adjectives) to test whether the n-gram count method and the SVM model have the ability to filter out bad deletions. We define an adjective as undeletable if the removal of an adjective in a noun phrase significantly affects the naturalness of the resulting sentence. The second author of this paper manually selected 76 undeletable cases from the British National Corpus (BNC) as the negative data.

Adjectives in pleonasms can be seen as extreme redundancies in text, and removing those redundancies would not reduce the level of security in terms of steganography. However, pleonasms are not general enough so might not be found frequently in text, which diminishes the amount of secret information which can be embedded in the text. Thus we collect more positive and negative data which are more frequent in text for training, developing and testing the n-gram count method and the SVM model. This additional set serves as our main data source (described in Section 5.2), with the pleonasm set serving as a useful pilot study.

5.2 Human Annotated Data

In order to have a labelled dataset for training and testing a classifier, we asked 30 native English speakers to judge whether the removal of an adjective in a noun phrase significantly affects the naturalness of the resulting sentence. The guideline is the same as that used for the pilot study data. Note that we only care about the naturalness of the resulting sentence rather than the meaning retention of the original sentence. In other words, the evaluation is based on the sentence-level naturalness rather than the coherence of the whole document. Table 3 shows the six examples that were used as part of the annotator instructions.

The sentences for creating the data were randomly selected from section A of the British National Corpus (BNC) with the constraint that each passed the syntax check as described in Section 3. We collected 1200 sentences, each of which contains one marked adjective to be annotated. In order to measure the inter-annotator agreement, 300 of the 1200 sentences were assessed by 3 different judges; the others were labelled only once. We calculated the inter-annotator agreement using Fleiss' kappa (Fleiss et al., 2003) scored between 0 and 1. Fleiss' kappa works for any fixed number of annotators and allows different items rated by different individuals. For the 300 multi-judged instances, the Fleiss' kappa is 0.49, which can be interpreted as *moderate agreement* according to Landis and Koch (1977).

The 300 multi-judged instances were labelled using the majority rule and were treated as the test set; the other 900 instances were randomly split into a 700-instance training set and a 200-instance development set. The ratio of the number of deletable adjectives to the number of undeletable adjectives is around 2:1 for all the datasets.

6 Experiments and Results

The performance on this adjective deletion task is measured in precision and recall on the positive deletable cases. From a steganography aspect, accuracy is not useful, while the trade-off between precision and recall is more relevant. A precision baseline is obtained by always saying

[5] A collection of pleonasms can be found at http://www.pleonasms.com.

Judgement	Example sentence
Deletable	He was putting on his *heavy* overcoat, asked again casually if he could have a look at the glass.
Deletable	We are seeking to find out what *local* people want, because they must own the work themselves.
Deletable	We are just at the beginning of the *worldwide* epidemic and the situation is still very unstable.
Undeletable	He asserted that a modern artist should be in tune with his times, careful to avoid *hackneyed* subjects.
Undeletable	With various groups suggesting police complicity in township violence, many blacks will find *little* security in a larger police force.
Undeletable	There can be *little* doubt that such examples represent the tip of an iceberg.

Table 3: Judgement examples given to annotators

(b) Results on the development data

Figure 2: Performance of the n-gram count method

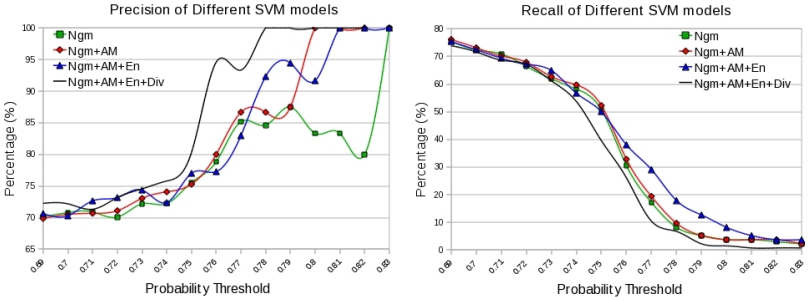
an adjective is deletable. The precision baselines in the pilot study data, development data and test data are 54.2%, 67.0% and 64.0%, respectively.

6.1 Experiments Using N-gram Count Method

We test the n-gram count method on the pilot study data and the development data. Figure 2(a) and Figure 2(b) show the precision and recall curves with respect to different thresholds for the pilot study data and the development data, respectively. For the pilot study data, the best precision 72.1% is achieved with a 48.9% recall by using a threshold equal to 1.05. For the development data, the best precision 84.2% is achieved using a threshold equal to 1.9. However, the recall value drops to 11.9% which means many deletable adjectives are being ignored.

6.2 Experiments using SVM

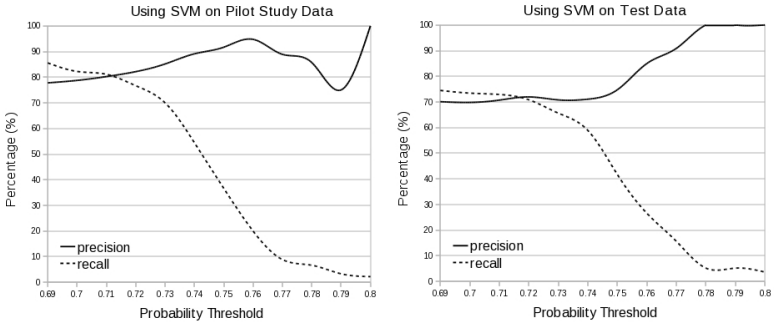
For the SVM learning approach, we first train models with different features and test the models on the development data. Figure 3(a) and Figure 3(b) show the precision and recall curves of the models with probability thresholds greater than 0.69 and lower than 0.83 (since these



(a) Precision curves of the models

(b) Recall curves of the models

Figure 3: Performance of SVM models using different features



(a) Results on the pilot study data

(b) Results on the test data

Figure 4: Performance of the Ngm+AM+En+Div model

values result in a reasonable precision range). In addition, we ignore results that have recall values lower than 10% even though a high precision is achieved. The SVM Ngm model is trained using the 58 features described in Section 4.1. Its best precision is 85.2% (with a recall greater than 10%) which is similar to that achieved by using the n-gram count method, but the corresponding recall is slightly improved to 17.2%. Next we add two association measures MI and LLR to the features and train the model Ngm+AM. The best precision of the Ngm+AM model is 86.7% and the corresponding recall is 19.4%. We then add features by including entropies and modification probabilities described in Section 4.3 and train the Ngm+AM+En model. This model achieves 92.3% precision with 17.9% recall. Finally, the Ngm+AM+En+Div model is trained with the divergence measure added to the features. The best precision of this model is 94.6% with 26.1% recall when the probability threshold 0.76 is used. Since the Ngm+AM+En+Div model achieves the best precision value among all the models, we further evaluate this model using the pilot study dataset and the test dataset.

Figure 4(a) shows the performance of the Ngm+AM+En+Div model on the pilot study data.

With 50% recall on the pilot study data, the SVM model achieves a precision of 90%, while the n-gram method only achieves 72.1% precision at this level of recall. We can see that there is a large improvement on classifying deletable adjectives from undeletable adjectives in the pilot study data compared to both the baseline and the n-gram count method. Finally, we use the probability threshold 0.76 that gives the best precision on the development set to evaluate the pilot study data and the test data. For the pilot study data, the classifier achieves a precision of 94.7% and a recall of 20%; for the test data, the classifier achieves a precision of 85% and a recall of 26.6%. Note that a precision of 100% is not necessarily required because the inter-annotator agreement on the collected human judgements is not 100% and therefore it is not clear whether the precision upper bound on this task is 100%.

Figure 4(b) shows the full range of precision-recall scores using different probability threshold values on the test data.[6] From this figure, we can clearly see the trade-off between precision and recall, which corresponds to the trade-off between imperceptibility and payload for the linguistic steganography application. In practice, steganography users can decide the threshold according to their requirements on the security level and embedding capacity. In addition, since the cover text can be selected by users, the payload can be improved by choosing a text containing more adjectives such as fictions or fairy tales, which might increase the density of deletable adjectives in text.

7 Linguistic Steganography Application

For linguistic steganography, there exists a convenient modularity between the linguistic transformation and the embedding method. In other words, the utility of a specific embedding method does not imply a particular linguistic transformation, although it will put some constraints on what transformation can be used. For example, synonym substitution, paraphrasing and translation can be applied to an embedding method which reconstructs the secret message as concatenating codewords that are directly associated with a choice. We will demonstrate that the adjective deletion technique can be integrated into our earlier Chang and Clark (2010a) secret embedding scheme.

In Chang and Clark (2010a) we proposed a secret embedding method based on text paraphrasing as shown in Figure 5. In the secret embedding phase, a cover text is first divided into embedding units of which each has an equal number of sentences and contains at least one paraphrasable sentence. In this example, the paraphrasable sentences are t_1, t_3, t_4, t_7 and t_8; the text can be divided into three embedding units u_1, u_2 and u_3 with the size equal to three sentences. One secret bit is then embedded in one embedding unit. If the secret bit is 0, all the paraphrasable sentences in the embedding unit are transformed into non-paraphrasable sentences; if the secret bit is 1, the embedding unit remains unchanged. The secret bitstring in this example is 101 so the paraphrasable sentence t_4 in u_2 is transformed into a non-paraphrasable sentence, and u_1 and u_3 are unmodified. The secret extracting can be easily performed by dividing the stego text into embedding units and using the existence of paraphrasable sentences to decide whether the embedding unit represents secret bit 0 or 1. In this embedding scheme, the embedding unit size is treated as the secret key that is only shared between the sender and the receiver.

We can replace the text paraphrasing in the above method with the adjective deletion technique as the linguistic transformation, so that each embedding unit contains at least one deletable

[6] Note that we are not optimising for one single score on the test set, e.g. F-score, but showing the full range of the precision-recall tradeoff that corresponds to a security-payload tradeoff in the steganography setting.

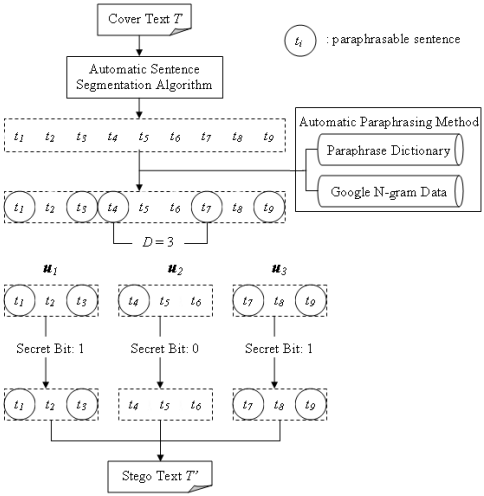


Figure 5: The Chang and Clark (2010a) stegosystem

adjective. If we want to embed 0, all the deletable adjectives will be removed from the embedding unit. Since the deletable adjectives are checked by the proposed model, the removal of the adjectives should achieve a certain level of naturalness in the sentences. If we want to embed 1, the embedding unit will not be modified. It is important to note that the recovery of the secret bitstring does not require the original text. The receiver only needs the secret key to define the size of an embedding unit and the adjective checking model to see whether there is a deletable adjective in an embedding unit.

8 Secret Sharing Scheme

We propose a novel secret sharing scheme based on the adjective deletion technique and text alignment. The secret sharing scheme converts a secret bitstring into two shares, $Share_0$ and $Share_1$, that are camouflaged in the form of natural language text. $Share_0$ holds secret bits as 0s and $Share_1$ holds secret bits as 1s. The order of the 0s and 1s can only be reconstructed by aligning the two texts.

Figure 6 illustrates an example of the secret sharing scheme. The secret bitstring is 101. We first give $Share_0$ and $Share_1$ the same text and use the proposed adjective checking method to determine deletable adjectives in the text. In this example, the n-gram count method with threshold equal to 1 is applied. The adjectives passing the check are *mysterious*, *terrible* and *single*, and one deletable adjective will embed a secret bit. The embedding rule is: to embed a secret bit 0/1, the target adjective is kept in the share that holds 0s/1s, and is removed from the other share. For example, the first secret bit is 1 so *mysterious* is kept in $Share_1$ and is deleted from $Share_0$. Next, we embed the second secret bit 0 by keeping *terrible* in $Share_0$ and removing it from $Share_1$. The third secret bit is 1 so we keep *single* in $Share_1$ and remove it from $Share_0$. Now the secret bitstring 101 is converted into two meaningful texts. The reconstruction of the

Secret bits: 101	Text: "Have you heard of the **mysterious** death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A **terrible** change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone.
Embed 1st bit: 1 Target adj: *mysterious*	$Share_0$: "Have you heard of the death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A **terrible** change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone. $Share_1$: "Have you heard of the **mysterious** death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A **terrible** change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone.
Embed 2nd bit: 0 Target adj: *terrible*	$Share_0$: "Have you heard of the death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A **terrible** change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone. $Share_1$: "Have you heard of the **mysterious** death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone.
Embed 3rd bit: 1 Target adj: *single*	$Share_0$: "Have you heard of the death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A **terrible** change came over the woman's face as I asked the question. It was some seconds before she could get out the word "Yes" – and when it did come it was in a husky, unnatural tone. $Share_1$: "Have you heard of the **mysterious** death of your late boarder Mr. Enoch J. Drebber, of Cleveland?" A change came over the woman's face as I asked the question. It was some seconds before she could get out the **single** word "Yes" – and when it did come it was in a husky, unnatural tone.

Figure 6: An example of the secret sharing scheme

secret bitstring can be done by aligning the two texts. The alignment will reveal the positions of the deletable adjectives, which gives the order of the 0s and 1s, and therefore the secret can be extracted. Note that this scheme does not require either the original text or the adjective checking model to recover the secret bitstring.

Conclusion

One of the contributions of this paper is to explore the identification of redundant adjectives in noun phrases. We proposed two methods for checking the sentence naturalness after removing an adjective, which were evaluated by human judgements. The results suggest that the adjective deletion technique is applicable to cryptosystems since the transformation is able to achieve satisfactory imperceptibility leading to a high security level. According to our observations from section A of the BNC, on average there are two deletable adjectives per five sentences. In other words, the payload upper bound of using the adjective deletion technique is around 0.4 bits per sentence if a deletion encodes a secret bit. Apart from the cryptosystem applications, the proposed adjective checking model can also benefit other studies such as sentence compression, text simplification and text summarisation.

Another contribution of this paper is the integration of the adjective deletion technique into an existing stegosystem and the proposal of a novel secret sharing scheme based on adjective deletion. An advantage of our proposed system is that it is somewhat language and domain independent. For future work, we would like to explore more lexical redundancies in other POS, such as adverbs and punctuation, so the payload capacities of our cryptosystems can be further improved.

Acknowledgments

We would like to thank Dr. Laura Rimell and the anonymous reviewers for useful comments and the annotators for their time.

ABSTRACT
Linguistic steganography is a form of covert communication using natural language to conceal the existence of the hidden message, which is usually achieved by systematically making changes to a cover text. This paper proposes a linguistic steganography method using word ordering as the linguistic transformation. We show that the word ordering technique can be used in conjunction with existing translation-based embedding algorithms. Since unnatural word orderings would arouse the suspicion of third parties and diminish the security of the hidden message, we develop a method using a maximum entropy classifier to determine the naturalness of sentence permutations. The classifier is evaluated by human judgements and compared with a baseline method using the Google n-gram corpus. The results show that our proposed system can achieve a satisfactory security level and embedding capacity for the linguistic steganography application.

1 Introduction

Linguistic steganography is a form of covert communication using natural language to conceal the existence of the hidden message so that the very act of communication is undetectable to an outside observer (human or computer) (Fridrich, 2009). In other words, the covert communication would fail if an outside observer is suspicious of the existence of the hidden message. Note that the outside observer here is not the recipient; the recipient needs to expect to receive a hidden message in order to extract it. (Consider the scenario of covert communication between political activists, where the observer is a government "listening" agency, for example.)

In order to embed messages, a cover text must provide information carriers that can be modified to represent the secret. For example, a lexical substitution-based stegosystem substitutes selected words (the information carriers) with their synonyms so that the concatenation of the bitstrings represented by the synonyms is identical to the secret. Note that an unmodifiable text cannot carry information. Ideally the changes made to the text must be imperceptible, resulting in a high security level. In addition, an ideal linguistic steganography scheme should allow sufficient embedding capacity to achieve efficient information transmission, resulting in a large payload capacity. There is a fundamental trade-off between security and payload since any attempt to embed additional information is likely to increase the chance of introducing anomalies into the text, thus degrading the security level.

Existing studies have exploited different linguistic transformations for the application of steganography, such as lexical substitution (Chapman and Davida, 1997; Bolshakov, 2004; Taskiran et al., 2006; Topkara et al., 2006c; Chang and Clark, 2010b), phrase paraphrasing (Chang and Clark, 2010a), sentence structure manipulations (Atallah et al., 2001a,b; Liu et al., 2005; Meral et al., 2007; Murphy, 2001; Murphy and Vogel, 2007b; Topkara et al., 2006b), semantic transformations (Atallah et al., 2002; Vybornova and Macq, 2007) and text translation (Grothoff et al., 2005; Stutsman et al., 2006; Meng et al., 2011). These transformations often rely on sophisticated NLP tools and resources. For example, a lexical substitution-based stegosystem may require synonym dictionaries, POS taggers, word sense disambiguation tools and language models; a syntactic transformation-based stegosystem may require syntactic or semantic parsers and language generation tools. However, given the current state-of-the-art, such NLP techniques cannot guarantee the transformation's imperceptibility. Hence it is important to evaluate the security level of a stegosystem.

The security assessment methods used so far can be classified into two categories: automatic evaluation and human evaluation. Topkara et al. (2006b) and Topkara et al. (2006a) used Machine Translation (MT) evaluation metrics BLEU and NIST, automatically measuring how close a stego sentence is to the original. Topkara et al. (2006b) admitted that MT evaluation metrics are not sufficient for evaluating stegosystems; for example, BLEU relies on word sequences in the stego sentence matching those in the cover sentence and thus is not suitable for evaluating transformations that change the word order significantly. The other widely adopted evaluation method is based on human judgements. Meral et al. (2007), Kim (2008), Kim (2009) and Meral et al. (2009) asked subjects to edit stegotext for improving intelligibility and style. The fewer edit-hits a transformed text received, the higher the reported security level. Murphy and Vogel (2007b) and Murphy and Vogel (2007a) first asked subjects to rate the acceptability (in terms of plausibility, grammaticality and style) of the stego sentences on a seven-point scale. Then subjects were provided with the originals and asked to judge to what extent meaning was preserved on a seven-point scale. Chang and Clark (2010a) asked subjects to judge whether a

paraphrased sentence is grammatical and whether the paraphrasing retains the meaning of the original. In our work, we also use human judgements to evaluate the proposed stegosystem as this is close to the linguistic steganography scenario. Note that it is hard to compare the security level of different systems since there are no standard methods to measure the security (imperceptibility) of a linguistic steganography system.

The other aspect of the stegosystem evaluation is to calculate the amount of data capable of being embedded in a stego text, which can be quantified in terms of bits per language unit, for example per word or per sentence. Payload measurements can be theoretical or empirical. The theoretical payload measurement only depends on an encoding method and is independent of the quality of a stego text; whereas the empirical measurement takes the applicability of a linguistic transformation, namely the security of a stego text, into consideration and measures the payload capacity while a certain security level is achieved. Most of the payload rates reported in existing work are based on empirical measurements.

For the lexical substitution transformation, Topkara et al. (2005) and Topkara et al. (2006c) achieved an average embedding payload of 0.67 bits per sentence. The payload attained by syntactic transformations was around 0.5 to 1.0 bits per sentence (Atallah et al., 2001b; Topkara et al., 2006b; Meral et al., 2009). Since the ontological semantic transformation is currently impractical, the empirical payload is not available. Another semantic method (Vybornova and Macq, 2007) achieves a payload of 1 bit per sentence. Stutsman et al. (2006) showed that their translation-based stegosystem has a payload of 0.33 bits per sentence.

In this paper, we exploit word ordering as the linguistic transformation. A cover sentence is first used to provide a bag-of-words as input to the Zhang et al. (2012) word ordering realisation system. The generated permutations provide alternatives to the original and thus the cover sentence can play the role of an information carrier. However, not all the permutations are grammatical and semantically meaningful. To solve this problem we train a Maximum Entropy classifier (Berger et al., 1996) to distinguish natural word orders from awkward wordings, and evaluate the classifier using human judgements. Note that the proposed maximum entropy classifier is trained to classify sentence-leval naturalness and thus, it is possible that even individual natural sentences might lead to an unnatural document. Modeling the document-level coherence of modified text would be useful but is outside the scope of our study. In addition, we review some translation-based stegosystems and show that the word ordering transformation can be used with the existing translation-based embedding algorithms. For readers unfamiliar with linguistic steganography, Chang and Clark (2010a) present the general linguistic steganography framework and describe several existing stegosystems using different linguistic transformations.

A contribution of this paper is to create a novel link between word ordering realisation and linguistic steganography. The various permutations provide a possible covert channel for secret communication. To our knowledge, this is the first linguistic steganography system using word ordering as the transformation. In addition, we propose a maximum entropy classifier to determine the naturalness of a permutation. The collected human judgements of sentence naturalness and the resulting classifier may be of use for other NLP applications.

2 Word Ordering-based Steganography

The general word ordering problem is to construct grammatical, fluent sentences from a set of un-ordered input words. There have been some word ordering realisation systems that take a

Rank (binary)	Permutation	Secret Bitstring $s=1$	$s=2$	$s=3$
1 (001)	In our products now there is no asbestos.	1	01	001
2 (010)	No asbestos there is now in our products.	0	10	010
3 (011)	Now in our products there is no asbestos.	1	11	011
4 (100)	There is no asbestos in our products now.	0	00	100
5 (101)	There no asbestos in our products is now.	1	01	101
6 (110)	There now is no asbestos in our products.	0	10	110

Figure 1: Ranked sentence permutations and their secret bits

bag-of-words as input and automatically generate permutations (Wan et al., 2009; Zhang and Clark, 2011; Zhang et al., 2012). Any of these word ordering realisation systems can be treated as a module integrated into the proposed secret embedding method.

For linguistic steganography, there exists a convenient modularity between the linguistic transformation and the embedding method. In other words, a secret embedding method can treat the linguistic transformation as a black box for outputting alternatives for a given cover text. How an alternative encodes secret bits is decided by the embedding algorithm. In the next section, we propose an embedding method designed to use permutations from a word ordering system as alternatives for a given cover sentence. Later, in Section 6 we show that the word ordering technique can also be combined with existing translation-based embedding algorithms.

2.1 The Embedding Method

Before any message exchange can take place, the sender and receiver must share a word ordering system and a method to sort a set of sentence permutations, such as alphabetical ordering, or ordering by realisation quality scores determined by the generation system or a language model. The sorting method must be independent of the cover sentence since the receiver does not receive it, and only those permutations having the same length as the cover are considered during sorting. In addition, the number of secret bits carried by a permutation must be fixed and known by the sender and the receiver.

The sender first turns a cover sentence into a bag-of-words and then uses the pre-agreed word ordering system to generate permutations. After eliminating permutations shorter than the cover sentence (if any), the rest are sorted using the pre-agreed method. The rank of a permutation in the sorted list is converted into a binary string, and the lowest s bits are the secret bits carried by that permutation, where s is the pre-fixed payload. Figure 1 shows six alphabetically ranked permutations and the secret bit(s) carried by them when s is equal to 1, 2 and 3. Note that, in order to embed s bits, there must be at least 2^s permutations in the ordered list; otherwise, there will be at least one desired secret bitstring not carried by any permutation. For example, in Figure 1 secret bitstring 000 and 111 cannot be found when s is equal to 3. Finally, the sender can choose a permutation that represents the secret bitstring as the stego sentence.

To recover the secret bitstring, the receiver first transforms the received stego sentence into a bag-of-words. Since we only consider permutations having the same length as the cover during embedding, the bag-of-words obtained from the stego sentence will be identical to that originally obtained from the cover sentence. Next, the receiver reproduces the ordered

permutations. According to the rank of the stego sentence and the pre-agreed payload of s bits, the receiver can extract the secret bitstring. Note that, in the proposed stegosystem, the receiver can extract the secret without knowing the cover text.

The payload of the system is controlled by the variable s, and the security level depends on the quality of the selected permutations. For example, although "In our products now there is no asbestos" and "There no asbestos in our products is now" both carry secret bits "01" in Figure 1, using the latter would significantly decrease the security level as it is an unnatural sentence. Therefore, in Section 4.2 we develop a Maximum Entropy classifier to determine the naturalness of a permutation which can be integrated into the stegosystem during data embedding. Note that, in this paper, we do not investigate the document-level coherence of stego text generated using the word ordering transformation since this requires sophisticated knowledge of natural language semantics and pragmatics. Instead, we tackle the problem of distinguishing the naturalness of a sentence permutation in isolation from the rest of a document.

3 Resources

3.1 Word Ordering Realisation System

The word ordering realisation system plays a crucial role in the proposed steganography method as it largely determines the security level and payload capacity of the stegosystem. The sender in the proposed scheme uses the n-best list output from a word ordering system as the set of possible alternatives for a cover sentence; so the security level largely depends on the quality of the n-best list. In addition, the more acceptable permutations an n-best list has, the larger the payload the stegosystem can use.

Some recent work used syntax models to certify the grammaticality of generated sentences. The combination of permutation and syntactic modelling results in a large search space, which was tackled using heuristic search (Wan et al., 2009; Zhang and Clark, 2011; Zhang et al., 2012). Wan et al. (2009) use a dependency grammar to model word ordering and apply greedy search to find the best permutation. Zhang and Clark (2011) use a syntax-based discriminative model together with best-first search to find the highest scoring permutation plus CCG derivation. Zhang et al. (2012) is an extension of Zhang and Clark (2011) using online large-margin training and incorporating a large-scale language model. The three approaches are evaluated using the generation task of word order recovery, which is to recover the original word order from an input bag-of-words. The BLEU scores reported by Wan et al. (2009), Zhang and Clark (2011) and Zhang et al. (2012) are 33.7, 40.1 and 43.8, respectively, on WSJ newspaper sentences. In this paper, we use the Zhang et al. (2012) system to generate n-best permutations for a cover sentence, but, in practice, any word ordering realisation system can be integrated into the proposed word ordering-based stegosystem.

3.2 Human Judgement Corpus

Since not all the sentence permutations generated by the Zhang et al. (2012) system are grammatical and semantically meaningful, we develop a maximum entropy classifier to determine the naturalness of permutations. In order to have a labelled corpus for training and testing the classifier, we first randomly selected 765 sentences having length between 8 and 25 tokens from sections 02-21 of the Penn Treebank (Marcus et al., 1993) as the cover sentences. The restriction on the sentence length is because a short sentence may not have enough good permu-

Score	Explanation
1	Completely or largely non-fluent, and/or completely or largely lacking in meaning.
2	Very awkward wording, major punctuation errors, and/or logical errors, but still possible to understand.
3	Slightly awkward but still relatively fluent, clear and logical; may contain slightly awkward wording and/or minor punctuation errors.
4	Perfectly natural – both grammatical and semantically meaningful.

Figure 2: Rating scale and guidelines for human evaluation

Score	Permutation
3	As a price-conscious shopper, so far, Manville hasn't bought much.
1	So, as a price-conscious shopper, far Manville hasn't bought much.
1	Far so, as a price-conscious shopper, Manville hasn't bought much.
4	So far Manville, as a price-conscious shopper, hasn't bought much.
1	Far Manville, as a price-conscious shopper, so hasn't bought much.

Figure 3: A set of five permutations rated by a subject

tations for the steganography application, and a long cover sentence increases the complexity of finding acceptable word orders from the bag-of-words and therefore is unlikely to result in good permutations.

For each cover sentence, we created a bag-of-words as input and generated 100 permutations using the Zhang et al. (2012) system. For 88% of the sentences, the original cover sentence is in the 100-best list. This not only serves as a sanity check for the realisation system, but also means the original sentence can be used to carry secret bits without any modification.

To cut down a 100-best list for the human evaluation, we only keep five permutations that retain the most grammatical relationships of the original cover sentence since these permutations are more likely to convey the same meaning as the original. We parsed the cover sentences and their permutations using a CCG parser (Clark and Curran, 2007), and calculated a dependency F-score for each permutation by comparing the CCG predicate-argument dependencies of the permutation and its original. For each cover sentence, the top five F-score permutations which are different from the cover were chosen for human annotation, which results in 3,825 sentences (765 sets of 5 permutations).

A total of 34 native English speakers were asked to judge the naturalness of the sentence permutations on a 4-point scale. The guidelines are shown in Figure 2. The annotations were carried out via a web interface; on each page, a subject was presented with 5 permutations consisting of the same words, and a total of 125 permutations (25 sets) were annotated by each subject. Figure 3 shows a set of five permutations along with the scores rated by a subject. In order to calculate the inter-annotator agreement, 425 permutations were selected to be judged by two annotators.

For the steganography application, those permutations rated as perfectly natural (score 4) can achieve a high security level and are treated as positive data when training a Maximum Entropy classifier; those permutations with scores lower than 4 are treated as negative data. After converting the scores into a positive/negative representation, we measured the inter-annotator

agreement on the binary labelled data using Fleiss' kappa (Fleiss et al., 2003). The resulting kappa score of 0.54 for the data represents "moderate" agreement according to Landis and Koch (1977). There were 47 out of the 425 agreement-measuring sentences that received different labels after applying the positive/negative representation, for which the second author of this paper made the definitive judgement. In the end, the collected human judgement corpus contained 478 positive (perfectly natural) permutations and 3,347 negative examples.

According to the human judgements, 321 out of the 765 cover sentences have at least one natural sounding permutation in the top five F-score permutations. Therefore, the upper bound of the number of possible information carriers is roughly 42% of the cover sentences. Next, since there are studies using automatic evaluation metrics to evaluate the security level of a stegosystem as described in Section 1, we observe how well the BLEU score of a permutation correlates with the human judgement. For those multi-judged sentences, an average score is assigned. Both Pearson's correlation coefficient and Spearman's rank correlation coefficient between the human judged scores and the BLEU scores are calculated, which are 0.10 and 0.09, respectively, and are significant at $p < 0.001$. This result indicates there is little association between the human judgement of sentence naturalness and the BLEU score, indicating the need for a manual evaluation to determine the likely security level.

4 Sentence Naturalness Classification

According to the human judgement corpus, most of the machine-generated permutations are not natural. In addition, as described in Section 2, the proposed secret embedding algorithm sometimes involves choosing a permutation from a group of candidates that all encode the same secret bit(s). Therefore, it is crucial to develop a method that can distinguish acceptable permutations from those having awkward wordings in a word ordering-based stegosystem. It is important to note that the checking method can take the original sentence into consideration because the permutation selection happens at the secret embedding stage and is not needed during the decoding. Having the cover sentence available at the checking stage is a feature we will exploit.

A research area that relates to the proposed permutation checking method is realisation ranking (Cahill and Forst, 2010; White and Rajkumar, 2012) where a system is given a set of text realisations and is asked to rate each text in the set. However, in the realisation ranking task there is no "cover text". Since our methods require the knowledge of the original text, they cannot be applied to the realisation ranking task.

In this section we first explain a baseline method using the Google n-gram corpus (Brants and Franz, 2006) to check whether a particular word ordering has been used frequently on the Web. Then we propose another approach using some syntactic features to train a Maximum Entropy classifier (Berger et al., 1996). Both methods require a score/probability threshold to decide the acceptability of a permutation.

4.1 Google N-gram Method

The Google n-gram corpus (Brants and Franz, 2006) contains frequency counts for n-grams from unigrams through five-grams obtained from over 1 trillion word tokens of English Web text collected in January 2006. Only n-grams appearing more than 40 times were kept in the corpus. The Google n-gram corpus has been applied to many NLP tasks such as spelling correction (Carlson et al., 2008; Islam and Inkpen, 2009), multi-word expression classification

(Kummerfeld and Curran, 2008) and lexical disambiguation (Bergsma et al., 2009). Recently, in Chang and Clark (2010b) and Chang and Clark (2010a) we have used the corpus to check the text paraphrasing grammaticality and the synonym acceptability in context in our earlier steganography systems. Therefore, we propose a baseline method similar to Chang and Clark (2010b) and Chang and Clark (2010a) using the Google n-gram corpus to calculate a score based on the n-gram counts before and after word ordering. The task is as follows: given a cover sentence and corresponding permutation, decide if the permutation is acceptable. The baseline method will do so by comparing Google n-gram counts from the two sentences.

In the Google n-gram corpus, sentence boundaries are marked by <S> and </S>, where <S> represents the beginning of a sentence and </S> represents the end of a sentence. Both tags are treated like word tokens during the n-gram collection. Hence, after tokenising the cover sentence and its corresponding permutation, we add <S> and </S> tags to the beginning and end of the sentences as shown in Figure 4. Then we extract every bi- to five-gram from the cover sentence and the permutation. Since we are only interested in newly generated wordings in the permutation, n-grams that appear in both the cover and the permutation are eliminated, and the remaining n-grams and their Google n-gram frequencies are used to calculate the score. For example, after comparing the two sentences, there are 21 n-grams from the cover and 21 n-grams from the permutation left in Figure 4. We sum up all the logarithmic counts[1] for the cover and permutation n-grams and derive Sum_{Cover} and $Sum_{Permutation}$. The *Score* of a permutation is defined as the ratio of $Sum_{Permutation}$ and Sum_{Cover}, which measures how much the *Sum* varies after performing the word ordering. In the given example, the *Score* of the permutation is 0.81. Similar to Chang and Clark (2010b) and Chang and Clark (2010a), a score threshold is needed to determine the acceptability of a permutation. Even though this baseline method is only an n-gram count comparison, Bergsma et al. (2009) show that the approach works well for lexical disambiguation tasks and produces comparable performance to other more complex methods.

4.2 Maximum Entropy Classifier

In addition to the baseline method, we propose a machine learning approach to classify natural and unnatural permutations. We choose the method of maximum entropy modelling (MaxEnt for short) because of its proven performance for NLP tasks, such as part-of-speech tagging (Ratnaparkhi et al., 1996; Curran and Clark, 2003), parsing (Ratnaparkhi, 1999; Johnson et al., 1999) and language modelling (Rosenfeld, 1996), and the ease with which features can be included in the model (Ratnaparkhi, 1999). In addition, some work has shown that MaxEnt is viable for ranking the fluency of machine generated sentences (Nakanishi et al., 2005; Velldal and Oepen, 2006; Velldal, 2008). The concept of MaxEnt is to use observed features about a certain event (y) occurring in the context (x) to estimate a probability model $p(y|x)$. Its canonical form is:

$$p(y|x) = \frac{1}{Z(x)} exp \sum_{i=1}^{n} \lambda_i f_i(x, y)$$

where $Z(x)$ is a normalisation constant over all events in context x and λ_i is the weight of the feature $f_i(x, y)$. The standard way to train a maximum entropy model is to use conditional maximum likelihood (with a Gaussian prior for smoothing), which is equivalent to picking the most uniform model subject to constraints on the feature expectations (Berger et al., 1996).

[1] log(0) and division by zero are taken to be zero.

Figure 4: An example of the Google n-gram method

After training a maximum entropy classifier, we can calculate the probabilities of a permutation being a natural sentence according to the feature weights. Our proposed method says that a permutation is natural if the ratio of its naturalness probability to its unnaturalness probability is greater than a threshold α. The threshold α controls the trade-off between precision and recall of the maximum entropy classifier and can be decided by steganography users. The MaxEnt implementation we used was from the Curran and Clark (2003) tagger, adapted for classification rather than sequence tagging.

4.2.1 Features

In the formulation of MaxEnt we use, a feature f_i is an "indicator function" on events which simply indicates the presence of a feature. The first feature we included is the Levenshtein distance (Levenshtein, 1966) which measures the minimum number of edits needed to transform one cover sentence into its permutation, with the allowable edit operations being insertion, deletion, or substitution. After deriving the edit distance d, an indicator "EDIST_D" becomes the feature for that permutation, where D=$\lfloor log_2 d \rfloor$. For example, a permutation with an edit distance 4 and another permutation with an edit distance 5 both have the same indicator function "EDIST_2". In addition, if the difference between a permutation and its original sentence is only a single word movement, we add the *POS* tag of the moved word to the indicator function, so the feature becomes "EDIST_1-*POS*".

The second type of feature is derived by comparing the Stanford typed dependencies (De Marneffe and Manning, 2008) of a permutation and its original sentence. The Stanford typed dependencies provide descriptions of the grammatical relationships as well as semantically contentful information in a sentence, which can be obtained from the Stanford parser (De Marneffe et al., 2006). The Stanford typed dependencies are triples denoting a relation between a governor and a dependent. For example, *amod(wine, red)* denotes that *red* is an adjectival modifier of *wine*, and *agent(killed, spy)* denotes that an agent *spy* is the complement of a verb *killed*.

Figure 5: An example of the dependency indicator functions

We first parse a permutation and its original sentence using the Stanford parser and compare their Stanford typed dependencies. If a dependency *TYPE(WORD1, WORD2)* in the permutation cannot be found in the original, two indicator functions "P_dep_*TYPE*" and "P_deppos_*TYPE_POS1_POS2*" are added to the permutation's feature set, where *POS1* and *POS2* are the POS tags of *WORD1* and *WORD2*, respectively. If a dependency *TYPE(WORD1, WORD2)* in the permutation is the same as that in the original, two indicator functions "R_dep_*TYPE*" and "R_deppos_*TYPE_POS1_POS2_DISTANCE*" are added to the permutation's feature set, where *POS1* and *POS2* are the POS tags of *WORD1* and *WORD2*, and *DISTANCE* is the difference of the distance between the two words compared to the original. Figure 5 shows the dependency indicator functions of the permutation "our products there is no asbestos in now". In this example, *nsubj(asbestos, products)* is a newly generated relation after word ordering so two indicator functions *P_dep_nsubj* and *P_deppos_nsubj_NN_NNS* are added to the permutation's feature set; *poss(products, our)* is a recovered relation from the original and the distance between *product* and *our* remains the same as that in the origial so two indicator functions *R_dep_poss* and *P_deppos_poss_NNS_PRP$_0* are added to the permutation's feature set.

5 Experiments and Results

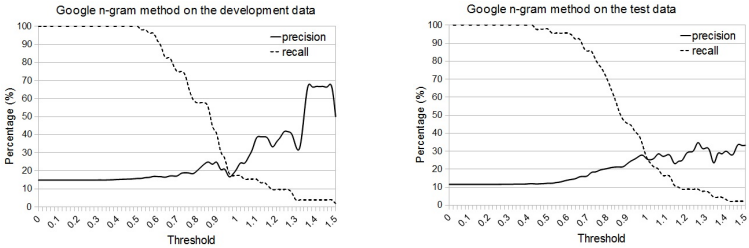
We evaluate the Google n-gram method and the maximum entropy classifier using the collected human judgements. The performance of the systems is measured in precision and recall over the natural permutations (i.e. the positive examples in the test set). Note that the trade-off between precision and recall implies the trade-off between security and payload capacity from a steganography perspective. A higher precision value means that the system-passed permutations are of high quality so using those permutations as stego sentences is unlikely to arouse suspicion; whereas a larger recall value can be interpreted as the system making the most of natural permutations and therefore embedding as much data as possible.

5.1 Data Sets

We divided the collected human judgement corpus described in Section 3.2 into a 2700-instance training set, a 350-instance development set and a 775-instance test set. The development set was mainly used for preliminary experimentation. We will present results on the development and test sets. Note that the 425 multi-judged sentences are all included in the test set. We treat

	Training set	Development set	Test set
number of positives	467	52	90
number of negatives	2,364	298	685

Table 1: Statistics of the experimental data sets



(a) Results on the development set

(b) Results on the test set

Figure 6: Performance of the Google n-gram method

natural permutations as positives and unnatural sentences as negatives. Since the number of negatives is 7 times more than the number of positives in the training set, we added another 131 positives annotated by the authors to the training set (but not the test set), in an attempt to address the imbalance. Table 1 presents the statistics of the data sets.

5.2 Experiments Using Google N-gram Method

We evaluated the Google n-gram method on the development set. Figure 6(a) shows the precision and recall curves with respect to different threshold values. The best precision achieved by the system is 66.7% with a very low recall of 3.9% when the threshold is equal to 1.36. Then we use the threshold 1.36 to classify positive and negative data in the test set. The derived precision and recall values are 28.6% and 4.4%, respectively. Figure 6(b) gives the precision and recall curves obtained by using the Google n-gram method on the test data. From the diagram we can see that, even when a threshold 1.26 is chosen, the best precision on the test set is only 34.8%, which is not appropriate for the steganography application since the low precision value would result in an unnatural stego text and hence fail the secret communication requirement.

A possible explanation of the poor performance of the n-gram baseline is that the n-gram method might be useful for checking local word changes (e.g. synonym substitution), but not the whole sentence rearrangement. In addition, longer n-grams are not frequently found in the Google n-gram corpus according to our data so in these cases the n-gram method only relies on checking the changes in lower-order n-grams, such as bi-grams or tri-grams.

(b) Results on the test set

Figure 7: Performance of the maximum entropy classifier

5.3 Experiments Using Maximum Entropy Classifier

Next we train a maximum entropy classifier using sentences in the training set. Each permutation in the training set is first represented by its indicator functions and is labelled as either a positive or a negative instance according to the human judgements. A total of 4,490 indicator functions are extracted from the training set. Since in the training set, the ratio of positives to negatives is about 1:5, we duplicate the positives 5 times to balance the amount of positives and negatives in the training set. The trained 5,815 weights are used to calculate the probabilities of a test instance being positive and negative. As mentioned in Section 4.2, the system determines an instance as positive if:

$$\frac{exp\sum_{i=1}^{n}\lambda_i f_i(x,positive)}{exp\sum_{i=1}^{n}\lambda_i f_i(x,negative)} > \alpha \implies \sum_{i=1}^{n}\lambda_i f_i(x,positive) - \sum_{i=1}^{n}\lambda_i f_i(x,negative) > ln(\alpha)$$

We observe the precision and recall values of the classifier with different α values. Figure 7(a) shows the performance of the classifier on the development set. The classifier achieves a 90% precision with 17.3% recall when the threshold $ln(\alpha)$ is equal to 2.2. A precision of 100% can be obtained by raising the threshold to 2.6 with the corresponding recall being 13.5%. Since the inter-annotator agreement on the collected human judgements is not 100%, as shown in Section 3.2, it is not clear whether the 90% precision achieved by the classifier really means that the remaining 10% sentences (false positives) would be viewed as suspicious in a real steganography setting. Therefore, we consider 90% to be a high level of precision/security.

The same classifier is then used to determine natural permutations in the test set and the $ln(\alpha)$ is set to 2.2 since this setting gives a satisfactory imperceptibility and payload capacity for the development set. The classifier achieves a precision of 93.3% and a recall of 15.6% with the 2.2 threshold, which again provides a confident security level and reasonable embedding capacity for the steganography application. This result is much better than the precision of 34.8% achieved by the baseline Google n-gram method. Since the training data used in our classifier is imbalanced (the number of negatives is five times more than that of positives), the features observed from positive data may not be enough to gain a higher recall. Therefore, we expect the recall value can be improved using more balanced training data.

In order to show the trade-off between precision and recall, which corresponds to the trade-off between imperceptibility and payload capacity for the linguistic steganography application, the precision and recall curves of the classifier on the test set are given in Figure 7(b). Note that we are not optimising on the test set; Figure 7(b) is just a demonstration of where on the precision-recall tradeoff a practical stegosystem might lie. In practice, the threshold value would depend on how steganography users want to trade off security for payload.

6 Word Ordering-based Stegosystem

In this section we first review the existing translation-based stegosystems. Then we explain how those translation-based embedding algorithms can not only work with a machine translation system, but can also be combined with a word ordering realisation system.

6.1 Translation-based Steganography

The first translation-based stegosystem was proposed by Grothoff et al. (2005). In their method, the sender and the receiver first agree on a set of machine translation systems that generate multiple translations for a given cover sentence. According to the translation probabilities, the sender then encodes each translation using Huffman coding (Huffman, 1952). Using Huffman coding, translations with higher probability (higher quality) have shorter codes and thus are more likely to match the secret bitstrings. After choosing translations that represent the secret bits, both the cover text and the stegotext are sent to the receiver. To extract the message, the receiver uses the same set of translation systems to generate translations for each cover sentence and runs the Huffman coding algorithm. Using the stegotext, the receiver can reconstruct the secret.

Grothoff et al. (2005) also proposed another scheme which does not require sending the original text to the receiver. Instead of using a set of machine translation systems as the secret key, the sender and the receiver share a hash function that transforms a sentence into a bitstring. The sender first generates multiple translations for a given cover sentence and then hashes each translation into a bitstring. A translation having its least significant bit as identical to the secret bit is selected as the stego sentence. To recover the message, without knowing the original text, the receiver only needs to compute the hash codes of the received sentences and concatenate the lowest bits of every stego sentence. Unlike the previous method that may be able to embed more than one bit in a translation, this embedding scheme has an upper bound of 1 bit per sentence.

Later Stutsman et al. (2006) improved the payload capacity of the hash function embedding scheme by introducing a header (h bits) to indicate that b bits are embedded in a translation, where h is shared between the sender and the receiver, and b is the integer represented by the header bits. The lowest h bits of a translation hash bitstring are the header bits and the lowest $[h{+}1, h{+}b]$ bits carry the secret. For example, assume $h = 2$; a hash bitstring "...10111" has header bits "11" to indicate 3 bits are embedded in this translation, and the three secret bits are "101". The problem of using a hash function is that the generation of a desired bitstring cannot be guaranteed. Therefore, error correction codes must be used in this protocol when there is no feasible hash code available, which increase the size of the transmission data.

Since Grothoff et al. (2005) and Stutsman et al. (2006) use multiple machine translation systems to generate alternative translations, the selected stego sentences may not have uniform style and therefore it is easy to detect the existence of the secret message (Meng et al., 2010;

Chen et al., 2011). Instead of obtaining alternative translations from multiple translation systems, Meng et al. (2011) use a statistical machine translation system to generate the n-best translations for a given cover sentence. Since translations are from one system, each of them is more similar to the rest than that derived from another translation system. Meng et al. (2011) show that the existing steganalysis methods cannot distinguish ordinary translation text and the stegotext generated by their stegosystem.

6.2 Using Word Ordering in Translation-based Embedding

The translation-based embedding algorithms described in the previous section take a cover sentence as the input and choose one of the translations as the stego sentence. We can easily replace the machine translation system(s) in these algorithms with a word ordering realisation system: a cover sentence is used to provide a bag-of-words as input, and the generated permutations can be seen as the "translations" of the cover sentence. One difference between the proposed embedding method and the translation-based embedding methods is that the former restricts the length of a permutation to be the same as the cover sentence so that the receiver is able to recover the list of permutations; while the latter allows a permutation to only include a subset of the input words and therefore provides more choices for a given cover sentence. However, dropping words introduces the risk of deleting information in the cover sentence and may lead to incoherence in the resulting text.

Conclusion

In this paper we have explored the applicability of using word ordering for linguistic steganography. We proposed a steganography method using word ordering as the linguistic transformation and also showed that the word ordering technique can be applied to existing translation-based embedding algorithms. As well as the embedding method, we also proposed a method for determining the naturalness of sentence permutations by training a maximum entropy classifier. The classifier was evaluated by human judgements and compared with a baseline method using the Google n-gram corpus. The results show that the classifier achieves 93.3% precision with 15.6% recall on the test set, which is much better than the best precision of 34.8% achieved by the Google n-gram method. In addition, the ultimate precision of 100% is reported from the experiments when using a higher probability threshold. This means the proposed maximum entropy classifier can provide a high security level for the linguistic steganography application.

For future work, it is worth tackling the problem of low embedding capacity in the existing linguistic stegosystems compared with other steganography systems using images or audios as the cover medium. For example, although the proposed classifier can achieve 100% precision on the task of determining natural sentence permutations, the corresponding recall of 10% means that many available permutations are ignored, which is a waste of information carriers.

Acknowledgments

We would like to thank Dr. Yue Zhang for providing the word ordering realisation system. In addition, we would like to thank Dr. Laura Rimell, Dr. Yue Zhang and the anonymous reviewers for useful comments and the annotators for their time.

ABSTRACT
Compared to the amount of research that has been done on English event extraction, there exists relatively little work on Chinese event extraction. We seek to push the frontiers of supervised Chinese event extraction research by proposing two extension to Li et al.'s (2012) state-of-the-art event extraction system. First, we employ a joint modeling approach to event extraction, aiming to address the error propagation problem inherent in Li et al.'s pipeline system architecture. Second, we investigate a variety of rich knowledge sources for Chinese event extraction that encode knowledge ranging from the character level to the discourse level. Experimental results on the ACE 2005 dataset show that our joint-modeling, knowledge-rich approach significantly outperforms Li et al.'s approach.

TITLE AND ABSTRACT IN CHINESE

运用丰富语言学特征的中文事件抽取联合模型

与英文的事件抽取研究相比，对于中文的事件抽取研究工作相对较少。在 Li et al.(2012) 的基于监督学习的事件抽取系统基础上，我们提出了两个扩展以进一步推动中文事件抽取的研究。首先，我们使用了一个联合模型，以解决 Li et al. 管道式系统中的错误传播问题。其次，针对中文信息抽取，我们研究了一系列从字符层面到文章层面的特征。在 ACE2005 数据上的实验结果表明，我们运用丰富语言学特征的联合模型显著地优于 Li et al. 的方法。

KEYWORDS: event extraction, Chinese language processing.

1 Introduction

Recent years have seen a surge of interest in automatically extracting events from textual documents. While diverse types of event extraction have been examined in the literature, the one we will focus on in this paper is ACE event extraction, which involves extracting instances of a predefined event type from documents. For example, consider the following Chinese text segment:

Resneft 收购尤甘斯克付出了仅 93.5 亿美元
(Resneft acquired Yugansk, paying only 9.35 billion US dollars)

When applied to this example, an ACE event extraction system for Chinese should identify one event instance, which (1) is *triggered* by the verb 收购 [acquired] whose type is TRANSFER-MONEY, and (2) has three *arguments*, Resneft, 尤甘斯克 [Yugansk] and 93.5 亿美元 [9.35 billion], which fulfill the roles of BUYER, ARTIFACT and PRICE, respectively.

This example illustrates the four primary subtasks of an ACE event extraction system, namely, (1) *trigger identification* (e.g., 收购 [acquired] should be identified as the trigger of an event); (2) *trigger type determination* (e.g., 收购 [acquired] should be assigned the type TRANSFER-MONEY; (3) *argument identification* (e.g., Resneft, 尤甘斯克 [Yugansk] and 93.5 亿美元 [9.35 billion] are the arguments of this TRANSFER-MONEY event); and (4) *argument role determination* (e.g., Resneft, 尤甘斯克 [Yugansk] and 93.5 亿美元 [9.35 billion] play the roles of BUYER, ARTIFACT and PRICE respectively in this event).

Compared to the amount of research on English event extraction (e.g., Finkel et al. (2005), Grishman et al. (2005), Ahn (2006), Hardy et al. (2006), Maslennikov and Chua (2007), Ji and Grishman (2008), Patwardhan and Riloff (2009), Liao and Grishman (2010), Hong et al. (2011)), there is considerably less work on Chinese event extraction. Work on end-to-end Chinese event extraction was pioneered by Chen and Ji (2009b), who adopt a pipeline system architecture composed of four components that correspond to the four major subtasks mentioned above. More specifically, in *training*, they learn a classifier to perform each of the four subtasks independently using primarily lexico-syntactic features but also a couple of semantic features (see Section 3 for an overview of these features); and in *testing*, they feed a raw document through the pipeline of components where the output of one component is the input of the subsequent one. Li et al.'s Chinese event extraction system also employs a pipeline architecture, but aims to improve the first component, trigger identification, via two techniques, namely compositional semantics and discourse consistency. They show that with these two techniques, their system substantially outperforms Chen and Ji's system, achieving state-of-the-art results.

Our goal in this paper is to improve the state of the art in Chinese event extraction. Specifically, we take Li et al.'s event extraction system as a baseline, and investigate two extensions to their system. Our first extension is a machine learning extension where we employ *joint learning* for event extraction. As is commonly known in the natural language processing (NLP) community, a pipeline architecture, such as the one adopted by Chen and Ji and Li et al. , suffers from the *error propagation* problem, where the errors made by an upstream component will propagate to and could adversely affect the performance of a downstream component. We address this problem by recasting event extraction as two *joint learning* tasks where we (1) jointly learn trigger identification and trigger type determination and (2) jointly learn argument identification and argument role determination.[1]

[1] A natural alternative would be to jointly learn the four subtasks. Though possible, this would substantially increase the complexity of the learning task. In fact, our preliminary experiments indicate that this alternative yields inferior results to our way of applying joint learning to event extraction and therefore will not be pursued in this paper.

Our second extension is linguistic extension where we employ a *knowledge-rich* approach, investigating a variety of knowledge sources for Chinese event extraction. In this extension, not only do we propose more effective use of existing features such as character-based features, but we also investigate novel features that exploit results of zero pronoun resolution and noun phrase (NP) coreference resolution, as well as features that exploit trigger probability and trigger type consistency (see Section 3 for details). The strength of our linguistic extension stems in part from the richness in the variety of features it considers: these features capture linguistic information ranging from the character level to the discourse level, and exploit Chinese-specific phenomena such as the presence of zero pronouns.

We evaluate our approach on the ACE 2005 Chinese event extraction task, which involves identifying event instances that belong to one of 33 predefined event types. Unlike previous work (Chen and Ji, 2009; Li et al., 2012), which reserves only 10% of the annotated data for testing and uses the rest for training, we provide a more robust evaluation of our system via performing 10-fold cross-validation experiments. We discover that the F-scores achieved on different folds can vary by as many as 10 percentage points for all four subtasks. The sensitivity of the system performance can be attributed in part to the small size of the ACE 2005 dataset, which is composed of only 633 documents, suggesting that cross validation is needed to more accurately reveal the performance of an event extraction system when evaluated on this dataset. Overall, our experimental results demonstrate that our joint-learning, knowledge-rich approach substantially improves Li et al.'s system, suggesting that (1) joint learning offers benefits over the pipeline approach; (2) all but the coreference features improve performance; and (3) while each of our features provide small gains, their cumulative benefits are substantial.

The rest of the paper is organized as follows. Section 2 discusses related work. In Section 3, we provide an overview of our baseline Chinese event extraction system. Sections 4 and 5 describe our machine learning extension and our linguistic extension to the baseline system, respectively. We present evaluation results in Section 6 and conclude in Section 7.

2 Related Work

Much attention has been devoted to the event extraction task in the NLP community. In the early years, researchers focused on sentence-level extraction, employing local information from just one sentence (e.g., Grishman et al. (2005), Hardy et al. (2006), Ahn (2006)).

However, in many cases local information alone is insufficient to make the right decisions, so later work incorporates more context around a sentence and seeks high level information. For example, Gu and Cercone (2006) and Patwardhan and Riloff (2009) consider broader sentential context. Ji and Grishman (2008) extend the scope to a cluster of topic-related documents and utilize global information from related documents. Gupta and Ji (2009) employ cross-event information to extract implicit time information. Liao and Grishman (2010) leverage document-level cross-event inference; Liao and Grishman (2011a) extract topic features to improve event extraction; and Liao and Grishman (2011b) present a self-training strategy and combine it with global inference. McClosky et al. (2011) use the tree of event-argument relations in a reranking dependency parser to capture global event structure properties. Hong et al. (2011) explore entity type consistency to predict event mentions. Huang and Riloff (2012b) initially identify arguments and then include discourse properties to model textual cohesion. More recently, some researchers have tried to improve other aspects of event extractions. For example, Lu and Roth (2012) introduce a novel sequence labeling framework called structured preference modeling, and Huang and Riloff (2012a) propose a bootstrapping solution for argument extraction with little annotated data.

As far as work on Chinese event extraction is concerned, Chen and Ji (2009b) point out the Chinese-specific issue of word segmentation errors and create an errata table to alleviate this problem, analyzing the impactof different types of features. Chen and Ji (2009a) bootstrap Chinese event extraction with extra information from an English event extraction system using cross-lingual information projection. Ji (2009) extracts cross-lingual predicate clusters and uses a cross-lingual information extraction system to improve Chinese event extraction. Li et al. (2012) explore compositional semantics and discourse consistency to address the unknown trigger problem and word segmentation errors.

3 Baseline System

In order to establish a strong baseline Chinese event extraction system adopting the pipeline architecture mentioned in the introduction, we train a classifier for each of the four components by using a feature set that is the *union* of the features employed by Chen and Ji (2009b) and Li et al. (2012). We augment it with compositional semantics and discourse consistency, the two extensions proposed by Li et al. that aim to improve the trigger identification component, as described in detail in this section. Below we will discuss our implementation of each of the four components of the baseline Chinese event extraction pipeline. All classifiers are trained using the implementation of SVM available from the SVM^{multiclass} package[2]. Word segmentation, syntactic parsing, and dependency parsing are performed using Stanford's Chinese NLP and Speech Processing tool.[3].

3.1 Trigger Identification Component

Following Li et al. (2012), we employ a two-step approach to identify triggers. First, in the *extraction* step, we use heuristics to extract candidate triggers. Then, in the *pruning* step, we aim to improve precision by employing two types of pruning, namely *heuristic-based* pruning and *learning-based* pruning. Both steps are detailed below.

Extraction. To extract candidate triggers, we first follow Chen and Ji (2009b), positing a word in a test document as a candidate trigger if it appears in a training document as a (true) event trigger. Li et al. (2012) observe that this simple candidate extraction method has a low recall: it fails to extract many true triggers in a test document since many of them do not appear in the training set. To improve recall, they propose a technique to extract additional candidate antecedents based on *compositional semantics*.

The use of compositional semantics is motivated by the observation that the meaning of a Chinese word is largely determined by the meaning of its component characters. For instance, the meaning of 刺伤 [injure by stabbing] can be determined from the meaning of its component characters, 刺 [stab] and 伤 [injure]; similarly, the meaning of 撞伤 [injure by hitting] can be determined from the meaning of 撞 [hit] and 伤 [injure]. Now, assume that 撞伤 appears in a test document. If 撞伤 does not appear in the training data but 刺伤 appears as a trigger in the training data, we want to be able to infer that 撞伤 is a trigger from the fact that 刺伤 is a trigger since the two verbs both describe an "injure" event.

To be able to do this kind of inference for extracting additional candidate triggers, we employ a simple method proposed by Li et al.: (1) add all single-character verb triggers to a set (call it BV[4]); (2) split all other verb triggers in the training set into characters and add each character to BV; and

[2]http://svmlight.joachims.org/svm_multiclass.html
[3]http://nlp.stanford.edu/projects/chinese-nlp.shtml
[4]Li et al. (2012) refer to these verbs as "basic verbs" (BV).

(3) posit a word in a test document as a candidate trigger if it contains an element in BV. It should be easy to see that this method can easily handle cases such as the 撞伤 example discussed above.

Heuristic-based pruning. To prune spurious triggers from the list of candidate triggers, we employ the three heuristics proposed by Li et al.: non-trigger filtering, POS filtering, and verb structure filtering. We refer the reader to their paper for details of these heuristics.

Learning-based pruning. After heuristic-based pruning, we follow Li et al. and apply learning-based pruning to further prune the candidate triggers. Specifically, we train a classifier on the training data to determine whether a candidate is a trigger or not. Since Li et al. did not specify the training instance creation method, we experiment with several methods and found that creating one training instance from each word worked best. We train the classifier using 19 linguistic features, most of which were proposed by Chen and Ji, as shown below:

- Lexical features (6): trigger word; POS of trigger word; previous word + trigger word; previous POS + trigger POS; trigger word + next word; trigger POS + next POS
- Syntactic features (5): depth of trigger word in syntax parse tree; the path from leaf node of trigger to the root in syntax parse tree; the phrase structure expanded by the father of the trigger; phrase type of the trigger; the path from the leaf node of the trigger to the governing clause
- Semantic dictionaries (2): whether trigger word exists in a predicate list from Chinese PropBank (Xue and Palmer, 2008); the entry number of the trigger in a Chinese synonym dictionary[5]
- Nearest entity information (6): entity type of the syntactically/physically nearest entity to the trigger in syntax parse tree; entity type of the syntactically/physically left/right nearest entity to the trigger in syntax parse tree + entity

Reclassifying unconfidently labeled instances. Not all trigger candidates were classified with the same confidence by the trigger identifier. For our SVM-based trigger identifier, those instances that are closer to the hyperplane are classified with less confidence than those that are farther away. Li et al. propose to improve the accuracy of trigger identification by reclassifying those instances that were not confidently classified[6], specifically by training a *discourse consistency* (DC) classifier.

Before describing the DC classifier, let us motivate DC. Consider the sentence *The talks are serious*, where *talks* is a trigger of a MEET event whose arguments are not in the same sentence as the trigger itself. Because of the absence of nearest entity information (and hence the inability to compute the nearest entity information features), Li et al. observe that the corresponding test instances were typically classified with low confidence. To address this problem, they make an observation. Given a candidate trigger word t, if many other occurrences of t in the same discourse are being classified as a trigger, then t is likely to be a trigger due to DC. Similarly, if many other occurrences of t in the same discourse are being classified as non-triggers, then t is not likely to be a trigger due to DC.

Li et al. create five linguistic features that encode this observation (see their paper for details), train a DC classifier on a feature set composed of these five features as well as the 19 features used by the trigger identifier, and use it to reclassify those instances not confidently classified by the trigger identifier. Following Li et al., we train this DC classifier on the development set, which comprises 5% of the available training data reserved solely for the purpose of training this classifier.

[5]This dictionary is created by Harbin Institute of Technology's NLP Group and is available from http://ir.hit.edu.cn/phpwebsite/index.php?module=pagemaster&PAGE_user_op=view_page&PAGE_id=162. The entry number can be thought of as the equivalent of the synset id in English WordNet.

[6]Following Li et al., we posit that an instance is not confidently classified if the probability associated with its classification is between 0.05 and 0.95. We obtain these probability values by converting the signed distance values returned by the SVM using a sigmoid function.

3.2 Trigger Type Determination Component

Given a word identified as a trigger by the preceding component, the trigger type determination component employs a classifier to classify a word as belonging to one of the 33 predefined subtypes. Following Li et al., we train this classifier using the same 19 linguistic features that were used to train the trigger identifier.

3.3 Argument Identification Component

Given a typed trigger produced by the trigger type determination component, the argument identification component employs a classifier to determine whether a candidate argument is its actual argument or not. The list of candidate arguments for a trigger includes all and only those entity mentions, values and time expressions that appear in the same sentence as the trigger under consideration. Hence, training instances are created by pairing each trigger with each of its candidate arguments. The class value of a training instance is either YES (if the candidate is a true argument) or NO (if it is not). Following Li et al., we train this classifier using 19 linguistic features, as shown below.

- Basic features (6): trigger subtype; type of entity mention; head word of entity mention; event subtype + head word; event subtype + entity subtype; POS of trigger word
- Neighboring words (6): left/right neighbor word of entity; left/right neighbor word of the entity + word's POS; left/right neighbor word of the trigger + word's POS
- Syntactic features (4): the phrase structure expanding the parent of the trigger in the syntactic parse tree; whether the trigger is before or after the trigger; the minimal path from the entity to the trigger in the syntactic parse tree; the shortest length of the above minimal path
- Dependency feature (1): the dependency path from the entity to the trigger

3.4 Argument Type Determination Component

Given an entity mention identified as an argument of a trigger, the argument type determination component employs a classifier to determine its argument role. Following Li et al., we train this classifier using the same 19 linguistic features that were used to train the argument identifier.

We conclude this section with a note on feature computation. Following the setting of the ACE diagnostic tasks, we use ground truth entities, times and values in argument identification and argument type determination, but the rest of the features are all computed entirely automatically. This is also the setup adopted by Chen and Ji (2009b) and Li et al. (2012).

4 Machine learning Extension

In this section, we present our machine learning extension to the baseline system, which involves joint modeling of the event extraction subtasks. Unlike in pipeline modeling where we train four classifiers (i.e., one classifier per subtask), in joint modeling we train only two classifiers: the joint trigger classifier jointly performs trigger identification and trigger type determination, and the joint argument classifier jointly performs argument identification and argument role determination. Below we describe how these two joint models are trained.[7]

[7] Like us, Tan et al. (2008) also train two classifiers for event extraction, one related to labeling trigger type and the other argument type. So, at first glance, it seems that they are also performing some sort of joint learning for event extraction. However, there is an important difference between our goal and theirs: while we are performing end-to-end event extraction, they are *not*. Their first classifier, the trigger type labeler, is a multi-label *sentence* classifier that assigns to a sentence the

4.1 The Joint Trigger Classifier

To train the joint trigger classifier, we create one training instance for each word in the training set. If the word is not a trigger, the class label of the corresponding training instance is NONE. Otherwise, the class label is the type of the trigger. Each instance is represented by the same 19 features that were used to train the trigger identifier in the baseline system. As in the baseline, we employ SVM^{multiclass} to train this multiclass classifier.

After training, we apply the resulting SVM classifier to classify the test instances. Test instances are created via the same trigger candidate extraction process (including the use of compositional semantics) as described in the baseline system and are represented using the same 19 features as the training instances. If a test instance is assigned the class NONE by the classifier, the corresponding trigger candidate will be posited as a non-trigger. On the other hand, if the instance is classified as belonging to one of the 33 trigger types, the corresponding trigger is posited as a true trigger, and its type is the class value assigned by the classifier.

4.2 The Joint Argument Classifier

To train the joint argument classifier, we create a training instance by pairing each predicted trigger with each of its candidate arguments, where a candidate argument can be an entity mention, a value, or a time expression that appears in the same sentence as the predicted trigger. If the candidate argument is indeed a true argument of the trigger, the class label of the training instance is the argument's role. Otherwise, its class label is NONE. Each instance is represented by the same 19 features that were used to train the argument identifier in the baseline system. As in the baseline, we employ SVM^{multiclass} to train this multiclass classifier.

After training, we apply the resulting SVM classifier to classify the test instances. Test instances are created in the same way as the training instances. If a test instance is assigned the class NONE by the classifier, the corresponding argument candidate is classified as not an argument of the trigger under consideration. Otherwise, the argument candidate is indeed a true argument of the trigger, and its role is the class value assigned by the classifier.

5 Linguistic Extension

In this section, we describe our linguistic extension to the baseline system, where we introduce six groups of features for Chinese event extraction. Before we describe these features, there are two points that deserve mention. First, while this is a linguistic extension to the baseline system, there is nothing that prevents it from being applied to an event extraction system that employs joint learning. Second, solely for the sake of convenience, we follow the convention adopted in the baseline system, ensuring that (1) the trigger identifier and the trigger type labeler employ the same set of features, and (2) the argument identifier and the argument role labeler employ the same set of features. This implies that any group of features that we introduce below has to be used by either (1) both trigger-related classifiers; or (2) both argument-related classifiers, or (3) all four classifiers.

set of trigger types of the triggers it contains, but unlike ours, it does not explicitly identify triggers, even though it has some joint learning flavor in the sense that it allows the NULL class to be assigned to a sentence to indicate that it does not contain any triggers. Their second classifier, the argument type labeler, assumes that the input arguments of a trigger are correctly identified and simply performs argument labeling.

5.1 Character-Based Features

Recall that Li et al. (2012) have employed compositional semantics to improve the extraction of candidate triggers, enabling us to extract 撞伤 [injure by hitting], which appears in the test set but not the training set, as a candidate trigger if 刺伤 [injure by stabbing] is present in the training set as a true trigger, for instance.

Now, recall that each trigger candidate will be classified by the learned trigger identifier as either a true trigger or a non-trigger. Consider, for example, how the instance corresponding to 撞伤 will be classified. One of the linguistic features representing this instance is the word itself. But since 撞伤 never appears in the training set, the word feature is useless as far as classification is concerned. In other words, although 撞伤 and 刺伤 are similar verbs, the word feature does not capture such similarity, and therefore the classifier cannot exploit this similarity when classifying 撞伤.

To address the problem, we decompose a word into two units, putting the two units into separate bins. There are a four cases to consider: (1) if the word has two characters, we put the first character into the first bin and the second character into the second bin; (2) if the word has only one character, we put this character into both bins; (3) if the word has three characters and it can be segmented by a word segmenter, we put the resulting units into the two bins (for example, given the word 公开信 [open letter], 公开 [open] is placed in the first bin and 信 [letter] in the second); and (4) if the word has four characters or the word has three characters that cannot be segmented, we simply put the first two characters into the first bin and the remaining characters into the second bin.

Given these bins, we create four character-based features for the two trigger-related classifiers: The first two features come from the characters in the first and second bins respectively. The third and fourth features consist of the Harbin Institute of Technology NLP Group's synonym dictionary entry numbers for characters in the first and second bins respectively.

5.2 Semantic Role Labeling

It should be easy to see why semantic role labeling is useful for event extraction. First, a large portion of the triggers defined in event extraction task are predicates. Second, if a predicate happens to be a trigger, the predicate's arguments are essentially its event arguments. Furthermore, even though a semantic role labeler typically assigns PropBank-style roles (e.g., Arg0, Arg1) and the event argument roles are FrameNet-style roles, there is a close correspondence between the roles in these two styles.

Given the above observation, we hypothesize that semantic roles are useful for argument identification and argument role labeling. Consequently, we introduce four binary features for the argument classifiers: whether the trigger under consideration is a predicate according to the semantic role labeler, and whether the argument is the predicate's Arg0, Arg1, and time argument. We obtain semantic roles automatically using a publicly available semantic role labeling tool (Björkelund et al., 2009).

In addition, we hypothesize that semantic roles are also useful for trigger identification and trigger type classification. Our hypothesis stems in part from two observations: (1) many predicates identified by a semantic role labeler are triggers; and (2) knowing the entity types of the arguments identified by the semantic role labeler can help predict the type of the trigger. As a result, we propose to employ features that encode semantic role information for trigger identification and trigger type classification. Specifically, we introduce five features: whether the word under consideration is a predicate according to the semantic role labeler; if yes, the entity type and subtype of its Arg0;

the entity type and subtype of its Arg1.

5.3 Trigger Probability Feature

We define *trigger probability* of a word *w* as the probability that *w* appears as a true trigger in the training set. This probability is potentially useful for trigger identification: a word with a higher probability is more likely to be a true trigger.

We create a new feature for the two trigger-related classifiers whose value is the trigger probability of the word under consideration. If the word does not appear in the training set, we determine whether one of its "similar" verbs appears as a trigger in the training set.[8] If so, its trigger probability is that of its similar verb.[9] Otherwise, its trigger probability is set to zero.

5.4 Zero Pronoun Features

To motivate zero pronoun features, consider the following sentence:

国家主席江泽民今天晚上乘专机离开深圳前往文莱。
President Jiang Zemin took the plane tonight, left Shenzhen and went to Brunei.

The verb 乘 [took] has an overt subject 江泽民 [Jiang Zemin]. However, neither of two verbs 离开 [left] or 前往 [went] has an overt subject. Here, the two gaps before 离开 [left] and 前往 [went] are called zero pronouns. A zero pronoun has as its antecedent an entity mention that can fill the gap. In this example, 江泽民 [Jiang Zemin] is the entity mention that should be used to fill the gap: as we can see, 江泽民 [Jiang Zemin] is coreferent with those two zero pronouns.

Kim (2000) studied the difference of the usage of overt subject between English and Chinese. He found that the usage percent of overt subject in Chinese is only 64%, while for English the percent is more than 96%. Thus, zero pronoun is a prominent phenomenon in Chinese, and also appears frequently in the ACE 2005 dataset.

For event extraction, if there is a zero pronoun before a trigger, the entity mention to which this zero pronoun refers is likely to be an argument of this trigger. Thus, zero pronoun resolution, which involves (1) detecting zero pronouns and (2) finding their antecedents, is helpful for argument extraction. To our knowledge, results of zero pronoun resolution have not been exploited to improve event extraction.

In order to exploit zero pronoun resolution for use in event extraction, we need to build a zero pronoun resolver. In our experiments, we apply a rule-based method for zero pronoun resolution. Specifically, to detect zero pronouns, we employ a simple heuristic, which posits that a zero pronoun exists before a word if it is a verb and it has no overt subject in the corresponding syntactic parse tree. After detecting a zero pronoun, we resolve it in one of two ways:

Case 1: the verb following the zero pronoun is in a CP node and modifies a NP to its right (i.e., the

[8] We adopt Li et al.'s (2012) method for determining whether two Chinese verbs are similar. Specifically, we first analyze the structure of each of the verbs under consideration. According to Li et al.'s empirical observation, Chinese verbs possess one of six main structures, where BV is one of the elements of the set *BV* (as defined in Section 3): (1) BV (e.g., " 逮" [arrest]); (2) BV + verb (e.g., " 追杀" [chase to kill]); (3) verb + BV (e.g., " 躲进" [hide]); (4) BV + complementation (e.g., " 进了" [enter]); (5) BV + noun/adjective (e.g., " 开枪" [shoot]); (6) noun/adjective + BV (e.g., " 内战"[civil war]). If the two verbs have the same BV (basic verb) and the same structure, they are considered similar to each other.

[9] It is, of course, possible for a verb to have more than one similar verb. In this case, we compute its trigger probability based on one of its randomly selected similar verbs.

character " 的" appears between the verb and the NP), as shown in the following example, where 歼敌 [kills] modifies 胡修道 [Hu XiuDao]

歼敌 280 人的胡修道.
Hu XiuDao, who kills 280 enemies.

In this case, we resolve the zero pronoun to the NP modified by the verb, 胡修道 [Hu XiuDao].

Case 2 (default case): we resolve the zero pronoun to the nearest preceding NP that occupies the subject position and appears in the same sentence as the zero pronoun.

Next we create features that encode the output of the zero pronoun resolver for the two argument-related classifiers. Recall that each instance in the argument-related classifiers corresponds to a trigger and one of its candidate arguments. Keeping this in mind, the first feature we create encodes whether or not there is a zero pronoun before this trigger. If so, the second feature tells whether or not this argument is coreferent with the zero pronoun.

5.5 Trigger Type Consistency Features

All the features we have described thus far have focused on sentence-level extraction. However, document-level information also plays an important role in event extraction task. A good example is DC (Li et al., 2012). In this subsection, we propose another kind of document-level information, which we call trigger type consistency, to improve event extraction.

Trigger type consistency is motivated by one observation: documents in the ACE 2005 Chinese corpus are mostly news articles, each of which describes one theme, and most of the true triggers are compatible with this document theme. For example, if a document is about a fire accident, most of the annotated triggers in the gold standard are of type DIE. Therefore, knowing the document theme may help to identify triggers. We represent the theme of a document by the trigger type that occurs most frequently among the triggers in the document.[10] For example, if a document has 10 triggers and six of them have type DIE, then we use DIE to represent its theme. If a candidate trigger's type is the same as that of the majority of the triggers in the document, it is being *trigger-type-consistent* with the other triggers in the document and is more likely be a true trigger.

We create 33 features for the two trigger-related classifiers based on trigger type consistency. Each feature corresponds to one of the 33 predefined trigger types in the ACE 2005 event extraction task. We compute the feature values as follows. If, for example, one trigger has type DIE, then (1) the value of the feature corresponding to DIE is the probability that a trigger in this document has type DIE; and (2) the values of the remaining 32 trigger type consistency features are all zero.

A natural question is: since the type consistency features are to be used by the trigger-related classifiers, how is it possible that they are computed based on knowing which words are triggers and what their types are? The answer is that before computing the type consistency features, we run the baseline trigger identifier and the trigger type classifier to identify triggers and predict their types on each document.[11]

[10] For another way of computing the document theme, see Liao and Grishman (2011a).

[11] To identify triggers and predict their types on a test document, we train the two trigger-related baseline classifiers on the training set. On the other hand, to identify triggers and predict their types on a training document, we employ cross validation on the training set: we partition the training set into 9 folds, train the baseline classifiers on 8 folds, apply them to the documents in the remaining fold, and repeat this process 9 times so that we can obtain triggers and their types for each document in the training set.

5.6 Argument Consistency Feature

Another piece of document-level information we employ is argument consistency. It is based on the following observation: the true triggers typically correspond to events that are related to the main person or some major entities mentioned in the documents. Hence, if a candidate trigger has arguments that are coreferent with the arguments of true triggers, the candidate trigger will likely be a true trigger. Consider, for example, the following sentences:

[一家三口] 在昨天深夜集体喝下农药 [自杀].

[A family of three] drank pesticide to [suicide] last night.

[三个人] 总算是稳住了 [病情].

[Three people] finally stabilize the [patient's condition].

Since 自杀 [suicide] is a predicate that is frequently annotated as a trigger in the training data, it should be fairly easy for the learned trigger identifier to predict 自杀 as a trigger. On the other hand, it is difficult to predict 病情 [patient's condition] in the second sentence as a true trigger because many useful features, such as being a predicate or having many entities nearby, cannot be computed due to the lack of useful local information. However, if we know that (1) 病情 takes the argument 三个人 [Three people]; (2) 三个人 is coreferent with 一家三口 [A family of three]; and (3) 一家三口 is an argument of a true trigger 自杀, then we may be able to provide useful document-level information to make the classifier correctly classify the trigger candidate 病情 as a true trigger.

Based on the above observation, we create one feature that encodes this kind of document-level information, which we call argument consistency, for the trigger-related classifiers. The feature is the *role* of the argument that is coreferent with a predicted true trigger's argument.[12] Here is the reason behind using roles as feature values: some roles are more important than the others. Specifically, roles for arguments that serve as subjects or objects, such as VICTIM, are intuitively more important than roles of adjunct arguments, such as PLACE. Using the above two sentences as an example, the role of 三个人 [Three people] is VICTIM, so we will set the value of the feature corresponding to VICTIM as 1.

A natural question is: since the argument consistency feature is to be used by the argument-related classifiers, how is it possible that it is computed based on knowing which words are triggers and what their arguments and argument roles are? The answer is that before computing this feature, we run the baseline classifiers to identify triggers, predict their types, their arguments, and the argument roles on each document (see Footnote 11 for details on how to train these baseline classifiers).

6 Evaluation

Next, we evaluate our joint-learning, knowledge-rich approach to Chinese event extraction.

6.1 Experimental Setup

Dataset and evaluation methodology. All 633 Chinese documents in the ACE 2005 training corpus[13] are used in our evaluation. Unlike previous work (Chen and Ji, 2009b; Li et al., 2012) which designate 10% of the 633 documents as the test set, we perform 10-fold cross-validation experiments in order to obtain more accurate estimation of system performance. While we report

[12] As mentioned at the end of Section 3, since our evaluation setting follows that of the ACE diagnostic tasks, we compute our argument consistency feature based on gold coreference information.

[13] Note that the ACE 2005 test documents are not made publicly available.

results that are averaged over 10 folds, it is worth noting that the results achieved for each of the four subtasks on different folds vary considerably, sometimes by as many as 10 percentage points in F-score, due to the small size of the training and test sets. This suggests the importance of reporting cross-validation results when conducting experiments on the ACE 2005 corpus.

Evaluation measures. For each subtask, we report performance in terms of recall (R), precision (P), and F-score (F). These performance measures are computed based on the following definitions of correctness for the subtasks. For trigger identification, a trigger is correctly identified if its offsets exactly match a reference trigger. For trigger type determination, a trigger type is correctly determined if its trigger type and offsets exactly match a reference trigger. For argument identification, an argument is correctly identified if its offset, related trigger type and trigger's offsets exactly match a reference argument. Finally, for argument role determination, an argument role is correctly determined if its offsets, role, related trigger type and trigger's offsets exactly match a reference argument. Note that these definitions are also adopted by Chen and Ji (2009b) and Li et al. (2012).

6.2 Feature Selection

To determine which of the feature groups described in Section 5 are useful when used in combination with the baseline features in Section 3, we conduct feature selection experiments to identify the best feature subset. There are seven feature groups to be considered in our feature selection experiments: (G1) discourse consistency features (Li et al., 2012); (G2) semantic role labeling features; (G3) trigger probability features; (G4) character-based features; (G5) the argument consistency feature; (G6) trigger type consistency features; and (G7) zero pronoun features. Two points deserve mention. First, among these seven feature groups, G1, G2, G3, G4, G5 and G6 are used for training the trigger-related classifiers whereas G2 and G7 are used for training the argument-related classifiers. Second, while G1 is not a feature group proposed by us, we consider it in our feature selection experiments. The reason is that some of our feature groups (e.g., G5 and G6) also capture document-level information like G1, and because they overlap in terms of the information they capture, we may be better off not retaining all of them.

Feature selection is done using cross validation on the training documents. Specifically, we partition the training documents into 9 folds, train the classifier whose features are to be selected on 8 folds, apply the classifier to the remaining fold, and repeat this process 9 times in order to select the feature groups that have the best average performance over the 9 folds when used in combination with the baseline features.

As far as the feature selection algorithm is concerned, we employ backward elimination. It starts with the full feature set (containing the 7 feature groups to be selected plus the baseline features), and removes in each iteration the feature group whose removal yields the best system performance. We run the algorithm until all but the baseline features are removed, and identify the feature subset that achieves the best performance during the feature selection process.

Note that feature selection is performed separately for each of the four classifiers used in the pipeline approach and each of the two classifiers used in the joint learning approach.

Table 1 shows the feature groups selected for each classifier. Let us first consider the classifiers for the pipeline approach. For trigger identification, all feature groups are retained. For trigger type identification, only G4 (character-based features) are retained. This makes sense because other feature groups are designed only to help discriminate true triggers from wrong triggers. Finally,

G2 (semantic role labeling) and G7 (zero pronoun features) prove to be effective for argument identification but not argument role labeling. This means that the best result for argument role labeling is achieved by training the classifier on only the baseline features.

Approach	Classifier	Selected Features
Pipeline	Trigger Identification	G1, G2, G3, G4, G5, G6
	Trigger Type Determination	G4
	Argument Identification	G2, G7
	Argument Role Determination	---
Joint	Trigger Component	G2, G3, G4, G6
	Argument Component	G2, G7

Table 1: Feature selection results

Let us turn to the two classifiers in the joint approach. Interestingly, for the trigger classifier, G1 (discourse consistency) and G5 (argument consistency) are removed. This result provides suggestive evidence that G1 and G5 serve overlapping purposes with the rest of the feature groups we proposed and therefore not all of them need to be retained to achieve the best performance. For the argument classifier, both G2 (semantic role labeling) and G7 (zero pronoun features) are retained. This is consistent with the pipeline results, where both feature groups are shown to be useful for argument identification.

6.3 Test Set Results

Using the features selected for each classifier, we obtain test set results. The average 10-fold cross-validation results for the pipeline approach and the joint approach are shown in Tables 2 and 3, respectively. In each case, we compare our approach against two baselines, one where the classifiers are trained using the baseline feature set without the discourse consistency features, and one where the classifiers are trained using the baseline feature set including the DC features. This setup enables us to better evaluate the usefulness of the DC features: since our feature selection experiments indicate that the DC features are not always useful when used in combination with our proposed features, we want to examine whether they are always useful when used in combination with the baseline features.

	Trigger Identification			Trigger Type Determination			Argument Identification			Argument Role Determination		
Feature Set	R	P	F	R	P	F	R	P	F	R	P	F
Baseline features without DC	50.6	75.5	60.6	47.5	70.8	56.8	35.1	52.3	42.0	31.2	46.5	37.4
Baseline features with DC	55.6	72.7	63.0	52.0	67.9	58.9	38.9	50.2	43.8	34.8	45.0	39.2
Our selected features	60.5	70.1	**64.9**	56.6	65.6	**60.8**	43.8	50.2	**46.8**	39.3	45.1	**42.0**

Table 2: Pipeline modeling results on the test set.

	Trigger Identification			Trigger Type Determination			Argument Identification			Argument Role Determination		
Feature Set	R	P	F	R	P	F	R	P	F	R	P	F
Baseline features without DC	50.0	77.0	60.7	47.5	73.1	57.6	34.1	58.7	43.2	30.4	52.3	38.5
Baseline features with DC	55.3	75.6	63.9	52.6	71.8	60.7	38.2	57.4	45.9	34.3	51.5	41.1
Our selected features	62.2	71.9	**66.7**	58.9	68.1	**63.2**	43.6	57.3	**49.5**	39.2	51.6	**44.6**

Table 3: Joint modeling results on the test set.

A few points about these results deserve mention. First, the DC features offer benefits when used

in combination with the baseline features in both the pipeline and joint approaches. Second, we can see that joint modeling always offers benefits over pipeline modeling when we consider comparable rows in the two tables. In fact, using the selected features, the joint approach performs significantly better than the pipeline approach on all four subtasks (paired t-test; $p < 0.05$). Finally, our best-performing system (row 3 of Table 3) significantly outperforms the approach adopted by state-of-the-art event extraction systems (row 2 of Table 2) on all four subtasks (paired t-test, $p < 0.05$): F-score increases by 3.7% for trigger identification, by 4.3% for trigger type determination, by 5.7% for argument identification, and by 5.4% for argument role labeling.

6.4 Feature Analysis

To gain better insight into the contribution of each feature group to our best-performing system (row 3 of Table 3), we add each feature group incrementally to the baseline feature set. Results are shown in Table 4. Recall that the DC features were not selected by the feature selection algorithm for our best-performing system, so none of the results in this table involves DC features. In particular, we start with the baseline features without any DC features (row 1), and add the feature groups incrementally to this baseline feature set.

	Trigger Identification			Trigger Type Determination			Argument Identification			Argument Role Determination		
Features	R	P	F	R	P	F	R	P	F	R	P	F
Baseline features without DC	50.0	77.0	60.7	47.5	73.1	57.6	34.1	58.7	43.2	30.4	52.3	38.5
+G2 (Semantic role labeling)	52.1	77.7	62.4	49.8	74.4	59.7	36.9	61.7	46.2	33.2	55.4	41.5
+G3 (Trigger probability)	56.0	75.3	64.3	53.3	71.5	61.1	39.2	59.7	47.3	35.2	53.7	42.5
+G4 (Character features)	59.8	73.8	66.1	56.6	69.6	62.6	41.2	57.9	48.2	37.2	52.3	43.5
+G6 (Trigger type consistency)	62.2	71.9	66.7	58.9	68.1	63.2	42.7	56.5	48.6	38.5	50.9	43.8
+G7 (Zero pronouns)	62.2	71.9	66.7	58.9	68.1	63.2	43.6	57.3	49.5	39.2	51.6	44.6

Table 4: Results of incremental addition of features to the joint model on the test set

As we can see, except for the argument consistency feature, all feature groups provide gains when added to the feature set in an incremental fashion. For example, in each of the four subtasks, adding semantic role labeling improves F-score by 1.7%, 2.1%, 3.0%, and 3.0%, respectively. Adding trigger probability next improves F-score by 1.9%, 1.4%, 1.1% and 1.0%. After that, adding character features improves F-score by 1.8%, 1.5%, 0.9% and 1.0%. Note that the zero pronoun features are only designed to improve the two argument-related subtasks. So, with the addition of these zero pronoun features, the two trigger-related subtasks are unaffected, while argument identification and argument role determination are improved by 0.9% and 0.8% in F-score, respectively.

Conclusion and Perspectives

We proposed a joint-learning, knowledge-rich approach to a relatively under-studied yet important task, Chinese event extraction, aiming to extend Li et al.'s (2012) state-of-the-art Chinese event extraction system. Linguistically, not only did we propose more effective use of existing features such as character-based features, but we also investigated novel features that exploit results of zero pronoun resolution and noun phrase coreference resolution, as well as those that exploit trigger probability and trigger type consistency. In 10-fold cross-validation experiments on the ACE 2005 dataset, we showed that our system outperformed Li et al.'s system by 3.7−5.7% on the four event extraction subtasks. Our results also indicated that all but the argument consistency feature contributed positively to overall performance. In particular, while each of these feature groups provided small gains, their cumulative benefits were substantial.

ABSTRACT

Integration of domain specific knowledge into a general purpose statistical machine translation (SMT) system poses challenges due to insufficient bilingual corpora. In this paper we propose a **s**implification-**t**ranslation-**r**estoration (*STR*) framework for domain adaptation in SMT by simplifying domain specific segments of a text. For an in-domain text, we identify the critical segments and modify them to alleviate the data sparseness problem in the out-domain SMT system. After we receive the translation result, these critical segments are then restored according to the provided in-domain knowledge. We conduct experiments on an English-to-Chinese translation task in the medical domain and evaluate each step of the *STR* framework. The translation results show significant improvement of our approach over the out-domain and the naïve in-domain SMT systems.

用於跨領域統計式機器翻譯系統之簡化-翻譯-還原架構

摘要

因為雙語語料的不足，將特定領域知識整合到一般用途的統計式機器翻譯(SMT)系統具有相當挑戰性。在本篇論文中，我們提出一個簡化-翻譯-還原(*STR*)的架構，藉由簡化特定領域的片段來達成SMT的領域調適。對於一篇領域內的文字，我們首先辨識其中重要的片段再做修改以減輕領域外SMT系統的資料稀疏問題。我們取得翻譯結果後，根據提供的領域內知識將這些重要片段還原。最後我們進行了醫療領域的英中翻譯的實驗，並且評估*STR*架構內的每一步驟。翻譯結果顯示我們的方法顯著地優於領域外的SMT系統，以及簡易型的領域內SMT系統。

1 Introduction

Over the past decades, the rapid growth of available parallel corpus makes SMT development feasible, and SMT system has gradually moved toward practical use because of its relatively acceptable translation speed and quality. A phrase-based SMT system (Koehn et al., 2003; Koehn, 2004), for example, trains a phrase table from a large bilingual corpus as its translation model, and decodes source language input in polynomial time with greedy algorithms such as beam search. It translates phrases as basic units, and thus captures short-range reordering phenomena between source and target languages. Generally phrase-based SMT models outperform word-based ones (Koehn et al., 2003). However, an SMT system fails to capture long-range contextual knowledge due to the limited horizon and the sparseness nature of lexical n-grams. These drawbacks reduce the translation quality in terms of translation and reordering errors, especially when limited bilingual corpus is available for estimating translation model.

The data sparseness problem may worsen when we build an SMT system for a specific domain but have small or no bilingual in-domain corpus. The translation performance could be seriously degraded since the SMT system cannot gather the statistical evidence of a segment containing out-of-vocabulary (OOV) words. For some domains, a bilingual dictionary containing source-target term pairs is available. With such in-domain knowledge, one can force an SMT system to translate OOV terms according to the dictionary. In this way, we correctly translate in-domain terms. However, translation quality may still be unsatisfying under this naïve integration because in-domain terms are rare or unseen in the background SMT model. Hence the context of these in-domain terms can hardly be captured. FIGURE 1 shows an incorrect English-Chinese translation of a sentence in a medical record by the online Google Translate service. In this example, it correctly translates the diagnosis term "crystal induced arthritis". However, it mistranslates its nearby phrasal verb "suffered from" by translating these two words separately. This example shows an SMT system may recognize the domain specific terms with either bilingual dictionary or its background SMT model, but still gives improper translations of the surrounding words due to insufficient context knowledge of these in-domain terms.

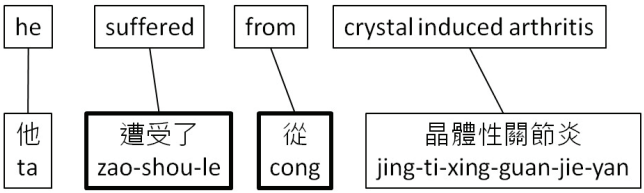

FIGURE 1 – Translating domain specific text with Google Translate. The bold target phrases are the inappropriate translations.

Our work originates from the following idea: modifying an in-domain segment in a source text such that the background SMT model not only recognizes it but also translates it together with its context words. Based on the motivation, for example, we modify the complicated diagnosis term "crystal induced arthritis" in FIGURE 1 into a more general term that occurs more frequently in the background SMT model, such as "cancer", "pneumonia" or "hypertension". Since these terms are more common in the general corpora, the general SMT system is able to better handle the modified text. Take the common word "cancer" as an example, the Google Search engine shows

that Web pages containing "suffered from cancer" significantly outnumber those containing "suffered from crystal induced arthritis".

In this paper, we propose a **s**implification-**t**ranslation-**r**estoration (*STR*) framework to address domain adaptation in SMT by modifying in-domain text in favour of the background SMT system. The *STR* framework includes four steps to produce a cross-domain translation with higher quality than a general purpose SMT system. More specifically, to translate an in-domain source text, we identify the domain-specific segments and simplify them into more general expressions. The modified text is then translated by an out-domain SMT system. After that, we manipulate the translation result by replacing the modified parts and their translations with the correct bilingual segments in our in-domain knowledge (e.g., bilingual dictionary). Our framework is suited to the cross-domain SMT scenario where an out-domain SMT system and bilingual in-domain dictionaries are available. We show the effectiveness of the framework through a case study by building an SMT system for the medical domain. In this domain, OOV is a frequent problem if a general purpose SMT system is applied. On the other hand, there are plenty of bilingual dictionaries in this area. We implement the *STR* framework and report the experimental results of the translation tasks on medical summaries in a hospital. The central issues in this framework include (1) collecting bilingual in-domain knowledge and identifying in-domain segments in a source text, (2) replacing the in-domain segments with the proper simplified forms, (3) translating the modified text with a background SMT system and (4) restoring the original in-domain segments after receiving the translation results from the background SMT system.

We are not the first to rephrase source language text in order to improve SMT output. As a pilot study, Resnik et al. (2010) proposed a targeted paraphrasing approach which identifies the critical source segments difficult for the background SMT system to translate. These segments are then manually paraphrased in many ways in order to provide the SMT system with more choices of decoding paths. Different from their work, we automatically identify the critical segments with in-domain knowledge, simplify them with linguistic information, and restore these critical segments after receiving the SMT results.

This paper is organized as follows. In Section 2, we review the previous works on domain adaptation and related work of our approach in SMT. In Section 3, we formally describe our simplification-translation-restoration framework to deal with domain adaptation in SMT. In Section 4, we evaluate the effectiveness of our *STR* framework by conducting a case study of English-Chinese medical summary translation, and discuss the experimental results. Section 5 draws the conclusion, indicates the potentials of our method, and shows some future work.

2 Related Work

Building an SMT system from large scale bilingual data for a specific application has become a practical option today. On the other hand, SMT model heavily relies on the statistical evidences in the training corpus. As a result, it may learn a biased SMT model, and suffer from the data sparseness problem of the training corpus when dealing with the ambiguity nature of human language. This drawback results in some typical issues such as translation disambiguation problem (Carpuat et al., 2007; Chan et al., 2007), in which a word has several senses, but the corpus is biased towards a particular subset of the senses. The SMT model trained from such a corpus is therefore prone to give the wrong translation due to the wrong choice of sense.

When a cross-domain SMT application is concerned, data sparseness problem is worsened by limited in-domain bilingual corpus. Domain adaptation techniques therefore play a key role in building an in-domain SMT system under a resource poor environment. A number of adaptation approaches have been proposed by leveraging either bilingual or monolingual in-domain resources. Foster and Kuhn (2007) proposed a mixture-model approach that divides and trains a bilingual corpus into several models. Different models were then weighted by estimating the similarity between a model and the in-domain development data. Matsoukas et al. (2009) devised sentence-level features and weighted the domain relevance to each sentence in the bilingual training corpus by optimizing an objective function. Foster et al. (2010) further raised the granularity by weighting at the level of phrase pairs. Similarly, a mixture-model approach was also applied in word-alignment task (Civera and Juan, 2007). Zhao et al. (2004) applied information retrieval techniques to select in-domain documents from large monolingual text collections and enhanced the baseline language model. Bertoldi and Federico (2009) exploited an in-domain monolingual corpus to synthesize a pseudo bilingual corpus and trained an in-domain translation model from the synthesized corpus.

While previous works concentrated on model and parameter estimation to achieve domain adaptation, they worked on the data sets with similar lexicons. Few studies dealt with large domain gap, which is a practical issue for a cross-domain SMT system. In the medical domain, for example, a term may not even appear in training corpus and therefore SMT system gives no translation to it. This OOV problem is common when translating domain specific terms such as diagnosis and surgical names in biomedical literature or medical records using a general purpose SMT system. Different from the previous works, we address cross-domain issues in SMT across two largely distinct domains by simplifying in-domain segments to the ones that can be recognized by the out-domain or the background SMT system, and restoring the in-domain segments after receiving the SMT results.

Text simplification (Zhu et al., 2010; Woodsend and Lapata, 2011; Wubben et al., 2012) itself has some straightforward NLP applications. For example, we produce a simpler version of a text by modifying the lexical contents and shortening the grammatical structures without changing the original text at the semantic level. Such simplified contents are beneficial for language learners and people with lower levels of literacy. One of the real world applications is Simple English Wikipedia (http://simple.wikipedia.org), which uses simple English words and grammar, and thus English language learners can benefit from it. In this paper we apply sentence simplification techniques to improve machine translation quality. The source language input is simplified into the version that makes it easier for the SMT system to translate. This simplification step serves as a pre-processing module of the out-domain SMT model which has poor in-domain knowledge.

The simplification approach can be viewed as a variant of paraphrasing, which expresses the same meaning in different ways. Paraphrasing is employed for various NLP tasks, such as machine translation, natural language generation and computer assisted language learning. For SMT task, paraphrasing is often used to alleviate the data sparseness problem in translation model. For example, we paraphrase a source language text so that the paraphrased parts are easier for the background SMT system to translate. Callison-Burch et al. (2006) pioneered a pivoting approach through parallel corpus to improve phrase-based SMT model. Marton et al. (2009) proposed a monolingual framework to select paraphrases of a term by comparing its context with those of candidate paraphrases. Aziz et al. (2010) proposed a semi-automatic approach to mine paraphrases from hypernyms and hyponyms in ontology. Resnik et al. (2010)

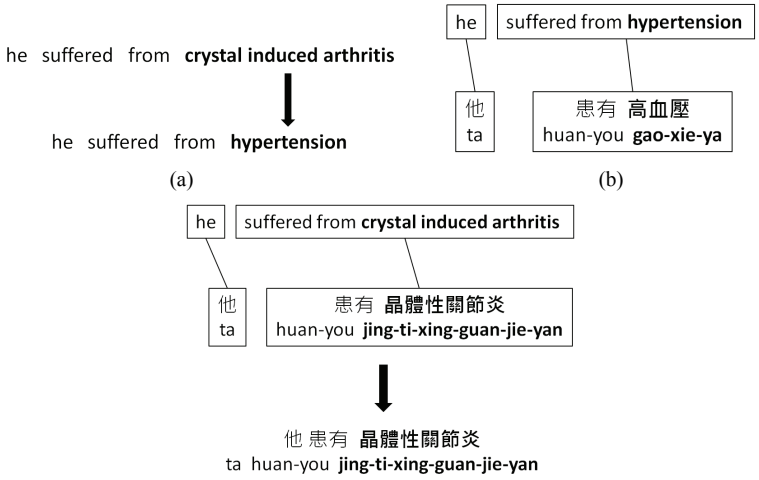

FIGURE 2 – The idea behind our *STR* framework applied to the bold phrases. We (a) simplify the source diagnosis term before translation, (b) translate the simplified sentence with an SMT system, and (c) restore the original diagnosis term and produce the translation result.

conducted a pilot study of targeted paraphrasing in which monolingual speakers on both sides collaborate to improve SMT output by paraphrasing the critical segments of source text.

Different from previous studies that applied paraphrasing to SMT in the general domain, our work focuses on addressing cross-domain issues. We aim at adapting in-domain knowledge into the out-domain SMT system in a more smooth fashion than the naïve integration approach. While other works paraphrase general segments to provide more decoding options, we concentrate on domain specific segments which account for the performance degradation of a cross-domain SMT system. We try to identify these in-domain segments and simplify them to better fit the background out-domain SMT model.

3 A Simplification-Translation-Restoration (*STR*) Framework

We express the basic idea behind our *STR* framework through the example of the incorrect translation result shown in FIGURE 1. In order to fit the in-domain term to its general context, we change the obscure medical term to a more general one. In this example, the rare source medical term "crystal induced arthritis" in FIGURE 1 is thus simplified to the more public diagnosis term "hypertension", as illustrated in FIGURE 2(a). This simplified sentence is then sent to Google Translate. FIGURE 2(b) shows the translation result, which gives not only the correct translation of the diagnosis term "高血壓", but also the nearby context "患有". Moreover, the phrase "suffered from hypertension" is translated as a unit, implying that the translation model capture the context distribution of the simple diagnosis term "hypertension". Finally, to acquire the actual translation rather than the simplified one, the simplified parts are then cut out and the

original bilingual in-domain terms are restored as illustrated in FIGURE 2(c). The final translation result is correct and fluent in contrast with the one in FIGURE 1.

The proposed *STR* framework is composed of four steps as follows.

1. Identifying in-domain segments s_1, s_2, …, s_n from an input sentence S.
2. Simplifying s_1, s_2, …, s_n in S and deriving a new source sentence S'.
3. Translating the source sentence S' into a target sentence T'.
4. Restoring the bilingual in-domain segments s_1-t_1, s_2-t_2, …, s_n-t_n back to S'-T' and deriving the final translation result T.

The following subsections describe each of them in detail.

3.1 Identification

An SMT system performs worse when translating segments which are rare in the background model. Therefore, in the first step of our framework, we identify the in-domain segments in an input source text for the next simplification step. To this end, we collect bilingual in-domain resources which include source-target string pairs.

Although a parallel corpus may not be available in a special domain, there are various ways to collect bilingual in-domain knowledge. For example, bilingual dictionaries can be found in the specific areas with long histories, such as medicine, physics and economics. They provide in-domain terminology with high quality and less noise. Not limited to the hand-crafted dictionaries, the bilingual in-domain knowledge may include phrase pairs or synchronous grammar rules, depending on the translation model and the decoding style of our background SMT system. Such bilingual knowledge can be collected by using automatic approaches (Wu and Chang, 2007; Haghighi et al., 2008) or semi-automatic approaches (Morin et al., 2007; Chen et al., 2011).

3.2 Simplification

In the simplification step, the identified in-domain segments of a text are transformed into the more general expressions. The modified text is then ready to be translated by the background SMT system. The simplification step serves as a pre-processing step before translation. We simplify an in-domain segment according to its type – say, **terminological unit** and **syntactic unit**, in this study.

Terminological units refer to terms that appear in domain specific dictionaries and glossaries without specifiers and modifiers. For these in-domain terms, we simplify them by finding the related terms such as hypernyms or synonyms which have relatively more occurrences and contextual information in the background SMT model. Syntactic units are linguistically meaningful segments which constitute special writing styles of a domain. These units usually bear syntactic categories at clausal or phrase levels such as S, NP, VP, PP, etc. They contain heads along with their modifiers. These syntactic categories can be derived from the parsed or the chunked results. We simplify a syntactic unit based on the rule corresponding to its syntactic category shown as follows.

(a) NP (Noun Phrase)

We keep the head of an NP and remove its specifier and modifier. If the head noun is a domain specific term, then it is further treated by the simplification rule to a terminological unit.

FIGURE 3 shows a parsing tree of a string as an example. The string is labelled as NP at the root node which contains two sub-trees with categories NP and PP, respectively. According to this simplification rule, we therefore remove its PP modifier. As a result, the string "a patient of skin rash with multiple erythematous papules" is simplified to only its head "a patient".

(b) VP (Verb Phrase)

VP → V + NP: We keep V untouched and simplify NP according to the simplification rule (a). For example, we simplify "had underlying diseases of ventricular tachycardia and dyslipidemia" to "had diseases".

VP → V + PP: We keep V untouched and remove PP if PP is a modifier. If PP is mandatory, it is further simplified based on the simplification rule (c). Whether PP is optional or mandatory is determined by the subcategory of V. For example, we simplify the sentence "he was discharged on the morning of 6/30" to "he was discharged".

(c) PP (Prepositional Phrase)

PP → P + NP: We keep P and simplify NP according to the simplification rule (a). For example, we simplify "with underlying diseases of ventricular tachycardia and dyslipidemia" to "with diseases".

(d) S (Clause)

We simplify a clause by simplifying its children recursively according to the above simplification rules.

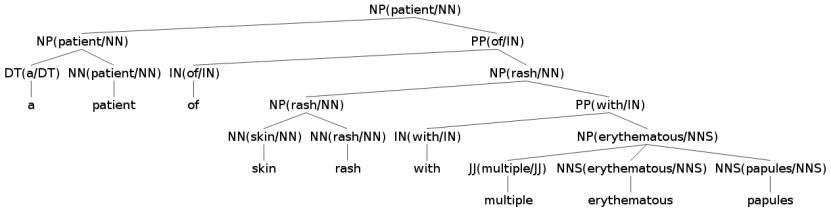

FIGURE 3 – A parse tree of a syntactic unit. A bracketed string at each non-terminal node is the head of the corresponding syntactic category.

The rule-based simplification approach is straightforward, but can be effectively applied to most of the syntactic units as discussed in Section 4. Applying transformation or rewriting rules on source sentences based on their syntactic structures has been adopted in other works. Wang et al. (2007) listed a set of prominent syntactic reordering rules that systematically describe the word order difference between the source and target languages. Based on these rules, they parsed a source language input and reordered its structure to match the target language grammar for training a better translation model and improving a phrase-based SMT system. In their work, source side syntactic reordering also serves as a pre-processing module of the SMT system. Different from their work, we simplify a source language input in favour of the background SMT system instead of changing the order of its structure.

3.3 Translation

In the translation step, the background SMT system translates the simplified in-domain text and produces its translation result. Since the input source text is simplified in favour of the translation system, the contextual distributions of the phrases can be estimated better than those of the original text, as demonstrated in FIGURE 2(b).

Our *STR* framework performs domain adaptation under the scenarios where bilingual in-domain segments are available. It is possible to be combined with other domain adaptation approaches that exploit monolingual or bilingual in-domain corpus to help further improve the translation quality. For example, if a parallel in-domain corpus is available, we can perform learning-based domain adaptation approaches described in Section 2, and tune the background translation model toward the specific domain. In this way, we may receive better translation results from the background SMT system and facilitate the next restoration step.

For a phrase-based SMT system and its variations (Chiang, 2005; Xiong et al., 2006; Huang and Chiang, 2007), we can further customize the decoder to produce the translation with higher quality and facilitate the next restoration step of our framework. For example, the in-domain segments in a text are either terminological or syntactic units in our experiments, and therefore their translations are continuous without other interleaving translations. However, an out-domain SMT system may give wrong ordering without in-domain knowledge. For instance, the translation of the medical term "bone lesion" is separated as illustrated in FIGURE 4. In our work, we set up a Moses (Koehn et al., 2007) SMT system and apply its advanced feature of specifying reordering constraint to each of the simplified phrases. Under the constraint, a simplified phrase is translated as a block and its translation is continuous on the target side.

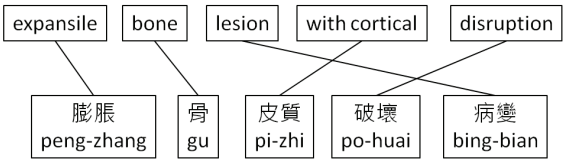

FIGURE 4 – The incorrect reordering of the in-domain segments "bone lesion".

3.4 Restoration

In the restoration step, we receive the translation result from the background SMT system and perform post-processing steps. We locate the simplified phrase pairs and replace them with their corresponding bilingual in-domain segments as illustrated in FIGURE 2(c). The resulting parallel text is the final output of our framework and its target side is the translation of the in-domain text.

To successfully restore the bilingual in-domain segments, we need the internal alignment information between the source and the target sides. Depending on the difficulty of extracting the simplified phrase pairs, different levels of granularity including phrase alignment, word alignment and word alignment score are needed. The restoration methods under different situations are summarized in FIGURE 5. We apply these restoration approaches one by one in the order of increasing granularity: **phrase alignment**, **word alignment** and **probability-based extraction**. As will be discussed in the later section, the empirical results show that these approaches are simple but can be effective to deal with most of the cases.

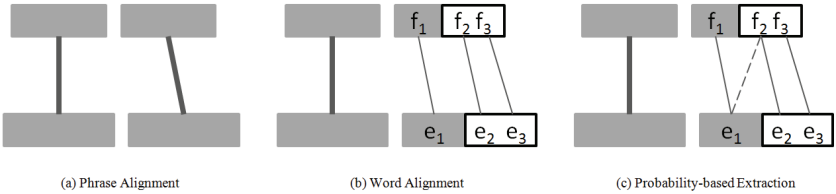

FIGURE 5 – Three restoration methods: phrase alignment, word alignment and probability-based extraction. The thick lines are phrase alignments and the thin lines are word alignments.

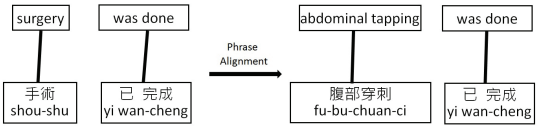
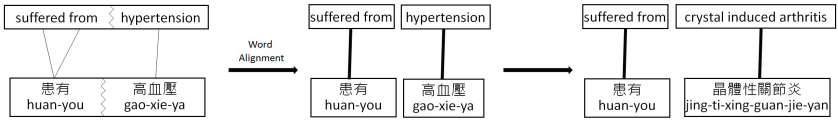
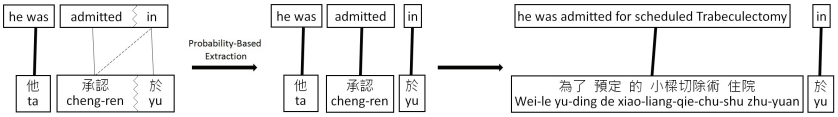
If a simplified source phrase is translated alone without its nearby context, phrase-level alignment information is sufficient to perform the restoration: we replace the simplified phrase pairs with the original bilingual in-domain segments. FIGURE 5(a) illustrates the phrase alignment method. The shaded blocks and thick lines denote simplified phrase pairs. By checking the phrase alignments provided by the decoder, the simplified phrase pairs can be replaced without further processing. The method is exemplified in FIGURE 6(a). In this example, the simplified term "surgery" is translated as a single phrase. Based on the phrase alignments, the simplified phrase pair "surgery-手術" is replaced with its original form "abdominal tapping-腹部穿刺".



(a) Restoration with phrase alignment.



(b) Restoration with word alignment.



(c) Restoration with probability-based extraction.

FIGURE 6 – Three restoration methods applied with different levels of alignment information. The thick lines are phrase alignments and the thin lines are word alignments.

In some cases, a simplified phrase is translated together with its nearby context, and therefore we need to determine the translation of the simplified phrase before we can restore its original form, such as the term "hypertension" in FIGURE 2(b). Phrase level alignments are insufficient now and higher granularity is needed, such as word-level alignments, to separate a simplified phrase from

its contexts. With word alignment information, we may extract a simplified phrase pair without violating the consistency judgment of a phrase pair (Och et al., 1999). We then replace the simplified phrase pair with its original bilingual in-domain segment. Our word alignment method is illustrated in FIGURE 5(b). The hollow blocks denote the context f_2f_3, which is translated together with its nearby simplified term f_1. The thin lines and the thick lines are word alignments and phrase alignments, respectively. Compliant with the consistency of phrase extraction, we separate the phrase pair f_1-e_1 from the phrase pair $f_1f_2f_3$-$e_1e_2e_3$, and perform the restoration. The method is exemplified in FIGURE 6(b). Based on the word alignments, the simplified term "hypertension" can be separated from its context "suffered from" without violating the consistency. Therefore, we can successfully restore the original form "crystal induced arthritis".

There are still cases in which word alignment method fails due to the fertility feature between source and target languages under IBM models (Brown et al., 1993). For a simplified term, which is usually a content word, its translation may be aligned to non-content words on the source side. In this case, extracting simplified phrase pairs would violate the consistency of phrase extraction. Here we apply a probability-based extraction of simplified phrases. This approach deletes weak word alignments based on alignment probabilities. For a source simplified phrase $f_{i,j}$ spanning from word f_i to f_j which is aligned to its target translation $e_{i,j}$, we examine each word in $e_{i,j}$. If there exists an e_k ($i<=k<=j$) which is aligned to two source words within $f_{i,j}$ and outside $f_{i,j}$ respectively, we try to delete one of the alignments by comparing their word alignment probabilities. FIGURE 5(c) illustrates the probability-based extraction method. The word e_1 is aligned to both f_1 and f_2. The fuzzy alignment causes the unsuccessful separation of f_1-e_1 from its context f_2f_3-e_2e_3. If the word alignment probabilities show $P(f_1|e_1) > P(f_2|e_1)$, we can delete the weak word alignment f_2-e_1, and meet the consistency judgment. The method is exemplified in FIGURE 6(c) where the word alignment method is unsuccessful. In this case, we fail to determine the translation of the simplified syntactic unit "he was admitted" because the target word "承認" is aligned to both "admitted" and "in". With the probability-based extraction approach, we delete the alignment (the dashed line) "in-承認", because P(in|承認) < P(admitted | 承認). After that, we are able to extract the phrase pair "admitted-承認". By determining the translation of "he was admitted" with two consecutive phrase pairs, the restoration of the original form "he was admitted for scheduled Trabeculectomy" can be done easily.

4 Experiments

We experiment our *STR* framework on an English-Chinese SMT application in the medical domain. Moses is built as our general domain SMT system. The translation model is trained on 6.8M sentence pairs collected from Hong Kong corpus (LDC2004T08) and UN corpus (LDC2004E12). We train the trigram language model on the Chinese part of the above parallel corpus and the Central News Agency part of the Tagged Chinese Gigaword (LDC2007T03).

We test our method with the English-Chinese translation task on the medical summaries from the National Taiwan University Hospital (NTUH). The dataset comprises 1,077 parallel sentences within 18 medical summaries. In our SMT application, the gap between in-domain and out-domain corpora is very large in terms of vocabulary and writing styles. In our test set, the average length of a sentence in a medical summary is short (12.58 words) compared to the background general corpus (29 words). TABLE 1 shows some interesting statistics of the domain specific segments in the test set, including the average number of terminological units, syntactic units and OOV words per sentence, and the percentages of words they account for in the test data.

On the average, the in-domain segments (terminological and syntactic units) constitute over 36% of the experimental dataset. Nearly 21% of OOV words including surgical, diagnosis and drug terms occur in a sentence and most of them are parts of terminological and syntactic units. This justifies our motivation to alleviate the OOV problem in our cross-domain SMT system by simplifying the text in this special domain before sending it to the background SMT system.

	Occurrence	Percentage
Terminological Unit	2.04/sentence	18.37%
Syntactic Unit	0.65/sentence	17.86%
OOV Word	2.93/sentence	21.18%

TABLE 1 – Statistics of the in-domain segments and the OOV words in the test set.

To identify the in-domain segments in a text, we collect bilingual terminological and syntactic units from the medical domain. Section 3.1 describes the identification step and discusses various ways to collect the bilingual in-domain knowledge with automatic and semi-automatic approaches. In our experimental domain (i.e., English medical summaries), bilingual medical dictionaries are available from plenty of resources and thus they are sufficient for collecting bilingual terminological units. On the other hand, bilingual syntactic units are relatively hard to obtain. Only monolingual corpus can be obtained in this domain, and obtaining parallel text by manual translation incurs high cost due to the involvements of domain experts (e.g., doctors). Therefore we collect the bilingual syntactic units by taking a semi-automatic approach in order to make the best of manual efforts. The collection of terminological and syntactic units is briefly described below, and readers can refer to Chen et al. (2011) for more details.

The terminological units are collected from both public and non-public resources. They include public medical dictionaries from domestic medical colleges and Department of Health. We are also provided with frequent bilingual term pairs used by NTUH staff. Merging these bilingual dictionaries causes ambiguity in which a medical term has multiple translations with similar meanings but in different styles. Since consistent translation of terminology is desired in this application, ambiguous translations are reviewed and edited by the staff at NTUH. So far nearly 70,000 bilingual terminological units are collected and stored in our database.

The syntactic units are semi-automatically collected with a pattern mining algorithm and annotations by the in-domain experts. Since we choose phrase-based SMT as our background SMT system, the n-gram based syntactic units are preferred for easier integration. We first automatically extract the candidate n-grams from the experimental medical summary corpus with medical entity recognition (Ben Abacha and Zweigenbaum, 2009) and NLP techniques. These source language n-grams are then reviewed and fast translated by doctors with the help of a user-friendly annotation tool. The resulting bilingual n-grams are then collected and organized into the bilingual syntactic units. The NLP techniques aim to reduce the cost of annotations by doctors, and increase the coverage of bilingual syntactic units. TABLE 2 gives some samples of these n-gram based syntactic units in this domain. Both source and target n-grams are listed for each bilingual syntactic unit. The words in bold denote the medical categories which represent diseases or symptoms (**DIAGNOSIS**), medical tests (**TEST**), surgical or non-surgical treatments (**TREATMENT**), etc. These syntactic units capture in-domain writing styles and local reorderings (note the different orders of medical categories between source and target sides).

Source Syntactic Unit Target Syntactic Unit	Syntactic Label
underwent **TEST** on **DATE**	VP
於 **DATE** 接受 **TEST** 檢查 yu jie-shou jian-cha	
DRUG was given for **DIAGNOSIS**	S
使用 **DRUG** 用於治療 **DIAGNOSIS** shi-yong yong-yu-zhi-liao	
received **TREATMENT** with **DRUG**	VP
接受 **TREATMENT** 及 **DRUG** 治療 jie-shou ji zhi-liao	
DIAGNOSIS at the right **REGION**	NP
在右側 **REGION** 之 **DIAGNOSIS** zai-you-ce zhi	
TREATMENT of the right **REGION**	NP
右側 **REGION** 的 **TREATMENT** you-ce de	

TABLE 2 – Samples of bilingual syntactic units.

In the simplification step, we simplify the identified in-domain segments of a text. For runtime efficiency, we perform the simplification on all of the collected terminological and syntactic units in advance and store the results to avoid redundant work. The terminological units are simplified based on the ontology provided by Unified Medical Language System (UMLS). For a medical term, we search for its hypernyms and find the most frequent one in the background translation model and designate it as the simplified form.

The syntactic units are parsed with Stanford parser (Klein and Manning, 2003) and simplified with the rules described in Section 3.2. TABLE 3 gives the number of syntactic units for each syntactic label. There are parsing errors for few n-grams and they are manually corrected. As shown in TABLE 3, more than 70% of the n-grams are correctly simplified. Most of the errors come from the unexpected syntactic labels which can be processed with new simplification rules. For example, the common syntactic unit "was admitted due to **DIAGNOSIS**" can be simplified to "was admitted". However, the syntactic label ADJP which covers "due to **DIAGNOSIS**" is not considered in our rules and therefore remains unchanged after the simplification step. We plan to devise a more robust method beyond the rule-based one for future work.

In the restoration step, we receive and post-process the SMT results as described in Section 3.4. In our experiments, phrase level alignments are provided by the Moses decoder, and word level alignments are obtained as the intermediate results after training the phrase table. Our methods successfully perform the restorations on most of the test data. Total 1,004 (93.22%) of the 1,077 sentences can be successfully restored with the three proposed restoration methods. For the other 73 sentences, most of these failure cases result from translation errors of the simplified phrases by Moses, which in turn affect the word alignments and introduce difficulties. TABLE 4 shows the performance of each restoration method. The second column counts the number of applications of each restoration method on the test set, and the third column counts how many

Syntactic Unit	Count	Parsing Error	Simplification Error
NP	697	4.85%	28.15%
VP	287	2.94%	27.12%
PP	228	1.85%	8.89%
S	342	1.23%	9.59%
Other	12	33.33%	

TABLE 3 – Parsing and simplification performances on syntactic units. We manually simplify the 12 syntactic units with minority labels.

	Total Count	Sentence Count
Phrase Alignment	1,767 (60.93%)	865 (86.16%)
Word Alignment	981 (33.83%)	657 (65.44%)
Probability-based Extraction	152 (5.24%)	137 (13.65%)

TABLE 4 – Various restoration methods.

sentences include the application of each restoration method. Total 2,900 applications of the restoration methods have been done in the testing. With phrase alignments, we can deal with over 60% of the simplified phrases. For the remaining simplified phrases, the background SMT model captures their contexts with higher confidence, and therefore they are translated with the surrounding words. For these cases, we use word alignment information, and perform the word alignment and the probability-based extraction methods. Although the probability-based extraction accounts for only 5.24% of the restorations, it is applied on 13.65% of the sentences, as shown in the third column. This confirms that the approach of deleting weak word alignment is simple but effective in handling the inconsistency during phrase extraction.

We compare our *STR* framework against three baselines. These four SMT systems share the same background translation and language models which are trained from the corpus described in the beginning of this section. The Moses system is trained with its default scripts without any in-domain prior knowledge. We choose Moses' default behaviour to handle OOV words, i.e., they are copied to translation results. We also use an advanced feature of Moses to build another setting (Moses+Terminology) by adding an in-domain phrase table with the terminological units. It serves as the back-off model during the runtime decoding. That is, Moses searches the back-off model only when no translation for a phrase is found in the background model. In the naïve integration system, we apply the identification step to a source sentence and mark the in-domain segments. Rather than simplifying these segments, we use the XML markup function of Moses to force the translations of these terminological and syntactic units.

TABLE 5 shows 4-gram BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores of these systems. With poor in-domain knowledge, the baseline Moses achieves the low performance on the test set. On the other hand, the Moses system with terminology back-off model eliminates most of the OOV problems and gets better performance. The naïve integration system gives further improvement over the Moses+Terminology system by performing medical entity recognition on a source input before sending it to Moses. Therefore, it can identify the multiword terminological units and the syntactic units during the identification step. The system

with the *STR* framework achieves the best translation performance among the four systems measured by both BLEU and TER scores. Comparing the translation results of the *STR* framework and the naïve integration system, we find the former gives better translations and reorderings on the general segments. In summary, the experimental results and observations show that our simplification approach improves the baseline SMT systems by identifying specific segments with bilingual in-domain knowledge and modifying these special segments to better fit the background SMT model.

	BLEU-4	TER
Moses	14.35	64.911
Moses+Terminology	20.56	55.712
Naïve Integration	26.29	47.683
STR Framework	35.87	40.650

TABLE 5 – Translation performances on medical summaries.

Conclusion and Future Work

This paper proposes a simplification-translation-restoration framework for cross-domain applications in SMT. We integrate bilingual in-domain knowledge into a background out-domain SMT system. That deals with the cross-domain and the data sparseness problems at the same time. The in-domain text goes through identification, simplification, translation, and restoration steps. Important issues are addressed and discussed for each step, including preparing bilingual in-domain knowledge, simplification with syntactic information, and different restoration strategies for extracting simplified phrases from the SMT results. We evaluate the performance of our framework through a cast study of medical summary translation. The empirical results show the effectiveness of our approach at each step of the framework. For the end-to-end translation task, our method outperforms the background SMT system and the systems with different integration approaches.

Currently, we apply a rule-based simplification approach to four common syntactic units, i.e., NP, VP, PP, and S. The alternative is to simplify in-domain segments based on statistical evidence. Searching for a simplified form for a phrase in a more robust way will give more hints to aid the background SMT system. That is worthy of further investigation. Besides, to introduce a feedback mechanism to improve an *STR*-based MT system is also one of the research issues. Which parts, pre-processing (i.e., identification and simplification), translation, and post-processing (i.e., restoration), have to be modified through the feedback and how they are modified are critical. In our scenario, the doctors post-edit the MT results of English medical summaries and produce the correct Chinese medical summaries. The editing logs can be analysed to improve identification, simplification, translation, and restoration steps for further domain adaptation.

Abstract

Microblogging services have brought users to a new era of knowledge dissemination and information seeking. However, the large volume and multi-aspect of messages hinder the ability of users to conveniently locate the specific messages that they are interested in. While many researchers wish to employ traditional text classification approaches to effectively understand messages on microblogging services, the limited length of the messages prevents these approaches from being employed to their full potential. To tackle this problem, we propose a novel semi-supervised learning scheme to seamlessly integrate the external web resources to compensate for the limited message length. Our approach first trains a classifier based on the available labeled data as well as some auxiliary cues mined from the web, and probabilistically predicts the categories for all unlabeled data. It then trains a new classifier using the labels for all messages and the auxiliary cues, and iterates the process to convergence. Our approach not only greatly reduces the time-consuming and labor-intensive labeling process, but also deeply exploits the hidden information from unlabeled data and related text resources. We conducted extensive experiments on two real-world microblogging datasets. The results demonstrate the effectiveness of the proposed approaches which produce promising performance as compared to state-of-the-art methods.

Title and abstract in Chinese

基于半监督贝叶斯网络模型的微博主题分类模型研究

微博作为一种新型的社会媒体，其海量数据及展现主题的多样性使得用户要找到感兴趣主题的微博非常困难。 当前的一些研究主要采用面向长文本的挖掘方法来分类微博的主题，但微博作为一种短文本，其稀疏性和用词不规范严重影响了这些方法的性能。 针对微博的特点，本文提出了一种半监督贝叶斯网络模型，其充分利用外部相关的网络资源来丰富微博的文本特征， 并利用少量的未标注数据以及辅助的外部资源来预测大量待标注微博数据的主题。 本文的方法不仅能减少繁琐的人工标注过程，而且能够从未标注的微博数据以及相关资源中挖掘出微博隐藏主题的相关语义信息。 我们的实验基于Twitter和新浪微博两个数据集，试验结果表明，与目前的方法相比，本文提出方法的性能有显著提高。

1 Introduction

Microblogging services are becoming immensely popular in breaking-news disseminating, information sharing, and events participation. This enables users to express their thoughts and intentions in short textual snippets on a daily and even hourly basis. The most well-known one is Twitter (`www.twitter.com`), which has more than 140 million active users with 1 billion Tweets every 3 days[1] as of March 2012. Over time, a tremendous number of messages have been accumulated in their repositories, which greatly facilitate general users seeking information by querying their interested topics using the corresponding hashtag.

However, users often have to browse through large amount of results in order to find the information of their interests. This is due to the ambiguous hashtag and the presentation style. The microblogging platforms mix search results in a ranked list, determined by their relevance to the corresponding hashtag and published time. Unfortunately, most hashtags are very short, ambiguous and even vague, leading to unsatisfactory search results. For example, the returned list for queried hashtag "#apple" is extremely messy and diversified, potentially covering several different sub-topics: smartphone, computer, fruit and so on. In this case, users can benefit from overviews of search results based on meaningful and structural categories, such as, grasping at a glance the spread of categories covered by a given search topic and quickly locating the information of their interests with the assistance of the labeled categories. This is especially important for mobile search through handheld devices such as smartphones.

Classifying microblogs into pre-defined subtopic-oriented classes poses new challenges due to the following reasons. First, unlike normal documents, these messages are typically short, consisting of no more than 140 characters. They thus do not provide sufficient word co-occurrences or shared contexts for effective similarity measure (Hu et al., 2009). The data sparseness hinders general machine learning methods to achieve desirable accuracy. Second, microblogging messages are not well conformed as standard structures of documents. Sometimes they do not even obey grammatical rules (Hu and Liu, 2012b). Third, microblogs lack label information. It is time and labor consuming to label the huge amounts of messages.

Intensive efforts have been made on the classification of short texts utilizing machine learning techniques (Nie et al., 2011). Some representative research efforts are based on topic model (Ramage et al., 2009) (Zhao et al., 2011). As these approaches heavily rely on the term co-occurrence information, the sparsity of short and informal messages unduly influence the significant improvement of the performance. Some others explore some traditional supervised learning methods to classify microblogging messages (Lee et al., 2011) (Zubiaga et al., 2011) (Sriram et al., 2010) (Tang et al., 2012). The sparsity problem again hinders the similarity measurement. Moreover, it is laborious and time consuming to obtain labeled data from microblogging. Consequently, new approaches towards microblog classification are highly desired.

In this paper, we propose a semi-supervised learning approach to the classification of microblogging messages. We aim to tackle three challenges in this paper. First, to handle the data sparseness problem, our approach submits a query that is related to hashtag and category to Google Search Engine; meanwhile it incorporates the external information provided by search engine results to enrich the short microblogs. Second, to alleviate negative effect brought by informal words in microblogging, we employ linguistic corpus to detect informal words in microblogging messages and correct them into formal expressions. Third, with the integration of hashtag related resources,

[1] http://blog.twitter.com/2012/03/twitter-turns-six.html

our model is robust with only a small amount of training data, which greatly reduces the manually labeling costs. Our algorithm alternates between performing an E-step and M-step. Specifically, it first trains a classifier based on the available labeled messages as well as some auxiliary cues mined from the web, and probabilistically predicts the class labels of the unlabeled messages. It then trains a new classifier using all messages and the auxiliary cues, and iterates to convergence. We conduct experiments on the real-world datasets, and demonstrate that our proposed scheme yields significant accuracy in microblogging messages categorization.

The main contributions of this research can be summarized as follows,

- To the best of our knowledge, this work is the first attempt towards microblogs categorization using semi-supervised learning approach, which requires less labeled data and can thus be practically extended to large-scale datasets.
- Our approach incorporates external statistical knowledge to enrich the short microblogs, which greatly remedies the data sparseness issue.
- Our approach adopts a category-word distribution analysis, which well addresses the broader phenomenon existed in microblogs: non-standard language presentation and abundant spelling errors.

The reminder of this paper is organized as follows: we introduce the details of our proposed approach and experimental results in Section 2 and Section 3 respectively. In section 4, we briefly reviews of the related work, followed by concluding remarks in Section 5.

2 Semi-Supervised Graphical Model for Microblogs Classification

Before formulating our approach, we first define some notations. A set of messages is collected by a given hashtag t, which are partitioned into two subsets: a labeled set $M^l = \{m_1, m_2, \ldots, m_L\}$ and an unlabeled set $M^u = \{m_{L+1}, m_{L+2}, \ldots, m_{L+N}\}$. M^l includes only the example messages provided through user interaction, where each instance is associated with a predefined category c_i with belonging to $C = \{c_1, c_2 \ldots c_K\}$; while M^u includes all the other messages. We aim to predict the category label for each data point in M^u. Here we assume that each tweet belongs to only one category. Similar idea of assigning a single topic or category to a short sequence of words has been used before in (Diao et al., 2012) (Gruber et al., 2007) (Zhao et al., 2011).

2.1 The General Framework

We now introduce the overview of the whole processing that aims to classify microblogging messages by exploiting the internal and external resources. The workflow consists of three phrases, as shown in Figure 1. It includes the preprocessing of external resources, preprocessing of microblogging messages, and construction of Semi-Supervised Bayesian Network (SSBN) model.

Phrase 1: Preprocessing of External Resources Due to their short length, microblogging messages do not provide sufficient word co-occurrence or context shared information for effective similarity measure. Thus we utilize the external Google Search snippets to enrich the original feature space of the microblogging messages. The procedure of enrichment is as follows: we mine the list of hot topics from Google such as Apple, Obama, NBA, Facebook, *etc*. For each hot topic, we search them as hashtags for microblog messages from Twitter. The results contain a list of proper sub-hashtags, such as stock, ipad, ipo, app, ticket, education, *etc*. These sub-hashtags are manually

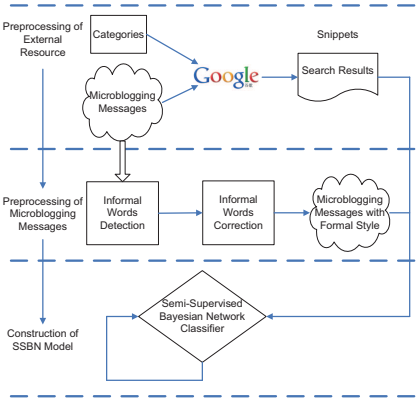

Figure 1: The General Framework

classified into K pre-defined categories. For a given hashtag t (for example, stock), we build K hashtag-category pairs (for example, stock Sports, stock Business, *etc.*), and consider each pair as a query to return 20 extended documents from Google Search Engine, denoted as S. Comparing with the way that only takes each hashtag as a query, the combination of hashtag and category can find more accurate documents. Next, we assign the tf.idf weight of each word for each category in S. We further use the google search results to estimate the category prior distribution.

Phrase 2: Preprocessing of Microblogging Messages It is worth noting that there is a large amount of misspelled and informal expressions in microblogging messages. This is different from the formal expressions and words used in Google Search results. To handle this mismatch problem, we first construct a microblog dictionary containing all the abbreviate forms of words used in Twitter from some dictionaries, such as Twitternary[2], twitterforteachers[3]. The dictionary contains 727 words. Giving a microblogging message, we first use this dictionary to detect the informal words, then correct them to the formal words. In this way, we are also able to collect more words related to the predefined categories from the labeled messages to tackle the sparseness problem in microblogging messages.

Phrase 3: Construction of SSBN model In order to fully integrate hashtag related resources and unlabeled data to a classifier, we propose a semi-supervised Bayesian network model. The semi-supervised classifier can offer robust solution to microblog topic classification for two reasons. First, it utilizes those labeled microblogging messages with hashtags by training a topic model based classifier, which is then used to find the category (label) distribution of unlabeled messages accurately. Second, it leverages the related external resources to provide a valuable context to microblogging messages. In this way, compared with supervised learning methods, we need only few labeled data for training. The details of SSBN model construction will be introduced in the next subsection.

θ	The vector indicating category weights for message data collection.
ϕ	The vector indicating category weights for specific message.
θ', ϕ'	The $\|C\| \times \|N\|$ matrix indicating category-word distribution.
λ	The contribution of unlabeled data to prior probability.
α	The contribution of prior knowledge from θ.
$1-\alpha$	The contribution of prior knowledge from ϕ.
β	The contribution of likelihood probability from θ'.
$1-\beta$	The contribution of likelihood probability from ϕ'.
η_d, η_g	Hyperparameters and priors of Dirichlet distributions.
C	The category vector.
c_j	The jth category.
M	The message collection in the original message data.
m	The message.
N	The word collection in the original message data.
t	The hashtag.
w	The word.
y	The category label of message.

Table 1: Important notations used in this paper and their descriptions.

2.2 Probabilistic Graph Model Construction

The above formulations intuitively reflect that the category prediction task comprises two estimations: coarse-grained category distribution and fined-grained category-word distribution. It is schematically illustrated in Figure 2, in which the corresponding notations are summarized in Table 1.

1. Category distribution: There are two kinds of category distribution in the data. Let θ denotes the category distribution obtained from the original message M, which is a weight vector representing the weight for each category. Similarly, let ϕ denotes the category distribution for external resources obtained from the search results S. The category distribution for the total data D is assumed to be a linear combination of θ and ϕ. Parameter α is employed as the weight to adjust the contributions of different sources. In addition, the original message data also consists of labeled and unlabeled data; and λ is used to denote the contribution of unlabeled data in generating the category distribution for M.

2. Category-word distribution: The category-word distribution also has two parts: θ' denotes the distribution of different words over different categories in the original messages, which is a $|C| \times |N|$ matrix. Here, $|C|$ is the number of categories, and $|N|$ is the number of words in the data. Similarly, ϕ' denotes the category-word distribution in the search results. The category-word distribution for data D is again assumed to be a linear combination of θ' and ϕ', where parameter β is employed as the weight to adjust the contributions of different sources.

Our semi-supervised Bayesian Network (SSBN) belongs to probabilistic graphical model, which formally denotes the probability of a message m falling into a category c as,

$$P(c|m) = \frac{P(c)P(m|c)}{\sum_c P(c)P(m|c)} \tag{1}$$

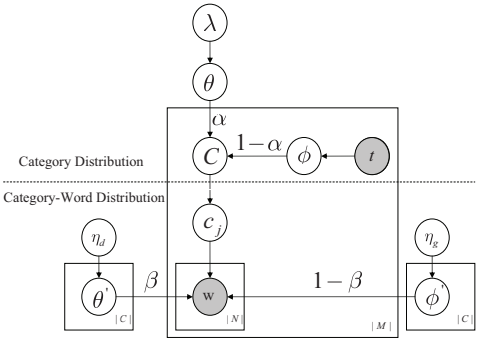

Figure 2: Probabilistic graphical representation of semi-supervised Bayesian network model.

where $P(c)$ is the prior probability of category in the message data collection. By assuming the presence of a word w is independent to the presence of any other word in m, we derive

$$P(m|c) = \prod_{w \in m} P(w|c) \tag{2}$$

2.3 Parameter Inference

In this section, we turn our attention to procedures for parameter inference with EM approach. In the expectation step, the distributions θ, ϕ, $\hat{\theta'}^{w_k}_{c_j}$ and $\hat{\phi'}^{w_k}_{c_j}$, will be estimated. Besides the labeled data and external resource, the parameter estimations also make use of the unlabeled data. Initially we assign category labels to unlabeled data with an uniform distribution, i.e., the probability is $\frac{1}{|C|}$ for each category. In the following iterations, labels of unlabeled data and SSBN model are alternatively updated and reinforced until convergence.

Estimating θ: θ represents the probability of each category in the original message data collection. It is proportional to the expected number of messages that was assigned to this category.

$$\hat{\theta_{c_j}} \equiv P(c_j|\hat{\theta}) = \frac{1 + \sum_{i=1}^{|M|} \Lambda(i) P(y_i = c_j|m_i)}{|C| + |M^l| + \lambda|M^u|} \tag{3}$$

As aforementioned in section 2.2, the message data collection consists of labeled messages M^l and unlabeled messages M^u. They have different contribution to the category probability estimation. The function $\Lambda(i)$, defined as in equation (4), is employed to achieve that goal. The parameter $\lambda \in [0, 1]$.

$$\Lambda(i) = \begin{cases} \lambda & \text{if} \quad m_i \in M^u; \\ 1 & \text{if} \quad m_i \in M^l. \end{cases} \tag{4}$$

Estimating ϕ: ϕ denotes the prior category probability distributes over the Google Search results. In this paper, the prior probability of category c_j for a hashtag t completely depends on the

relationship between the corresponding hashtag t and the predefined category names,

$$\hat{\phi_{c_j}} \equiv P(c_j|\hat{\phi}) = \frac{\frac{1}{NGD(t,c_j)} + \mu}{\sum_{j=1}^{|C|} \frac{1}{NGD(t,c_j)} + |C|\mu} \tag{5}$$

where μ is a smoothing factor and $NGD(t, c_j)$ is the Normalized Google Distance[4], which is employed to calculate distance between the tag t and the category c_j. It can be observed that a smaller value of NGD leads to more contribution of c_j for the specific message.

Estimating θ' and ϕ': θ' and ϕ' respectively denote the category-word distributions over original message collection and Google Search results. Both of them are $|C| \times |N|$ matrices. They can be estimated using the following formulas:

$$\hat{\theta'}_{c_j}^{w_k} \equiv P(w_k|c_j, \hat{\theta'}) = \frac{n_{d_{c_j}}^{w_k} + \eta_d}{\sum_{p'=1}^{|N|} n_{d_{c_j}}^{w_{p'}} + |N|\eta_d} \tag{6}$$

$$\hat{\phi'}_{c_j}^{w_k} \equiv P(w_k|c_j, \hat{\phi'}) = \frac{n_{g_{c_j}}^{w_k} + \eta_g}{\sum_{q'=1}^{|N|} n_{g_{c_j}}^{w_{q'}} + |N|\eta_g} \tag{7}$$

where $n_{d_{c_j}}^{w_k}$ and $n_{g_{c_j}}^{w_k}$ are respectively the number of times that the word w_k has occurred in the category c_j in message data collection and Google Search results (retrieved by the combination of hashtag t and the name of the j-th category). η_d and η_g are hyperparameters with a small value for smoothing purpose to avoid the zero problem.

The maximum likelihood category label for a given message m_i is,

$$y_i = \arg\max_{c_j} P(c_j|m_i, \hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'}) = \frac{P(c_j|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'})P(m_i|c_j, \hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'})}{P(m_i|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'})} \tag{8}$$

where $P(m_i|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'})$ is formally written as follows,

$$P(m_i|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'}) = \sum_{c_j} P(c_j|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'})P(m_i|c_j, \hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'}) \tag{9}$$

where the prior probability for category c_j is obtained by linearly fusing two estimations on two resources,

$$P(c_j|\hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'}) = P(c_j|\hat{\theta}, \hat{\phi}) = \tilde{\alpha}P(c_j|\hat{\theta}) + (1 - \tilde{\alpha})P(c_j|\hat{\phi}) \tag{10}$$

where α is a trade-off parameter to balance the contributions between two kinds of category distribution. The maximum likelihood probability for the each message m_i can be derived as:

$$\begin{aligned} P(m_i|c_j, \hat{\theta}, \hat{\phi}, \hat{\theta'}, \hat{\phi'}) &= P(m_i|c_j, \hat{\theta'}, \hat{\phi'}) = \prod_{k=1}^{|m_i|} P(w_k|c_j, \hat{\theta'}, \hat{\phi'}) \\ &= \prod_{k=1}^{|m_i|} \{\beta P(w_k|c_j, \hat{\theta'}) + (1 - \beta)P(w_k|c_j, \hat{\phi'})\} \end{aligned} \tag{11}$$

Similar to α, β is tuned to control the contribution between the the category-word distribution over two different resources.

[4] `http://en.wikipedia.org/wiki/Normalized_Google_distance`, here in case of NGD not equal to zero, we add a small constant closing to zero.

3 Experiments

In this section, we first evaluate our proposed model on two real-world datasets, utilizing a range of popular metrics. We then compare our model with the state-of-the-art text classification approaches on microblogs. Also, we study the sensitivity of the training dataset size, convergence analysis followed by the impact analysis on the parameters.

3.1 Experimental Settings

In our experiments, two large-scale real-world datasets were constructed:

- **Twitter**: The Twitter dataset was generated from Trec-Twitter2011[5]. First, we collected 10 hot topics from Google Trends[6], including NBA, Apple, facebook, *etc.* For each topic, we manually selected several low-level sub-topics and combined each of them with the high-level topic. Take the topic "Apple" as an example. We extended it with "Apple stock", "Apple ipad", etc. We manually determine which category the sub-topics belong to. For example, "stock" is classified to Business, while "ipad" is assigned to science. These pairs are naturally viewed as queries. Then the Twitter dataset was constructed by retrieving all the related messages from Trec-Twitter2011 based on these queries. To validate the robustness of our proposed model on partially noisy data, we deliberately did not provide ground truth for this dataset. Instead, the returned messages under a query are directly considered as belongings to the same category as the sub-topic. The Twitter dataset is in this way labeled semi-automatically based on sub-topics. The ground truth is so-called pseudo ground truth. For example, all the messages searched by "Apple stock" are regarded as business category.
- **Sina Weibo**: Based on selected trending topics of Sina Weibo, we crawled a collection of messages. And then manually assigned each messages into one of 7 predefined categories: sports, politics, science&tech, game, movie, music and others. The messages fallen into "others" are removed; and up to $15,811$ unique messages were remained. To build the ground truth, we adopted a manual labeling procedure. We divided 15 people with different background into 3 teams to manually label these messages. Every team labeled the complete dataset. The voting method was employed to combine the label results from different teams. For each message, only one category label with the majority voting was selected as the ground truth label. For the cases that a message received three different categories, a discussion was carried out among the labelers to decide the final ground truths.

The distributions of different categories over two datasets are displayed in Table 2. For each dataset, we devise 4 test configurations with different amount of training data: 5%, 20%, 50% and 90% for training respectively, and use the corresponding reminders for testing. The training data is randomly selected.

In this work, we utilize several widely-used performance metrics to evaluate our classification task: average accuracy, precision, recall, and $F1$ score (Sokolova and Lapalme, 2009) (Rosa et al., 2011). Average accuracy evaluates the average effectiveness for each category of a classifier. Precision is the fraction of retrieved messages that are relevant to the search, while recall is the percentage of the relevant messages that are successfully retrieved, and F1 measure combines both of recall and precision. For some cases, we also provide the $macro-$ and $micro-$ values. The $micro-$ assigns equal weight to each message, while $macro-$ treats each category equally.

3.2 On Classification Performance Analysis

We first conducted experiment to evaluate the effectiveness of our proposed SSBN model on two datasets. Table 3 displays the average performance in terms of different metrics. Here the parameters are set as $\alpha = 0.5$, $\beta = 0.9$, $\lambda = 0.4$ for Twitter and $\alpha = 0.9$, $\beta = 0.9$, $\lambda = 0.3$ for Sina Weibo, respectively. The parameters selection will be introduced later.

It is observed that our proposed scheme achieves promising precision, recall and $F1$ scores despite of limited availability of labeled data. For twitter dataset, most of the categories achieve precision score higher than 0.85, and the best precision score is up to 0.93 (sports). Half of the categories obtain good results in terms of recall and F1, higher than 0.94 and 0.83, respectively. Our approach yields significant performance over the dataset with pseudo ground truths. This demonstrates the robustness of our method to noisy data. When it comes to Sina Weibo, all the categories achieve remarkable performance of greater than 0.80 across all evaluating metrics. This observation verifies that our method is more stable in less training data. However, our method fails for certain categories such as the Business and Education categories in Twitter dataset. This poor performance mainly comes from the unreliable pseudo ground truths. "Business" and "Education" frequently broaden to various sub-topics. Therefore, the messages retrieved by these types of queries are not internal coherent, at least not as strong as others' categories, even they are assumed to belong to the same category. The unreliable pseudo ground truths bring unpredictable noise to our model.

3.3 On Classification Performance Comparison

To demonstrate the effectiveness of our proposed approach, we compare it against the following the state-of-the-art classifying methods (Phyu, 2009) (Kotsiantis, 2007):

Classifier	*Accuracy*	*MicroP*	*MicroR*	*MicroF1*	*MacroP*	*MacroR*	*MacroF1*
SSBN	**0.8875**	**0.8875**	**0.8875**	**0.8875**	0.8282	0.7627	0.7845
SVM	0.8670	0.8670	0.8670	0.8670	0.8768	0.7611	**0.7860**
NB	0.8722	0.8696	0.8722	0.8722	**0.8879**	0.7329	0.7587
KNN	0.7268	0.7268	0.7268	0.7268	0.6721	0.6471	0.6516
Rocchio	0.8180	0.8204	0.8180	0.8192	0.7361	**0.8384**	0.7605
L-LDA	0.8605	0.8605	0.8605	0.8605	0.8467	0.7223	0.7532

Table 4: Performance comparison among SSBN and other supervised baseline methods on twitter with 90% training data.

Classifier	*Accuracy*	*MicroP*	*MicroR*	*MicroF1*	*MacroP*	*MacroR*	*MacroF1*
SSBN	**0.9020**	**0.9020**	**0.9020**	**0.9020**	0.8976	**0.9045**	**0.9004**
SVM	0.8991	0.8991	0.8991	0.8991	**0.9017**	0.8971	0.8991
NB	0.9015	0.9015	0.9015	0.9015	0.8990	0.9024	0.9003
KNN	0.8565	0.8565	0.8565	0.8565	0.8589	0.8486	0.8526
Rocchio	0.8802	0.8803	0.8802	0.8802	0.8769	0.8832	0.8781
L-LDA	0.8905	0.8905	0.8905	0.8905	0.8876	0.8989	0.8932

Table 5: Performance comparison among SSBN and other supervised baseline methods on Sina Weibo with 90% training data.

- **SVM** (Cortes and Vapnik, 1995) is a supervised learning method. In our experiment, we use an open source package LIBSVM[7] with linear kernel function as baseline.
- **Naive Bayesian** (NB) is a simple probabilistic classifier by applying Bayesian theorem with strong independence assumptions. We use a multi-nomial naive bayesian classifier in our experiment (Yang and Pederson, 1997).
- **K Nearest Neighbors** (KNN) clusters objects based on the closest training examples in the feature space (Creecy et al., 1992). An unlabeled message is assigning the label which is most frequent among the K training samples nearest to the message.
- **Rocchio** (Schapire et al., 1998) is a variant of the Vector Space Model. The average of the relevant documents is viewed as the centroid of the "class".
- **Labeled LDA** (L-LDA) incorporates supervision by constraining LDA model to use only those topics that correspond to an observed label set (Ramage et al., 2009).
- **Transductive SVM** (Trans-SVM) is a semi-supervised SVM method. We extend the binary Transductive SVM in svm-light (Joachims, 1999) to multi-class classifier by incorporating one-against-all strategy.
- **Semi-Naive Bayesian classifiers** (Semi-NB) is a famous semi-supervised text classification method (Nigam et al., 2000). We employ it by using only unlabeled microblogging messages as a prior.

For each aforementioned approaches, the involved parameters are carefully tuned, and the parameters with best performance are used to report the final comparison results. In addition, the same underlying features are utilized for approaches learning. To be fair, our proposed SSBN model was trained with up to 90% data compared with supervised methods, while only 5% training data when compared with semi-supervised approaches. Here, the values of the parameters in SSBN model are set as $\alpha = 0.5, \beta = 0.9$, $\lambda = 0.4$ for Twitter dataset and $\alpha = 0.9$, $\beta = 0.9$, $\lambda = 0.3$ for Sina Weibo dataset.

$Classifier$	$Accuracy$	$MicroP$	$MicroR$	$MicroF1$	$MacroP$	$MacroR$	$MacroF1$
SSBN	**0.7979**	**0.7979**	**0.7979**	**0.7979**	**0.7934**	**0.6043**	**0.6128**
Trans-SVM	0.6707	0.6707	0.6707	0.6707	0.6602	0.5108	0.4491
Semi-NB	0.7156	0.7156	0.7156	0.7156	0.7308	0.5653	0.549

Table 6: Performance comparison among SSBN and other semi-supervised baseline methods on Twitter with 5% training data.

$Classifier$	$Accuracy$	$MicroP$	$MicroR$	$MicroF1$	$MacroP$	$MacroR$	$MacroF1$
SSBN	**0.8798**	**0.8798**	**0.8798**	**0.8798**	**0.8737**	**0.8764**	**0.8738**
Trans-SVM	0.8084	0.8084	0.8084	0.8084	0.8049	0.8085	0.8052
Semi-NB	0.8198	0.8198	0.8198	0.8198	0.8225	0.8217	0.8204

Table 7: Performance comparison among SSBN and other semi-supervised baseline methods on Sina Weibo with 5% training data.

The comparison results with supervised methods on two datasets are illustrated in Table 4 and Table 5, respectively. It is observed from the tables that our proposed model in general performs better than SVM, NB and L-LDA, and remarkably better than KNN and Rocchio. Even the performance of our method for $MacroP$, $MacroR$ and $MacroF1$ on Twitter and $MacroP$ on Sina Weibo does not achieve the best results, they are still comparable and convincing. Table 6 and Table 7 respectively display the comparison results with semi-supervised methods on two datasets, using 5% as training data. It can be observed that our proposed approach are consistently and significantly better than the current publicly disclosed the state-of-the-art semi-supervised algorithms, across various evaluating metrics. This comprehensive improvements are due to the facts that the integrated external knowledge enriches the message representation and the leveraging intrinsic information detected from abundant unlabeled data enhances the prediction accuracy.

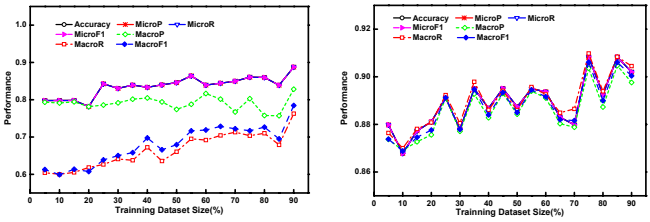
3.4 On the Sensitivity of Training Data Size and Convergence Analysis

In this section, we conduct experiments to investigate the influence of training data size on the overall performance. We progressively increase the size of training corpus at step size of 10%. The experimental results on Twitter and Sina Weibo are respectively illustrated in Figures 3a and 3b. It is observed that the overall trend is upwards along with increasing training set. This is coherent and consistent with our common sense. Also, it is observed that a smaller training set size still produces a robust model on less noisy dataset, with greater than 87% on Sina Weibo.

Perplexity, which is widely used in the topic modeling fields to analyze the convergence of a model (Blei et al., 2003) (Zhao et al., 2010). We do perplexity comparison of SSBN and L-LDA on the testing data when parameters in SSBN model are set as $\alpha = 0.5, \beta = 0.9$, $\lambda = 0.4$ for Twitter and $\alpha = 0.9$, $\beta = 0.9$, $\lambda = 0.3$ for Sina Weibo dataset. Compared with L-LDA model, SSBN model has a lower perplexity value, which means that the words are less surprising to SSBN model, and SSBN model has a powerful predication than L-LDA model.

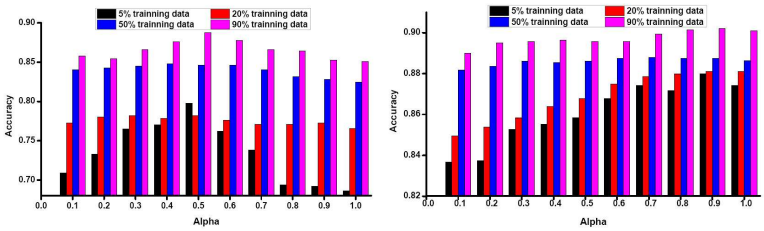
3.5 On the Sensitivity of Parameters

Parameters of α, β and λ are important in our method. In this subsection, we further conduct experiments to study the effect of these parameters. A grid search is performed to select the optimal parameter values.



(a) Twitter (b) Sina Weibo

Figure 3: Performance sensitivity of training set size on Twitter and Sina Weibo.



(a) Twitter (b) Sina Weibo

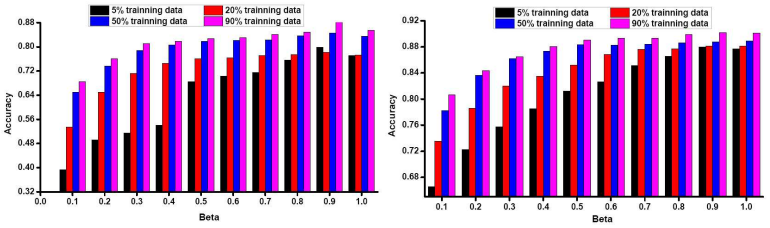
Figure 4: The Performance with varying α and training data size when other parameters are fixed.

3.5.1 Effect of Parameter α

The trade-off parameter α is used to balance the effects of two kinds of prior knowledge at category level: microblogging data collection and external resources. A larger α indicates that more information is preserved from our data collection into the category distribution. A smaller α means that the cues mined from external resources play a dominant role in our model. Figure 4 illustrates the average performance with various α and training collection size on two different datasets. It is observed that the performance increases with the gradual increase of α, and arrives at a peak at certain α, then the performance decreases. This result reflects that an optimal performance comes from an appropriate combination of external and internal resources, rather than pure individual knowledge. Also it verifies that the incorporation of Google resources has been proven useful. Empirical optimal value of α is within $[0.5, 1]$.

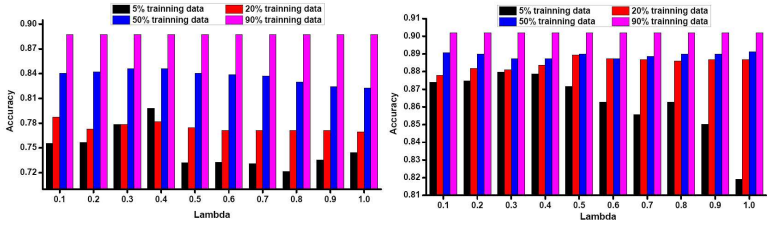
3.5.2 Effect of Parameter β

There are two category-word distributions, θ' and ϕ', which are respectively generated from our data collection and google search results; and parameter β is utilized to adjust the contribution between these two different resources in category-word level. Larger β implies larger likelihood a word is generated from θ'. The effects of parameter β on Twitter and Sina Weibo are shown in Figure 5. It is clearly observed that larger values of β frequently lead to higher accuracies with different training set sizes, and the accuracy reaches peak value when β locates at 0.9. However, when β trends to 1, the performance slightly decreases. Empirical optimal value of β is within $[0.5, 1]$.



(a) Twitter (b) Sina Weibo

Figure 5: The Performance with varying β and training data size when other parameters are fixed.



(a) Twitter (b) Sina Weibo

Figure 6: The Performance with varying λ and training data size when other parameters are fixed.

3.5.3 Effect of Parameter λ

λ indicates the contribution from unlabeled data points, between 0 and 1. When λ is close to 1, knowledge from unlabeled data is considered as important as labeled data. On the other hand, when λ at near-zero value, our model approaches a supervised learning algorithm. The results are illustrated in Figure 6, from which we observe some insights: (1) varying λ has little impact on average accuracy for a large training set, such as 50 percent as training set, especially for 90 percent as training set; (2) the best accuracy occurs at $\lambda = 0.4$ and $\lambda = 0.3$ respectively for Twitter and Sina Weibo, and then drops down quickly, which illustrates unlabeled data could give some feedback to improve classification performance. Empirical optimal value of λ is within $[0.3, 0.5]$.

4 Related Work

The task of topic classification of microblogging messages is to assign the pre-defined class labels to unlabeled messages given a collection of messages. It has been demonstrated to be a fundamental task for many applications, such as query disambiguation (Teevan et al., 2011), location prediction (Gao et al., 2012) and hot topic tracking (Weng and Lee, 2011), *etc*. To the best of our knowledge, our work is the first attempt to utilize semi-supervised learning methods to classify microblogging messages. There are, however, several lines of related work.

The significance of topic models has been exploited in microblog clustering and classification. A representative work was proposed in 2010 (Hong and Davison, 2010), where latent dirichlet allocation (LDA) (Blei et al., 2003) and author-topic model (Rosen-Zvi et al., 2010) were deeply investigated to automatically find hidden topic structures on Twitter. Following that, Zhao et al. (2011) performed content analysis through Twitter-LDA modeling on a Twitter corpus collected within a three month span. Several variants of LDA to incorporate supervision have been proposed

by Ramage et al. (2009, 2010), and have been shown to be competitive with strong baselines in the microblogging environment. Although these LDA-based topic model greatly save cognitive and physical effort required from user interaction, their performances are usually not very satisfactory. The main reason is due to the sparsity of short informal messages that makes similarity comparison difficult. Different from previous models, we employed a two-step pre-processing: detecting informal words using dictionary and correcting the words into formal ones. This helps to alleviate the negative effects brought by short message sparsity to some extent.

Lee et al. (2011) classified tweets into pre-defined categories such as sports, technology, politics, *etc*. Instead of topic models, they constructed word vectors with tf-idf weights and utilized a Naive Bayesian Multinomial classifier to classify tweets. Further, Support Vector Machines achieved good performance to classify Twitter messages, as reported by Zubiaga et al. (2011). Sriram et al. (2010) proposed to use a small set of domain-specific features extracted from the author's profile and text to represent short messages. Their method, however, requires extensive pre-processing to conduct effectively feature analysis, which was impractical to as a general solution for classification of microblogging messages. The performance improvement of the supervised methods mainly depend on a large scale of labeled training data, which is laborious and time consuming. Further, the sparsity problem hinders significant performance improvement. To break the current impasse between annotation cost and effectiveness, we proposed to utilize semi-supervised learning methods. We trained a semi-supervised classifier by using the large amount of unlabeled data, together with labeled data. In addition, our work is novel in that we mined the information cues from Google Search Engine and seamlessly fused them with informal microblogging messages.

5 Conclusion and Future Work

In this paper, we proposed a novel scheme to classify microblogging messages, which addresses three concerns in microblog classifications. First, the incorporation of external resources to supplement the short microblogs well compensates the data sparseness issue. Second, the semi-supervised classifier seamlessly fuse labeled data structure and external resources into the training process, which reduced the requirement for manually labeling to a certain degree. Third, we model the category probability of a given message based on the category-word distribution, and this successfully avoided the difficulty brought about by the spelling errors that are common in microblogging messages. We proposed a semi-supervised learning approach to classify microblogging messages, and the experimental results demonstrated its effectiveness as compared to existing the state-of-the-art methods, as well as practically extension to large-scale dataset.

This work suggests some interesting directions for further exploration. It is interesting to explore whether: (1) the incorporation of social network structure can improve the performance of microblogging classification (Hu and Liu, 2012a); (2) the use of external resources such as Wikipedia and WordNet might be valuable for understanding microblogging messages; and (3) the provision of category summarization can help to organize microblogging messages.

A System For Multilingual Sentiment Learning On Large Data Sets

Alex CHENG[1] *Oles ZHULYN*[1]
(1) Department of Computer Science, University of Toronto, Canada
hyc@cs.toronto.edu, oles@cs.toronto.edu

Abstract
Classifying documents according to the sentiment they convey (whether positive or negative) is an important problem in computational linguistics. There has not been much work done in this area on general techniques that can be applied effectively to multiple languages, nor have very large data sets been used in empirical studies of sentiment classifiers.
We present an empirical study of the effectiveness of several sentiment classification algorithms when applied to nine languages (including Germanic, Romance, and East Asian languages). The algorithms are implemented as part of a system that can be applied to multilingual data. We trained and tested the system on a data set that is substantially larger than that typically encountered in the literature. We also consider a generalization of the n-gram model and a variant that reduces memory consumption, and evaluate their effectiveness.

Keywords: sentiment, classification, multilingual, empirical verification.

Proceedings of COLING 2012: Technical Papers, pages 577–592,
COLING 2012, Mumbai, December 2012.

1 Introduction

Classifying text documents according to the sentiment they convey is an important problem in computational linguistics. Sentiment reflects the emotional content in the document or the attitude of the speaker to the subject matter in the document, and can be positive or negative. For example, "Thank you for the pleasant time we spent together" conveys a positive sentiment, while "I was devastated when you left" conveys a negative sentiment.

Sentiment classifiers that can process massive amounts of data quickly and accurately have applications in many segments of society. Marketing and brand management firms that are interested in how consumers generally feel about particular companies and their products can apply sentiment classifiers to social media documents containing relevant keywords. Government agencies that monitor electronic communications in order to identify and locate dissidents can use sentiment classifiers to find subversive messages.

To the best of our knowledge, there has not been much work done in this area on general techniques that can be applied effectively to multiple languages, nor have very large data sets been used in empirical studies of sentiment classifiers. In this paper, we present an empirical study of two sentiment classification algorithms applied to nine languages (including Germanic, Romance, and East Asian languages). One of these algorithms is a naive Bayes classifier, and the other is an algorithm that boosts a naive Bayes classifier with a logistic regression classifier, using majority vote. These algorithms are implemented as part of a system that can be applied to multilingual data. Our implementation is fast, allowing a large number of documents to be classified in a short amount of time, with high accuracy.

Automatic sentiment classification of text documents requires that the documents be modeled in a way that is amenable to the algorithm being used. The typical approach is to model the documents using n-grams. In this paper, we consider a generalization of the n-gram model that is more suitable for languages with a flexible word order, and a variant of this generalized n-gram model that helps reduce memory consumption. These models are built into our system.

For the empirical study, we trained and tested our system on a data set that is substantially larger than that typically encountered in the literature. To generate this data set, we wrote custom crawlers, and mined various web sites for reviews of products and services. The reviews were annotated by their authors with star ratings, which we used to automatically label the reviews as conveying either a positive or a negative sentiment. For each experiment in the study, we sampled disjoint training and testing sets uniformly at random from this large data set. Unlike the usual approach in the literature, the testing sets were much larger than the training sets (at least four times larger), and the experiments were repeated many times. We did this to ensure that our results were statistically significant.

The paper is organized as follows. In Section 2, we provide a brief overview of related work done in this area. In Section 3, we describe our large data set and how we acquired it. In Section 4, we discuss the generalization of the n-gram model and its variant. In Section 5, we describe the sentiment classification algorithms that we considered. In Section 6, we describe our experimental setup, and present the results. We then conclude and suggest future directions for this work.

2 Related Work

Pang and Lee (Pang and Lee, 2008) have written an excellent survey on the work done in the area of sentiment classification.

Pang et al. (Pang et al., 2002) undertook an empirical study that resembles our own. They evaluated the effectiveness of several machine learning methods (naive Bayes (Domingos and Pazzani, 1997; Lewis, 1998), maximum entropy (Csiszár, 1996; Nigam et al., 1999), and support vector machines (Cortes and Vapnik, 1995; Joachims, 1998)) for sentiment classification of English-language documents. They generated their data set by mining movie reviews from the Internet Movie Database (IMDb)[1] and classifying them as positive or negative based on the author ratings expressed with stars or numerical values. They modeled the movie reviews as n-grams.

Bespalov et al. (Bespalov et al., 2011) presented a method for classifying the sentiment of English-language documents modeled as high-order n-grams that are projected into a low-dimensional latent semantic space using a multi-layered "deep" neural network (Bengio et al., 2003; Collobert and Weston, 2008). They evaluated the effectiveness of this method by comparing it to ones based on perceptrons (Rosenblatt, 1957) and support vector machines. Their data set was derived from reviews on Amazon[2] and TripAdvisor[3], which were labeled as positive or negative based on their star ratings.

3 Large Data Set

Our large data set consists of reviews of products and services mined from various web sites. We wrote custom crawlers for each of these web sites. The domain for the reviews is quite diverse, including such things as books, hotels, restaurants, electronic equipment, and baby care products. We only looked at web sites where the reviews were accompanied by star ratings (which we normalized to a scale between 1- and 5-stars). This enabled us to automatically assign a sentiment to each review.

We considered reviews accompanied by a rating of 1- or 2-stars as having a negative sentiment, and those accompanied by 5-stars as having a positive sentiment. For some of the web sites (e.g. Ciao![4]), along with the star ratings, the reviews were also accompanied by a binary (recommended or not-recommended) rating. In this case, we assigned a negative sentiment to reviews accompanied by a rating of 1- or 2-stars, and a not-recommended rating, and a positive sentiment to reviews accompanied by a rating of 5-stars, and a recommended rating.

The approach of automatically assigning sentiment to reviews based on accompanying author ratings has precedents in the literature (Pang et al., 2002; Bespalov et al., 2011). Although it is likely that there is some noise in the data with this kind of approach, an automated approach is nevertheless essential for generating a large data set.

The data for English, French, Spanish, Italian, and German was mined from Amazon, Ciao!,

and TripAdvisor. The Portuguese data was mined from Walmart[5], Opinaki[6], Buscapé[7], and TripAdvisor. The Dutch data was mined from bol.com[8], Ciao!, and TripAdvisor. The Chinese data was mined from Amazon, dangdang.com[9], and TripAdvisor. The Japanese data was mined from Amazon, Rakuten[10], and Kakaku.com[11]. Across these web sites, these languages are not equally well-represented. As a consequence, for some of the languages (e.g. Japanese) we were able to mine substantially more data than for others (e.g. Portuguese) (Table 1).

4 Document Representation

A text document is a sequence of tokens. Tokens can simply be single characters within the text document. However, in sentiment classification, the tokens of interest are typically n-grams, which are n-length sequences of contiguous whitespace-separated words. For example, if a document is the sequence $(w_1, w_2, \ldots, w_{N-1}, w_N)$, where $w_2, \ldots, w_{N-1}$ are whitespace-separated words, and w_1 and w_N are the special symbol `<BOUNDARY>`, signifying the beginning or the end of the document, then the 2-grams are $(w_1, w_2), (w_2, w_3), (w_3, w_4), \ldots, (w_{N-2}, w_{N-1}), (w_{N-1}, w_N)$.

In Chinese and Japanese, words are not delimited by whitespace in writing. For the results we present in this paper, we used third-party libraries (Taketa, 2012; Lin, 2012) to segment Chinese and Japanese documents into words. These libraries are based on machine learning methods, and do not require large dictionary files. Nie et al. (Nie et al., 2000) considered tokenizing Chinese documents as n-grams. We also experimented with this approach for both Chinese and Japanese documents (i.e. we treated single characters as tokens). Although we do not present them here, the results we achieved in these experiments were comparable to (though not quite as good as) the results we achieved with the third-party libraries.

Figure 1: English 2-grams most indicative of positive sentiment.

4.1 Generalized N-gram

We can generalize the n-gram model by introducing a window size $k \geq n$. To iterate over all the tokens in a sequence, we first consider every window in the sequence (that is, every contiguous subsequence of length k). The tokens are all the (not necessarily contiguous) subsequences of length n within each window. When $k = n$, this is just the standard n-gram model. Guthrie et al. (Guthrie et al., 2006) refer to this as the skip-gram model.

This model is suitable for languages with a flexible word order (e.g. German). With a flexible word order, the co-occurrence of several specific words in proximity may be indicative of a particular sentiment irrespective of any intermediary words. In the standard n-gram model, the relevant words can only be captured in a token along with the intermediary words. Due to the potential variety in the intermediary words, a single document may contain many tokens that are different, but that all correspond to the co-occurrence of these relevant words. In contrast, the generalized n-gram model enables these relevant words to be captured in a single token. This helps to mitigate against noise. However, for a given document, the generalized n-gram model requires that more tokens are processed than does the standard n-gram model.

4.2 Hitting N-gram

The hitting n-gram model is a variation on the generalized n-gram model. In the hitting n-gram model, only the windows that are centered around (i.e. "hit") words from a predefined lexicon are considered. We can specify where inside a window we would like the hit to occur by giving the window size in terms of the number of words preceding a word from the lexicon and the number of words following that word from the lexicon.

Table 4: Top French words most indicative of positive and negative sentiment.

In contrast to the generalized n-gram model, the hitting n-gram model can drastically reduce the number of tokens that need to be processed, depending on the lexicon that is chosen. For this project, we processed our large data set using Pearson's chi-squared test to find the words that are most indicative of positive and negative sentiment to build a lexicon for each language. We discuss this in more detail in Section 5.

5 Classifiers

For our experiments, we modeled documents using the 2-gram model, the generalized 2-gram model with window size 3, the generalized 2-gram model with window size 5, and the hitting 2-gram model with (preceding) window size 1. For each of these models, we trained a naive Bayes classifier and a logistic regression classifier. During testing, we considered the results from the naive Bayes classifier, and the naive Bayes classifier boosted with the logistic regression classifier using majority vote. We repeated this for each language.

5.1 Hitting 2-gram Model

Yang and Pedersen (Yang and Pedersen, 1997) evaluated several automatic methods for selecting features that were useful for categorizing text. Pearson's chi-squared test proved

to be the most effective. We used Pearson's chi-squared test to find, for each language, the top 200 words most indicative of positive sentiment and the top 200 words most indicative of negative sentiment, without filtering for stop words (e.g. Table 2, Table 3, and Table 4). We used these words as the lexicon for the hitting 2-gram model.

Following Yang and Pedersen, we computed, for each word w and each sentiment s, the goodness of fit measure:

$$\chi^2(w,s) = \frac{N \times (AD - CB)^2}{(A+C) \times (B+D) \times (A+B) \times (C+D)}$$

where A is the number of documents with sentiment s in which w occurs, B is the number of documents without sentiment s in which w occurs, C is the number of documents with sentiment s in which w does not occur, D is the number of documents without sentiment s in which w does not occur, and N is the total number of documents. We did this once over our entire data set, and took the words that scored highest according to this measure.

In our experiments, we set the window size to be 1 preceding word. We also tried other window sizes, but they did not produce substantially better results. We do not report these other results.

The technique we used to build the lexicon can be applied to other kinds of tokens. For example, Figure 1 is a word cloud of the English 2-grams most indicative of positive sentiment in our data set. We generated the word cloud using Wordle (Feinberg, 2012).

5.2 Naive Bayes Classifier

For the 2-gram model, we used the training data to compute for each 2-gram, $(\mathscr{W}, \mathscr{W}')$, the probability that it belongs to a document with a positive sentiment, $\mathscr{P}_{pos}(\mathscr{W}, \mathscr{W}')$, and the probability that it belongs to a document with a negative sentiment, $\mathscr{P}_{neg}(\mathscr{W}, \mathscr{W}')$. Given a document $(\mathscr{W}_1, \mathscr{W}_2, \ldots, \mathscr{W}_{N-1}, \mathscr{W}_N)$[12] to classify, we apply a decision rule based on the ratio

$$\prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i, \mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_i, \mathscr{W}_{i-1})}$$

computed using the probabilities determined from our training data. If this ratio is greater than 1, then we classify the document as positive. Otherwise, we classify the document as negative.

The following derivation show what this ratio means.

$$\prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i, \mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_i, \mathscr{W}_{i-1})} = \prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i | \mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_i | \mathscr{W}_{i-1})} \times \frac{\mathscr{P}_{pos}(\mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_{i-1})} \tag{1}$$

$$= \prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i | \mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_i | \mathscr{W}_{i-1})} \times \prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_{i-1})} \tag{2}$$

$$= \prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i | \mathscr{W}_{i-1})}{\mathscr{P}_{neg}(\mathscr{W}_i | \mathscr{W}_{i-1})} \times \prod_i \frac{\mathscr{P}_{pos}(\mathscr{W}_i)}{\mathscr{P}_{neg}(\mathscr{W}_i)} \tag{3}$$

[12] $\mathscr{W}_2, \ldots, \mathscr{W}_{N-1}$ are whitespace-separated words, and $\mathscr{W}_1$ and $\mathscr{W}_N$ are the special symbol `<BOUNDARY>`, signifying the beginning or the end of the document.

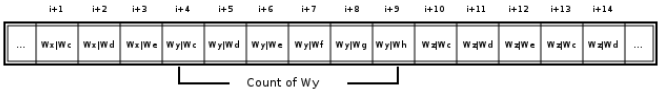

Figure 2: Sum over the range to get the count for W_y.

Line (1) follows from the definition of conditional probability. Line (2) follows from commutativity and associativity of multiplication. Line (3) follows from the fact that the missing term

$$\frac{\mathscr{P}_{pos}(\mathscr{W}_N)}{\mathscr{P}_{neg}(\mathscr{W}_N)} = 1$$

since the occurrence of $\mathscr{W}_N$, the special symbol <BOUNDARY>, in a document with a positive sentiment is equally likely to its occurrence in a document with a negative sentiment. The numerator in the expression in line (3) is the probability that the given document has a positive sentiment according to both the 2-gram model and the 1-gram model. The denominator is the probability that the document has a negative sentiment according to both models. Our decision rule classifies the document according to which of these two probabilities is the greater. Notice that our confidence that the sentiment of the document was classified correctly can be increased using a threshold parameter. For example, if the ratio between the numerator and the denominator is very high, then we have high confidence that the document has a positive sentiment. At the cost of leaving some documents unclassified, the threshold parameter can be used to achieve arbitrarily high classification accuracies.

Our implementation allows these values to be computed quickly. We represent each distinct word that we encounter in the training data with a nonnegative 32-bit integer, and use a hash map to store this representation. We represent each 2-gram that we encounter in the training data by packing the two integers corresponding to the two words in the 2-gram in a 64-bit integer. After processing the training data, we sort all the 64-bit integers representing the 2-grams, and store the sorted list in an array. We use the index of each 2-gram in this array as an index into two other arrays: one representing the number of occurrences of the 2-grams in positive documents, and the other representing the number of occurrences of the 2-grams in negative documents. This approach gives us a minimal perfect hash function from 2-grams to their counts in positive and negative documents. Looking up a count for a given 2-gram is fast: binary search on the sorted array gives us the index to the counts for occurrences in positive and negative documents. Our minimal use of pointers also keeps memory consumption low.

One might be interested in computing the probabilities for a document under the 1-gram and 2-gram models. Our implementation allows this to be computed quickly. Given a word, one can perform binary search on the sorted list of 2-grams to find the first occurrence of a 2-gram whose first word is the given word. After this 2-gram is found, one needs only to sum up all the values in the list up to the last occurrence of a 2-gram whose first word is the given word (Figure 2), and divide by the total sum of all the values in the list (which can be computed once, when the list is built). This is the probability for a 1-gram. The

probability for a 2-gram can be evaluated directly from this using Bayes' rule.

The approach we took for the generalized 2-gram models, and the hitting 2-gram model is the same. However, the derivation for the value in our decision rule does not work out exactly, and only gives us a rough approximation of the probabilities. The results of the experiments reflect this fact: although classification speed is very fast, the accuracies are somewhat less impressive than what one might expect.

5.3 Logistic Regression Classifier

We used a logistic regression classifier provided by the `LIBLINEAR` software (Fan et al., 2008). For logistic regression, it is necessary to represent documents as feature vectors. We tried three representations. In all three cases, we had a feature for each token encountered in the training data. For the first representation, the value we used for each feature was the frequency of occurrence of the corresponding token, in the document. We normalized each feature to fall in the range $[0,1]$ (details in the following paragraph). The second representation was like the first, except we normalized the whole vector to the unit vector, instead of normalizing per feature. For the third representation, the value we used for each feature was 1 or 0, depending on whether the corresponding token was present in the document or not. We normalized the whole vector to the unit vector. All three approaches produced similar results. We only report the results for the first representation.

The normalization that we used for the first representation is the following. Suppose $\mathscr{D}$ is the total set of training documents, and $\mathscr{T}$ is the total set of tokens encountered across all documents in $\mathscr{D}$. For each document $d \in \mathscr{D}$ and each token $t \in \mathscr{T}$, let $freq_d(t)$ be the frequency of occurrence of token t in document d (e.g. if d contains 10 tokens and t occurs 5 times in d, then $freq_d(t) = 5/10 = 0.5$). The normalized value $freq'_d(t)$ of $freq_d(t)$ is

$$freq'_d(t) = \frac{freq_d(t) - \min_{d' \in \mathscr{D}}(freq_{d'}(t))}{\max_{d' \in \mathscr{D}}(freq_{d'}(t)) - \min_{d' \in \mathscr{D}}(freq_{d'}(t))}.$$

Notice that if d is a document from the testing set, then $freq'_d(t)$ can fall outside the range $[0,1]$. This is the intended behavior (Fan et al., 2008; Hsu et al., 2010).

For our experiments, we boosted the naive Bayes classifier with the logistic regression classifier using majority vote. If both classifiers agreed, then we returned the value they agreed on. Otherwise, we returned no answer.

6 Experiments

6.1 Experimental Setup

For the empirical study, we evaluated two algorithms: a naive Bayes classifier, and a naive Bayes classifier boosted with a logistic regression classifier, using majority vote. In evaluating each algorithm, we considered four ways of modeling text documents: the 2-gram model (`2g`), the generalized 2-gram model with window size 3 (`2g-w3`), the generalized 2-gram model with window size 5 (`2g-w5`), and the hitting 2-gram model with (preceding) window size 1 (`2g-h`). We repeated this for nine languages: French (`fr`), Spanish (`es`), Italian (`it`), Portuguese (`pt`), Traditional and Simplified Chinese (`zh`), Japanese (`ja`), German (`de`), English (`en`), and Dutch (`nl`). In total, this constitutes 72 different experiments. We ran each experiment 10 times to validate the results.

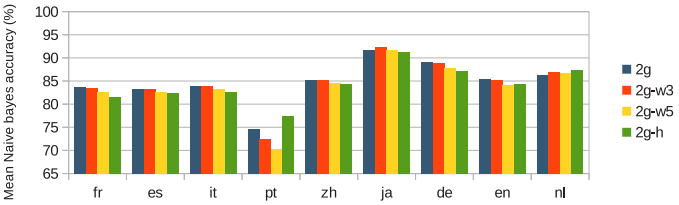

Figure 3: Mean accuracy (in percent, over ten runs) of naive Bayes classifier for each model and each language.

For each of the ten runs and each language, we sampled disjoint training and testing sets uniformly at random from the large data set. We ensured that the testing set was always at least four times larger than the training set. For each way of modeling text documents, we trained each algorithm using the training set, and tested it using the testing set. In Table 8, we report the mean and standard deviation, over ten runs, for the number of positive and negative documents in the training and testing sets for each language.

We performed our experiments using commodity hardware consisting of a quad-core Core 2 (Q9650) processor running at 3.0GHz, 16GB DDR2 memory running at 800MHz, and a 64-bit operating system with Linux kernel version 3.0. Our sentiment classification system was implemented using Java, and we ran it using Oracle Java SE Runtime Environment (build 1.6.0_30-b12). Our system makes use of several third-party libraries. The versions of these that we used are Java `LIBLINEAR` version 1.8 (Waldvogel, 2012), Apache Lucene Core version 3.6.0 (The Apache Software Foundation, 2012), cMeCab-Java version 2.0.1 (Taketa, 2012), and IK Analyzer 2012 upgrade 5 (Lin, 2012).

6.2 Results

Our multilingual sentiment classification system achieved very high accuracy (Table 6 and Table 7), without resorting to ad hoc NLP techniques, like parts-of-speech tagging and regular expression matching. It was also very fast (Table 5), because it did not rely on these techniques, which tend to be slow. The no answer rate for the naive Bayes classifier boosted with the logistic regression classifier is the rate at which documents were left unclassified because the two classifiers did not agree. Despite some documents being left unclassified, the two classifiers boosted together achieved a significantly higher accuracy than the naive Bayes classifier alone.

Recall from 5.2 that, in our implementation, the probability ratio in the decision rule of the naive Bayes classifier is only a rough approximation of the true value for the generalized 2-gram model and the hitting 2-gram model. The consequence of this is that we do not see a substantial improvement in classification accuracy for these models (Figure 3).

The less impressive performance overall for the Portuguese language is due to the quality of the data. For Portuguese, we had fewer documents to train on (Table 8), and the testing documents were, on average, quite short in length (Table 10). Notice that while we also had fewer training documents for the Dutch language, the average testing document length

Table 6: Accuracy (mean and standard deviation, in percent, over ten runs) of naive Bayes classifier for each model and each language.

for Dutch is substantially greater than that for Portuguese. This is why the classification accuracy for Dutch did not suffer as much as it did for Portuguese. On the other hand, while the average testing document length for Chinese and Japanese is very short, we trained the algorithms with far more documents for these languages, and so the classification accuracies did not suffer. Thus, we can see a tradeoff between the amount of training data and the average length of the documents being classified. In our experiments with data from Twitter[13] (which we do not report in this paper), we found the same tradeoff: more training data is needed to achieve higher classification accuracies with documents that are so short in length.

As expected, more unique tokens need to be processed during training as the window size for the generalized 2-gram model is increased (Table 9 and Figure 5). These are the unique tokens that are used to compute the probabilities, and construct the data structure discussed in 5.2. When the number of unique tokens encountered during training is greater, the amount of memory that is consumed during classification is also greater. The classification speed also decreases as the number of unique tokens increases. The hitting 2-gram model drastically reduces the number of unique tokens, and, unsurprisingly, has a faster classification speed than the other models. The hitting 2-gram model also achieves

[13]http://www.twitter.com

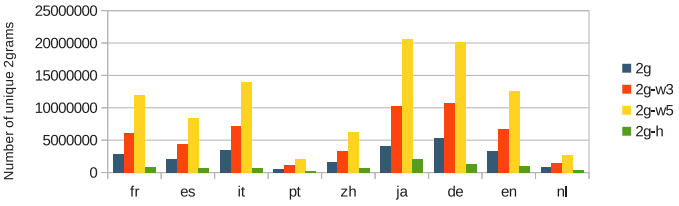

Figure 5: Mean number of unique tokens after training (over ten runs) for each model and each language.

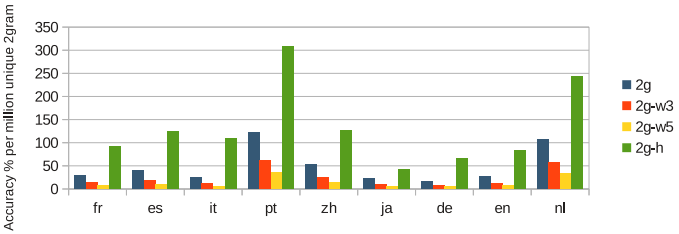

Figure 6: Mean accuracy per million unique tokens after training (in percent, over ten runs) of naive Bayes classifier for each model and each language.

greater accuracy than the other models when the amount of training data is less (i.e. for Portuguese and Dutch). In Figure 6, we see that when we normalize for the number of unique tokens, the hitting 2-gram model achieves far greater accuracy than the other models. Thus, for faster classification speed, reduced memory consumption, and lower quality training data, the hitting 2-gram is the way to go.

Our sentiment classification system was aggressively optimized for high speed and reduced memory consumption. The data for each language was aggregated in one flat file for ease of processing. Running the full set of ten runs of all experiments took less than an hour. Loading everything into memory consumed less than 3.5GB of the heap, which is unprecedented. When we ran the same set of experiments using LingPipe (Alias-i, 2012) for only the Spanish language and using only the 2-gram model, we found that more than 12GB of heap memory were required to even finish training.

Our results show that a simple and straightforward statistical approach with a large amount of training data rivals the many complex, ad hoc NLP approaches that are optimized for small amounts of training data. Important advantages of our approach are increased training and classification speeds, and reduced memory consumption. These are practical concerns that are not generally adequately addressed in the literature, particularly for the NLP approaches, which place a great emphasis on classification accuracy at the cost of speed and memory consumption. Our sentiment classification system achieves a good balance between these concerns.

Conclusion and Future Work

In this paper, we presented an empirical study of two sentiment classification algorithms applied to nine languages (including Germanic, Romance, and East Asian languages). One of these algorithms is a naive Bayes classifier, and the other is an algorithm that boosts a naive Bayes classifier with a logistic regression classifier, using majority vote. We implemented these algorithms as part of a system for classifying the sentiment of multilingual text data. Our implementation is fast, and has high classification accuracy.

We also considered a generalization of the n-gram model for representing text data, and

a variant of this generalization that helps reduce memory consumption. Along with the standard n-gram model, these two models are built into our system. We evaluated all of these models in the empirical study that we presented in this paper.

For the empirical study, we trained and tested our system on a data set that is substantially larger than that typically encountered in the literature. We generated this data set by crawling and mining various web sites for reviews of products and services. For each experiment in the study, we sampled disjoint training and testing sets uniformly at random from this large data set. Unlike the usual approach in the literature, the testing sets were much larger than the training sets (at least four times larger), and the experiments were repeated many times. We did this to ensure that our results were statistically significant.

As we have shown in this paper, statistical methods applied to large amounts of data are effective for the sentiment classification problem. It would be interesting to investigate the application of this approach to the problem of relevance (i.e. determining whether a document conveys any sentiment at all). Previous efforts have been overly complicated (Pang and Lee, 2004). One approach that we are considering is to take a list of n-grams that are most indicative of sentiment (determined using Pearson's chi-squared test, as discussed in 5.1), and computing the mean and standard deviation for the frequency of occurrence of these words in the training documents. During testing, the frequency of occurrence for these words in the test documents can be compared to the mean we computed. If the frequency of occurrence is not less than one standard deviation below the mean, then a document can be deemed relevant.

We are also interested in commercializing our sentiment classification system by selling it to social media analytics firms, such as Sysomos[14] and BrandWatch[15]. The existing players in the sentiment classification field (e.g. Saplo[16], Lexalytics[17], OpenAmplify[18], and SNTMNT[19]) are not transparent about what they are doing, and it is not clear how robust their offerings are. If commercialization fails, then we intend to make our sentiment classification system freely available under the GPL[20], since one of our great passions is educating the public on the power of machine learning methods.

ABSTRACT

In this paper we consider a new approach for domain-specific sentiment lexicon extraction in Russian. We propose a set of statistical features and algorithm combination that can discriminate sentiment words in a specific domain. The extraction model is trained in the movie domain and then utilized to other domains. We evaluate the quality of obtained sentiment vocabularies intrinsically. Finally we combine the sentiment lexicons from five domains to obtain one general lexicon for the product meta-domain. We demonstrate the robustness of the extracted lexicon in the cross-domain sentiment classification in Russian.

TITLE AND ABSTRACT IN RUSSIAN

Извлечение Словаря Оценочной Лексики на Русском Языке для Мета-Области Товаров

В данной работе рассматривается новый подход к извлечению предметно-ориентированного словаря оценочной лексики на русском языке. Мы предлагаем использовать совокупность статистических и лингвистических признаков, позволяющих выявлять оценочные слова, и комбинировать эти признаки с помощью алгоритмов машинного обучения. Модель извлечения создается для предметной области фильмов, а затем применяется в других предметных областях. Мы оцениваем качество полученных словарей оценочных слов посредством ручной разметки. Наконец, мы собираем из отдельных словарей общий словарь оценочных слов, рассматривая его как оценочный словарь в широкой области товаров. Мы демонстрируем полезность полученного общего лексикона в задаче переноса модели анализа тональности с одной области на другую для отзывов пользователей на русском языке.

KEYWORDS IN RUSSIAN: Анализ Тональности, Оценочные слова, Настройка на Предметную Область

Proceedings of COLING 2012: Technical Papers, pages 593–610,
COLING 2012, Mumbai, December 2012.

В последнее время большие усилия были направлены на решение задачи анализа мнений в различных предметных областях. Автоматизированные подходы к анализу тональности могут быть полезны для государственных органов и политиков, компаний и простых пользователей. Одной из важнейших задач, являющейся основой для анализа мнений в текстах, написанных на различных языках, является создание словарей оценочных слов.

Многие исследователи создают словари общеупотребительных оценочных слов для своих языков. Вместе с тем известно, что в разных предметных областях могут применяться достаточно разные наборы оценочных выражений. Наконец, предметные области могут иметь сходство между собой в используемой оценочной лексике. Так, такие оценочные слова как *негодяй* или *зло* одинаково неприменимы ко всем областям оценки качества товаров.

В данной работе мы исследуем новую идею разработки русского словаря оценочной лексики для широкой области товаров. При этом важно подчеркнуть, что в настоящее время нет общественно доступного русскоязычного словаря оценочной лексики. Наш метод базируется на обучении алгоритма извлечения русской оценочной лексики в одной предметной области, и затем переносе обученной модели на другие предметные области. Мы показываем, что модель извлечения оценочной лексики может быть перенесена на другие предметные области, если имеются все необходимые для работы системы данные. Мы применяем нашу модель к нескольким предметным областям и затем из оценочных словарей отдельных предметных областей собираем единый словарь оценочной лексики, рассматривая его как словарь оценочной лексики в широкой области товаров.

Извлечение оценочных слов в заданной предметной области основано на нескольких текстовых коллекциях: коллекции отзывов о продуктах с оценками пользователей, коллекции описаний продуктов и контрастной коллекции (например, новостная коллекция). Такие коллекции могут быть автоматически сформированы для разных предметных областей. Кроме того, мы предположили, что можно выделить некоторые части корпуса мнений (например, о фильмах), в которых концентрация оценочных слов выше: предложения, заканчивающиеся на «!» или «…»; короткие предложения не более чем из 7 слов; предложения, содержащие слово «фильм» без других существительных. Условно назовем этот корпус – малый корпус.

Для каждого слова в коллекции отзывов мы вычисляем набор статистических и лингвистических признаков.

Для обучения алгоритмов нам необходимо размеченное множество слов. Для этого мы вручную разметили множество всех слов с частотой выше трех из предметной области о фильмах (18362 слова). Мы относили слово к категории оценочных в случае если могли представить его в каком-либо оценочном контексте.

Мы решали задачу классификации на два класса: разделение всех слов на оценочные и неоценочные. Для этих целей использовались следующие алгоритмы: *Logistic Regression*, *LogitBoost* и *Random Forest*. Все параметры алгоритмов были выставлены в соответствии с их значениями по умолчанию.

Используя данные алгоритмы, мы получили списки слов, упорядоченные по вероятности оценочности слов. Для оценки качества этих списков использовалась мера *Precision@n*. Для сравнения качества работы системы в разных предметных областях мы использовали значение n = 1000.

Мы заметили, что извлеченные списки оценочных слов существенно различаются в зависимости от алгоритма. Поэтому мы решили вычислить среднее от значений вероятностей в каждом из списков. В результате качество автоматического извлечения оценочных слов в области фильмов *Precision@1000* составило 81.5%.

Для использования системы в новой предметной области необходимо собрать аналогичный набор коллекций, как и предметной области о фильмах. Мы применили модель извлечения оценочных слов в таких областях, как книги, игры, цифровые камеры, мобильные телефоны.

Для того чтобы собрать обобщенный список оценочной лексики в области товаров, мы применили формулу, поощряющую нахождение оценочного слова в начале наибольшего количества полученных списков оценочной лексики в разных предметных областях. Качество полученного списка составило P@1000 = 91.4%.

Для проверки полезности полученного обобщенного списка оценочных слов в мета-области товаров мы протестировали его в задаче переноса системы анализа тональности с одной области на другую.

Для тестирования мы взяли по 1000 положительных и 1000 отрицательных отзывов в четырех предметных областях. Мы обучали классификатор тональности в одной области на трех разных наборах признаков: всех словах, извлеченному списку оценочных слов этой предметной области и обобщенному списку оценочных слов. Далее мы применяли обученный классификатор на другой предметной области. Всего было рассмотрено 9 пар предметных областей. Было показано, что в среднем классификатор, обученный на обобщенном списке предметных областей, лучше переносится на новую предметную область.

Таким образом, в нашей работе мы создали русскоязычный список оценочных слов для широкой области товаров и показали его полезность в задачах, связанных с настройкой систем анализа тональности на новую предметную область. Мы планируем опубликовать полученный список оценочных слов, и это будет первый общественно доступный список оценочной лексики для русского языка.

1 Introduction

Over the last few years a lot of efforts were made to solve sentiment analysis tasks in different domains. Automated approaches to sentiment analysis can be useful for state bodies and politicians, companies, and ordinary users. Most of these efforts concern English, where a lot of resources and tools for natural language processing and especially for sentiment analysis exist.

One of the important tasks, considered as a basis for sentiment analysis of documents written in a specific language, is a creation of its sentiment lexicon (Abdul-Mageed et al., 2011; Peres-Rosas et al., 2012).

Usually authors try to gather general sentiment lexicons for their languages. However a lot of researchers stress the differences between sentiment lexicons in specific domains. For example, "must-see" is a strongly opinionated word in the movie domain, but neutral in the digital camera domain (Blitzer et al., 2007). For these reasons, supervised learning algorithms trained in one domain and applied to other domains demonstrate considerable decrease in the performance (Ponomareva & Thelwall, 2012; Read & Carroll, 2009; Taboada et al., 2011).

To overcome this issue various adaptation methods are proposed, like ensembles of classifiers (Aue & Gamon, 2005) or graph-based approaches (Wu et al., 2009). Nevertheless such approaches usually do not work well for domains whose lexicons differ significantly and recent studies are focused on bridging the gap between domain-specific words (Pan et al, 2010). Indeed, sentiment lexicons adapted to a particular domain or topic have been shown to improve task performance in a number of applications, including opinion retrieval (Jijkoun et al., 2010), and expression-level sentiment classification (Choi & Cardie, 2009). In addition sentiment word extraction from a text collection enables to find slang and non-vocabulary words, which can be strong sentiment predictors.

Stressing the differences in sentiment lexicons between domains, one should understand that domains can form clusters of similar domains. So a lot of sentiment words relevant to various product domains are not relevant to the political domain or the general news domain and vice versa. For example, such words as *evil* or *villain* are not applicable to all product domains. Therefore we suppose that gathering a specialized sentiment lexicon for the product meta-domain can be useful for researchers and practitioners.

In the current study we focus on the novel idea of construction of Russian sentiment lexicon for the product meta-domain. At this moment we should also emphasize that no publicly available Russian sentiment lexicon exists. Our method is based on training of the supervised algorithm for sentiment lexicon extraction in one domain and further transfer of the model to other domains. We show that in comparison with supervised sentiment classifiers, our sentiment lexicon extractor can be transferred to other domains if all necessary data are available. The trained sentiment lexicon extraction model is applied to an extensive number of domains and then extracted lexicons are summed up to the single list of sentiment words. So we obtain the generalized sentiment lexicon for the group of domains.

We opt to focus on recognizing sentiment words without any polarity scores. It is pointed in the research papers that the two-stage approach is often beneficial, in which on the first stage we determine main sentiment bearers in a text and on the second stage classify them according to the polarity (Pang and Lee, 2008). Thus such sentiment lexicons can be very useful for more accurate processing of user opinions.

We evaluate the extracted general lexicon intrinsically, by manually labelling of word lists, and extrinsically, by transferring of sentiment classifiers based on our general lexicon to domains without any labelled data. The results demonstrate the effectiveness of our constructed general sentiment lexicon.

The reminder of this article is organized as follows. In Section 2 we observe state-of-the-art methods for the sentiment lexicon generation, Section 3 describes the data collections and features involved in the model, in Section 4 we utilize our approach for four other domains and combine sentiment word vocabularies from all of them in Section 5. Finally, in Section 6 we conduct the experiments on the cross-domain sentiment classification involving extracted sentiment words.

2 Related work

The related works can be divided into two categories: the creation of a sentiment lexicon for a specific language, and the creation of a sentiment lexicon for a specific domain.

2.1 Creation of sentiment lexicons for specific languages

There are four main methods that are exploited by researchers to develop the sentiment lexicons for their languages: use of translated English sentiment resources, use of language-specific wordnets aligned to Princeton WordNet, use of corpora-based techniques similar to the techniques proposed for English sentiment lexicon extraction, use of electronic dictionaries of specific languages.

In (Mihalcea et al., 2007) two methods for translating sentiment lexicons to Romanian are proposed. The first method uses bilingual dictionaries to translate an English sentiment lexicon gathered using OpinionFinder (Wiebe & Riloff, 2005) and obtain 4,983 Romanian sentiment words. The evaluation of randomly chosen units shows the percentage of the sentiment words in the list is around 50%; besides, the low coverage of existing Romanian sentiment expressions is revealed. The second method is based on parallel corpora. The corpus on the source language is annotated with sentiment information, and the information is then projected to the target language. The problems arise due to mistranslations, e.g. because irony is not recognized.

Researchers in (Banea et al., 2008) propose to use a monolingual dictionary to acquire a sentiment lexicon from 60 manually selected seeds, equally sampled from verbs, nouns, adjectives and adverbs. To filter erroneous entries the LSA similarity measure is used.

In (Perez-Rosas et al., 2012) a method to derive Spanish lexicons by using manually or automatically annotated data available in English is presented. The multilingual sense-level aligned WordNet structure is used to generate a highly accurate (90%) polarity lexicon comprising 1,347 entries, and one with accuracy (74%) encompassing 2,496 words.

(Clematide & Klenner, 2010) begin their work with German polarity lexicon from 8000 polarity words obtained from GermaNet, a WordNet-like lexical database. Revealing rather low coverage of German novels by polarity-bearing adjectives from this list, they expand the set of 2899 German sentiment adjectives extracting coordinated adjectives pairs similar to (Hatzivassiloglou & McKeown, 1997).

To enhance the quality of dictionary-based methods for the general sentiment vocabulary generation in other languages, (Steinberger et al., 2011) create two source sentiment vocabularies: English (2400 entries) and Spanish (1737 entries). Both lists are translated by Google translator to the target language. Only overlapping entries from each translation are taken into further consideration. The set of target languages comprises six languages including Russian. The extracted Russian list of sentiment words contained 966 entries with accuracy of 94.9%.

In comparison with these approaches we create a Russian lexicon for a very broad domain - meta-domain of products and services, for which we do not use any dictionaries - only users' reviews, and in this paper we show usefulness of this general lexicon.

2.2 Development of sentiment lexicons for specific domains

In many studies domain-specific sentiment lexicons are created using various types of propagation from a seed set of words, usually a general sentiment lexicon (Kanayama & Nasukawa, 2007; Lau et al., 2011; Qiu et al., 2011). In such approaches an important problem is to determine an appropriate seed lexicon for propagation, which can heavily influence the quality of the results. Besides, the propagation often lead to unclear for a human sentiment lists. So, for example, in (Lau et al., 2011) only 100 first obtained sentiment words were evaluated by experts, *precision@100* was around 80%, what means that the intrinsic quality of the extracted 4000 lexicon (as announced in the paper) can be quite low.

Another approaches apply statistical measures based on domain-specific corpora to extract domain-specific sentiment words: $\chi 2$ (Jijkoun et el., 2010), divergence from randomness (DFR), which measures the divergence between a term's probability distribution in a set of relevant and opinionated documents and its probability distribution in a set of relevant documents (He et al., 2009) etc.

The sentiment lexicon extraction method proposed in this paper exploits a set of statistical and linguistic measures, which can characterize domain-specific sentiment words from different sides. We combine these features into a single model using machine learning methods. Then we train it on one domain and show that such a model can be effectively transferred to other domains for extraction of their sentiment lexicons.

3 Extraction of sentiment lexicon in a specific domain

In the current study a new supervised method for domain-specific sentiment lexicon extraction is presented. We train our model in one domain and then apply it to several others. Finally, we combine the extracted word lists to construct a general lexicon of sentiment words typical for products and services.

Our approach is based on several text collections, which can be automatically formed for many domains, such as: a collection of product reviews with authors' evaluation scores, a text collection of product descriptions and a contrast corpus (for example, a general news collection). For each word in the review collection we calculate a set of linguistic and statistical features using the aforementioned collections and then apply machine learning algorithms for term classification.

Our method does not require any seed words, and is rather language-independent, however, lemmatization (or stemming) and part-of speech tagging are desirable. Working with Russian language, we use a dictionary-based morphological processor, including unknown word processing. Below in the text we will speak only about lemmatized words.

3.1 Data preparation

We collected 28, 773 movie reviews of various genres from the online recommendation service *www.imhonet.ru*. For each review, user's score on a ten-point scale was extracted. We called this collection the **review collection**.

Example of the movie review:

Nice and light comedy. There is something to laugh - exactly over the humour, rather than over the stupidity… Allows you to relax and gives rest to your head.

We also required a contrast collection of texts for our experiments. In this collection the concentration of opinions should be as little as possible. For this purpose, we collected 17, 680 movie descriptions. This collection was named the **description collection**.

One more contrast corpus was a collection of two million news documents. We had calculated a document frequency of each word in this collection and used only this frequency list further. This list was named the **news corpus**.

3.2 Collections with higher concentration of opinions

We suggested that it was possible to extract some fragments of reviews from the review collection that had higher concentration of sentiment words. These fragments may include:

- Sentences ending with a "!";
- Sentences ending with a "…";
- Short sentences, no more than seven word length;
- Sentences containing the word «movie» without any other nouns.

We called this collection the **small collection**.

3.3 Statistical features

Our aim is to create a high quality list of sentiment words based on the combination of various discriminative features. We propose the following set of features for each word:

- Frequency-based

- Collection frequency $f(w)$ (i.e. number of occurrences in all documents in the collection)
- Document frequency
- Frequency of capitalized words
- Weirdness
- TFIDF

- Rating-based
  - Deviation from the average score
  - Word score variance
  - Sentiment category likelihood for each *(word, category)* pair

We will consider some of them in more detail.

Frequency of capitalized words. The meaning of this feature is the frequency (in the review corpus) of each word starting with the capital letter and not located at the beginning of the sentence. With this feature we are trying to identify potential proper names, which are always neutral.

Weirdness. To calculate this feature two collections are required: one with high concentration of sentiment words and the other – contrast one. The main idea of this feature is that sentiment words will be «strange» in the contexts of the contrast collection. This feature is calculated as follows (Ahmad et al., 1999):

$$Weirdness = \frac{P_s(w)}{P_g(w)}$$

where $P_s(w)$ – probability of the word in a special corpus, $P_g(w)$ – probability of the word in a general corpus. Here and further we consider maximum likelihood estimation of the probabilities. Instead of the collection frequency one can use the document frequency for the probability calculation.

Weirdness was calculated using the following collection pairs: *opinion-news*, *opinion-description, description-news* with document frequency and *small-description*, *opinion-description* with collection frequency.

TFIDF. We use TFIDF variant described in (Callan et al., 1992), based on BM25 function. We calculate TFIDF using the collection pairs: *small-news*, *small-description*, *opinion-news*, *opinion-description, description-news.*

3.4 Rating-based features

As we mentioned above we had collected user's numerical score (on a ten point scale) for each review. Let $C = \{1...10\}$ to be the set of rating categories in the review collection. First, we want to give some definitions, which we will use further.

Definition 1.

i. The probability of a rating category **c** given a word ***w***:

$$P(c \mid w) = \frac{f(w,c)}{\sum_{c_i \in C} f(w,c_i)}$$

ii. The probability of a word ***w*** given a rating category **c**:

$$P(w \mid c) = \frac{f(w,c)}{\sum_{w_i \in C} f(w_i,c)}$$

Definition 2.

i. An expected category for a given word:

$$E(c \mid w) = \sum_{c_i \in C} c_i \cdot P(c_i \mid w)$$

ii. An expected category in the review collection:

$$E(c) = \sum_{c_i \in C} c_i \cdot P(c_i)$$

Using our definitions we suggest the following features:

Deviation from the average score.

$$Dev(w) = \left| E(c \mid w) - E(c) \right|$$

This feature can discriminate words appearing in a wide range of rating categories.

Word score variance. One more useful predictor is word score variance. If a word has small variance then it might be used in reviews with similar scores and has high probability to be a sentiment word.

$$Var(w) = E(c^2 \mid w) - E(c \mid w)^2$$

Scaled likelihood. To get some intuition about how likely a word is to appear in each sentiment class we define a scaled log-likelihood:

$$Lhc(w) = \log \frac{P(w \mid c)}{P(w)}$$

Scalability is required to be comparable between words. We have also added some features aggregating *Lhc values* like maximum and average.

3.5 Morphological Features

Some linguistic features were also added to our system because they can play crucial role in improving the sentiment lexicon extraction.

- Four binary features indicating the word part of speech (noun, verb, adjective and adverb)

- Two binary features reflecting POS ambiguity (i.e. word can have various parts of speech depending on a context) and the feature indicating if this word is recognized by the POS tagger.
- Predefined list of prefixes of a word (for example, Russian prefixes "*ne*", "*bes*", "*bez*" etc. similar to English "*un*", "*in*", "*im*" etc.)

The last feature is a strong predictor for words starting with negation.

3.6 Algorithms and evaluation

To train supervised machine learning algorithms we needed a set of labeled sentiment words. For our experiments we manually labeled words with the frequency greater than three in the movie review collection (18362 words). We marked up a word as a sentiment one in case we could imagine it in any opinion context in the movie domain. All words were tagged by two assessors. If there was a disagreement about the sentiment of a specific word, the collective judgment after discussion was used as a final ground truth. As a result of our assessment procedure we had obtained the list of 4079 sentiment words in the movie domain.

We solved the two class classification problem: to separate all words into sentiment and neutral categories. For this purpose Weka[1] data mining tool was used. We considered the following algorithms: *Logistic Regression*, *LogitBoost* and *Random Forest*. All parameters in the algorithms were set to their default values. For each experiment 10 fold cross-validation was used.

Using this algorithms we obtained word lists, ordered by the predicted probability of their opinion orientation. To measure the quality of these lists the *Precision@n* metric was used. This metric was very convenient for measuring the quality of list combinations and it could be used with different thresholds. To compare quality of the algorithms in different domains we chose n = 1000. This level was not too large for the manual labeling and demonstrated the quality in an appropriate way.

The results of classification are in Table 1.

Logistic Regression	**LogitBoost**	**Random Forest**	**Average**
75.7%	75.3%	72.4%	81.5%

TABLE 1 – Precision@1000 of word classification

We noticed that the lists of sentiment words extracted by the algorithms differ significantly. So we decided to average word probability values in these three lists. The result of this summation can be found in the last column of the Table 1.

As the baseline for our experiments we used the lists ordered by frequency in the review collection and deviation from the average score. *Precision@1000* in these lists was 26.9% and 35.5% accordingly. Thus our algorithms gave significant improvements over the baselines. All the other features can be found in Table 2.

[1] http://www.cs.waikato.ac.nz/ml/weka/

Let us look at some examples of sentiment words with the high probability value in the sum list: *Trogatel'nyi (affective), otstoi (trash), fignia (crap), otvratitel'no (disgustingly), posredstvenniy (satisfactory), predskazuemyi (predictable), ljubimyj (love) etc.*

Feature	Collection	Precision @1000
TFIDF	small – news	38.5%
TFIDF	small – descr	36.4%
TFIDF	review – news	30.5%
TFIDF	review – descr	39.8%
Weirdness	review – news (doc. count)	31.7%
Weirdness	review – descr (doc. count)	48.1%
Weirdness	small – descr (frequency)	49.1%
Weirdness	review – descr (frequency)	46.6%
Dev	review	35.5%
Var	review	21.5%
Lhc	review	33.0%
Frequency	review	26.9%
Frequency	small	31.9%
Document Frequency	review	27.8%

TABLE 2 – Precision@1000 for different features

4 Model adaptation

In the previous section we described the construction of the sentiment lexicon extraction model for the movie domain. The next step of the current research is utilizing this model in four other domains and combining obtained results to form a general sentiment lexicon for the product meta-domain.

	Review Collection	Description Collection	Source
Books	23, 883	22, 321	Imhonet
Games	7, 928	1, 853	Imhonet
Digital Cameras	10, 208	920	Yandex Market
Mobile Phones	30, 620	890	Yandex Market

TABLE 3 – The characteristics of the data collections

4.1 Additional datasets

We collected[2] data in the four domains: books, computer games, mobile phones and digital cameras. The structure of the datasets is the same as for movie domain. Data collection characteristics for each domain can be found in Table 3.

In further experiments we use the same **news corpus** as for movie domain.

4.2 Model utilization and evaluation

For all words in a particular field (excluding low frequent ones) we computed feature vectors (see Sections 3.3-3.5) and constructed a domain word-feature matrix. We applied our classification model, which was trained in the movie domain, to these word-feature matrixes and manually evaluated the first thousand of the most probable sentiment words in each domain. The results of the evaluation are in Table 4.

	Average
Books	86.0%
Games	72.2%
Digital Cameras	62.0%
Mobile Phones	73.2%

TABLE 4 – The results of domain adaptation

Despite the drop in some other domains the quality of sentiment word extraction continues to be much higher than the quality level of single features (Table 2). So we can conclude that the sentiment lexicon extraction model is robust enough to be transferred to other domains.

5 Developing the Russian lexicon for product meta-domain

To construct the general sentiment lexicon for products and services we combine sentiment word lists from five domains. We want to boost words that occur in many different domains and have high weights in each of them. We propose the following function for the word weight in the resulting list:

$$R(w) = \max_{d \in D}(prob_d(w)) \cdot \sum_{d \in D} \frac{1}{|D|} \cdot \left(1 - \frac{pos_d(w)}{|d|}\right)$$

where D – is the domain set with five domains, d is the sentiment word list for a particular domain and $|d|$ is the total number of words in this list. Functions $prob_d(w)$ and $pos_d(w)$ are the sentiment probability and position of the word in the list d .

The *Precision@1000* of the obtained sentiment word list is **91.4%.** The inter-rater agreement between the two Russian annotators is measured at 0.84 (κ = 0.63).

[2] Review data collections in the book and digital camera domains are obtained from Russian Seminar of Information Retrieval Methods (www.romip.ru)

As a baseline for our method of construction of the general sentiment lexicon for product meta-domain, we take the combined *weirdness* list (review – descr) as rather simple, but high quality one. We construct it from weirdness lists in the same manner as described in the beginning of the section. The Precision@n plots of the extracted lexicon and weirdness list combination are depicted on Figure 1.

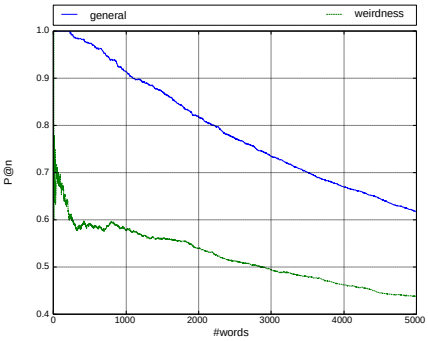

FIGURE 1 – Precision@n depending on #words

The first ten most probable sentiment words are: *bespodobniy (matchless), kleviy (cool), obaldenniy (astounding), neponiatniy (incomprehensible), neprivichniy (unusual), srednenkiy (mediocre), posredstvenniy (moderate), neploho (not bad), otlichneishiy (splendiferous), nenuzhniy (unnecessary).* This sentiment lexicon is clean enough to be used in various sentiment analysis tasks.

This meta-domain list of sentiment words consists of words really used in users' reviews and its creation does not require any dictionary resources. We plan to make it available for further research in sentiment analysis of Russian texts.

6 Lexicon evaluation on the cross-domain sentiment classification task

6.1 Experimental setup

To evaluate usefulness of our meta-domain sentiment list we test it in the cross-domain sentiment classification task as described for example in (Blitzer et al., 2007; Bollegala et al., 2011; Pan et al., 2010). In these studies the dataset consisting of Amazon product reviews for four different product types (books (B), DVDs (D), electronics (E) and kitchen appliances (K)) is used. There are 1000 positive and 1000 negative reviews selected randomly and labeled for each domain. Domain-adaptation algorithms are trained on the one domain (source domain) and tested on the other domain (target domain).

We do not compare our approach with these approaches because we do not make any efforts to adapt a classifier to a new domain. We use the similar setup to show the

generalization abilities of the sentiment word lists. In these experiments we try to demonstrate the influence of our meta-domain list on the sentiment classification quality in a new domain without any labeled data.

So we randomly take 1000 positive and 1000 negative labeled Russian reviews from four domains: movies (**M**), books (**B**), mobile phones (**P**) and digital cameras (**C**). The reviews with user's score 9-10 are considered as positive and reviews with authors' score 1-4 are considered as negative.

Taking pairs of the domains, we train a sentiment classifier in one domain (source domain) and then transfer the classifier to the other domain (target domain). We treat a review text as a bag-of-words and use the following features for classification:

- All frequent words of the source domain (**F**ull **L**ist),
- Sentiment words from the generated sentiment lexicon of the source domain (**S**ource **D**omain **L**exicon),
- Words from the meta-domain sentiment lexicon, excluding the sentiment vocabulary of the target domain during the extraction (**G**eneral **L**exicon).

In this task we utilize the LIBLINEAR realization of the support vector machine (SVM) classification algorithm with the default parameter values.

Additionally we include TFIDF weights for each feature, as it is pointed to give higher quality of the classification in comparison with the binary weights and we also take into account the polarity influencers, which can revert or magnify the polarity of the following words. The specific details can be found in (Chetviorkin & Loukachevitch, 2011).

We performed experiments with the proposed feature sets on the 9 domain pairs: ***B→C, M→C, P→C, B→P, M→P, C→P, M→B, P→B, C→B*** where the letter before an arrow corresponds with the source domain and the letter after an arrow corresponds with the target domain. We do not consider cross-domain sentiment classification with the movie domain as a target one, because we manually labeled and trained the sentiment word extraction model in it, and the results of the classification can be unclear.

For domain specific and general sentiment lexicons we explored different word quantity thresholds: {1000, 2000, 3000, 4000, 5000, 6000, 7000, 8000, 9000, 10000} and report the results with each of them (see Figure 2 and 3).

6.2 Metrics

We denote by $A(S,T,L)$ the accuracy obtained during the transfer from source domain ***S*** to target domain ***T*** of the sentiment classifier trained using the lexicon ***L***. The main point of comparison in the current research is the accuracy $A(S,T,FL)$, which corresponds to the accuracy obtained by the *baseline* lexicon, i.e. all frequent words from the source domain.

Thus we can define the main measure in the current experiment:

$$\Delta(S,T,L) = A(S,T,L) - A(S,T,FL)$$

This is the difference between the accuracy obtained with the lexicon L and baseline lexicon FL, during the transfer from source domain S to target domain T. We also use the averaged variant of this measure:

$$\overline{\Delta}(L) = \frac{1}{|D|} \sum_{(S,T) \in D} \Delta(S,T,L)$$

In our case $|D| = 9$.

6.3 Main results

We report all results in this section using first 4000 words in the general lexicon and domain specific lexicons. This is the maximum amount of words with rather reliable intrinsic precision values ~70% in the general lexicon (see Section 5). We also provide the results of cross-domain sentiment classification quality with the other threshold values in general and domain specific lexicons on the Figure 2 and 3.

On all tasks the general sentiment lexicon performs on bar or better than the other feature sets. In Table 5 and Table 6, we summarize the comparison results of cross-domain classification using different feature sets.

A	**B->C**	**M->C**	**P->C**	**B->P**	**M->P**	**C->P**	**M->B**	**P->B**	**C->B**
FL	74.0	72.55	78.65	70.05	70.5	79.9	78.15	65.1	66.5
SDL	76.1	75.2	75.55	73.45	71.15	78.85	79.0	64.3	66.9
GL	76.1	75.7	81.9	73.35	72.55	79.8	78.05	66.6	67.2

TABLE 5 – The accuracy of cross-domain classification

Δ	**B->C**	**M->C**	**P->C**	**B->P**	**M->P**	**C->P**	**M->B**	**P->B**	**C->B**	$\overline{\Delta}$
SDL	2.1	2.65	-3.1	3.4	0.65	-1.05	0.85	-0.8	0.4	0.57
GL	2.1	3.15	3.25	3.3	2.05	-0.1	-0.1	1.5	0.7	1.76

TABLE 6 – The difference with baseline of cross-domain classification

The results demonstrate the effectiveness of the general meta-domain sentiment lexicon. In the Table 6 one can see that for some domain pairs our lexicons show significantly better results than the baseline. The average difference over all domain pairs between **FL** (baseline) and **GL** is 1.76%.

In some domain pairs the difference is very small or even negative. We connect this issue with the similarity of the domain lexicons in general (Ponomareva & Thelwall, 2012) and sentiment lexicons in particular. Sometimes sentiment words from one domain can be utilized in the other one, but not vice versa.

We suppose that such a general lexicon for the product meta-domain can serve as a good source of sentiment seed words to generate domain-specific vocabularies in a lot of specific domains.

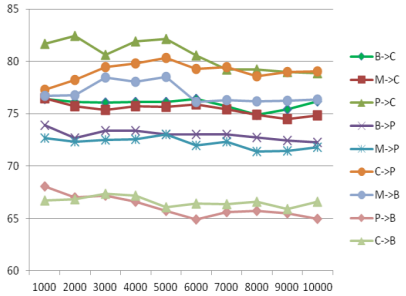

FIGURE 2 – The dependence of the classification quality on the threshold in the general lexicon

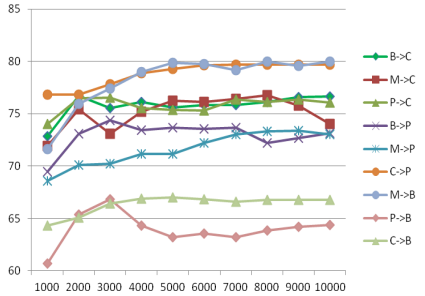

FIGURE 3 – The dependence of the classification quality on the threshold in the domain specific lexicons

Conclusion and perspectives

In this paper, we described a method for sentiment lexicon extraction for any domain on the basis of several domain-specific text collections. We utilized our algorithm in different domains and showed that it had good generalization abilities. We combined sentiment lexicons from various domains and constructed the general meta-domain sentiment lexicon for products and services. This lexicon was evaluated intrinsically, with P@1000 = 91.4% and extrinsically in the cross-domain classification task. The sentiment classification algorithm based on the meta-domain sentiment lexicon outperformed all baselines and proved usefulness of the constructed resource. Besides, this meta-lexicon can be a useful source of sentiment seeds for sentiment lexicon extraction in new domains of products and services.

We extracted such a general lexicon for Russian language, for which sentiment analysis resources practically do not exist. We plan to make our general lexicon for the product meta-domain publicly available.

ABSTRACT
Many evaluation issues for grammatical error detection have previously been overlooked, making it hard to draw meaningful comparisons between different approaches, even when they are evaluated on the same corpus. To begin with, the three-way contingency between a writer's sentence, the annotator's correction, and the system's output makes evaluation more complex than in some other NLP tasks, which we address by presenting an intuitive evaluation scheme. Of particular importance to error detection is the skew of the data – the low frequency of errors as compared to non-errors – which distorts some traditional measures of performance and limits their usefulness, leading us to recommend the reporting of raw measurements (true positives, false negatives, false positives, true negatives). Other issues that are particularly vexing for error detection focus on defining these raw measurements: specifying the size or scope of an error, properly treating errors as graded rather than discrete phenomena, and counting non-errors. We discuss recommendations for best practices with regard to reporting the results of system evaluation for these cases, recommendations which depend upon making clear one's assumptions and applications for error detection. By highlighting the problems with current error detection evaluation, the field will be better able to move forward.

KEYWORDS: grammatical error detection, system evaluation, evaluation metrics.

Proceedings of COLING 2012: Technical Papers, pages 611–628,
COLING 2012, Mumbai, December 2012.

1 Introduction

With hundreds of millions of people worldwide learning second, or even third, languages (Leacock et al., 2010), there is a large and growing need for NLP systems that automatically detect and correct the grammar and word usage errors that learners make. In response to this need, NLP researchers have developed tools to target errors involving articles (Han et al., 2006), prepositions (Tetreault and Chodorow, 2008b), particles (Dickinson et al., 2011), verb forms (Lee and Seneff, 2008), and collocations (Dahlmeier and Ng, 2011). Research in this field has surged over the last few years, culminating notably in two recent "Helping Our Own" (HOO) Shared Tasks (Dale and Kilgarriff, 2010) and (Dale et al., 2012), which are concerned with automated error correction in texts authored by non-native speakers of English working in NLP. However, despite this high level of activity and interest, there is relatively little consensus on how best to evaluate grammatical error detection/correction systems. This makes it hard to measure performance and compare systems, which is essential for progress in the field.

The goal of this paper is to draw attention to the many evaluation issues in error detection that have largely been overlooked in the past and which make it hard to draw meaningful comparisons between different approaches, even when they are evaluated on the same corpus. Of particular importance is the skew of the data – the low frequency of errors as compared to non-errors – which distorts some traditional measures of performance and limits their usefulness. Many issues in evaluation remain outside the scope of this paper, and we will not have recommendations for every problem that we discuss. However, we feel that highlighting the problems will help to move the field forward.

The lack of consensus in evaluation is due, in large part, to the nature of the error detection task. Consider (1a), a sentence that a learner of English might write.[1] It could be corrected by a human annotator or a system as (1b), (1c), (1d), or any number of other grammatical variants.

(1) a. Book of my class inpired to me.
    b. A book in my class inspired me.
    c. Books for my class inspired me.
    d. The books of my class were inspiring to me.

How we count the number, type, and scope of errors in the learner's sentence depends on the relation between what was written and the annotator's correction. However, on the task of error detection, how we score the performance of an NLP system depends on the relation between the system's output and **both** the learner's sentence and the annotator's correction. This three-way contingency makes the evaluation inherently more complex than in some other NLP tasks where the only comparison is between system and annotator. In Section 3.1, we describe the standard measures of system performance (Accuracy, Precision, Recall, F-measure), and in Section 3.2, we map a three-way contingency table of matches and mismatches among writer, annotator, and system onto the standard evaluation measures. Section 3.3 examines general problems that arise in using these measures, and Section 3.4 describes the variety of

[1] For the sake of simplicity, we use constructed examples of grammatical errors to illustrate the evaluation issues discussed in this paper. One example of a sentence with grammatical errors, taken from the first Helping Our Own Shared Task (Dale and Narroway, 2011), is: *First of all, we focus on an analysis on sentences in product reviews regarding the two views: personal and impersonal views.* where *analysis on* can be corrected to *analysis of*, *regarding the two* can be corrected to *regarding two* and *impersonal views* can be corrected to *impersonal*.

metrics found in published reports of system performance. Sections 3.5 and 3.6 deal with three issues that are particularly vexing for error detection: how to specify the size or scope of an error, how to properly treat errors as graded rather than discrete phenomena, and how to count non-errors. Each subsection contains recommendations for best practices with regard to reporting the results of system evaluation. Certain metrics are more or less appropriate depending on the type of task the system is used for, so we begin with a brief overview of applications of grammatical error detection.

2 Applications

It is not surprising that most applications of grammatical error detection are in education, where it has been used for student assessment and to support language learning. A more recent set of applications focuses on improving systems within the domain of NLP itself.

Automatically scoring essays Error detection is a fundamental component in most systems which perform automated essay scoring (Yannakoudakis et al., 2011; Attali and Burstein, 2006; Burstein et al., 2003; Lonsdale and Strong-Krause, 2003). The goal here is to find aspects of grammar and word usage related to overall text quality so that a holistic score, usually on a 5- or 6-point scale, can be generated. Essay scoring systems also measure the range of vocabulary, discourse structure, and the mechanics of writing (e.g., spelling) as predictors of the writing score. These systems are used for large scale high-stakes tests taken by native and non-native speakers, such as the Graduate Record Exam (GRE), and for tests of non-native proficiency, such as the Test of English as a Foreign Language (TOEFL).

Improving writing quality To date, most work that focuses on writing assistance tools has targeted non-native English writers. Grammatical error detection in this context is used to assist one in producing better essays or other documents (Chodorow et al., 2010; Hirst and Budanitsky, 2005; Kukich, 1992). In the short term, the goal of providing this assistance is to improve the current document by highlighting errors and suggesting corrections. In the longer term, the goal is to help writers learn more about the language they are studying so that they can produce higher quality writing, as described next.

Assisting language learning An indicative example of assisting language learners can be found in various Intelligent Tutoring Systems, which provide learners with immediate feedback on their language constructions (Meurers, 2012; Heift and Schulze, 2007). Learners not only need to observe their errors but also to understand the meta-linguistic properties of such errors. Furthermore, systems must track not just what the learner is doing incorrectly, but also what the learner is doing correctly, in order to properly model behavior (Amaral and Meurers, 2007). For both purposes, error detection is needed to detect errors, suggest corrections, and provide information about the linguistic properties of the writer's mistakes.

Applications within NLP Grammatical error detection can be a useful component in correcting and evaluating text generated in various NLP applications. Among other applications, it can be used to detect errors in machine translation (MT) output (such as in Knight and Chander (1994) and Peng and Araki (2005)) and can even be incorporated in quality metrics to assess MT (Parton et al., 2011). In these contexts, an NLP system takes the place of the writer, but the goal is similar, namely to produce more error-free language.

3 Measuring Performance

3.1 Traditional Evaluation Measures

To illustrate the traditional measures of NLP system evaluation, consider as an example the task of comma restoration (see, e.g. Shieber and Tao, 2003), in which the commas are removed from a well-edited text (the gold standard) and a system attempts to restore them by predicting their locations. For evaluations involving a binary distinction such as this one (the presence vs. absence of a comma), a comparison between the system's output and the annotator's judgments (the gold standard) can be organized as a two-by-two contingency table, shown in Figure 1. Presence of a comma is the target or positive class, and absence is the negative class. Positions in the text where both the system and the gold standard indicate that there should be a comma are true positives (TP); those where both indicate no comma are true negatives (TN); those where the system predicts a comma but the gold standard shows no comma are false positives (FP); and those positions where the system predicts no comma but the gold standard shows a comma are false negatives (FN). Given counts for these four contingencies, it is straightforward to calculate measures such as Accuracy (A), Precision (P), Recall (R), true-negative rate (TNR), and F-score (F_1), as shown in Figure 2.

		Annotation (Gold Standard)	
		Comma (+)	No comma (-)
System prediction	Comma (+)	TP	FP
	No comma (-)	FN	TN

Figure 1: The basis for typical NLP system evaluation

Accuracy (A) $= \frac{TP+TN}{TP+TN+FP+FN}$
Precision (P)$= \frac{TP}{TP+FP}$
Recall (R)$= \frac{TP}{TP+FN}$
True Negative Rate (TNR) $= \frac{TN}{TN+FP}$
F-measure (F_1) $= 2 \cdot \frac{P \cdot R}{P+R}$

Figure 2: Evaluation metrics

3.2 Error Detection and the Three-Way Contingency Table

Now consider a task that is similar to comma restoration, the task of comma error detection (Israel et al., 2012), in which a system seeks to find and correct errors in the writer's usage of commas. For this task, the positive class is not the presence of a comma but rather an error of the writer's that involves a comma. Therefore, it is necessary to compare what the writer has written to an annotator's judgment, and only if there is a mismatch between the two do we have an error (the positive class); when writer and annotator agree, the case is a non-error (the negative class). The traditional 2x2 table is no longer sufficient to represent all of the contingencies, which must instead be laid out in the more complex three-way table of Figure 3.

Figure 3 has the virtue of being complete in the sense that it shows all 2x2x2 (=8) possible combinations of binary values for the writer's, annotator's, and system's output. However, we believe that the scheme in Figure 4, which we refer to as the Writer-Annotator-System (WAS)

		Annotation (Gold Standard)			
		Comma		No comma	
Writer's form		Comma	No comma	Comma	No comma
Pos (+) / Neg (-) class		No Error (-)	Error (+)	Error (+)	No error (-)
System prediction	Comma	TN	TP	FN	FP
	No comma	FP	FN	TP	TN

Figure 3: The basis for error detection evaluation

evaluation scheme, is a simpler and more intuitive way of characterizing the relationships. To determine whether a case is a TN, TP, FN, or FP, the three sources of input are compared to see which, if any, agree. The X, Y, and Z in the figure are variables that can be replaced with any type of token; what is important is whether or not they match.

	Written	Annotated	System
TN	X	X	X
FP	X	X	Y
FN	X	Y	X
TP	X	Y	Y
*	X	Y	Z

Figure 4: *WAS* evaluation scheme

Note that the first row in Figure 4 (with answers of X from each input) can apply to multiple outcomes, as in preposition selection, or to a binary classification task, such as the presence or absence of a comma; we focus on the binary task, to be consistent with the previous figures. If all three inputs agree, the case is tallied as a TN. If the System agrees with the Annotator but the Writer does not, then it is a TP. For binary classification tasks, the first four rows are sufficient for both detection and correction, as detecting an error naturally suggests the correct answer. For tasks that involve more than two classes, further distinctions are needed to distinguish detection and correction. The final row in the figure represents a situation where all three sources provide different answers. This is marked with a * because it belongs in different categories depending on whether the evaluation is for detection or correction. For detection, this is a TP because the system is flagging an error, even if it does not produce the correct answer according to the annotator or gold standard (essentially this reduces to X Y Y). From the TP, FP, FN, and TN counts, all the measures in Figure 2 can be calculated.[2]

As far as we are aware, evaluation has not previously been schematized as in Figure 4, and we recommend setting up one's evaluation in such a way whenever possible. For the rest of the paper, we will assume TP, FP, FN, and TN as clarified by this scheme.

3.3 Traditional Metrics and the Problem of Skewed Data

At first glance, A (accuracy) seems to be the most straightforward and easily interpreted measure of system performance, but when the distribution of positive and negative classes is highly skewed, as is most often the case with writing errors, accuracy can be quite misleading. For example, Han et al. (2006) report a rate of usage errors of 13% for prepositions in a

[2]For error correction, X Y Z is both a FP (system $\neq$ writer) and FN (system $\neq$ annotator).

corpus of English essays written by native speakers of Chinese, Japanese, and Russian. For that corpus, a baseline system that always predicts "no error" will have an A of 87%, reflecting the overwhelming proportion of negative cases. Similar or even greater levels of skew are commonly found in the error detection literature (Leacock et al., 2010). With high baselines such as these, it is often difficult to see, from a single summary measure such as A, just how a system is performing, especially on the non-majority class, in this case, the errors.

The metrics most frequently reported in NLP research are intended to address this problem. R compares the number of errors the System correctly detects (TP) to the total number of errors in the Annotated gold standard (TP+FN); P compares TP to the total number of errors that the System reports (TP+FP); and F_1 is the harmonic mean of R and P. Unfortunately, all three measures are affected by the proportion of cases that are annotated as errors in the gold standard (referred to as the **prevalence** of the errors, which is equal to (TP+FN)/N, where N is the total number of cases, i.e., N = TP+TN+FP+FN) and by the proportion of cases that are reported by the System as errors (referred to as the **bias** of the System, which is equal to (TP+FP)/N). Powers (2012) demonstrates how a system that performs no better than chance will nonetheless show an increase in R when prevalence increases and an increase in P when bias increases. To understand this behavior, we must consider what it means to perform at chance.

If the class labels Error and No Error are assigned to cases independently by the Annotator and the System, then these labels are expected to match a proportion of the time by chance alone - a proportion equal to the product of their probabilities. For example, the expected proportion of TP matches is equal to the product of the proportion of cases assigned the Error label by the Annotator (i.e., the prevalence) and the proportion of cases assigned the Error label by the System (i.e., the bias). This is illustrated in Figure 5, with the value in each cell of the table equal to the product of the marginal proportions in the cell's row and column (e.g., expected proportion of TP = .20 x .20 = .04; expected proportion of FP = .20 x .80 = .16; etc.).

		Annotation (Gold Standard)		Marginal
		Error (+)	No Error (-)	proportion
System prediction	Error (+)	TP .04	FP .16	.20 (bias)
	No Error (-)	FN .16	TN .64	.80
Marginal proportion		.20 (prevalence)	.80	

Figure 5: Performance of a hypothetical system with Accuracy = .68 and Kappa = .00

The A which is expected by chance, E(A), is .04 + .64 = .68, the sum of the expected proportions of TP and TN. Cohen's kappa (κ) statistic (Cohen, 1960), shown in Figure 6, uses E(A) to correct the observed A found between Annotator and System. This provides a measure of performance over and above chance.

$$\kappa = \frac{A - E(A)}{1 - E(A)}$$

Figure 6: Formula for Cohen's kappa

To illustrate the use of κ, consider the hypothetical data in Figure 7, which has the same marginal proportions, and therefore the same E(A), as Figure 5. It shows a System that has an observed A of .10 + .70 = .80, but, when corrected for chance agreement, the Accuracy value (i.e., κ) is (.80 - .68)/(1.00 - .68) = .38. This says that after removing the proportion of cases

expected to show agreement by chance alone, the System is correct (agrees with the Annotator) on 38% of the remaining cases.

		Annotation (Gold Standard)		Marginal
		Error (+)	No Error (-)	proportion
System prediction	Error (+)	TP .10	FP .10	.20 (bias)
	No Error (-)	FN .10	TN .70	.80
Marginal proportion		.20 (prevalence)	.80	

Figure 7: Performance of a hypothetical system with Accuracy = .80 and Kappa = .38

Now consider the hypothetical data in Figure 8, which show a system that is performing no better than expected by chance. Its κ of .00 is the same as the κ of Figure 5, but the A values for the two sets of data are quite different, .68 vs. .54. This illustrates the earlier observation that A can be misleading as a measure of system performance, but A is not alone in this regard. R, P, and F_1 are also affected by changes in the marginal proportions.

		Annotation (Gold Standard)		Marginal
		Error (+)	No Error (-)	proportion
System prediction	Error (+)	TP .12	FP .18	.30 (bias)
	No Error (-)	FN .28	TN .42	.70
Marginal proportion		.40 (prevalence)	.60	

Figure 8: Performance of a hypothetical system with Accuracy = .54 and Kappa = .00

For the data in Figure 5, R is .04/(.04 + .16) = .20, and P and F_1 also have values of .20. These differ from those of Figure 8, where R is .12/(.12 + .28) = .30, P is .12/(.12 + .18) = .40, and F_1 is .34. A comparison of the marginal proportions in the two figures shows that an increase in bias can be expected to increase R, while an increase in prevalence can be expected to increase P, even when systems are performing at chance levels. These are not desirable properties for system performance measures. As Powers (2012, p. 345) points out, "traditional evaluation measures used in Computational Linguistics (including Error Rates, Accuracy, Recall, Precision, and F-measure) are of limited value for unbiased evaluation of systems, and are not meaningful for comparison of algorithms unless both the dataset and algorithm parameters are strictly controlled for skew (Prevalence and Bias)".

Sensitivity to skew may be especially problematic for evaluation of error detection/correction systems. Until recently (Dale et al., 2012), error-annotated learner corpora were not generally available for use in system testing. As a result, systems that were developed by different researchers were tested on different datasets having different error rates (Leacock et al., 2010). The variability in error rates (prevalence) could be due in part to different populations of learners with different native languages and different levels of proficiency in their second language. In addition to the variability in prevalence, there is also variability in bias when parameters of error detection systems are tuned, as they typically are, on development data to optimize performance. For example, if a system's decision to output an Error label is based on a probability that it computes for each case, then a probability threshold can be set which will increase or decrease the number of Error labels that will be output. Lower thresholds correspond to higher bias, and higher thresholds to lower bias.

Because of sensitivity to bias, system evaluation is limited if it only examines performance at one setting of a threshold. By varying the threshold through the full range of values, P-R curves can be generated to give a better picture of performance. In a similar manner, other types of curves can be produced, such as the Receiver Operating Characteristic (ROC), which plots the true positive rate (TP/(TP+FN)) against the false positive rate (FP/(FP+TN)). Area under the ROC curve has been used for evaluating and ranking machine learning models (Bradley, 1997), but Kaymak et al. (2010) argue that the area under the κ curve (κ plotted against the false positive rate) is superior to the area under the ROC curve because it accounts for skew in the data while the area under ROC does not.

While κ has advantages over R and P, it too has come under increased scrutiny. Although it properly takes changes in prevalence and bias into account, κ is known to favor correct classifications of the minority class (for error detection, Errors) over those of the majority class (Non-errors). Kaymak, et al.(2010, p. 9) have argued that "this property of Kappa is actually a virtue for many real world classification problems in which it is more important to correctly classify the minority rather than the majority class." Error detection is arguably such a problem. Another issue is that there are several kappa-like reliability measures which take chance agreement into account, but it is not clear which one or ones are best. For example, Krippendorff (2004) criticizes the use of κ for measuring the reliability of annotators in content analysis because, for a given level of agreement, the value will actually increase when there are greater differences in the annotators' preferences for using the various category labels. Krippendorff's alpha measure is designed, in part, to address this problem. Recently, Powers (2012) has shown that in some situations, Cohen's kappa is inferior to another kappa-like variant formed from a different combination of the values of the contingency table (Powers, 2003). Finally, despite its attractive features, κ is not informative about system performance in the terms that an end user cares about because, as shown above, it does not reflect A, P, or R. This limits its value for decisions about whether a system is ready for use in real world applications.

3.4 Variety in Reporting Evaluation Measures

As a result of the many issues involved in evaluating grammatical error correction systems, it is perhaps unsurprising that there is little consensus about which evaluation metric to use. For example, Leacock et al. (2010) describe how, in 2008, there were three papers on preposition error detection and each used slightly different evaluation metrics making comparison impossible. More recently, Tetreault et al. (2010) and Dickinson et al. (2011) report P and R for work done on prepositions and particles, respectively. Gamon (2010) also used P and R, while Rozovskaya and Roth (2010b) and Rozovskaya and Roth (2011) reported A of usage in a test corpus before and after corrections were made by their system. Sometimes, different metrics have been used for two aspects of the same task, as in Han et al. (2010), where A was reported for determining the presence vs. absence of a preposition, but P and R were used to evaluate performance in detecting when an incorrect preposition was used by the writer. Some researchers have even looked towards more holistic, sentence-level metrics like BLEU and METEOR (see, e.g. Park and Levy, 2011), or modifying measures like P and R to consider entire sentences, as in Gamon (2011). In the two HOO Shared Tasks, P, R and F_1 were all reported, but no preference was given to which one to use to rank the systems in the end.

Recommendations It is clear that no single measure of performance is best for all purposes; each one has its own set of advantages and disadvantages. However, all of the measures, aside from BLEU and METEOR, are based on the same four values, the counts for TP, FP, FN, and TN. We recommend reporting these four in addition to any metrics derived from them. This will enable readers to calculate other measures that the authors of a particular paper did not choose to include (e.g., Matthews Correlation), and will provide the flexibility needed to accommodate new developments in evaluation as debates over how best to measure performance are resolved. In other words, it will make it possible for future readers to go back to any publications that report these four values and retrofit new measures to old data. We also recommend κ (and the κ curve) for its ability to take the skew of the class and the label distributions into account. When reporting P and R, prevalence and bias should also be reported. For a given test corpus, prevalence will be constant, but bias will vary when threshold values change, so bias should be represented, perhaps along the horizontal axis, in displaying P, R, and F_1 curves.

3.5 Positives

In error detection, the target, or positive, class consists of an error in the writer's text. Defining a positive is complicated both by the variability in the unit size and scope of errors and by the variability in human judgments of errors.

3.5.1 Unit Size

Often there is no simple 1:1:1 correspondence between the writer's erroneous string, the annotator's correction, and the type of error the system was designed to detect. Looking back at (1a), for example, *Book* may be treated as an article error corrected by (1b), a number error corrected by (1c), or both an article error and a number error corrected by (1d). Each diagnosis has implications for how the error will be counted and mapped onto a correction.

Even when there is no ambiguity about the type of error, decisions must still be made about the size of the units over which the error is defined. In (2a), the noun-verb number disagreement involves two discontinuous substrings (e.g., *The book . . . inspire*), either one of which could be changed to correct the error, as in (2b) and (2c). This highlights the question of what size of unit is most appropriate for measuring errors and corrections: is it the morpheme, the word, the phrase, or the string? In this case, a strictly token-based definition may identify only a single word as the error (either *book* or *inspire*) or identify two separate errors, whereas a string-based definition can refer to both words as a single error.

(2) a. The **book** in my class **inspire** me.
b. The book in my class **inspires** me.
c. The **books** in my class inspire me.

There are several issues involved in choosing the unit size. First, the definition of unit size affects whether a system is given credit for finding all and only the errors, as these examples illustrate. Identifying *inspire* as an error may or may not be sufficient; identifying both words may be overkill. Defining error detection metrics in terms of edit distance mitigates this problem for evaluation comparisons (Dahlmeier and Ng, 2012), as correcting *inspire* to *inspires* is handled the same as *book ... inspire* corrected to *book ... inspires*. In essence, edit distance measures (EDMs) compare the system output to the correct *string*, ignoring exactly how it was derived.

Moreover, EDMs naturally handle multiple, overlapping errors, a problem for systems that target only a specific error type (Gamon, 2010; Rozovskaya and Roth, 2010a). Taking an example from Dahlmeier and Ng (2012), the sequence ... *development set similar with test set* ... can be corrected as a preposition selection error *with* → *to* and an adjacent article omission error $\epsilon \rightarrow$ *the*, or it can also be corrected as a single error (*with* → *to the*). Because EDMs can calculate the best match between the system's edits and those of the gold standard, they make it possible to define errors over multiple units, not just words but sequences of words as well.

Despite the benefits of basing metrics on edit distance, issues remain, depending upon the specific application of error detection or correction (see section 2). The selection of unit size is consequential for the specificity of feedback that a system can give to the writer. If *book* and *inspire* are not linked, for instance, it is harder to provide feedback on subject-verb agreement. Or if *with* → *to* and $\epsilon \rightarrow$ *the* really are different error types, then feedback should deal with them separately. Focusing on matching the string, but not on how it was derived, works well when the task is to produce a final corrected string, but it comes with a cost for applications such as intelligent tutoring systems, where the goal is to determine which types of errors the writer has made.

Additionally, errors can be defined over multiple units, but are still constrained by what the base units are. Consider if the learner had written *inpire* in (2a), thereby adding a misspelling on top of an agreement error. If the base units are words, then there is one correction to make, mapping *inpire* to *inspires*, for what are clearly two distinct errors. Character-level edits would handle this particular problem, but are difficult to work with as soon as the error is on the level of the morpheme (e.g., the two-character, one-morpheme *-es*), the word, or the sentence. The issue is that errors are defined across types of linguistic units; some errors are morpheme-level, some phrase-level, and it is difficult to group them all together.[3] EDMs can only work from the smallest unit they define, and in general the units seem to be variable.

Finally, one benefit of EDMs is that they easily fit into calculations of P and R. However, by defining matches in terms of string distance, there is no way to talk about true negatives. Errors can be of variable sizes, but this means that the size of non-errors is, in a sense, undefined. Thus, alternative measures like κ cannot be calculated.

The issue of unit size becomes more complicated when error types interact. In (3), for instance, if a learner's preposition *in* should be corrected to *to*, then the article can be dropped. If, however, the preposition is not changed, then dropping the article makes the sentence worse. This is because one correction leads to another, as noted by many doing error annotation (Boyd, 2010; Hana et al., 2010; Lee et al., 2012; Dickinson and Ledbetter, 2012). As far as we aware, no system evaluation accounts for this problem, and we do not solve it, either.

(3) Every day we go { in the school → to school }

Recommendations How one treats positives depends upon one's purpose(s). If matching to a correct string and P/R are all that is required, EDMs have several excellent properties, including being able to account for errors of variable type and size (above the level of the base unit). If feedback is desired, EDMs are not a good choice because each error type must be taken into account separately (which is largely done in Dale and Narroway (2011)). EDMs should not

[3]While the typical base syntactic unit varies for different languages, e.g., morphemes for Hungarian (Dickinson and Ledbetter, 2012), the principles discussed here apply across languages.

be used if the goal is to control for skew in the data by calculating measures such as κ, which require counts of true negatives (see section 3.6).

3.5.2 Reliability: Clear-Cut vs. Contentious Errors

For some errors, such as the extraneous preposition *to* in (1a), the judgment is unequivocal, but for others, such as the writer's choice to use *of* instead of another preposition, judgments are likely to be contentious. Arguably, an error detection system which fails to mark *to* as an error is performing more poorly than one which fails to mark *of*, but in current practice, all errors are generally assigned equal weight (though, see the "with bonus" correction in Dale and Narroway, 2012). Tetreault and Chodorow (2008a) examined some problems posed by disagreements in judgment. Using a cloze task, they asked two trained professional annotators to fill in a blank in well-formed sentences where a preposition had been removed. The results showed only 75% agreement on the prepositions that they filled in. When the same experts were asked to mark preposition usage errors in non-native writing, the system's evaluation differed by as much as 10% in P depending on which expert's annotations were used as the gold standard. Madnani et al. (2011) have argued that a better approach to system evaluation when errors are not clear-cut, as in preposition selection, is to treat them as graded and to assign them weights based on the distribution of judgments for each error obtained through crowdsourcing. Using this approach for system evaluation, if 80% of judgments for a case are Error and the system labels it as an Error, then the TP count is incremented by .80 and the FP count by .20. If, instead, the system outputs Non-error for this case, the FN count is incremented by .80 and the TN count by .20. Madnani et al. (2011) present weighted versions of the P and R formulas, and they argue that these measures are more stable than their unweighted counterparts, especially when test sets are small.

Recommendations For error types that are not judged with high reliability, authors should consider evaluation metrics based on weighted counts where the weights reflect the distributions of human judgments. The standard metrics otherwise apply.

3.6 Negatives

The non-target, or negative, class in error detection consists of the non-errors in the writer's text. At first glance, this would simply seem to be the complement of the positive class. However, an appropriate set of non-errors for system evaluation is not that easily specified, even for errors of only a single token (see discussion in section 3.5 for variable-length errors). Consider the task of enumerating the article non-errors in (1a). No article should be inserted before *of*, *my*, *class*, *inspired*, *to*, *me*, and the punctuation at the end of the sentence. Should all 7 of these positions be treated as negatives? Should only the noun phrases be counted? Most can be trivially ruled out as sites for articles (e.g., **a my*, **a me*). Similarly, when detecting missing prepositions, as in (4), performance measures can be affected not just by the system's ability to insert the proper preposition (*of*) in the correct position (after *fond*) but also by how we count the positions where a preposition is not inserted by the system. In (4), are there four positions where prepositions were not inserted or are there zero positions?

(4) He is fond beer .

Decisions of this sort have consequences for measures of system performance. When positions are included that can always be correctly identified as non-errors by trivial means, then the result will be an inflation in the count of TN, but no change in the other counts of the contingency table. This will not affect R, P, or F_1, but it will cause both A and κ to increase. This is illustrated in Figure 9 and Figure 10. Figure 9 is the same as Figure 5 except that the counts, based on an N of 100, have been included in the cells of the table. Figure 10 shows the effect of increasing the TN count by 100. This changes the proportions and, as a result, both A and κ increase.

		Annotation (Gold Standard)		Marginal
		Error (+)	No Error (-)	proportion
System prediction	Error (+)	TP 12(.12)	FP 18(.18)	.30 (bias)
	No Error (-)	FN 28(.28)	TN 42(.42)	.70
Marginal proportion		.40 (prevalence)	.60	

Figure 9: Cell counts (proportions) of a hypothetical system: Accuracy = .54 and Kappa = .00

		Annotation (Gold Standard)		marginal
		Error (+)	No Error (-)	proportion
System prediction	Error (+)	TP 12(.06)	FP 18(.09)	.15 (bias)
	No Error (-)	FN 28(.14)	TN 142(.71)	.85
Marginal proportion		.20 (prevalence)	.80	

Figure 10: Cell counts (proportions) of a hypothetical system: Accuracy = .77 and Kappa = .21

Recommendations When using κ or other measures that rely on true negatives, authors should be very explicit about what constructions or parts of speech were included in the negative class. If the TN count was based, in part, on a set of heuristics that identified obvious negative cases even before a statistical classifier was used, then the number of TNs identified in this way should also be reported so that the metrics can be adjusted appropriately.

Conclusion

We have presented the *WAS* evaluation scheme for mapping the writer's, annotator's, and system's output onto traditional NLP evaluation measures, and we have argued that the choice of metric should take into account factors such as the skew of the data and the type of application that the system will be used for. κ can provide a way to evaluate systems across differences in skew, and new kappa-related measures are being developed. Our recommendations with regard to reporting results of system performance can be summed up simply: Wherever possible, provide the reader with the counts for the four cells of the contingency table in addition to metrics that are derived from them. They are the basis for current and future measures of performance. Along with these values, describe what N, the total number of cases, consists of by listing the criteria that determined which constructions the system has analyzed. As noted earlier, no single metric is best for all purposes. A measure that is useful for system comparisons may not be the best to determine if a system is good enough to be deployed operationally, and measures of overall sentence quality, such as edit distance, may not adequately support language learning. It is our hope that, by following these guidelines, reporting in the field of grammatical error detection will be more informative and more consistent.

Unsupervised and semi-supervised morphological analysis for Information Retrieval in the biomedical domain

Vincent CLAVEAU
IRISA-CNRS, Campus de Beaulieu
F35042 Rennes, France
Vincent.Claveau@irisa.fr

Abstract
In the biomedical field, the key to access information is the use of specialized terms. However, in most of Indo-European languages, these terms are complex morphological structures. The aim of the presented work is to identify the various meaningful components of these terms and use this analysis to improve biomedical Information Retrieval. We present an approach combining an automatic alignment using a pivot language, and an analogical learning that allows an accurate morphological analysis of terms. These morphological analysis are used to improve the indexing of medical documents. The experiments reported in this paper show the validity of this approach with a 10% improvement in MAP over a standard IR system.

Keywords: Morphology, biomedical terminology, alignment, analogical learning, morpho-semantic indexing, biomedical information retrieval.

Proceedings of COLING 2012: Technical Papers, pages 629–646,
COLING 2012, Mumbai, December 2012.

1 Introduction

In the biomedical domain, terminologies are the keystone of many applications. They are used for structuring the knowledge as well as retrieving and formalizing information contained in documents. For instance, the well-known MeSH®(Medical Subject Headings) `www.nlm.nih.gov/mesh` terminology is developed to index the very popular PubMED database (`www.pubmed.gov`). In most Indo-European languages, biomedical terms also have interesting inner characteristics in that they tend to be complex morphological constructions. Indeed, they are often resulting from the composition of several Greek or Latin roots, prefixes, and suffixes. This morphological complexity is an important point to take into account for basic operations like handling, understanding, translating or building semantic relationships between these terms, and furthermore for higher level applications like machine translation or, as we demonstrate in this paper, Information Retrieval (IR).

In this paper, we investigate the development of morphological resources and show how a biomedical Information Retrieval task can benefit from such resources. More precisely, we present several techniques aiming at breaking up a term into its morphological components, namely morphs[1], while labeling these morphs with some semantic information. To the contrary of existing studies (Deléger et al., 2008; Markó et al., 2005a, for example) which are chiefly based on human expertise, the techniques proposed here rely on unsupervised or semi-supervised approaches.

The original idea at the heart of our approach is to use the multilingualism of existing terminological databases. We exploit Japanese as a pivot language, or more precisely terms written in Kanjis, to help decompose the terms of other languages into morphs and associate them with the corresponding Kanjis, in a fully automatic way. Thus, Kanjis play the role of a semantic representation for morphs. The main advantage of Kanjis in this respect is that Japanese terms can be seen as a concatenation of elementary independent words that may even be found in general language dictionaries. For example, the term photochemotherapy can be translated in Japanese by 光化学法; splitting and aligning these two terms gives: photo ↔ 光 ('light'), chemo ↔ 化学 ('chemistry', 'medicine'), therapy ↔ 法 ('therapy'). As it is shown here, each morph is associated with Kanjis that may be used as descriptors more convenient to index a document than the term itself. In particular, we demonstrate here how such correspondences between morphs and Kanjis can be exploited, in different ways, to improve the results of an IR system.

The morphological analysis, and the document indexing that it allows, thus chiefly relies on an alignment step between morphs and Kanjis. This alignment is performed with an original technique, suited to the biomedical domain and based on a *Forward-Backward* algorithm and on analogy learning. In this paper, different versions of this alignment approach are proposed, either fully unsupervised, or semi-supervised.

The paper is structured as follows. After a review of the related studies in Section 2, we present the unsupervised alignment technique, its semi-supervised variants and their results respectively in Sections 3, 4 and 5. Then, in Section 6, the use of the obtained morphological decompositions in an IR framework is explained. Evaluations, conducted on a biomedical IR test collection, are detailed in Section 7.

[1]Following Mel'čuk (2006), we distinguish between morphs, elementary linguistic signs (segments), and morphemes, equivalence classes with identical signified and close signifiers.

2 Related work

Many studies have used morphology for terminological analysis. This is more particularly the case in the biomedical domain where terminologies are central to many applications and where terms are constructed by operations like neo-classical composition (e.g. *chemotherapy*, built from the Greek pseudo-word *chemo*, and *therapy*), which are very regular, and very productive. Unfortunately, no comprehensive database of morphs with semantic information is available, and splitting a term into morphs is still an issue. One can distinguish two views of the use of morphology as a tool for term (or word) analysis. In the lexematic view, relations between terms rely on the word form, but without the need to split them into morphs (Grabar and Zweigenbaum, 2002; Claveau and L'Homme, 2005; Hathout, 2009). Beside this implicit use of morphology, the morphemic view chiefly relies on splitting the term into morphs as a first step. Many studies have been made in this framework. They either rely on partially manual approaches in which an expert gives morphs and combination rules (Deléger et al., 2008; Markó et al., 2005a) or heuristics (Baud et al., 1999), or on more automatic approaches. The latter usually try to find recurrent letter patterns in word lists as morph-candidates (Kurimo et al., 2010). But such techniques cannot associate a semantic meaning with these morphs. To our knowledge, our approach is the first to make the most of a pivot language to perform an automatic morphological analysis, as we propose in this study. It can be explained by three peculiarities of the biomedical domain: the morphology of its terms is known to be very regular, with few exceptions, the morphological composition (producing compounds) is very fertile, and there exists many multilingual terminologies.

From a more technical point of view, the use of a bilingual terminology also evokes studies in transliteration, particularly Katakana or Arabic (Tsuji et al., 2002; Knight and Graehl, 1998, for example), or in translation. In this framework, Morin and Daille (2010) propose to map complex terms written in Kanjis with French ones, by using morphological rules. Yet, here again, these rules are to be given by an expert, and this study only concerns a special case of derivation. Moreover such an approach cannot handle neo-classical compounds. In other studies, translation methods for biomedical terms which considers terms as simple sequences of letters have been proposed (Claveau, 2009, inter alia). Such approaches share some similarities with the one presented here: they require aligning the words at the letter level. In most cases, this is performed with 1-1 alignment algorithms (one character, possibly empty, of the source language word is aligned with one another character of the target language word), but in recent work about phonetization (Jiampojamarn et al., 2007), authors have shown that the interest of *many-to-many* alignment.

Concerning the use of morphological processing in Information Retrieval, the literature is more important (Moreau and Sébillot, 2005, for a panorama). Although the results depend on numerous factors (language, morphological tool, size of collection, domain...), there is a broad consensus about the benefit of simple processes like *stemming* (or, rarer in IR, lemmatization): such tools are available in many languages, conceptually simple, and they usually improve the results of IR systems. It is noteworthy that the only morphological phenomena addressed by these tools are inflection and derivation. As they mostly perform simple operations on the prefix and suffix of the words, morphological composition remains out of their scope. Yet, many authors have noted the importance of clever tokenisation based on morpheme for the biomedical indexing (Jiang and Zhai, 2007; Trieschnigg et al., 2007), but without proposing effective solutions. Recently, advanced morphological tools developed in the framework of MorphoChallenge have been applied to IR problems (Kurimo

et al., 2009). Here again, the authors have observed an improvement for some languages, such as Finnish which is highly compositional, but results on English were significantly lower than when using a simple stemmer. In that respect, the good results presented in the next sections confirm the interest of our approach.

3 Analogy for Alignment

As it was previously explained, our morphological decomposition technique relies on the alignment of terms with their translation in a pivot language (Japanese, Kanjis). Thus, this approach makes a strong parallelism assumption: the term in Kanjis must be built in the same way than the one in the studied language. This hypothesis may appear as unrealistic, but the results presented hereafter show that it is reasonable. It is noteworthy that the choice of Kanjis as pivot is not fortuitous. Kanjis do not have morphology, their form is therefore invariable whatever their position in the term. One only needs to test a few combinations when trying to segment a term made of Kanjis, compared with a term written with the latin alphabet. Kanjis are independent of the Greek and Latin roots used in most European languages. This prevents learning irrelevant regularities based on common etymology. Last, a segment of a Kanji term is most of the time a valid Kanji term by itself (to the contrary of morphs). It is thus possible to use dictionaries to access their meaning. These different reasons make Kanji-based Japanese a very good pivot when compared to other alternatives.

Our alignment technique is mainly based on an *Expectation-Maximization* (EM) algorithm that we briefly present in the next sub-section (Jiampojamarn et al., 2007, for more details and examples of its use). The second sub-section explains the modification made to this standard algorithm so that it can naturally and automatically handle morphological variation, which is a phenomenon inherent to our morph splitting problem.

3.1 EM Alignment

The alignment algorithm at the heart of our approach is standard: it is a *Baum-Welch* algorithm, extended to map symbol sub-sequences and not only 1-1 alignments. In our case, it takes as input French terms with their Kanji translations, taken from a multilingual terminology for instance. The maximum length of the sub-sequences of letters and Kanjis considered for alignment are parametrized by $maxX$ and $maxY$.

For each term pair (x^T, y^V) to be aligned (T and V being the lengths of the terms in letters or Kanjis), the EM algorithm (see Algorithm 1) proceeds as follows. It first computes the partial counts of every possible mapping between sub-sequences of Kanjis and letters (*Expectation* step). These counts are stored in table γ, and are then used to estimate the alignment probabilities in table δ (*Maximization* step).

The *Expectation* step relies on a *forward-backward* approach (Algorithm 4): it computes the *forward* probabilities α and *backward* probabilities β. For each position t, v in the terms, $\alpha_{t,v}$ is the sum of the probabilities of all the possible alignments of (x_1^t, y_1^v), that is, from the beginning of the terms to the current position, according to the current alignment probabilities in δ (cf. Algorithm 2). $\beta_{t,v}$ is computed in a similar way by considering (x_t^T, y_v^V). These probabilities are then used to re-estimate the counts in γ. In this version of the EM algorithm, the *Maximization* (Algorithm 3) simply consists in computing the δ alignment probabilities by normalizing the counts in γ.

Algorithm 1 *EM Algorithm*

Input: list of pairs (x^T, y^V), $maxX$, $maxY$
while changes in δ **do**
 initialization of γ to 0
 for all pair (x^T, y^V) **do**
  γ = Expectation(x^T, y^V, $maxX$, $maxY$, γ)
 δ = Maximization(γ)
return δ

Algorithm 2 *Forward-many2many*

Input: (x^T, y^V), $maxX$, $maxY$
$\alpha_{0,0} := 1$
for $t = 0...T$ **do**
 for $v = 0...V$ **do**
  if $(t > 0 \vee v > 0)$ **then**
   $\alpha_{t,v} = 0$
  if $(v > 0 \wedge t > 0)$ **then**
   for $i = 1...maxX$ s.t. $t - i \geq 0$ **do**
    for $j = 1...maxY$ s.t. $v - j \geq 0$ **do**
     $\alpha_{t,v} \mathrel{+}= \delta(x^t_{t-i+1}, y^v_{v-j+1})\alpha_{t-i,v-j}$
return α

Algorithm 3 *Maximization*

Input: γ
for all sub-sequence a s.t. $\gamma(a, \cdot) > 0$ **do**
 for all sub-sequence b s.t. $\gamma(a, b) > 0$ **do**
  $\delta(a, b) = \frac{\gamma(a,b)}{\Sigma_x \gamma(a,x)}$
return δ

Algorithm 4 *Expectation*

Input: (x^T, y^V), $maxX$, $maxY$, γ
α := Forward-many2many(x^T, y^V, $maxX$, $maxY$)
β := Backward-many2many(x^T, y^V, $maxX$, $maxY$)
if $\alpha_{T,V} > 0$ **then**
 for $t = 1...T$ **do**
  for $v = 1...V$ **do**
   for $i = 1...maxX$ s.t. $t - i \geq 0$ **do**
    for $j = 1...maxY$ s.t. $v - j \geq 0$ **do**
     $\gamma(x^t_{t-i+1}, y^v_{v-j+1}) \mathrel{+}= \frac{\alpha_{t-i,v-j}\delta(x^t_{t-i+1}, y^v_{v-j+1})\beta_{t,v}}{\alpha^{T,V}}$
return γ

The EM process is repeated until the probabilities δ are stable. When the convergence is reached, the alignment simply consists in finding the mapping that maximizes $\alpha(T, V)$. In addition to this resulting alignment, we also store the final alignment probabilities δ, which are used to split unseen terms (cf. Section 6.2).

This technique is not very different from the one used in statistical translation. Yet, some particularities are worth noting: this approach allows us to handle *fertility*, that is the capacity to align from or to empty substrings (for lack of space, it does not appear in the above simplified version); conversely, *distortion*, that is reordering of morphs, cannot be handled easily without major changes in this algorithm.

3.2 Automatic morphological normalisation

The maximization step simply compute the translation probabilities of a Kanji sequence into a letter sequence. For example, for the Kanji 菌 ('*bacteria*'), there may exist one entry in δ associating it with bactérie, one with bactério (as in bactério/lyse) and another one with bactéri (in myco/bactéri/ose), each with a certain probability. This dispersion of probabilities, which is of course harmful for the algorithm, is caused by morphemic variation: bactério, bactérie, and bactéri are 3 morphs of the same morpheme, and we would like their probabilities to reinforce each other. The adaptation we propose aims at making the maximization phase able to automatically group the different morphs belonging to a same morpheme. To achieve this goal, we use a simple but well suited technique relying on formal analogical calculus.

3.2.1 Analogy

An analogy is a relation between 4 elements that we note: $a : b :: c : d$ which can be read *a is for b what c is for d* (Lepage, 2000, for more details about analogies). Analogies have been

used in many NLP studies, especially for translation of sentences (Lepage, 2000) or terms (Langlais and Patry, 2007; Langlais et al., 2008). Analogies are also a key component in the previously mentioned work on terminology structuring (Claveau and L'Homme, 2005). We rely on this latter work to formalize our normalization problem. In our framework, one possible analogy may be: dermato : dermo :: hémato : hémo. Knowing that dermato and dermo belong to a same morpheme, one can infer that this is the case for hémato and hémo. Such an analogy, build on the graphemic representation of words, is said a formal analogy.

After Stroppa and Yvon (2005), formal analogies can be defined in terms of factorizations. Let us note $\overleftarrow{\oplus}$ the (non-commutative) concatenation operator at the right ($abc\overleftarrow{\oplus}d = abcd$), and $\overleftarrow{\ominus}$ its associated string subtraction operator ($abc\overleftarrow{\oplus}d\overleftarrow{\ominus}d = abc\overleftarrow{\ominus}c\overleftarrow{\oplus}c = abc$), and similarly for $\overrightarrow{\oplus}$ and $\overrightarrow{\ominus}$ operating at the left of the first argument. Let a be a string (a term in our case) over an alphabet Σ, a factorization of a, noted f_a, is a sequence of n factors $f_a = (f_a^1, ..., f_a^n)$, such that $a = f_a^1 \overleftarrow{\oplus} f_a^2 \overleftarrow{\oplus} ... \overleftarrow{\oplus} f_a^n$. A formal analogy can be defined by as:

Definition 1 $\forall (a,b,c,d) \in \Sigma, [a : b :: c : d]$ *iff there exist factorizations* $(f_a, f_b, f_c, f_d) \in (\Sigma^{*n})^4$ *of* (a,b,c,d) *such that,* $\forall i \in [1,n], (f_b^i, f_c^i) \in \left\{(f_a^i, f_d^i), (f_d^i, f_a^i)\right\}$ *. The smallest n for which this definition holds is called the degree of the analogy.*

For most European languages, as French and English, morphology is mostly concerned with prefixation and suffixation. Thus, we are looking for formal analogies of degree at most 3 (ie, 3 factors: prefix $\oplus$ base $\oplus$ suffix). In our approach, such analogies are searched by trying to build a rule rewriting the prefixes and the suffixes to move from dermato to dermo and to check that this rule also applies to hémato-hémo. The base is considered as the longest common sub-string (lcss) between the 2 words. In the previous example, the rewriting rule r would be:
$r = \text{lcss}(\text{morph}_1,\text{morph}_2) \overleftarrow{\ominus} \text{ato} \overleftarrow{\oplus} \text{o}$.
This rule makes it possible to rewrite dermato into dermo and hémato into hémo; thus, hémato,hémo is in analogy with dermato,dermo.

3.2.2 Using analogy for normalization

The main problem is that we do not have examples of morphs that are known a priori to be related (like dermato and dermo in the previous example). Thus, we use a simple bootstrapping technique: if two morphs are stored in γ as possible translations of the same Kanji sequence, and if these two morphs share a sub-string longer than a certain threshold, then we assume that they both belong to the same morpheme. From these bootstrap pairs, we build the prefixation and suffixation rewriting rules allowing us to detect analogies, and thus to group pairs of morphs (which can be very short, unlike the bootstrapping pairs). The more a rule is found, the more certain it will be. Therefore, we keep all the analogical rules generated at each iteration along with their number of occurrence, and we only apply the most frequently found ones. The whole process is thus completely automatic.

This new *Maximization* step is summarized in Algorithm 5. It ensures that all the morphs supposed to belong to the same morpheme have equal and reinforced alignment probabilities.

4 Semi-supervision and bootstrapping

The approach described above can be considered as unsupervised since no example of alignment or decomposition is provided. Yet, in some cases, expert knowledge is available

Algorithm 5 *Maximization* with analogical normalization

Input: γ
for all sub-sequence a s.t. $\gamma(a, \cdot) > 0$ **do**
 for all m_1, m_2 s.t. $\gamma(a, m_1) > 0 \wedge \gamma(a, m_2) > 0 \wedge$ lcss$(m_1, m_2) >$ threshold **do**
  build the prefixation and suffixation rule r for m_1, m_2
  increment the score of r
 for all sub-sequence b s.t. $\gamma(a, b) > 0$ **do**
  build the set $\mathscr{M}$ of all morphs associated to b with the help of the n most frequent analogical rules from the previous iteration
  $\delta(a, b) = \frac{\sum_{c \in \mathscr{M}} \gamma(a, c)}{\sum_{x} \gamma(a, x)}$
return δ

and can be used to add some supervision to this morpho-semantic alignment task. It is important to note that this human intervention can be more or less costly and requires more or less expertise. While manually building a full morphological resource from scratch is a tedious task, providing light information during the alignment process is more accessible. In the following sub-sections, we propose different strategies to improve the unsupervised alignment process, implementing different trade-off between human cost and performance.

4.1 Active alignment

In analogy with active learning (Settles, 2009), the first semi-supervised strategy that we propose is active alignment. Its principle is the following: a human expert, the oracle, adds information about the pair during the expectation step. Different information can be used: decomposition of the Kanji term, of the English term, partial or full alignment. The interest of these pieces of information is twofold. First, it helps reduce the complexity, by avoiding to consider certain alignments in the pair. Secondly, it possibly improves the final results by reinforcing the probability for this pair on a few realistic alignments.

From an algorithmic point-of-view, the implementation is straightforward. The information provided by the oracle is interpreted as a set of constraints on the possible decomposition and/or alignments used to compute $\alpha_{t,v}$, $\beta_{t,v}$, and $\gamma(x_{t-i+1}^{t}, y_{v-j+1}^{v})$ in the Forward, Backward, and Expectation steps respectively.

As for active learning, one can think of different strategies to choose the pairs to be presented to the oracle (Settles, 2009). The goal is of course to find the strategy that best *helps* the alignment algorithm and thus results in a faster convergence and/or better performance. In this paper, two strategies are experimented and both will ask the oracle for providing full alignment of a pair. The first one is a random strategy and serves as baseline: at each iteration, randomly selected pairs are proposed to the oracle. The second strategy is a difficulty-driven one: at each iteration, pairs with many equi-probable alignments are proposed to the oracle. In practice, the equi-probability is measured with the probability gathered at the previous iteration.

4.2 Bootstrapping the oracle

The previous active alignment approach can also be used, to some extent, without human intervention. Indeed, when processing multiple languages, it is sometimes possible to make the most of the existing probabilities from a language L1 to help estimate the alignment

probabilities for the new language L2. Several ways to use these alignment probabilities of other languages can be imagined. In the experiments presented below, we used a simple approach. We adopt the difficulty-driven presented above, but instead of presenting the pairs (of L2) to a human oracle, they are processed as follows:
– if the Kanji term is known in the L1 alignment pairs, the closest term of L1 (edit distance) among the known translations is chosen; this L1-term and the Kanji term are then aligned and the alignment is propagated to the L2 pair. This step is done by representing alignment as characters in the L1 term and by adding the marks in L2 so that it minimizes the edit distance.
– if the Kanji is not known, the most probable alignment, based on the previous iteration probabilities is proposed.

5 Experiments

5.1 Evaluation Data

The data used in the experiments presented below come from the UMLS MetaThesaurus (Tuttle et al., 1990). The MetaThesaurus groups several terminologies for several languages and associates to each term a concept identifier (CUI). The CUI are language independent and thus make it easy to build lists of terms in the spotted language with their Japanese equivalents. In this paper, we present experiments for English and French. In both cases, we only considered Japanese terms composed of Kanjis, and only simple (one-word) French or English terms. About 14,000 English-Kanjis pairs and 8,000 French-Kanjis ones are formed this way. An ending mark (';') is added to each French or English term.

We randomly selected 1,600 pairs for French and 500 for English in order to evaluate the performance of our alignment technique. These pairs have been aligned manually to serve as gold standard.

5.2 Alignment results

In the different experiments presented below, the performance is evaluated in terms of precision: an alignment is counted as correct only if all the components of the pair are correctly aligned (thus, it is equivalent to the sentence error rate in standard machine translation).

For each pair, the EM algorithm indicates the probability of the proposed alignment. Therefore, it is possible to only consider alignments having a probability greater than a given threshold. By varying this threshold, we can compute a precision according to the number of terms aligned. Figures 1 and 2 respectively present the results obtained on the French and English test pairs. We indicate the curves produced by the EM algorithm with and without our morphemic normalization. For comparison purpose, we also report the results of giza++ (Och and Ney, 2003), a reference tool in machine translation. The different IBM models and sets of parameters available in giza++ were tested; the results reported are the best ones (obtained with IBM model 4 without distortion).

As expected, the interest of the morphemic normalization appears clearly in these two experiments; in the worst case (that is, when all the terms are kept for alignment), it yields a 70% precision for French and 80% for English. Indeed, the normalization brings a 10% improvement whatever the number of aligned pairs. Normalization also has an interest

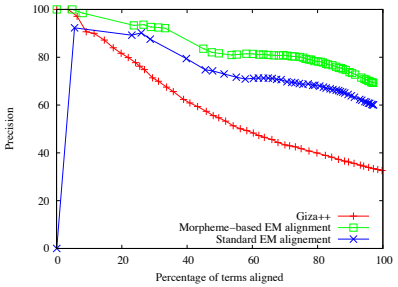

Figure 1: Precision of French-Kanji alignment according to the number of test pairs aligned

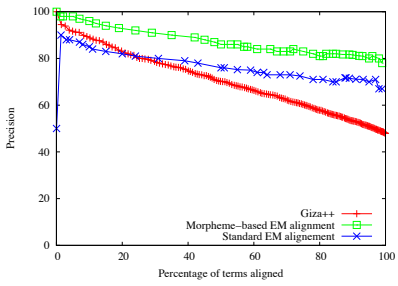

Figure 2: Precision of English-Kanji alignment according to the number of test pairs aligned

in terms of complexity since it reduces the needed iteration number by improving the convergence of the EM estimation.

A manual examination of the results shows that most of the errors are caused by the falsification of our hypothesis: some French-Japanese pairs cannot be decomposed in a similar way. For example, the French term anxiolytiques (anxiolytics) is translated by a sequence of Kanjis meaning literally 'drugs for depression'. Among these errors, some pairs imply terms that are not neo-classical compounds in French, Japanese or both (eg. méninges (meninges) is translated by 膜 'brain membrane'). Other errors are caused by a lack of training data: some morphs or sequences only appear once, or only combined with another morph, which mislead the segmentation.

5.3 Semi-supervised approaches

To compare the two active alignment strategies and the bootstrapped one presented in Section 4, we are interested in the alignment performance and the convergence speed. Thus, Figure 4 presents, for these three semi-supervised approaches together with the original unsupervised version, the precision on the French dataset after different number of iterations of the EM loop. For comparison purposes, we also report the results of the original unsupervised version. For a fair comparison between the unsupervised versions requiring the oracle, the same amount of pairs (20) is presented to the oracle at each iteration. The bootstrapped version is based on the alignment probabilities gathered from the English-Kanji alignment task. Of course, to prevent any bias, none of the pairs processed by the oracle are used as test pairs.

As expected, the three active alignment strategies converge faster than the original one, but also yield better overall results. Adding information at each iteration clearly helps the alignment to produce more relevant association between Kanjis and morphs. The difficulty-driven strategy obtains good results. In particular, it outperforms the random strategy after a few iterations. Before that, when iteration < 5, the probabilities collected are not reliable enough to propose interesting pairs to the oracle, and the oracle even seems to decrease the performance of the alignment. The combination of this strategy with the

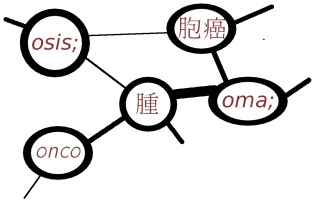

Figure 3: Morpheme-Kanji graph

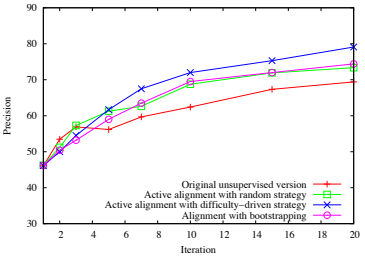

Figure 4: Precision of semi-supervised and unsupervised alignments according to the number of iterations

bootstrapping also performs better than the original version, but not as well as the real oracle one. This result can be explained by the fact that the difficulty-driven strategy asks for pairs that are difficult to align, not only for the studied language (here, French), but also for the one serving as bootstrap (English). Nonetheless, it still remains a good option to improve the results without any human supervision.

6 Morpho-semantic analysis for Information Retrieval

As it was previously said, biomedical Information Retrieval (IR) has some important characteristics due to the use of specialized terms. In that respect, taking into account rich morphological information has already been proved useful, but only with hand-crafted resources (Markó et al., 2005b). Beside the intrinsic evaluation of our approach presented in the previous section, we evaluate its use in a large scale IR experiment in English.

6.1 Morpho-semantic graphs

Once all the terms are aligned, one can study the recurrent correspondences between English morphs and Kanjis. The more a morph is aligned with a sequence of Kanjis, the more they are 'semantically' related. All these links can be represented as a graph: the vertices represent Kanjis and morphemes (i.e a set of morphs grouped during the analogical step of the alignment), and the edges are weighted according to the number of times that a particular morpheme is aligned with a Kanji sequence among the 14,000 training pairs from the umls. Figure 3 shows a toy example of such a graph. The size of the edge lines is proportional to the associated weight.

This representation allows us to shed light on different types of semantic relations between the morphemes. It is done by exploring the neighborhood of each morpheme: each vertex receives an amount of energy which is propagated to the connected vertices proportionally to the edge's weight. For instance, Figure 5 presents the closest morphemes reached, in the form of tag clouds, for the French morpheme ome (oma in English, a suffix for cancer-related terms). The size and color represent the energy that reach the neighboring morpheme vertices. The reached vertices are expected to be conceptually related and to exhibit synonym or quasi-synonym morphemes of the suffix ome. It is interesting to see that other

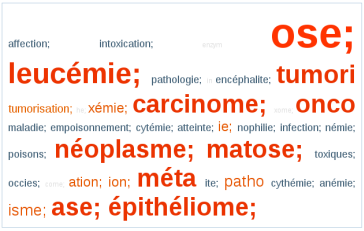

Figure 5: Cloud of 1st order affinities for French morpheme ome

Figure 6: Cloud of 2nd order affinities for French morpheme gastro

related suffixes are found, but also prefixes like onco.

The alignment and the segmentation produced by our algorithm also make it possible to study the co-occurrences of morphemes in English (or French) terms. One can study first-order affinities (which morphemes are frequently associated with other morphemes) and, more interesting, second order affinities (morphemes sharing the same co-occurring morphemes). The second-order affinity allows us to group morpheme according to their paradigm. For instance, the tag cloud in Figure 6 illustrates the morphemes associated with gastro (morpheme for stomach) according to this second order affinity. Most of the morphemes identify organs, and the closest ones are for biologically close organs.

This information of different nature makes it possible to identify relationships between terms, or build synonyms, or explore the termbase using these morphological elements. Yet, to our knowledge, such specialized morpho-semantic resources do not exist. It makes a direct evaluation of these three different uses of the alignment results not possible. But in the remaining of this paper, we propose to evaluate them in an Information Retrieval framework.

6.2 Morphemic representation for Information Retrieval

In order to integrate the morphological information in an IR system, we adopt a simple indexing representation: the documents are considered as bags-of-morphemes and words. The morphemes are those obtained by decomposing biomedical terms, and for some experiments those associated to the former ones as second order affinities. The goal is of course to be able to associate a query containing stomachalgia with a document containing gastrodynia.

Thus, when indexing the collection, terms are decomposed. Two cases may occur: the term is either known as it appears in the alignment pairs, either not. In the first case, we simply use the decomposition produced by the alignment algorithm. In the second case, we make the most of the δ probabilities to generate the most probable translation. To do so, we use a simple approach: the translation probability in δ are used by a Viterbi algorithm to generate the most probable Kanji translation. We do not use language modeling. It is

important to note that this translation process produces at the same time the decomposition of the initial term by associating each morph with its Kanji translation. This translation process is thus equivalent to the desired morpho-semantic analysis for unknown terms (i.e. absent from the pair list used in the alignment step).

In these two cases, another alignment product is also used: the analogical rewriting rules collected at the last alignment iteration. They allow us to detect the morphs belonging to a same morpheme. Such information makes it possible to match a query containing hemo with a document containing haemo, hemato or even emia;.

A *baseline* system and four indexing systems using the morphological information are proposed. They all rely on a standard IR approach, namely a vector space model with an Okapi BM25 weighting scheme (Robertson et al., 1998, for details, see) and a tokenizer similar to Terrier's one (Ounis et al., 2006); the standard values of the BM25 parameters b, k_1, k_3 have been kept. The *baseline* system performs a standard indexing of the documents with a Porter stemming (Porter, 1980).
1 – The first morphologically-enhanced system is morpheme-based. It simply considers the morphemes produced by the decomposition of the term in the documents (and queries) as words to index (the original terms are no longer used for indexing, only its morphemes). The morpheme weights take the decomposition probability into account; it is defined as the product of this probability and the BM-25 weight.
2 – The second system is Kanji-based. Here again, the terms of the documents are decomposed, and the closest Kanjis are used as indexing words. These Kanjis are those identified in the neighborhood of the morphs produced when decomposing the terms (see Section 6.1).
3 – The third system adopts the same morpheme-based representation as the first system, but expands the queries with first-order affinities of their morphemes. The morphemes used as expansion are weighted according to their proximity in the graph and the weight of the morphemes that they expand.
4 – The last system is similar to the third one but uses the second-order affinities to expand the queries.

7 Biomedical IR experiments

7.1 Experimental setting

For the following experiments, we use the dataset built for the filtering track of the TREC-9 conference. This dataset is itself based on the document collection ohsumed, which is composed of about 350,000 medline abstracts. In addition to this, about 4,000 queries and the corresponding relevance judgments were developed for TREC-9. The queries are composed of several fields: the subject, which a MeSH term, and a definition of this term. Although the collection was initially built for evaluating filtering systems, here we use this dataset as a standard IR collection, and only consider the subject field as the query.

7.2 Results

Table 1 presents the results of the baseline IR system and the system based on the morphological analysis. The performance of the systems are evaluated using the standard IR evaluation measures: we compute precision on top 5, 10... 1,000 documents (P@x), mean average precision (MAP), interpolated average precision (IAP) and the R-precision

	baseline (BM-25 + stemming)	System 1 morpheme-based	System 2 Kanji-based
MAP	29.93	33.94 (+13.4 %)	32.76 (+9.5 %)
IAP	31.74	35.55 (+12 %)	34.49 (+8.6 %)
R-prec	35.28	39.64 (+12.3 %)	38.59 (+9.4 %)
P@5	69.87	73.45 (+5.1 %)	71.70 (+2.6 %)
P@10	67.99	71.31 (+4.9 %)	*69.65 (+2.4 %)*
P@50	52.98	56.90 (+7.4 %)	55.24 (+4.3 %)
P@100	40.86	44.56 (+9.1 %)	43.39 (+6.2 %)
P@500	15.11	17.21 (+13.9 %)	16.92 (+12 %)
P@1000	8.72	10.10 (+15.86 %)	9.95 (+14.2 %)

Table 1: Performance of the morpheme and Kanji based IR systems on the OHSUMED collection, with the TREC queries

(R-prec).In order to assess if the differences between the two systems are statistically significant, we run a Wilcoxon test ($p = 0.05$) (Hull, 1993); those differences with the *baseline* that are not judged statistically significant are italicized.

The morpheme-based system, only relying on decomposing term and grouping its morph into morpheme, yields very good results with a 13% MAP gain. As expected, decomposing the terms improves more specifically the performance at the end of the retrieved document list (P@100 and higher), since it makes it possible to retrieve relevant documents even though they do not contain the exact terms of the queries. The Kanji-based system yields very similar results. Although the Kanjis were expected to be a more generic representation, no additional gain is obtained. In practice, in some queries, the Kanjis are too generic to capture the specific meaning expected or bring no additional information compared with the original morphemes. Moreover, no selection is performed on the morpheme to be translated into Kanjis, and some Kanjis have properties (document frequencies) that highly differ from the source morpheme since they can be translation of different morphemes. A weighting scheme taking the initial document frequencies into account seems an important foreseen work.

Table 2 presents the results of the two last systems, based on query expansion. The two expansion-based systems have more contrasted results. On the one hand, expanding the queries with first-order affinities gives good results; although it yields a lower precision at the top of list than system 1, it obtains a slightly better recall. On the other hand, second-order affinities produce bad results compared with morphological decomposition alone. The affinities added to the query, most of the time, break the specificity of the information asked; it makes the system retrieve too much non-related documents.

8 Conclusion and future work

The original idea of making the most of another language like Japanese in order to help the morphological decomposition and analysis of compounds offers many new opportunities to automatically handle biomedical terms. The new alignment approach based on analogy that we propose takes the particularities of the data into account, and also offers different ways to balance quality, convergence speed and human intervention through the semi-supervised approaches proposed. The high quality results obtained allow us to address IR problems

	baseline (BM-25 + stemming)	System with 1st order affinities	System with 2nd order affinities
MAP	29.93	34.40 (+14.9 %)	28.74 (-3.9 %)
IAP	31.74	36.63 (+15.4 %)	30.80 (-2.9 %)
R-prec	35.28	39.92 (+13.2 %)	34.38 (-2.6 %)
P@5	69.87	71.76 (+2.7 %)	*68.65 (-1.7 %)*
P@10	67.99	70.46 (+3.6 %)	*66.20 (-2.6 %)*
P@50	52.98	56.30 (+6.7 %)	50.50 (-4.68 %)
P@100	40.86	44.69 (+9.4 %)	39.07 (-4.38 %)
P@500	15.11	17.98 (+18.9 %)	*15.01 (-0.64 %)*
P@1000	8.72	10.56 (+21.1 %)	*8.77 +0.66 %)*

Table 2: Performance of the expansion based IR systems on the OHSUMED collection, with the TREC queries.

caused by the morphological complexity of the biomedical terminology that could not be addressed with usual IR tools like stemmers. In this respect, our concerns about the role of morphology to access information are similar to existing studies (Markó et al., 2005a; Deléger et al., 2008), but to our knowledge, we are the first to propose an automatic process, directly available for many languages. Of course, our approach chiefly relies on the availability of multilingual terminologies, but such databases like UMLS are now widely developed, on the contrary of usable morphological resources.

Many perspectives are foreseen from this work. First, from a technical point of view, we plan to consider more complex segmentation than the linear one we implemented. Indeed, the syntactic properties of the Kanjis (some of them expect an agent or object), could help to better structure the different morphemes. One could also exploit the semantic relations between Kanjis that can be easily found in general Japanese dictionaries.

Concerning the analysis aspects illustrated in the last section, many possibilities are also under consideration. As the links between morphs that we produce are not typed, the use of heuristics (such as string inclusion used by Grabar and Zweigenbaum (2002)) or techniques from distributional analysis could provide useful additional information to better characterize the relationships. Yet, the problem of evaluating this type of work arises, especially the ground truth construction, since such resources do not exist. The IR setting used in this paper could be used again, possibly with more biomedical collections such as the TREC Genomics ones (Hersch and Voorhees, 2009).

Finally, an adaptation of these principles for complex terms is under study. The main difficulty in this case is to manage the reordering of the words composing these terms, and thus manage the distortion in the alignment algorithm. This issue is important for IR since these multiword terms are known to occurs with many variants and thus prevent to match queries and documents with different variants of the same term (Nenadic et al., 2005).

ABSTRACT
Named entity recognition (NER) has been extensively studied for the names of genes and gene products but there are few proposed solutions for phenotypes. Phenotype terms are expected to play a key role in inferring gene function in complex heritable diseases but are intrinsically difficult to analyse due to their complex semantics and scale. In contrast to previous approaches we evaluate state-of-the-art techniques involving the fusion of machine learning on a rich feature set with evidence from extant domain knowledge-sources. The techniques are validated on two gold standard collections including a novel annotated collection of 112 abstracts derived from a systematic search of the Online Mendelian Inheritance of Man database for auto-immune diseases. Encouragingly the hybrid model outperforms a HMM, a CRF and a pure knowledge-based method to achieve an F1 of 77.07. Disagreement analysis points to further improvements on this emerging NE task. The annotated corpus and guidelines are available on request.

1 Introduction

Biomedical named entity recognition (NER) is a computational technique used to identify and classify strings of text (*mentions*) that designate important concepts in biomedicine. Over the last fourteen years there has been considerable interest in this problem with a variety of generic and entity-specific algorithms applied to extract the names of genes, gene products, cells, chemical compounds and diseases (Fukuda et al., 1998; Rindflesch et al., 1999; Collier et al., 2000; Kazama et al., 2002; Zhou et al., 2003; Settles, 2004; Kim et al., 2004; Leaman and Gonzalez, 2008). As the first stage in the integrated semantic linking of knowledge between literature and structured databases it is critically important to maximise the effectiveness of this step.

Despite significant progress in NER there is still no one size fits all solution. Barriers arise because of ambiguity in the text and coding schema. Ambiguity in the text comes in various forms according to the semantic type of the entity but can be caused by a lack of standard nomenclatures, extensive and growing nomenclatures for proteins/genes across multiple organisms or the widespread use of abbreviations and descriptive names. For example, (Krauthammer and Nenadic, 2004) illustrate uncontrolled naming in genes with *bridge of sevenless (boss)* (FlyBase ID FBgn0000206) and Hunter and Bretonnel Cohen (2006) discuss term class ambiguity (e.g. is *group* a chemical entity or an assemblage of organisms?). Such challenges have led to a variety of proposed solutions involving a wide range of resources. Among these, linguistically annotated corpora such as GENIA (Tateisi et al., 2000; Kim et al., 2003) have proven to be central to the NER solution. However due to the size of the vocabularies involved, annotated corpora by themselves do not provide a complete solution. Researchers have therefore also looked at the rich availability of formally structured biomedical knowledge (ontologies) such as the Unified Medical Language System (UMLS) (Bodenreider et al., 2002) and the Gene Ontology (Gene Ontology Consortium, 2000). Nevertheless corpora remain a key part of the solution as they provide the contextual evidence that link mentions to terms through the author's intentions. Creating such resources though is time consuming and expensive, especially when annotating new semantic types and relations.

In this paper we focus on the analysis and identification of a new class of entity: phenotypes. Two thoughts motivate this: (1) The database curation community has expressed a wish for full text entity indexing and the inclusion of phenotypes (Dowell et al., 2009; Hirschman et al., 2012), and (2) Biomedicine is rapidly moving towards full-scale integration of data, opening up the possibility to understand complex heritable diseases caused by genes. Association studies involving phenotypes are considered important to making progress (Lage et al., 2007; Wu et al., 2008). The ultimate goal of the work we present here is to allow relations mined from sentences such as the one we annotated below to feed into novel hypothesis generation procedures. From Ex 1. the reader can easily infer a relation between *IgG1 disorder* and three genes/gene products marked as GGP.

Ex 1. *Among* $[\text{patients}]_{ORG}$ *with* $[\text{systemic lupus erythematosus}]_{DIS}$ *(*$[\text{SLE}]_{DIS}$*), those with the* $[\text{IgG1 disorder}]_{PHEN}$ *have a higher prevalence of high titre* $[\text{rheumatoid factor}]_{GGP}$ *and* $[\text{antinuclear antibody}]_{GGP}$*, but a lower prevalence of* $[\text{anti-double-stranded DNA (anti-dsDNA) antibodies}]_{GGP}$ *above 30 U/ml.* (Source PMCID: PMC1003566).

Whilst other authors have tried similar approaches for other entity types, none have tried both machine learning and external resource lookup for a class as rich and semantically complex as phenotypes. The key contributions of this paper are: (1) To provide an operational semantics for identifying phenotype candidates in text, (2) To introduce a set of guidelines and an anno-

tated corpus based on a selection of 19 clinically significant auto-immune diseases from The Online Mendelian Inheritance of Man (OMIM) (Hamosh et al., 2005), one of the most widely used gene-disease databases, and (3) To mitigate linguistic variation whilst still meeting the conceptual expectations of biologists we propose a new named entity solution that uses statistical inference and external manually crafted resources. This method is tested on the new corpus and one extant corpus (Khordad et al., 2011) that has been used in previously reported experiments.

2 The challenge of phenotypes

Freimer and Sabatti (2003) describe phenotypes as referring to '*any morphologic, biochemical, physiological or behavioral characteristic of an organism. ...All phenotypic characteristics represent the expression of particular genotypes combined with the effects of specific environmental influences.*' Despite recent data integration efforts for phenotypes such as (Robinson and Mundlos, 2010), phenotypic descriptions still tend to be author/study specific and biological results may go undiscovered if the terms used lie outside an author's immediate research area (Bard and Rhee, 2004). Again, unlike genes or anatomic structures, phenotypes and their traits are complex concepts and do not constitute a homogeneous class of objects (i.e. a natural kind).

Traits such as 'eye colour', 'blood group', 'hemoglobin concentration' or 'facial grimacing' describe morphological structures, physiological processes and behaviours. When qualities or quantities of traits are used to describe a specific organism then we have phenotypic descriptions, e.g. 'blue eyes', 'blood group AB', 'not having between 13 and 18 gm/dl hemoglobin concentration'.

Traits and phenotypes can apply at all levels of anatomical granularity from chemical structures to cells and organs making it difficult to know where to draw a boundary. Phenotypes can include quantifications that are either specific (e.g. '18 gm/dl') or relative (e.g. 'normal' or 'increased'). Accordingly the first part of this paper deals with specifying exactly what we mean by the concepts of 'phenotype' with reference to current ontological research.

3 Methods

3.1 Schema

We employed two types of entity in our study: gene/gene product (GGP) and bodily feature (BF). GGP is proposed because (a) a subset of these entities are useful for applications that explore gene-phenotype relations, and (b) it allows us to compare our results against the many biomedical NER studies of the past, e.g. (Kim et al., 2004; Rebholz-Schuhmann et al., 2010). Because of space limitations we will not provide a rigidly formal definition or a taxonomic analysis (Beisswanger et al., 2008). Future work will explore the relationships between these and other entity types.

In line with BioTop (Beisswanger et al., 2008), GGP is relatively straightforward to define by the conjunction of (BioTop ID Nucleic Acid Structure) and (BioTop ID Peptide Structure).

Definition: A GGP (gene/gene product) entity is a mention of one of three major macromolecules DNA, RNA or protein. DNA and RNA are nucleic acid sequences containing the genetic instructions used in the development and function of an organism. Proteins are polypeptide sequences, or parts of polypeptide sequences, folded into structures that facilitate biological function.

Examples include: [cryoglobulins], [anticariolipin antibodies], [AFM044xg3], [chromosome 17q], [CC16 protein] .

Our definition of phenotype was taken from the formal analysis in Scheuermann *et al.* (Scheuermann et al., 2009) who define phenotype as '*A (combination of) bodily features(s) of an organism determined by the interaction of its genetic make-up and environment*'. It is important to recognise that this definition requires us to know the underlying cause. Since causality is often difficult to establish using narrow contextual evidence of the sort used in NER it seems reasonable that we focus here on identifying bodily features themselves, i.e. *phenotype candidates*, and then determine causality in another stage of processing.

Definition: A BF (bodily feature) entity is a mention of a bodily quality in an organism.

Examples include: [lack of kidney], [abnormal cell migration],[absent ankle reflexes] as well as more complex cases such as [no abnormality in his heart], [unfavorable serum lipid levels] and [suceptibility to ulcerative colitis].

Our definition of bodily features require two caveats (a) in contrast to Khordad et al. (2011) we did not apply a granular cut off at the level of cell, and (b) because of the diversity of bodily features across organisms we took a decision to focus our definition of this entity on mouse as a model organism and human as the most important species. Following the discussion of phenotypes as processes in physiology (Hoehndorf et al., 2012) we include some mentions of processes within the scope of our annotation schema.

Linguistic forms of entities require a number of policy decisions to be made about how to annotate mentions in text. For a class as complex as phenotypes this is a particular consideration. Although more complex approaches exist, for simplicity we make the common assumption here that named entities are 'continuous, non-nested and non-overlapping' (Alex et al., 2007). As a basic policy we do not allow embedding of entities within our corpus so annotators have to make a choice of entity class based on the longest matching span even though one entity may contain another entity of the same or a different type. We leave to future work consideration of other approaches, e.g. for handling discontinuous entity mentions. Within our guidelines we describe whether specific, generic, underspecified and negatively quantified mentions qualify. A summary of the rule set (available from the first author) is shown in Table 1. We follow (Magnini et al., 2006) in differentiating between specific, generic and underspecified mentions.

3.2 Annotated data sources

3.2.1 Phenominer

The Phenominer version 1 corpus contains 112 abstracts we selected from PubMed Central (PMC). 19 auto-immune diseases were selected from OMIM and from these records citations were then chosen. Diseases include Type 1 diabetes, Grave's disease, Crohn's disease, autoimmune thyroid disease, multiple sclerosis and inflammatory arthritis. In order to ground the article in discussion about both a disease and a phenotype, citations needed to contain the auto-immune disease term and at least one term from either OMIM's free form clinical synopsis field, the Human Phenotype Ontology (HPO) (Robinson and Mundlos, 2010) or the Mammalian Phenotype Ontology (MP) (Smith and Eppig, 2009).

Despite being small, the number of annotated abstracts is consistent with several previous specialised studies, e.g. (Suakkaphon et al., 2011; Collier et al., 2000). Annotation was carried

	BF	GGP
specific reference	Yes	Yes
generic reference	Yes	Yes
underspecified reference	No	No
modifiers	Yes[1,2]	No
conjunctions	Yes[3]	Yes[3]
processes	Yes[4]	No
negation	Yes[5]	No

Table 1: Referential semantics and scoping of mentions by entity type. Notes on annotation: [1] Quantitative modifiers are included, e.g. [having five fingers] as well as spatial modifiers, e.g. [abnormality in his left hand]. [2] Qualitative modifiers are included such as physical components: [black hair], underspecified ranges: [normal height], locational modifiers: [low set ears], and level modifiers: [quite small fingers].[3] Where there is elision of the head, e.g. [IA/H5 virus], then we annotate the whole expression. Otherwise we annotate each expression separately, e.g. [IA virus] and [H5 virus]. [4] We exclude finite verb forms, infinite verb forms with 'to', verbs in a progressive or perfect aspect, verb phrases, clauses or sentences and any phrase with a relative clause or complement clause. [5] If the negation appears in a noun phrase with an anatomical entity then we generally allow it, e.g. [absent ankle reflexes], [no left kidney].

out by the same highly experienced biomedical annotator who had annotated the GENIA corpus. The total number of tokens (sentences) in the corpus is 26,026 (1976) from which there were 1611 GGP entities and 472 BF entities.

3.2.2 KMR

As a basis of comparison we test our methods on the same corpus and tagging model as Khordad et al. (2011) who used a collection of 3784 tokens (120 sentences) with 110 annotated phenotype mentions. This is designated as the *KMR* corpus. In contrast to the Phenominer corpus sentences in KMR were taken from 4 PubMed papers from the year 2009 in the area of human genetics. Annotation was conducted with reference to the HPO so that a term was tagged as phenotype if it was in the HPO or if it was not in the HPO but its definition showed that it was caused by a genotype (Khordad, 2012). Finally we found that there was no cross over of sentences between the Phenominer and KMR corpora.

3.3 Models

The full system we developed (designated in the Results as *Hybrid*) employs machine learning and knowledge-based approaches, combined together with a rule-based Merge module. This is illustrated in Figure 1. Below we briefly describe its component modules and resources. As a baseline comparison we use Khordad's approach, designated in the Results as *Khordad* and in Figure 1 as the *Rule matching* module - see Khordad et al. (2011).

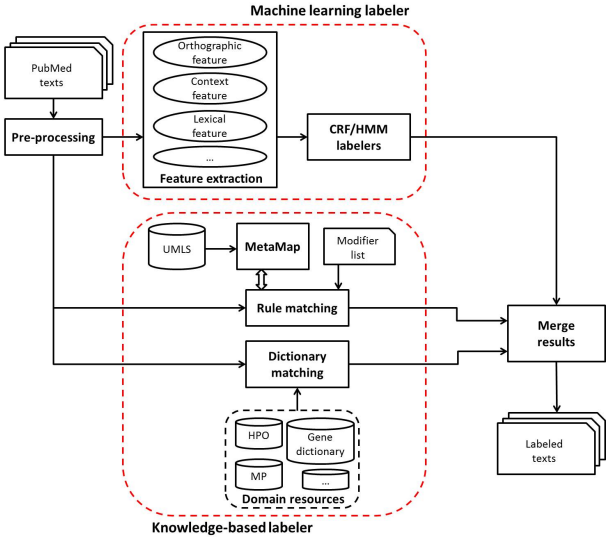

Figure 1: Phenotype tagging architecture

3.3.1 Pre-processing

The text collections are passed into a module which splits texts into sentences and tokens. This was done using the OpenNLP library with a Maximum Entropy model[1]. Abbreviation expansion is then done using BioText (Schwartz and Hearst, 2003) to make a list of local abbreviation occurring in each paper which we then replace with their full form. A similar approach is adopted by Khordad in their staged rules.

3.3.2 Machine learning labeler

Within the machine learning module we compare two widely used sequence labeling models: a second order Hidden Markov Models (HMM) (Rabiner and Juang, 1986; Bikel et al., 1997) with Viterbi decoding and a linear chain Conditional Random Fields (CRF) (Lafferty et al., 2001; McDonald and Pereira, 2005). Both are run as fully supervised models. Class labels for tokens follow the standard BIO system, i.e. each token receives the label O if it is not an NE, B plus the entity name when it starts an entity, and I plus the entity name when it is inside an entity. The main advantage of the CRF over the vanilla HMM is that it estimates the conditional probability distribution over labeled sequences. Both use the freely available Java-based MALLET implementation[2] with default parameters.

Previous research has found that utilizing various features for both the focus word (designated

[1]OpenNLP library: `http://opennlp.apache.org`
[2]Mallet: A machine learning for language toolkit: `http://mallet.cs.umass.edu/`

as w_i) and the surrounding words is crucial to obtain high performance. We take our feature set for BF and GGP labeling from the most typical and effective features used for biomedical NER (Kim et al., 2004). This is summarised in Table 2. Our experiments tested a variety of unigram, bigram and conjoined base features. These were taken from a ±2 window around the focus word for parts of speech, orthography and surface word forms. POS tagging was done using the OpenNLP library with Maximum Entropy model and Genia Corpus + WSJ Corpus (F-score 98.4%), there are 44 Penn Treebank POS tags and all of them are used. The HMM did not use conjoined features due to model memory limitations.

Feature	Description	Example
LX	Current word token	w_i
MM	MetaMap tag of the token[2]	cgab,fndg,neop
OR	Orthography of the token	initCap, isDate, allCap, isDigit
CT	Word token context	
	History context of the token	w_{i-2} , w_{i-1}
	Future context of the token	w_{i+1} , w_{i+2}
	Conjoined context	w_{i-2} . w_{i-1}
POS[1]	Part of speech tag of the token	RB, CD, NN, JJ, NNP

Table 2: Feature sets used in the machine learning labeler. [1]Part of speech tags are assigned by training the GENIA tagger (Tsuruoka et al., 2005). [2] The MetaMap semantic tags are chosen from the same group of 15 semantic types chosen by Khordad which are relevant for phenotypes.

In addition to the Phenominer and Khordad corpora outlined earlier we also make use of the JNLPBA04 corpus (Kim et al., 2004) for training the GGP labeler. The corpus contains 2000 Medline abstracts selected by a search using terms *human, blood cell, transcription factor* and then hand annotated for 5 NE classes including RNA, DNA and protein which we merge to form our GGP class. Table 3 summarises the features exploited by the two learner models.

Model	Target class	Phenominer corpus[1]	JNLPBA04 corpus	LX	MM	OR	CT	POS
HMM	BF	+	-	+	-	-	+	-
CRF	BF	+	-	+	+	+	+	+
HMM	GGP	+	+	+	-	-	+	-
CRF	GGP	+	+	+	+	+	+	+

Table 3: Resource combinations compared in our experiments. [1]This is applied within the 10-fold cross validation framework.

3.3.3 Knowledge-based labeler

The knowledge-based labeler is divided into *Rule matching* and *Dictionary matching* modules. Rule matching is an implementation of Khordad's approach using MetaMap, a subset of the UMLS, the HPO as well as 5 staged heuristics to identify phenotypes. For example, if a phrase has the form: "modifier (from the list of selected modifiers[3]) +[Anatomy] or [Physiology]" it is a phenotype name.

[3]The list of 85 high frequency modifiers from the HPO is available from the first author

Dictionary matching uses a longest string matching approach to recognise entities from the following resources: BF entities from the HPO (9500 terms describing human phenotypes) and the MP (9162 terms describing mouse phenotypes); GGP entities from the National Center for Biotechnology Information's gene list (9 million gene names). These sources were chosen because of their high standing within the biomedical community.

3.3.4 Merge results

Merge results assigns the final entity label to each token in the corpus by applying the following rules to each source module output. Processing proceeds sentence by sentence.

1. Following Jimeno et al. (2008) we combine the putative entity labels by collecting any entity-specific result that has been proposed by at least one method. This is intended to maximise recall. Thus, the O tag (non-entity label) has the least priority.
2. Based on our ontological analysis of BF and GGP it is often possible for a GGP to form a fully embedded part of a BF mention. For example, $[[\text{HLA-DQ}]_{GGP}\ \text{expression}]_{BF}$. We therefore apply a longest span rule and give priority to BF over GGP giving $[\text{HLA-DQ expression}]_{BF}$.
3. If there is a boundary conflict, we merge neighbouring entity mentions that share parts of their token sequence. For example, if we have $[\text{AB}]_{GGP}$ and $[\text{BC}]_{BF}$ then we merge them into one phrase [ABC] and label it with the highest priority tag, i.e. BF. Although this appears rare in GGP and BF we included this rule for expandability when we want to introduce further entity classes.

4 Evaluation

4.1 Metrics

We follow standard metrics of evaluation for the task using F1 as our primary method of comparison[4]. In these experiments matching is calculated using partial matching, i.e. a correct match is recorded when the span of text that is manually annotated in the gold standard corpus and the span of text output as an entity by the NER tagger partially overlap. For example a system annotation of *[median cleft lip]/palate* would be judged correct for a gold standard annotation of *median [cleft lip/palate]*. Various authors in the biomedical NER domain such as Kabiljo et al. (2009) have offered a reason for why this or other methods such as sloppy left boundary matching might be preferred to strict matching for genes and proteins. In summary it is thought that with partial matching, for the entity types examined so far, the core part of the entity was in most cases correctly found. In contrast, strict matching places too much faith in arbitrary choices in annotation guidelines.

4.2 Experiments on the KMR corpus

Our initial test run is conducted on the KMR corpus with micro-averaged F1 scores shown in Table 4. Since the corpus only contains phenotype tags no GGP results are shown.

We noted that curiously the results we observed for Khordad's method are slightly down by approximately 3 points of F1 on those given in their article. This appears mostly to affect

[4] F1 is the harmonic mean of recall (R) and precision (P) and is calculated as $F1 = 2PR/P + R$.

precision rather than recall and is possibly due to implementation differences such as changes to MetaMap/UMLS. Given the small amount of training data it is not surprising to see the pure machine learning based methods perform relatively poorly (F1:34.07,68.29) against the pure knowledge based approach (F1:83.29). Khordad's staged rule based system with dictionary lookup performs the best (F1:89.58) with the new Hybrid approach a reasonably close second (F1:85.27). It is encouraging though to see that the rule-based combination of the learner and KB outputs add value to the KB-only result.

		Model				
Class	**Metric**	**Khordad**	**HMM**	**CRF**	**KB**[1]	**Hybrid**[2]
BF	P	90.74	37.54	65.09	87.64	86.37
	R	88.44	31.18	71.83	79.36	84.19
	F	89.58	34.07	68.29	83.29	85.27

Table 4: (F)-scores, (R)ecall and (P)recision for each entity type on the KMR corpus using models with partial matching. [1]The KB method uses the Merge module to resolve conflicts. [2]Hybrid refers to the jointly applied system.

4.3 Experiments on the Phenominer corpus

For the Phenominer data set we chose to add the GENIA NER tagger trained on the JNLPBA04 corpus as a baseline for GGP. Note that we also combined this corpus data with Phenominer for training the CRF and HMM GGP recogniser. Khordad's method remains as our baseline for phenotypes. Micro-averaged F1 scores are shown in Table 5. With regard to GGP entities we observed that whilst the GENIA tagger performed robustly (F1:80.89), the Hybrid model appears to significantly outperform this (F1:85.48). The surprising result is that Khordad's method performs relatively poorly (F1:61.38) on BF. Again we try to dig down into the results in the Discussion to get an understanding behind the complex contributing factors.

			Model				
Class	**Metric**	**Khordad**	**GENIA**[3]	**HMM**[1,2]	**CRF**[1]	**KB**[4]	**Hybrid**[5]
BF	P	65.89	-	34.67	66.32	61.24	78.21
	R	57.44	-	38.11	64.17	60.91	75.96
	F	61.38	-	36.31	65.23	61.07	77.07
GGP	P	-	78.35	64.03	76.84	92.74	86.67
	R	-	83.61	65.80	80.07	61.31	84.32
	F	-	80.89	64.90	78.42	73.82	85.48
Total	Micro avg-F	-	-	56.46	75.19	71.62	85.04
	Macro avg-F	-	-	50.61	71.83	67.45	81.28

Table 5: (F)-scores, (R)ecall and (P)recision for each entity type on the Phenominer corpus using models with partial matching. [1]HMM and CRF are trained separately on each entity class and resolved in the Merge module. [2]Training included the JNLPBA04 corpus data for GGPs. [3]The GENIA method is the GENIA NER tagger trained on the GGP entities in the JNLPBA04 corpus. [4]The KB method uses the Merge module to resolve conflicts. [5]Hybrid refers to the jointly applied system.

5 Discussion

The results on the Phenominer corpus for Hybrid (F1:77.07) on BF are very encouraging and as we hoped demonstrate the strength of combining a mildly context sensitive ML approach with knowledge base lookup. Current NE methods based on a state-of-the-art learning approach such as CRF seem well suited to non-complex NE types such as GGP but maybe less effective for complex entities such as BF. Given the small size of the corpora we must be cautious in this conclusion. With regard to the KB approach for BF, our first impression was that the phenotype resources (HPO and MP) may to some extent lack coverage on the Phenominer corpus but we discuss below why this conclusion maybe too simplistic.

We start our analysis with the necessary observation that the Phenominer and KMR corpora do not offer a strict like-for-like comparison and are therefore most useful to highlight areas of difficulty. Importantly as we noted in Section 2, there is the issue of causality which is implicitly encoded into Khordad's schema and absent from ours. This means that our bodily features may not have a genetic or environmental cause. There is also the issue of granularity: our schema is more complex as it encodes bodily features from the genetic level upwards whereas Khordad's operates on the cellular level upwards. A statistical analysis points to further differences. We found that the average phenotype mention length in the KMR corpus was 1.72 tokens with the longest term being 5 tokens: [*hypoplasia of the corpus callosum*]. In contrast the average bodily feature mention in Phenominer is 2.89 tokens with the longest being [*susceptibility to psoriasis (PS) and psoriatic arthritis (PSA)*]. The longest GGP in Phenominer is 16 tokens: [*chromosomes 1 (D1S235), 4 (D4S1647), 12 (D12S373), 16 (D16S403), and 17 (D17S1301))*]. Both of these examples from Phenominer indicate structural term issues related to coordination and elipsis which are not easily handled by the simple longest term match approach that we have adopted.

Table 6 shows examples of where the Hybrid method disagreed with the KMR corpus. Whilst we have not conducted an in-depth analysis the examples seem reasonable and indicative of differences between the two coding schemas regarding causality of a bodily feature, algorithmic differences in how we prioritize UMLS semantic types related to *Disorder* and gaps in the knowledge resources.

No.	**Standard annotation**	**System annotation**	**Issue**[1]	**Cause of error**
1	eversion of the lateral eyelid	-	FN	Cannot be found in HPO or by rule matching
2	cervical rachischisis	-	FN	Hybrid system does not include default assignment for UMLS semantic types
3	absent nervi olphactorii	-	FN	
4	-	pregnancy	FP	Bodily feature does not differentiate between normal and abnormal
5	-	female	FP	
6	-	height	FP	

Table 6: Sources of error by the Hybrid system on the KMR corpus. [1] FN: False Negative; FP: False Positive.

Table 7 looks now at examples in the Phenominer corpus where the Hybrid approach disagreed

with Khordad's model. In the table the Hybrid model output agrees with the annotated corpus and the Issue column refers to the Khordad annotation. We see in particular that differences in the schema semantics account for many of the errors. The Phenominer schema for bodily features does not include disease mentions and simple anatomical entities but these may both be considered as phenotypes by the HPO. Clearly a notion of the compositional semantic relationships between types within terms is important to fully resolve the score differences.

Since Khordad's method relies to a greater extent than Hybrid on the HPO, we tested a number of terms from the Phenominer corpus by searching for them in the HPO. Using the exact match facility in OBO-Edit[5] we found several gaps. The following terms could not be found: complex terms such as [*perivascular distribution and granular deposits of immunoglobins*] as well as some gene specific terms such as [*IGG1 disorder*]. Surprisingly several seemingly common terms such as [*kidney impairment*] and [*abnormal thyroid function*] could also not be identified from a simple exact match. In the case of [*kidney impairment*] a suitable match might be found in *Abnormality of renal physiology* (HPO ID 0000082) by replacing the organ name with its anatomical adjective. Of 12 BF mentions in the Phenominer corpus that were not in the HPO our analysis revealed that 9 of them could be found by Hybrid. The ones that were not found tended to be very long and involved either coordination or a preposition phrase.

No.	**Hybrid annotation**[2]	**Khordad annotation**	**Issue**[1]	**Cause of error**
1	pathogenic process	-	FN	These entries do not belong to the UMLS's 15 target types, and are not in the HPO, and cannot be recognised by the pattern rules.
2	gene expression	-	FN	
3	RA susceptibility	- -	FN	
4	-	Inflammatory bowel disease	FP	Although this is present in HPO it is considered as a disease in our guidelines
5	-	enteropathy bowel disease	FP	Although this is present in HPO it is considered as an anatomical entity in our guidelines
6	-	asthma susceptibility gene	FP	Although this is present in HPO it is considered as GGP in our guidelines

Table 7: Sources of error by Khordad's system on the Phenominer corpus. [1] FN: False Negative; FP: False Positive. [2] We show here Hybrid system outputs that are correctly annotated.

Finally we show examples of disagreement for the Hybrid method on the Phenominer corpus in Table 8. As is common the biomedical literature we noticed a high proportion of coordination issues as well as ambiguity caused by generic terms.

[5]OBO-Edit: the OBO ontology editor: `http://oboedit.org/`

No.	Standard annotation[2]	Hybrid annotation	Issue[1]	Cause of error
1	FEV 1	-	FN	Because of orthographic similarity to genes this is tagged as GGP
2	[asthma]$_{BF}$ and [atopy phenotypes]$_{BF}$	[asthma and atopy phenotypes]$_{BF}$	FP	Coordination creates a boundary error
3	emotion	-	FN	This generic term is context sensitive
4	Diabetes Mellitus	[Diabetes Mellitus]$_{BF}$	FP	Entity class error
5	[citrullination]$_{BF}$ of the [endogenous antigen]$_{GGP}$	[citrullination of the endogenous antigen]$_{GGP}$	FP	Boundary error due preposition phrase

Table 8: Sources of error by the Hybrid system on the Phenominer corpus. [1] FN: False Negative; FP: False Positive. [2] We show here Hybrid system outputs that are correctly annotated.

6 Conclusions and future work

We have presented new results and analysis that add evidence to how phenotype candidates can be identified using named entity technology. The methods we have employed are aimed at making tractable the annotation of a critical semantics in the scientific literature. To do this we have matched surface forms to their attested forms in domain resources, balanced against contextual evidence from annotations in the scientific literature. The benchmark tests have demonstrated that the Hybrid method performs strongly on both the KMR corpus as well as the new Phenominer corpus. The evidence points towards complementarities between the existing phenotype resources and contextual evidence from annotated corpora.

Our methods have been formulated to be simple, effective and extensible with a focus on providing input to more knowledge intensive techniques downstream that can identify causality. Simplicity though may have sacrified both precision and recall in some cases, e.g. in the issue of coordination, in including generic and underspecified references and in adopting a longest matching approach to annotation.

There is considerable scope for further investigation. F1 might be increased using a machine learning framework such as integer linear programming (Koomen et al., 2005) to resolve hypotheses against multiple constraints much as we have tried to do manually in the Merge module. Coverage might be extended by including disjoint entities and a deeper analysis of embedded entity semantics such as that employed by Alex et al. (2007). In line with Hoehndorf et al. (2010) future solutions may need to focus on decomposing phenotypes in terms of their internal relations such as qualities [6].
