$$L_\theta = -\sum_{i=1}^{M} P_D(y_i|\boldsymbol{s}, \theta) \tag{2}$$

where θ refers to the parameters of the skeleton-to-sentence component.

3.3 Skeleton Extraction Module

Given a sentence $\boldsymbol{x}$, the skeleton extraction module E_γ is responsible for extracting its skeleton that only preserves the key information. Specially, we use the Seq2Seq model with the attention mechanism as the implementation. Both the encoder and the decoder are based on LSTM structures.

Since the extracted skeletons are treated as supervisory signals for the generative module, the extraction ability needs to be initialized. To pre-train the skeleton extraction module, we propose a weakly supervised method. We reformulate skeleton extraction as a sentence compression problem and use a sentence compression dataset to train this module. In sentence compression, the compressed sentence is required to be grammatical and convey the most important information. From the aspect of keeping important information, the sentence compression dataset can be used to help the training of the skeleton extraction module. However, since the style of the sentence compression dataset is very different from that of the narrative story dataset, it is difficult for the pre-trained module to give narrative text accurate compression results. Therefore, the supervisory signals are noisy and need to be further improved.

Given the training pair of the original text $\boldsymbol{x}$ and the compressed version $\boldsymbol{s} = \{s_1, \cdots, s_i, \cdots, s_T\}$, we use the following cross-entropy loss to pre-train E_γ:

$$L_\gamma = -\sum_{i=1}^{T} P_E(s_i|\boldsymbol{x}, \gamma) \tag{3}$$

where γ is the parameters of the skeleton extraction module.

3.4 Reinforcement Learning Method

We propose a reinforcement learning method to build the connection between the skeleton extraction module and the skeleton-based generative module for exploring better skeletons. The detailed training process is shown in Algorithm 1.

Algorithm 1 The reinforcement learning method for training the generative module G_ϕ and the skeleton extraction module E_γ.

```
Initialize the generative module $G_\phi$ and the skeleton extraction module $E_\gamma$ with random weights $\phi, \gamma$
Pre-train $E_\gamma$ using MLE based on Eq. 3
for each iteration $j = 1, 2, ..., J$ do
    Generate a skeleton $\boldsymbol{s}_j$ based on $E_\gamma$
    Given $\boldsymbol{s}_j$, train $G_\phi$ based on Eq. 1 and Eq. 2.
    Compute the reward $R_c$ based on Eq. 5
    Compute the gradient of $E_\gamma$ based on Eq. 4
    Update the model parameter $\gamma$
end for
```

Due to the discrete choice of words in skeletons, the loss is no longer differentiable over the skeleton extraction module. Therefore, we use policy gradient (Sutton et al., 1999) to train the skeleton extraction module.

First, we calculate a reward R_c based on the feedback of the generative module. The details of calculation process will be introduced in Section 3.4.1. Then, we optimize the parameters through policy gradient by maximizing the expected reward to train the skeleton extraction module. According to the policy gradient theorem, the gradient for the skeleton extraction module is

$$\nabla J(\gamma) = \mathbb{E}[R_c \cdot \nabla \log(P_E(\boldsymbol{s}|\boldsymbol{x}), \gamma)] \tag{4}$$

where $\boldsymbol{x}$ is the original sentence, $\boldsymbol{s}$ is the skeleton generated by a sampling mechanism.

3.4.1 Reward

To design an appropriate rewarding function, there is a critical question that needs to be considered: what will good/bad skeletons bring to the generative module.

We first define what is a good (or bad) skeleton. A good skeleton is expected to contain all key information and ignore other information. In contrast, the skeletons that contain too much detailed information or lack necessary information are considered as bad skeletons and should be punished. For ease of analysis, we classify possible scenarios into three categories: good skeletons, incomplete skeletons, and redundant skeletons.

If a skeleton contains too little information, it will get harder for the skeleton-to-sentence component to reconstruct the original sentence based on the skeleton. Therefore, the cross-entropy loss of this example will be higher compared with other skeleton-sentence pairs.

If a skeleton contains too much redundant information, the input-skeleton relation will be sparse. Therefore, the cross-entropy loss of this example will be higher compared with other input-skeleton pairs.

For a good skeleton that contains an appropriate amount of information, it will benefit the two components and will get balanced losses from the two components.

Therefore, to encourage good skeletons and punish bad skeletons, we use the multiplication of the cross-entropy loss in the input-to-skeleton component and that in the skeleton-to-sentence component as the reward:

$$R_c = [K - (R_1 \times R_2)^{\frac{1}{2}}] \tag{5}$$

where K is the upper bound of the reward, R_1 and R_2 are cross-entropy losses in the input-to-skeleton component and the skeleton-to-sentence component, respectively. Only if two components both output lower cross-entropy losses, the extracted skeleton can be rewarded.

4 Experiment

In this section, we evaluate our model on a narrative story generation dataset. We first introduce the dataset, the training details, the baselines, and the evaluation metrics. Then, we compare our model with the state-of-the-art models. Finally, we show the experimental results and provide the detailed analysis.

4.1 Dataset

We use the recently introduced visual storytelling dataset (Huang et al., 2016) in our experiments. This dataset contains the pairs of photo sequences and the associated coherent narrative of events through time written by humans. We only use the text data for our experiments. In our version of narrative story generation, the model should generate a coherent story based on a given sentence. We build a new dataset for this task by splitting the data into two parts. In each story, we take the first sentence as the input text, and the following sentences as the target text. The processed dataset contains 40153, 4990, and 5054 stories for training, validation, and testing, respectively. The maximum number of sentences in each story is 6. In total, the number of training sentences is over 20K and the number of training words is over 2M.

To pre-train the skeleton extraction module, we use a sentence compression dataset (Filippova and Altun, 2013). In this dataset, every compression is a subsequence of tokens from the input. The dataset contains 16999, 1000, and 1998 pairs for training, validation, and testing, respectively.

4.2 Baselines

We compare our proposed model with the following the state-of-the-art models.

Entity-Enhanced Seq2Seq Model (EE-Seq2Seq) (Clark et al., 2018). It regards entities as important context needed for coherent stories. When decoding a sentence, it combines entity context and text context together to reduce dependency sparsity.

Dependency-Tree Enhanced Seq2Seq Model (DE-Seq2Seq) (Cao et al., 2018). It defines some manual rules based on dependency parsing labels to find a simplified sentence representation. Following this work, we treat the extracted words based on the predefined rules as the skeleton.

Generalized-Template Enhanced Seq2Seq Model (GE-Seq2Seq) (Martin et al., 2018). It takes advantages of existing knowledge bases to get a generalized sentence representation. Following this work, we treat the generalized sentence representation as the skeleton.

4.3 Training Details

For narrative story generation, we set the number of generated sentences to 6 with the maximum length of 40 words for each generated sentence. Based on the performance on the validation set, we set the hidden size to 128, embedding size to 50, vocabulary size to 20K, and batch size to 10 for the proposed model and the state-of-the-art models. We use the Adagrad (Duchi et al., 2011) optimizer with the initial learning rate 0.6. All of the gradients are clipped when the norm exceeds 2. Both the generative module and skeleton extractive module are pre-trained for 30 and 40 epochs before reinforcement learning. The K in Equation 5 is set to 1. Due to the lack of annotated entities and dependency parsing labels, we use a popular natural language processing toolkit, Spacy[2], to extract entities and dependency parsing labels in the EE-Seq2Seq and DE-Seq2Seq models.

DE-Seq2Seq	8.48	3.54	5.48
GE-Seq2Seq	9.48	3.58	5.82
Proposed Model	8.69	5.62	**6.99 (+20.1%)**

Table 3: Human evaluations of the proposed model and the state-of-the-art models.

4.4 Evaluation Metrics

We conduct two kinds of evaluations in this work, automatic evaluation and human evaluation. The details of evaluation metrics are shown as follows.

4.4.1 Automatic Evaluation

Following the previous work (Li et al., 2016; Martin et al., 2018), we use the BLEU score to measure the quality of generated text. BLEU (Papineni et al., 2002) is originally designed to automatically judge the machine translation quality. The key point is to compare the similarity between the results created by the machine and the references provided by the human. Currently, it is widely used in many generation tasks, such as dialogue generation, story generation, summarization, and so on. For precise results, we remove all stop words, like “the”, “a”, before computing BLEU scores.

4.4.2 Human Evaluation

Although the quantitative evaluation generally indicates the quality of generated stories, it can not accurately evaluate the generated text. Therefore, we also perform a human evaluation on the test set. We randomly choose 100 items for human evaluation. Each item contains the stories generated by different models given the same source sentence. The items are distributed to the annotators who have no knowledge about which model the story is from. It is important to note that all the annotators have linguistic background. They are asked to score the generated stories in terms of fluency and coherence. Fluency represents whether each sentence in the generated story is correct in grammar. Coherence evaluates whether the generated story is coherent. The score ranges from 1 to 10 (1 is very bad and 10 is very good). To evaluate the overall performance, we use the geometric mean of fluency and coherence as an evaluation metric.

4.5 Experimental Results

Table 2 shows the results of automatic evaluation. The proposed model performs the best according to BLEU. In particular, the differences between the existing state-of-the-art models are within 0.07, while the proposed model supersedes the best of them by 0.13.

As we previously explained, the best evaluation for narrative story generation is human evaluation. The human evaluation results are listed in Table 3.[3]

As for fluency, the proposed model receives the score of 8.69, second to the GE-Seq2Seq model. It is expected that the generalized templates can constrain the search space in generation and the model achieves higher fluency by loss of expressive power. In particular, we find that only 0.48%, 1.01%, and 1.20% of the unigrams, bigrams, and trigrams are unique in the stories generated by the GE-Seq2Seq model, while the percentages are 3.16%, 15.33%, and 29.67% in the stories generated by our proposed model. Nonetheless, the proposed model outperforms the other two existing models by a substantial margin. In terms of coherence, the proposed model is better than all the existing models. We need to point out that the GE-Seq2Seq model is scored the lowest in coherence, while highest in fluency. It indicates that the GE-Seq2Seq model does not learn the dependency among sentences effectively, which results from the constraint of the templates. It also needs to be noted that the models are all scored below 6 in coherence, meaning that there is still a long way to go before the generated stories satisfy the requirement of humans. Overall, the proposed model is arguably better than the existing models in that it achieves a balance between coherence and fluency, with a G-score improvement of 20.1%.

Table 4 presents the examples generated by different models. Compared with the existing models, the sentences generated by our proposed model are connected more logically. For the EE-Seq2Seq model, while it connects *park* with *plants*

---

[3] The inter-annotator agreement is satisfactory considering the difficulty in the human evaluation. The Pearson’s correlation coefficient is 0.37 on coherence and 0.26 on fluency, with $p < 0.0001$.

and *rocks* successfully (4th ex.), it insists on telling *getting married* when it sees *[male]* or *[female]* (1st and 2nd ex.). Such examples suggest that some entities (e.g. *park*) embody semantics more independently, while for others (e.g. *male*), we have to associate them in the specific context. The rest of the models try to generalize the target sentences. The DE-Seq2Seq model uses the core dependency arguments as the skeleton. However, the results demonstrate the generated sentences are quite irrelevant. The sentence may have links such as *walked through* to *came out* (1st ex.), but the objects in the generated stories are hardly related. The GE-Seq2Seq model replaces the specific words with more general concepts and generates some good examples, e.g. the second one in the table. However, there can be over-generalizations. For example, as for the third example, the GE-Seq2Seq model associates *driving* with *car show*, causing the incoherent description. In the last example, the generated story completely diverges from the input. These results prove the drawbacks of static rule-based skeletons. The proposed model uses a skeleton extraction module to adaptively determine the appropriate granularity of skeletons. The skeleton keeps the main semantic of a sentence, which can be a whole sentence, phrases, or even segments. It makes the model learn the dependency of sentences more effectively so that the generated stories are much more coherent.

Input 1: *[Female] and her friend had a night out on the town.*
EE-Seq2Seq: *They were very happy to see us. [Male] and [female] were getting married today.*
DE-Seq2Seq: *We walked through the streets of the city and found a place to sit. The whole family came out to support their families.*
GE-Seq2Seq: *My friends and I went to a bar last night. [Female] was so happy to be there.*
Proposed Model: *They went to the bar. They had a great time.*

Input 2: *[Male] and [male] are talented artists.*
EE-Seq2Seq: *They were very happy to see us. [Male] and [female] were getting married today.*
DE-Seq2Seq:*The kids get to play with the kids. We had a great time.*
GE-Seq2Seq:*The art was very subjective. The artist had a keen eye.*
Proposed Model: *They are discussing the importance of the lecture.*

Input 3: *The bride was driving to the wedding.*
EE-Seq2Seq: *The family was so happy to be there. They were very happy to see us.*
DE-Seq2Seq: *The view from the top was amazing. There were a lot of people there.*
GE-Seq2Seq: *I went to the car show last weekend. People are getting ready to go.*
Proposed Model: *The groom and groomsmen watched the bride. They kissed and shared their pictures.*

Input 4: *The park was filled with beauty.*
EE-Seq2Seq: *The plants were so beautiful. The rocks were very pretty.*
DE-Seq2Seq: *The family was so happy to be there.*
GE-Seq2Seq: *There were a lot of people there. We had a great time.*
Proposed Model: *The trees were very sparse. There were also some flowers.*

Table 4: Examples generated by the proposed model and the state-of-the-art models.

4.6 Incremental Analysis

In this section, we conduct a series of experiments to evaluate the contributions of our key components. The results are listed in Table 5. The Seq2Seq model is scored the lowest according to BLEU. With the skeleton extraction module, the BLEU score is slightly improved, which suggests that the model starts to learn the connection of longer segments. Finally, with reinforcement learning, the BLEU score significantly overpasses the Seq2Seq model by 40%.

Models	BLEU
Seq2Seq	0.0028
+Skeleton Extraction Module	0.0029
+Reinforcement Learning	**0.0042**

Table 5: Automatic evaluations of key components.

Table 6 shows the human evaluation results. The slight improvement with the skeleton extraction module in BLEU reflects as the decreases in both fluency and coherence. It suggests the necessity of human evaluation. The decreased results can be explained by the fact that the style of the dataset for pre-training the skeleton extraction module is very different from the narrative story dataset. While it may help extract some useful skeletons, it is likely that many of them are not suitable for learning the dependency of sentences. Finally, when the skeleton extraction module is trained on the target domain using reinforcement learning, the human evaluation is improved significantly by 14% on G-score.

Table 7 further shows the results of the skeleton extraction module. As we can see, the module keeps only the essential parts of the sentence. Most of the adjectival phrases and adverbial phrases are removed. Furthermore, we can find that for longer sentences that contain too detailed information, it only extracts the key information. For shorter sentences where all information is nec-

Models	Fluency	Coherence	G-Score
Seq2Seq	7.54	4.98	6.13
+Skeleton Extraction Module	7.26	4.32	5.60
+Reinforcement Learning	8.69	5.62	**6.99**

Table 6: Human evaluations of the key components.

1) *There was a small power station on the side of the building.*
2) *The lady wearing the pink shirt decided to stop playing the video and chatted with other guests.*
3) *At the end of the night, guests taking pictures before saying goodbye to each other.*
4) *Afterwards, we celebrated with some drinks and watched the rest of the parade.*
5) *A few miles away was a lake that we really enjoyed watching.*
6) *Some of the guests partied harder than others.*
7) *The bride was driving to the wedding.*

Table 7: Analysis of the skeleton extraction module. Given a whole sentence as input, the words in red are the extracted skeleton.

essary, it choose to keep all words. It proves that the skeleton extraction module is effective and is expert in only removing detailed information that is not needed.

Furthermore, it is not quite surprising to see that on our dataset, the Seq2Seq model beats the existing state-of-the-art models (DE-Seq2Seq and GE-Seq2Seq) in human evaluation and automatic evaluation. It is mainly attributed to the over-simplification of sentences. For narrative sentences, the key information is usually expressed in a complicated way. It can be a segment, a phrase, or a whole sentence. The simple rules lead to the excessive loss of key information while our proposed model can adaptively determine the appropriate granularity.

4.7 Error Analysis

Although the proposed model outperforms the state-of-the-art models, it needs to be noted that the highest coherence score, 5.62, is a moderate result in human evaluation, indicating that there is still a long way to go before the generated stories reach the human level. Therefore, in this subsection, we give a detailed error analysis to explore what factors affect the performance.

First, we classify the generated stories with scores below 6 that are considered less coherent. We conclude 4 types of errors from these outputs and the distribution of error types are shown in Figure 3. It is expected that the irrelevant scenes make up most of the errors. In addition, there are several examples that are hard to be understood due to chaotic syntax. For the type of chaotic timeline, the model neglects the time order of scenes and the generated stories goes backward in time. The repeated scenes mean that the generated stories just describe the input again. The above errors show that there are many dimensions in coherence, including scene-specific relevance, temporal connection, and non-recurrence. Modeling such dimensions is still a hard problem.

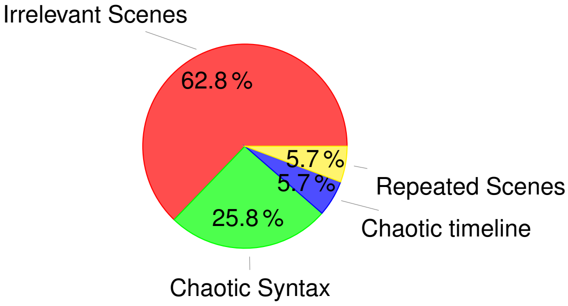

Figure 3: The distribution of error types.

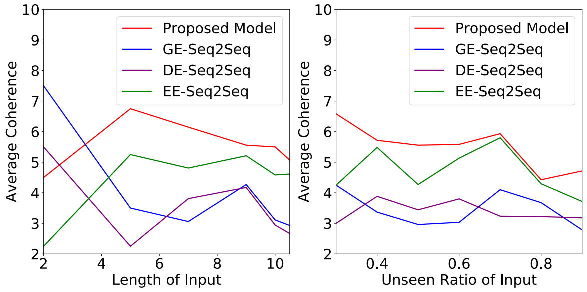

Figure 4: An illustration of how the performance is affected by the length of input (left) and the unseen ratio of input (right).

Furthermore, we explore how the performance is affected by the length of input and the unseen ratio of input. The results are shown in Figure 4. "Unseen ratio" is the percentage of the phrases that are not seen in the training data. We use the gap between 1 and the BLEU score with the training data as the reference to compute it. When the input is short and the model often sees the input, the generated story tends to have high coherence. However, when the length of input increases and the model is not familiar with the input, the coherence goes down. Since our model extracts the key semantics better, the dependency of sentences can be easier to learned, which brings the smaller decrease in coherence.

5 Conclusion and Future Work

In this work, we propose a new skeleton-based model for generating coherent narrative stories.

Different from traditional models, the proposed model first generates a skeleton that contains the key information of a sentence, and then expands the skeleton to a complete sentence. Experimental results show that our model significantly improves the quality of generated stories, especially in coherence. However, even with the best human evaluation results, the error analysis shows that there are still many challenges in narrative story generation, which we would like to explore in the future.

Abstract

Sequence-to-Sequence (seq2seq) models have become overwhelmingly popular in building end-to-end trainable dialogue systems. Though highly efficient in learning the backbone of human-computer communications, they suffer from the problem of strongly favoring short generic responses. In this paper, we argue that a good response should smoothly connect both the preceding dialogue history and the following conversations. We strengthen this connection through mutual information maximization. To sidestep the non-differentiability of discrete natural language tokens, we introduce an auxiliary continuous code space and map such code space to a learnable prior distribution for generation purpose. Experiments on two dialogue datasets validate the effectiveness of our model, where the generated responses are closely related to the dialogue context and lead to more interactive conversations.

1 Introduction

With the availability of massive online conversational data, there has been a surge of interest in building open-domain chatbots with data-driven approaches. Recently, the neural network based sequence-to-sequence (seq2seq) framework (Sutskever et al., 2014; Cho et al., 2014) has been widely adopted. In such a model, the encoder, which is typically a recurrent neural network (RNN), maps the source tokens into a fixed-sized continuous vector, based on which the decoder estimates the probabilities on the target side word by word. The whole model can be efficiently trained by maximum likelihood (MLE) and has demonstrated state-of-the-art performance in various domains. However, this architecture is not suitable for modeling dialogues. Recent research has found that while the seq2seq model generates syntactically well-formed responses, they are prone to being off-context, short, and generic. (e.g., "I dont know" or "I am not sure") (Li et al., 2016a; Serban et al., 2016). The reason lies in the one-to-many alignments in human conversations, where one dialogue context is open to multiple potential responses. When optimizing with the MLE objective, the model tends to have a strong bias towards safe responses as they can be literally paired with arbitrary dialogue context without semantical or grammatical contradictions. These safe responses break the dialogue flow without bringing any useful information and people will easily lose interest in continuing the conversation.

A_1: Do you know the movie Star Wars?
B_1: Only a bit. You can tell me about it!
A_2: Of course! This is about ...

Figure 1: A conversation in real life

In this paper, we propose NEXUS Network which aims at producing more on-topic responses to maintain an interactive conversation flow. Our assumption is that a good response should serve as a "nexus": connecting and being informative to both the preceding dialogue context and the follow-up conversations. For example, in Figure 1, the response from B_1 is a smooth connection, where the first half indicates the preceding context is a "Do you know" question and the second half informs that the follow-up would be an introduction about *Star Wars*. We establish this connection by maximizing the mutual information (MMI) of the current utterance with both the past and future contexts. In this way, generic responses can be largely discouraged as they contain no valuable information and thus have only weak correlations

with the surrounding context. To enable efficient training, two challenges exist.

The first challenge comes from the discrete nature of language tokens, hindering efficient gradient descent. One strategy is to estimate the gradient by methods like Gumbel-Softmax (Maddison et al., 2017; Jang et al., 2017) or REINFORCE algorithm (Williams, 1992), which has been applied in many NLP tasks (He et al., 2016; Shetty et al., 2017; Gu et al., 2018; Paulus et al., 2018), but the trade-off between bias and variance of the estimated gradient is hard to reconcile. The resulting model usually strongly relies on sensitive hyper-parameter tuning, careful pre-train and task-specific tricks. Li et al. (2016a); Wang et al. (2017) avoid this non-differentiability problem by learning a separate backward model to rerank candidate responses in the testing phase while still adhering to the MLE objective for training. However, the candidate set normally suffers from low diversity and a huge sample size is needed for good performance (Li et al., 2016b).

The second challenge relates to the unknown future context in the testing phase. In our framework, both the history and future context need to be explicitly observed in order to compute the mutual information. When applying it to generating tasks where only the history context is given, there is no way to explicitly take into account the future information. Therefore, reranking-based models do not apply here. (Li et al., 2016c) addresses future information by policy learning, but the model suffers from high variance due to the enormous sequential search space. Serban et al. (2017); Zhao et al. (2017); Shen et al. (2017) adopt the variational inference strategy to reduce the training variance by optimizing over latent continuous variables. However, they all stick to the original MLE objective and no connection with the surrounding context is considered.

In this work, we address both challenges by introducing an auxiliary continuous code space which is learned from the whole dialogue flow. At each time step, instead of directly optimizing discrete utterances, the current, past and future utterances are all trained to maximize the mutual information with this code space. Furthermore, a learnable prior distribution is simultaneously optimized to predict the corresponding code space, enabling efficient sampling in the testing phase without getting access to the ground-truth future conversation. Extensive experiments have been conducted to validate the superiority of our framework. The generated responses clearly demonstrate better performance with respect to both coherence and diversity.

2 Model Structure

2.1 Motivation

Let u_i be the ith utterance within a dialogue flow. The dialogue history H_{i-1} contains all the preceding context $u_1, u_2, \ldots, u_{i-1}$ and F_{i+1} denotes the future conversations $u_{i+1}, \ldots, u_T$. The objective of our model is to find the decoding probability $p_\theta(u_i|H_{i-1}, F_{i+1})$ that maximizes the mutual information $I(H_{i-1}, u_i)$ and $I(u_i, F_{i+1})$. Formally, the objective is:

$$\begin{aligned} &\max_\theta \lambda_1 I(H_{i-1}, u_i) + \lambda_2 I(u_i, F_{i+1}) \\ &\qquad u_i \sim p_\theta(u_i|H_{i-1}, F_{i+1}) \end{aligned} \tag{1}$$

λ_1 and λ_2 adjusts the relative weight. Mutual information is defined over $p_\theta(u_i|H_{i-1}, F_{i+1})$ and the empirical distribution $p(H_{i-1}, F_{i+1})$. Now we assume the future context F_{i+1} is known to us when training the decoding probability, we will address the unknown future problem later.

Directly optimizing with this objective is unfortunately infeasible because the exact computation of mutual information is intractable, and back-propagating through sampled discrete sequences is notoriously difficult to train. The discontinuity prevents the direct application of the reparameterization trick (Kingma and Welling, 2014). Low-variance relaxations like Gumbel-Softmax (Jang et al., 2017), semantic hashing (Kaiser et al., 2018) or vector quantization (van den Oord et al., 2017) lead to biased gradient estimations, which are accumulated as the sequence becomes longer. The Monte-Carlo-Simulation is unbiased but suffers from high variances. Designing a reasonable control variate for variance reduction is an extremely tricky task (Mnih and Gregor, 2014; Tucker et al., 2017). For this sake, we propose replacing u_i with a continuous code space c learned from the whole dialogue flow.

2.2 Continuous Code Space

We define the continuous code space c to follow the Gaussian probability distribution with a diagonal covariance matrix conditioning on the whole

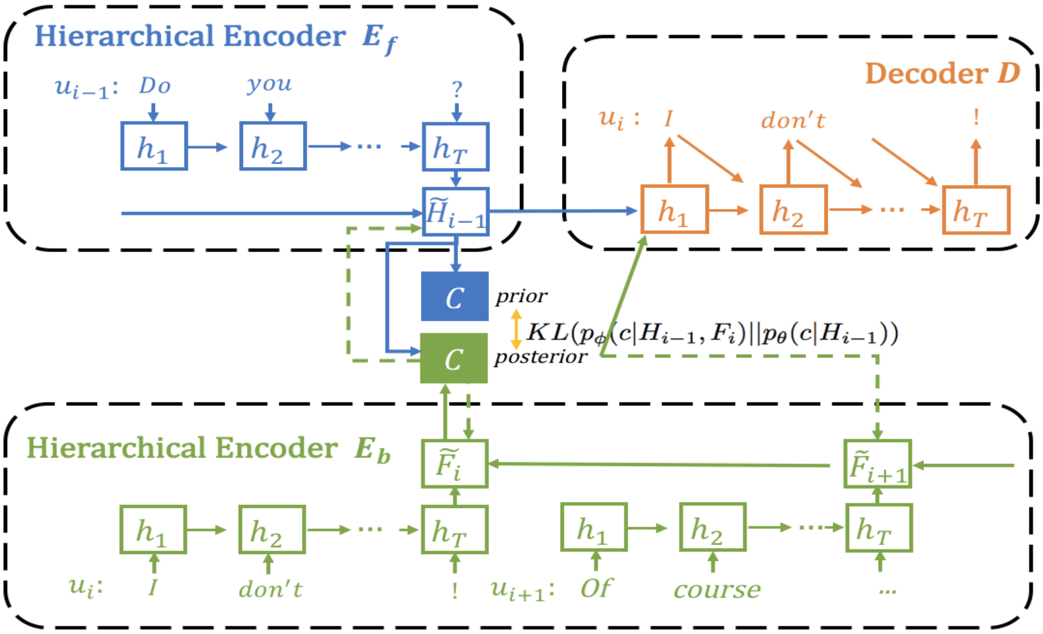

Figure 2: Framework of NEXUS Networks. Full line indicates the generative model to generate the continuous code and corresponding responses. Dashed line indicates the inference model where the posterior code is trained to infer the history, current and future utterances. Both parts are simultaneously trained by gradient descent.

dialogue:

$$c \sim p_\phi(c|H_{i-1}, F_i) = \mathcal{N}(\mu_c, \sigma_c^2 \mathbb{I}|H_{i-1}, F_i) \quad (2)$$

The dialogue history H_{i-1} is encoded into vector $\tilde{H}_{i-1}$ by a forward hierarchical GRU model E_f as in (Serban et al., 2016). The future conversation, including the current utterance, is encoded into $\tilde{F}_i$ by a backward hierarchical GRU E_b. $\tilde{H}_{i-1}$ and $\tilde{F}_i$ are concatenated and a multi-layer perceptron is built on top of them to estimate the Gaussian mean and covariance parameters. The code space is trained to infer the encoded history $\tilde{H}_{i-1}$ and future $\tilde{F}_{i+1}$. The full optimizing objective is:

$$\begin{aligned}
\mathcal{L}(c) = \max_\phi \mathbb{E}_{p_\phi(H_{i-1},F_i,c)}[\lambda_1 \log p_\phi(\tilde{H}_{i-1}|c) \\
+\lambda_2 \log p_\phi(\tilde{F}_{i+1}|c)] \\
p_\phi(H_{i-1}, F_i, c) = p(H_{i-1}, F_i) p_\phi(c|H_{i-1}, F_i) \\
p_\phi(\tilde{H}_{i-1}|c) = \mathcal{N}(\mu_{H_i}, \sigma^2_{H_i}\mathbb{I}|c) \\
p_\phi(\tilde{F}_{i+1}|c) = \mathcal{N}(\mu_{F_{i+1}}, \sigma^2_{F_{i+1}}\mathbb{I}|c)
\end{aligned} \quad (3)$$

where $\tilde{H}_{i-1}$ and $\tilde{F}_{i+1}$ are also assumed to be Gaussian distributed given c with mean and covariance estimated from multi-layer perceptrons. We infer the encoded vectors instead of the original sequences for three reasons. Firstly, inferring dense vectors is parallelizable and computationally much cheaper than autoregressive decoding, especially when the context sequences could be unlimitedly long. Secondly, sequence vectors can capture more holistic semantic-level similarity than individual tokens. Lastly, It can also help alleviate the posterior collapsing issue (Bowman et al., 2016) when training variational inference models on text (Chen et al., 2017; Shen et al., 2018), which we will use later. It can be shown that the above objective maximizes a lower bound of $\lambda_1 I(H_{i-1}, c) + \lambda_2 I(c, F_{i+1})$, given the conditional probability $p_\phi(c|H_{i-1}, F_i)$. The proof is a direct extension of the derivation in (Chen et al., 2016), followed by the Data Processing Inequality (Beaudry and Renner, 2012) that the encoding function can only reduce the mutual information. As the sampling process contains only Gaussian continuous variables, the above objective can be trained through the reparameterization trick (Kingma and Welling, 2014), which is a low-variance, unbiased gradient estimator (Burda et al., 2015). After training, samples from $p_\phi(c|H_{i-1}, F_i)$ hold high mutual information with both the history and future context. The next step is then transferring the continuous code space to reasonable discrete natural language utterances.

2.3 Decoding from Continuous Space

Our decoder transfers the code space c into the ground-truth utterance u_i by defining the probability distribution $p(u_i|H_{i-1}, c)$, which is implemented as a GRU decoder going through u_i word by word to estimate the output probability. The encoded history $\tilde{H_{i-1}}$ and code space c are concatenated as an extra input at each time step. The loss function for the decoder is then:

$$\begin{gathered}\mathcal{L}(d) = \max_{\phi} \mathbb{E}_{p_\phi(H_{i-1},F_i,c)} \log p_\phi(u_i|H_{i-1},c) \\ p_\phi(H_{i-1},F_i,c) = p(H_{i-1},F_i)p_\phi(c|H_{i-1},F_i)\end{gathered} \tag{4}$$

which can be proved to be the lower bound of the conditional mutual information $I(u_i,c|H_{i-1})$. By maximizing the conditional mutual information, c_i is trained to maintain as much information about the target sequence u_i as possible.

Combining Eq. 3 and 4, our model until now can be viewed as optimizing a lower bound of the following objective:

$$\begin{gathered}\max_{\phi} \lambda_1 I(H_{i-1},c) + \lambda_2 I(c,F_{i+1}) + I(u_i,c|H_{i-1}) \\ c \sim p_\phi(c|H_{i-1},F_i)\end{gathered} \tag{5}$$

Compared with the original motivation in Eq. 1, we sidestep the non-differentiability problem by replacing u_i with a continuous code space c, then forcing u_i to contain the same information as maintained in c by additionally maximizing the mutual information between them.

Nonetheless, Eq. 5 and Eq. 1 might lead to different optimums as mutual information does not satisfy the transitive law. In the extreme case, different dimensions of c could individually maintain information about history, current and future conversations and the conversations themselves do not share any dependency relation. To avoid this issue, we restrict the dimension of c to be smaller than that of the encoded vectors. In this case, optimizing Eq. 5 will favor utterances having stronger correlations with the surrounding context to achieve a higher total mutual information.

2.4 Learnable Prior Distribution for Unknown Future

The last problem is the sampling mechanism of c in Eq. 2, which conditions on the ground-truth future conversation. In the testing phase, when we have no access to it, we cannot perform the decoding process as in Eq. 4. To allow for decoding with only the history context, we need to learn an appropriate prior distribution $p_\theta(c|H_{i-1})$ for c. In the ideal case, we would like

$$p_\theta(c|H_{i-1}) = \sum_{F_i} p_\phi(c|H_{i-1},F_i) = p_\phi(c|H_{i-1}) \tag{6}$$

However, $p_\phi(c|H_{i-1})$ is intractable as it integrates over all possible future conversations. We apply variational inference on c to maximize the variational lower bound (Jordan et al., 1999):

$$\begin{gathered}\mathcal{L}(p) = \max_{\theta,\phi} \mathbb{E}_{p_\phi(c|H_{i-1},F_i)} \log p_\theta(\tilde{F_i}|H_{i-1},c) \\ -KL(p_\phi(c|H_{i-1},F_i)||p_\theta(c|H_{i-1})) \\ p_\theta(\tilde{F_i}|H_{i-1},c) \sim \mathcal{N}(\mu_{F_i},\sigma^2_{F_i}\mathbb{I}|H_{i-1},c) \\ p_\theta(c|H_{i-1}) \sim \mathcal{N}(\mu_{prior},\sigma^2_{prior}\mathbb{I}|H_{i-1}))\end{gathered} \tag{7}$$

It can be reformulated as maximizing:

$$\begin{gathered}\mathbb{E}_{p_\phi(c|H_{i-1})} KL(p_\phi(\tilde{F_i}|H_{i-1},c)||p_\theta(\tilde{F_i}|H_{i-1},c)) \\ -KL(p_\phi(c|H_{i-1})||p_\theta(c|H_{i-1}))\end{gathered} \tag{8}$$

We can see it implicitly matches $p_\phi(c|H_{i-1})$ to a tractable Gaussian distribution $p_\theta(c|H_{i-1})$ by minimizing the KL divergence between them. It also functions as a regularizer to prevent overfitting when learning $p_\phi(c|H_{i-1},F_i)$. In the testing phase, we can sample c from the learned prior distribution $p_\theta(c|H_{i-1})$, then generate a response based on it.

2.5 Summary

To sum up, the total objective function of our model is:

$$\mathcal{L} = \mathcal{L}(c) + \mathcal{L}(d) + \mathcal{L}(p) \tag{9}$$

Weighting can be added to individual loss functions for better performance, but we find it enough to maintain equal weights and avoid extra hyperparameters. All the parameters are simultaneously updated by gradient descent except for the encoders E_f and E_b, which only accept gradients from $\mathcal{L}(d)$ since otherwise the model can easily learn to encode no information for a lower reconstruction loss in $\mathcal{L}(c)$ and $\mathcal{L}(p)$. An overview of our training procedure is depicted in Fig. 2.

3 Relationship to Existing Methods

MMI decoding MMI decoder was proposed by (Li et al., 2016a) and further extended in (Wang et al., 2017). The basic idea is the same as our model by maximizing the mutual information with the dialogue context. However, the MMI principle is applied only at the testing phase rather than the training phase. As a result, it can only be used to evaluate the quality of a generation by estimating its mutual information with the context. To apply it in a generative task, we have to first sample some candidate responses with the seq2seq model, then rerank them by accounting for the MMI score. Our model differs from it in that we directly estimate the decoding probability thus no post-sampling rerank is needed. Moreover, we further include the future context to strengthen the connection role of the current utterances.

Conditional Variational Autoencoder The idea of learning an appropriate prior distribution in Eq. 7 is essentially a conditional variational autoencoder (Sohn et al., 2015) where the accumulated posterior distribution is trained to stay close to a prior distribution. It has also been applied in dialogue generation (Serban et al., 2017; Zhao et al., 2017). However, all the above methods stick to the MLE objective function and do not optimize with respect to the mutual information. As we will show in the experiment, they fail to learn the correlation between the utterance and its surrounding context. The generation diversity of these models comes more from the sampling randomness of the prior distribution rather than from the correct understanding of context correlation. Moreover, they suffer from the posterior collapsing problem (Bowman et al., 2016) and require special tricks like KL-annealing, BOW loss or word drop-out (Shen et al., 2018). Our model does not have such problems.

Deep Reinforcement Learning Dialogue Generation (Li et al., 2016c) first considered future success in dialogue generation and applied deep reinforcement learning to encourage more interactive conversations. However, the reward functions are intuitively hand-crafted. The relative weight for each reward needs to be carefully tuned and the training stage is unstable due to the huge search space. In contrast, our model maximizes the mutual information in the continuous space and trains the prior distribution through the reparamaterization trick. As a result, our model can be more easily trained with a lower variance. Throughout our experiment, the training process of NEXUS network is rather stable and much less data-hungry. The MMI objective of our model is theoretically more sound and no manually-defined rules need to be specified.

4 Experiments

4.1 Dataset and Training Details

We run experiments on the DailyDialog (Li et al., 2017b) and Twitter corpus (Ritter et al., 2011). DailyDialog contains 13118 daily conversations under ten different topics. This dataset is crawled from various websites for English learner to practice English in daily life, which is high-quality, less noisy but relatively smaller. In contrast, the Twitter corpus is significantly larger but contains more noise. We obtain the dataset as used in Serban et al. (2017) and filter out tweets that have already been deleted, resulting in about 750,000 multi-turn dialogues. The contents have more informal, colloquial expressions which makes the generation task harder. These two datasets are randomly separated into training/validation/test sets with the ratio of 10:1:1.

In order to keep our model comparable with the state-of-the-art, we keep most parameter values the same as in (Serban et al., 2017). We build our vocabulary dictionary based on the most frequent 20,000 words for both corpus and map other words to a UNK token. The dimensionality of the code space c is 100. We use a learning rate of 0.001 for DailyDialog and 0.0002 for Twitter corpus. The batch size is fixed to 128. The word vector dimension is 300 and is initialized with the public Word2Vec (Mikolov et al., 2013) embeddings trained on the Google News Corpus. The probability estimators for the Gaussian distributions are implemented as 3-layer perceptrons with the hyperbolic tangent activation function. As mentioned above, when training NEXUS models, we block the gradient from $\mathcal{L}(c)$ and $\mathcal{L}(p)$ with respect to E_f and E_b to encourage more meaningful encodings. The UNK token is prevented from being generated in the test phase. We implemented all the models with the open-sourced Python library Pytorch (Paszke et al., 2017) and optimized using the Adam optimizer (Kingma and Ba, 2015).

4.2 Compared Models

We conduct extensive experiments to compare our model against several representative baselines.

Seq2Seq: Following the same implementation as in (Vinyals and Le, 2015), the seq2seq model serves as a baseline. We try both greedy decoding

Model	DailyDialog			Twitter		
	Average	Greedy	Extreme	Average	Greedy	Extreme
Greedy	0.443	0.376	0.328	0.510	0.341	0.356
Beam	0.437	0.350	0.369	0.505	0.345	0.352
MMI	0.457	0.371	0.371	0.518	0.353	0.365
RL	0.405	0.329	0.305	0.460	0.349	0.323
VHRED	**0.491**	0.375	0.313	0.525	0.389	0.372
NEXUS-H	0.479	0.381*	**0.385***	**0.558***	0.392	0.373
NEXUS-F	0.476	0.383*	0.373	0.549*	0.393	0.386*
NEXUS	0.488	**0.392***	0.384*	0.556*	**0.397***	**0.391***

Table 1: Results of embedding-based metrics. * indicates statistically significant difference ($p < 0.05$) from the best baselines. The same mark is used in Table 2

and beam search (Graves, 2012) with beam size set to 5 when testing.

MMI: We implemented the bidirectional-MMI decoder as in Li et al. (2016a), which showed better performance over the anti-LM model. The hyperparameter λ is set to 0.5 as suggested. 200 candidates per context are sampled for re-ranking.

VHRED: The VHRED model is essentially a conditional variational autoencoder with hierarchical encoders (Serban et al., 2017; Zhao et al., 2017). To alleviate the posterior collapsing problem, we apply the KL-annealing trick and early stop with the step set as 12,000 for the DailyDialog and 75,000 for the Twitter corpus.

RL: Deep reinforcement learning chatbot as in (Li et al., 2016c). We use all the three reward functions mentioned in the paper and keep the relative weights the same as in the original paper. Policy network is initialized with the above-mentioned MMI model.

NEXUS-H: NEXUS network maximizing mutual information only with the history ($\lambda_2 = 0$).

NEXUS-F: NEXUS network maximizing mutual information only with the future ($\lambda_1 = 0$).

NEXUS: NEXUS network maximizing mutual information with both the history and future.

NEXUS-H and NEXUS-F are implemented to help us better analyze the effects of different components in our model. The hyperparameters λ_1 and λ_2 in NEXUS are set to be 0.5 and 1 respectively as we find history vector is consistently easier to be reconstructed than the future vector (A.6).

4.3 Metric-based Performance

Embedding Score We conducted three embedding-based evaluations (average, greedy and extrema) (Liu et al., 2016), which map responses into vector space and compute the cosine similarity (Rus and Lintean, 2012). The embedding-based metrics can to a large extent capture the semantic-level similarity between generated responses and ground truth. We represent words using Word2Vec embeddings trained on the Google News Corpus. We also measure the uncertainty of the score by assuming each data point is independently Gaussian distributed. The standard deviation yields the 95% confidence interval (Barany et al., 2007). Table 1 reports the embedding scores on both datasets. NEXUS network significantly outperforms the best baseline model in most cases. Notably, NEXUS can absorb the advantages from both NEXUS-H and NEXUS-F. The history and future information seem to help the model from different perspectives. Taking into account both of them does not create a conflict and the combination leads to an overall improvement. RL performs rather poorly on this metric, which is understandable as it does not target the ground-truth responses during training (Li et al., 2016c).

BLEU Score BLEU is a popular metric that measures the geometric mean of the modified n-gram precision with a length penalty (Papineni et al., 2002). Table 2 reports the BLEU 1-3 scores. Compared with embedding-based metrics, the BLEU score quantifies the word-overlap between generated responses and the ground-truth. One challenge of evaluating dialogue generation by BLEU score is the difficulty of accessing multiple references for the one-to-many alignment relation. Following Sordoni et al. (2015); Zhao et al.

Model	**DailyDialog**			**Twitter**		
	BLEU-1	**BLEU-2**	**BLEU-3**	**BLEU-1**	**BLEU-2**	**BLEU-3**
Greedy	0.394	0.245	0.157	0.340	0.203	0.116
Beam	0.386	0.251	0.163	0.338	0.205	0.112
MMI	0.407	0.269	0.172	0.347	0.208	0.118
RL	0.298	0.186	0.075	0.314	0.199	0.103
VHRED	0.395	**0.281**	0.190	0.355	0.211	0.124
NEXUS-H	0.418	0.279	**0.199***	**0.366***	0.212	0.126
NEXUS-F	0.399	0.260	0.167	0.359	0.213	0.123
NEXUS	**0.424***	0.276	0.198*	0.363*	**0.220***	**0.131***

Table 2: Results of BLEU score. It is computed based on the smooth BLEU algorithm (Lin and Och, 2004). p-value interval is computed base on the altered bootstrap resampling algorithm (Riezler and Maxwell, 2005)

(2017); Shen et al. (2018), for each context, 10 more candidate references are acquired by using information retrieval methods (see Appendix A.4 for more details). All candidates are then passed to human annotators to filter unsuitable ones, resulting in 6.74 and 5.13 references for DailyDialog and Twitter dataset respectively. The human annotation is costly, so we evaluate it on 1000 sampled test cases for each dataset. As the BLEU score is not the simple mean of individual sentence scores, we compute the 95% significance interval by bootstrap resampling (Koehn, 2004; Riezler and Maxwell, 2005). As can be seen, NEXUS network achieves best or near-best performances with only greedy decoders. NEXUS-H generally outperforms NEXUS-F as the connection with future context is not explicitly addressed by the BLEU score metric. MMI and VHRED bring minor improvements over the seq2seq model. Even when evaluated on multiple references, RL still performs worse than most models.

Connecting the preceding We define two metrics to evaluate the model's capability of "connecting the preceding context": **AdverSuc** and **Neg-PMI**. AdverSuc measures the coherence of generated responses with the provided context by learning an adversarial discriminator (Li et al., 2017a) on the same corpus to distinguish coherent responses from randomly sampled ones. We encode the context and response separately with two different LSTM neural networks and output a binary signal indicating coherent or not[1]. The AdverSuc value is reported as the success rate that the model fools the classifier into believing its false generations ($p(generated = coherent) > 0.5$). Neg-PMI measures the negative pointwise mutual information value $-\log p(c|r)/p(c)$ between the generated response r and the dialogue context c. $p(c|r)$ is estimated by training a separate backward seq2seq model. As $p(c)$ is a constant, we ignore it and only report the value of $-\log p(c|r)$. A good model should achieve a higher AdverSuc and a lower Neg-PMI. The results are listed in Table 3. We can see there is still a big gap between ground-truth and synthesized responses. As expected, NEXUS-H leads to the most significant improvement. MMI model also performs remarkably well, but it requires post-reranking thus the sampling process is much slower. VHRED and NEXUS-F do not help much here, sometimes even slightly degrade the performance. We also tried removing the history context when computing the posterior distribution in VHRED, the resulting model has similar performance among all metrics, which suggests VHRED itself cannot actually learn the correlation pattern with the preceding context. Surprisingly, though RL explicitly set the coherence score as a reward function, its performance is far from satisfying. We assume RL requires much more data to learn the appropriate policy than other models and the training process suffers from a higher variance. The result is thus hard to be guaranteed.

Connecting the following We measure the model's capability of "connecting the following context" from two perspectives: number of the simulated turns and diversity of generated re-

---

[1] We apply the same architecture as in Lu et al. (2017). In our experiment, the discriminator performs reasonably well in the 4 scenarios outlined in Li et al. (2017a) and thus can be used as a fair evaluation metric.

Model	AdverSuc	Neg-PMI	#Turns	Distinct-1	Distinct-2	Pri	Post	Flu
Greedy	0.21|0.13	47.4|45.8	0.2|0.6	.019|.017	.096|.072	0.45	0.04	0.92
Beam	0.16|0.12	47.2|45.3	0.2|0.7	.026|.019	.103|.086	0.52	0.06	0.90

Table 3: Coherence, diversity and human evaluations. Left: DailyDialog results, right: Twitter results

sponses. We apply all models to generate multiple turns until a generic response is reached. The set of generic responses is manually examined to include all utterances providing only passive dull replies[2]. The number of generated turns can reflect the time that a model can maintain an interactive conversation. The results are reflected in the **#Turns** column in Table 3. As in (Li et al., 2016a), we measure the diversity by the percentage of distinct unigrams (**Distinct-1**) and bigrams (**Distinct-2**) in all generated responses. Intuitively a higher score on these three metrics implies a more interactive generation system that can better connect the future context. Again, NEXUS network dominates most fields. NEXUS-F brings more impact than NEXUS-H as it explicitly encourages more interactive turns. Most seq2seq models fail to provide an informative response in the first turn. The MMI-decoder does not change much, possibly because the sampling space is not large enough, a more diverse sampling mechanism (Vijayakumar et al., 2018) might help. NEXUS network can effectively continue the conversation for 2.8 turns for DailyDialog and 2.5 turns for Twitter, which is closest to the ground truth (4.8 and 4.0 turns respectively). It also achieves the best diversity score in both datasets. It is worth mentioning that NEXUS-H also improves over baselines, though not as significantly as NEXUS-F, so NEXUS is not a trade-off but more like an enhanced version from NEXUS-H and NEXUS-F.

In summary, NEXUS network clearly generates higher-quality responses in both coherence and diversity, even in a rather small dataset like DailyDialog. NEXUS-H contributes more to the coherence and NEXUS-F more to the diversity.

4.4 Human Evaluation

We also employed crowdsourced judges to provide evaluations for a random sample of 500 items in the DailyDialog test dataset. Participants are asked to assign a binary score to each context-response pair from three perspectives: whether the response coincides with its preceding context (Pri), whether the response is interesting enough for people to continue (Post) and whether the response itself is a fluent natural sentence (Flu). Each sample gets one point if judged as yes and zero otherwise. Each pair is judged by three participants and the score supported by most people is adopted. We also evaluated the inter-annotator consistency by Fleiss'k score(Fleiss, 1971) and obtained k scores of 0.452 for Pri, 0.459 for Post (moderate agreement) and 0.621 for Flu (substantial agreement), which implies most context-response pairs reach a consensus on the evaluation task. We compute the average human score for each model. Unlike metric-based scores, the human evaluation is conducted only on the DailyDialog corpus as it contains less noise and can be more fairly evaluated by human judges. Table 3 shows the result in the last three columns. As can be seen, the pri and post human scores are highly correlated with the automatic evaluation metric "coherence" and "#turns", verifying the validity of these two metrics. As for fluency, there is no significant difference among most models. As we also manually examined, fluency is not a major problem and all models produce mostly well-formed sentences. Overall, NEXUS network does produce responses that are more acceptable to human judges.

Table 4 presents some randomly sampled context-response pairs provided by MMI,

---

[2] We use a simple rule matching method (see Appendix A.5). We manually inspect it on a validation subset and find the accuracy is more than 90%. Similar methods are adopted in (Li et al., 2016c).

Context	**Response**
Hi , Alice , what are you going to do this sunday ? __eou__	**MMI:** Oh , that' s great ! **VHRED :** Well , it seems that i'm going to be late . **RL :** How long he it be ? **NEXUS:** Nothing really , what ' s up ?
Did you watch the Oscars on Sunday night ? __eou__	**MMI:** I have no idea . **VHRED:** That's not too bad . **RL :** It's my mum's birthday on Sunday . **NEXUS:** No , nothing much. Could you help me ?
Let's go for a drink ! __eou__	**MMI:** Thanks . **VHRED:** all right . let me see you then . **RL :** Thank you inviting me . **NEXUS:** Sounds good . Where are we going ?
You won't want to miss our webinar tomorrow ! __eou__	**MMI:** lol ! **VHRED:** That ' s terrific ! **RL :** Sure, where where ? **NEXUS:** Thanks for your invitation! I'm free !
How I read the article ? __eou__	**MMI:** there!!! **VHRED:** What ' s good with it ? **RL :** : I dont know what to do with it ! **NEXUS:** Maybe the force is yourself !

Table 4: Examples of context-response pairs. __eou__ denotes end-of-utterance. First three rows are from DailyDialog and the last two rows are from Twitter

VHRED, RL and NEXUS model. We see NEXUS network does generate more interactive outputs than the other three. Though reranked by the bidirectional language model, the MMI decoder still produces quite a few generic responses. VHRED's utterances are more diverse, but it only cares about answering to the immediate query and makes no efforts to bring about further topics. Moreover, it also generates more inappropriate responses than the others. RL provides diverse responses but sometimes not fluent or coherent enough. We do observe that NEXUS sometimes generate over-complex questions which are not very natural, as in the second example. But in most cases, it outperforms the others.

5 Conclusion

In this paper, we propose "NEXUS Network" to enable more interactive human-computer conversations. The main goal of our model is to strengthen the "nexus" role of the current utterance, connecting both the preceding and the following dialogue context. We compare our model with MMI, reinforcement learning and CVAE-based models. Experiments show that NEXUS network consistently produces higher-quality responses. The model is easier to train, requires no special tricks and demonstrates remarkable generalization capability even in a very small dataset.

Our model can be considered as combining the objective of MMI and CVAE and is compatible with current improving techniques. For example, mutual information can be maximized under a tighter bound using Donsker-Varadhan or f-divergence representation (Donsker and Varadhan, 1983; Nowozin et al., 2016; Belghazi et al., 2018). Extending the code space distribution to more than Gaussian by importance weighted autoencoder (Burda et al., 2015), inverse autoregressive flow (Kingma et al., 2016) or VamPrior (Tomczak and Welling, 2018) should also help with the performance.

Abstract

We propose a local coherence model that captures the flow of what semantically connects adjacent sentences in a text. We represent the semantics of a sentence by a vector and capture its state at each word of the sentence. We model what relates two adjacent sentences based on the two most similar semantic states, each of which is in one of the sentences. We encode the perceived coherence of a text by a vector, which represents patterns of changes in salient information that relates adjacent sentences. Our experiments demonstrate that our approach is beneficial for two downstream tasks: Readability assessment, in which our model achieves new state-of-the-art results; and essay scoring, in which the combination of our coherence vectors and other task-dependent features significantly improves the performance of a strong essay scorer.

1 Introduction

Coherence is a key factor that distinguishes well-written texts from random collections of sentences. A potential application of coherence models is text quality assessment. Examples include readability assessment (Pitler and Nenkova, 2008; Li and Hovy, 2014) and essay scoring (Miltsakaki and Kukich, 2004; Burstein et al., 2010). Here, we address the problem of local coherence modeling, which captures text relatedness at the level of sentence-to-sentence transitions.

Several approaches to local coherence modeling have been proposed. Entity-based methods principally relate adjacent sentences by means of entities, which are mentioned as noun phrases, NPs, in sentences (Barzilay and Lapata, 2008; Elsner and Charniak, 2011; Guinaudeau and Strube, 2013; Tien Nguyen and Joty, 2017). Lexical models connect sentences based on semantic relations between words in sentences (Beigman Klebanov and Shamir, 2006; Heilman et al., 2007; Mesgar and Strube, 2016). Both of these approaches suffer from different weaknesses. The entity-based models require an entity detection system, a coreference model, and a syntactic parser. These subsystems need to be perfect to gain the best performance of entity-based coherence models. The weakness of the lexical models is that they consider words independently, i.e. regardless of context in that words appear. More concretely, such lexical models take sentences as a bag of words. Recent deep learning coherence work (Li and Hovy, 2014; Li and Jurafsky, 2017) adopts recursive and recurrent neural networks for computing semantic vectors for sentences. Coherence models that use recursive neural networks suffer from a severe dependence on external resources, e.g. a syntactic parser to construct their recursion structure. Coherence models that purely rely on the recurrent neural networks process words sequentially within a text. However, in such models, long-distance dependencies between words cannot be captured effectively due to the limits of the memorization capability of recurrent networks.

Our motivation is to overcome these limitations. We use the advantages of distributional representations in order to, first, identify and represent salient semantic information that connects sentences, and second, extract patterns of changes in such information as a text progresses. By representing words of sentences with their pre-trained embeddings, we take lexical semantic relations between words into account. We employ a Recurrent Neural Network (RNN) layer to combine information in word embeddings and actual context information of words in sentences. Our model encodes salient information that relates two adja-

cent sentences based on the two most similar RNN states in sentences. We accumulate two identified RNN states to represent semantic information that connects two adjacent sentences. We encode pattern of semantic information changes across sentences in a text by a convolutional neural network to represent coherence. Our end-to-end coherence model is superior to previous work because it relates sentences based on two semantic information states in sentences that are highly similar. So it does not need extra tools such as coreference resolution systems. Furthermore, our model incorporates words in their sentence context and models (roughly) distant relations between words.

We evaluate our model on two tasks: readability assessment and essay scoring. Both have been frequently used for coherence evaluation (Barzilay and Lapata, 2008; Miltsakaki and Kukich, 2004). Readability assessment is a ranking task where we compare the rankings given by the model against human judgments. Essay scoring is a regression task, in which we investigate if the combination of coherence vectors produced by our model and other essay scoring features proposed by Phandi et al. (2015) improves the performance of the essay scorer. The experimental results show that our model achieves the state-of-the-art result for readability assessment on the examined dataset (De Clercq and Hoste, 2016); and the combination of our coherence features with other essay scoring features significantly improves the performance of the examined essay scorer (Phandi et al., 2015).

2 Related Work

Early work on coherence captures different types of relations: entity-based (Grosz et al., 1995; Barzilay and Lapata, 2008), lexical-based (Beigman Klebanov and Flor, 2013; Somasundaran et al., 2014; Zhang et al., 2015), etc. Among these models, the entity-grid model (Barzilay and Lapata, 2005, 2008) has received a lot of attention. In this model, entities are defined, heuristically, by applying a string match over head nouns of all NPs in a text. The model, then, defines all possible changes over syntactic roles of entities in adjacent sentences as coherence patterns. The entity-grid model has been extended both by expanding its entity extraction phase (Elsner and Charniak, 2011; Feng and Hirst, 2012) and by defining other types of patterns (Lin et al., 2011; Louis and Nenkova, 2012; Ji and Eisenstein, 2014; Guinaudeau and Strube, 2013). Recently, Tien Nguyen and Joty (2017) fed entity grid representations of texts to a convolutional neural network (CNN) in order to overcome the limitation of predefined coherence patterns and extract patterns automatically. However, all of these models limit relations between sentences to entities that are shared by sentences. This makes the performance of these models dependent on the performance of other tools like coreference resolution systems and syntactic parsers. Our coherence model, in contrast, is based on relations between any embedded semantic information in sentences, and does not require entity annotations. A similar approach to ours is proposed by Mesgar and Strube (2016). Their approach encodes lexical relations between sentences in a text via a graph. Sentences are encoded by nodes, and lexical semantic relations between sentences are represented by edges. Coherence patterns are obtained by applying a subgraph mining method to graph representations of all texts in a corpus. This model involves words individually and independent of their sentence context. Our model uses a RNN layer over words in sentences to incorporate context information. Our approach for extracting coherence patterns also differs from this model as we employ CNNs rather than graph mining. Li and Hovy (2014) model sentences as vectors derived from RNNs and train a feed-forward neural network that takes an input window of sentence vectors and assigns a probability which represents the coherence of the sentences in the window. Text coherence is evaluated by sliding the window over sentences and aggregating their coherence probabilities. Similarly, Li and Jurafsky (2017) study the same model at a larger scale and use a sequence-to-sequence approach in which the model is trained to generate the next sentence given the current sentence and vice versa. Our approach differs from these methods; we represent coherence by a vector of coherence patterns. Moreover, our model takes distant relations between words in a text into account by relating two semantic states of sentences that are highly similar. Lai and Tetreault (2018) compare the performance of the aforementioned coherence models on texts from different domains. They conclude that the neural coherence models, which are explained above, surpass examined non-neural coherence models such as the entity-based models and the lexical-based model. Unlike their evaluation method, which predicts the coherence level of a text, we rank two texts with respect to their coherence levels for the readability assessment task. We also show that integrating our coherence model into an essay scorer improves its performance.

An important task for evaluating a coherence model is readability assessment (Li and Hovy, 2014; Petersen et al., 2015; Todirascu et al., 2016). The more coherent a text, the faster to read and easier to understand it is. Early readability formulas were based on superficial text features such as average word lengths (Kincaid et al., 1975). These formulas systematically ignore many important factors that affect readability such as discourse coherence (Barzilay and Lapata, 2008). Schwarm and Ostendorf (2005) and Feng et al. (2010) recast readability assessment as a ranking task, and employ different semantic (e.g. language model perplexity scores) and syntactic (e.g. the average number of NPs) features to solve this task. Pitler and Nenkova (2008) show that discourse coherence features are more informative than other features for ranking texts with respect to their readability. Following the related work on coherence modeling (Barzilay and Lapata, 2008; Mesgar and Strube, 2015), we evaluate our coherence model on this task.

Another popular task for evaluating coherence models is essay scoring (Beigman Klebanov and Flor, 2013; Somasundaran et al., 2014). Miltsakaki and Kukich (2004) employ an essay scoring system to examine whether local coherence features, as defined by a measure of Centering Theory's Rough-Shift transitions (Grosz et al., 1995), might be a significant contributor to the evaluation of essays. They show that adding such features to their essay scorer improves its performance significantly. Burstein et al. (2010) specifically focus on the impact of entity transition features, as proposed by the entity-grid model for coherence modeling, on the essay scoring task. They demonstrate that by combining these features with other features related to grammar errors and word usage, the performance of their automated essay scoring system improves. Likewise, we combine our coherence vectors with other features that are used by a strong essay scorer (Phandi et al., 2015) and show that our coherence vectors improve the performance of this system significantly.

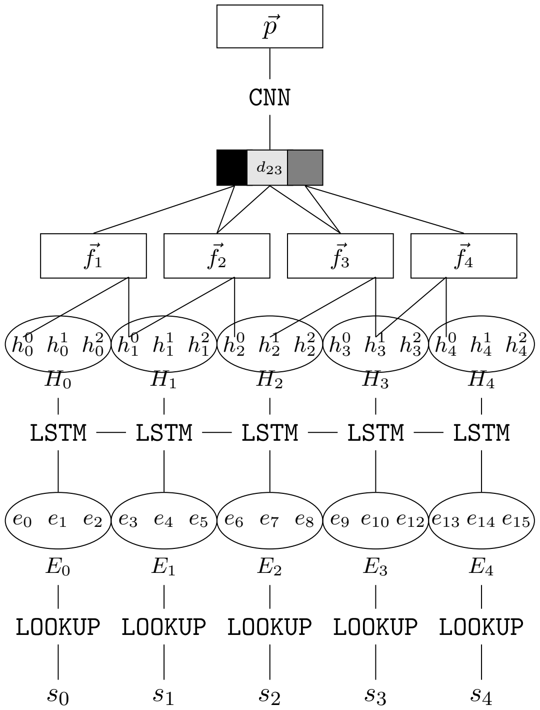

Figure 1: An illustration of our model. e_k is word embeddings associated with the k^{th} word in an input text. h_i^j depicts the j^{th} hidden state in LSTM states of sentence s_i. Two states in LSTM states of sentence s_i and sentence s_{i-1} that have the highest similarity are selected to connect sentences. Vector $\vec{f_i}$ captures information about the salient topic that relates sentence s_i to sentence s_{i-1}. d_{23} represents the similarity between $\vec{f_2}$ and $\vec{f_3}$ or the degree of continuity of the topic over adjacent sentences. Different shades of gray show different degrees of similarity. The `CNN` encodes patterns of changes as coherence vector $\vec{p}$.

3 Coherence Model

In this section, we describe details of our model. First, we explain how we encode words in their context (Section 3.1). Then we show how we relate sentences (Section 3.2), and finally we explain how we represent coherence based on sentence relations (Section 3.3). A general formulation of our model is a parametric function, $\vec{p} = L_\theta(d)$, where d is an input document, θ indicates parameters of neural modules, and $\vec{p}$ is a vector representation for the coherence of d. Figure 1 illustrates our model.

3.1 Word and Context Representations

We use a lookup table to associate all words in the vocabulary with word embeddings. The lookup table is initialized by existing pre-trained word embeddings because they capture lexical semantic relations between words. For sentence s_i, the lookup table returns matrix E_i whose rows are embeddings of words in s_i. A weakness of former lexical coherence models (Somasundaran et al., 2014; Mesgar and Strube, 2016) is that they only rely on semantic relations between words in sentences, regardless of the current context of words. In order to overcome this limitation, we use a standard unidirectional[1] RNN with Long Short-Term Memory (LSTM) cells to encode the current context of words in sentences. For embedding matrix E_i:

$$H_i = \texttt{LSTM}\left(E_i, h_{i-1}^{n-1}\right),$$

where H_i is a list of LSTM states, and h_{i-1}^{n-1} is the last LSTM state of sentence s_{i-1}. Parameter n is the number of words in a sentence. We take state vector $h_i^j \in H_i$ as a representation of its input word embedding, e_j, that is combined with its preceding word vectors in sentence s_i. For sake of brevity, the details of `LSTM` formulations are explained in Appendix A.

3.2 Sentence Relation Representations

The relation between sentences is encoded by the most similar semantic states of sentences. Given two adjacent sentences, two of their LSTM states that have the highest similarity are selected to connect them. Those LSTM states refer to the salient semantic information that is shared between sentences. To model this, we follow attention components in neural language models (Bahdanau et al., 2014; Vaswani et al., 2017) where the similarity between the last LSTM state and each of its preceding states is computed to measure the amount of attention that the model should give to its preceding context for generating the next word. More formally, for two adjacent sentences s_i and s_{i-1}, one LSTM state in H_i and one LSTM state in H_{i-1} that have the maximum similarity are selected to represent the relation between the sentences:

$$(\vec{u}, \vec{v}) = \underset{\substack{(\vec{h}_m \in H_i) \\ (\vec{h}_n \in H_{i-1})}}{\operatorname{argmax}} \left(sim(\vec{h}_m, \vec{h}_n)\right),$$

where H_i and H_{i-1} are LSTM states corresponding to sentences s_i and s_{i-1}. The similarity function, sim, returns the absolute value of the dot product between input vectors,

$$sim(\vec{h}_m, \vec{h}_n) = |\vec{h}_m \cdot \vec{h}_n|, \tag{1}$$

where the function $|.|$ computes the absolute value of its input[2]. We use the dot product function because in practice it enables our model to calculate the above equations efficiently in parallel and in matrix-space, i.e., directly on H_i and H_{i-1}. Since this is the details of implementation, we explain matrix-based equations in Appendix B. The absolute value in the similarity function is used to encode semantic relatedness between associated information with vectors, which is independent of the sign of the similarity function (Manning and Schütze, 1999).

We represent semantic information that relates two adjacent sentences by accumulating its selected LSTM states in the corresponding sentences. Since averaging in the vector space is an effective way to accumulate information represented in some vectors (Iyyer et al., 2015; Wieting et al., 2016), we compute the average of two identified vectors among the LSTM states of two adjacent sentences to represent semantic information shared by the sentences. More concretely, the vector representation of what relates sentence s_i to its immediately preceding sentence is obtained by averaging a vector of H_i and a vector of H_{i-1} that are identified as highly similar:

$$\vec{f_i} = avg(\vec{u}, \vec{v}) = \frac{\vec{u} + \vec{v}}{2},$$

where $\vec{u}$ and $\vec{v}$ are selected vectors. $\vec{f_i}$ is the vector representation of what connects s_i to its immediately preceding sentence.

3.3 Coherence Representations

Since sentences in a coherent text are about similar topics and share some semantic information, we compute semantic similarity between adjacent information states, i.e. $\vec{f_i}$s, to capture how they are changing through a text. We propose to encode changes by a continuous value between 0 and 1, where 1 shows that there is no change and 0 indicates that there is a big semantic drift in a text. Any value in between depicts how far a text is semantically changing. Given two adjacent vectors $\vec{f_i}$ and $\vec{f}_{i+1}$, the degree of continuity between them is:

---

[1] We use unidirectional RNN to model the way that an English text is read.

[2] In practice, the absolute function is implemented as $g(z) = \max(0, z) - \min(0, z)$ to be differentiable.

$$d = \frac{sim(\vec{f_i}, \vec{f_{i+1}})}{l},$$

where l is the length of input vectors, which is used to prevent large numbers (Vaswani et al., 2017), and sim is the similarity function (Section 3.2). The task of this layer is to check if the salient information that is shared by two adjacent sentences is salient in the subsequent sentence or not.

The last layer of our model is a convolutional layer to automatically extract and represent patterns of semantic changes in a text. CNNs have proven useful for various NLP tasks (Collobert et al., 2011; Kim, 2014; Kalchbrenner et al., 2014; Cheng and Lapata, 2016) because of their effectiveness in identifying patterns in their input (Xu et al., 2015). In the case of coherence, the convolution layer can identify coherence patterns that correlate with final tasks (Tien Nguyen and Joty, 2017). We use a temporal narrow convolution by applying a kernel filter k of width h to a window of h adjacent transitions over sentences to produce a new coherence feature. This filter is applied to each possible window of transitions in a text to produce a feature map $\vec{p}$, which is a coherence vector. Since we use a standard convolution layer, we explain details of the CNN formulations in Appendix C.

3.4 Variants of Our Model

In our experiments, we consider two variants of our model: **CohLSTM** that is the full version of our model as described above; and **CohEmb** that is an ablation. CohEmb has no RNN layer, so the model is built directly on word embeddings. In this model, relations between sentences are made over only content words by eliminating all stop words.

4 Implementation Details

Model configurations. Our model is implemented in PyTorch[3] with CUDA 8.0 support. In preprocessing we apply zero-padding to all sentences and documents to make their length equal. The vocabulary is limited to the 4000 most frequent words in the training data and all other words are replaced with the unknown token. We use the pre-trained word embeddings released by Zou et al. (2013), which are employed by state-of-the-art essay scoring systems. The dimensions of word embeddings and LSTM cells are 50 and 300, respectively. The convolution layer uses one filter with size 4. However, optimizing hyperparameters for each task may lead to better performance. For selecting two vectors with the highest similarity from the LSTM states of two adjacent sentences, we capture the similarity between any pair of LSTM states of the sentences as an element in a vector, and then apply a max-pooling layer to this vector of similarities to identify the pair with maximally similar LSTM states. Selected LSTM states are used for representing salient information shared by the sentences. In CohEmb, stop words are removed by the SMART English stop word list (Salton, 1971).

Training setup. We set the mini-batch size to 32 and train the network for 100 epochs. At each epoch we evaluate the model on the validation set and select the one with the best performance for test evaluations. We optimize with *Adam*, with an initial learning rate of 0.01. Word vectors are updated during training. The dropout method with rate 0.5 is employed for regularization. Loss functions are specifically defined for each task.

5 Experiments

We evaluate our model on two downstream tasks: readability assessment (Section 5.1), in which coherence representations of documents are mapped to coherence scores, and then documents are ranked based on these scores; and essay scoring (Section 5.2), in which the coherence representation of an essay is combined with other features for essay scoring to quantify the quality of the essay.

5.1 Readability Assessment

Readability assessment – How difficult is a text to read and understand? – depends on many factors one of which is coherence. Texts that are more coherent are supposed to be faster to read and easier to understand. Following earlier research on local coherence (Barzilay and Lapata, 2008; Pitler and Nenkova, 2008; Guinaudeau and Strube, 2013), we evaluate our coherence model on this task by ranking texts with respect to readability, instead of predicting readability scores. More formally, we approach readability assessment as follows: Given a text-pair, which text is easier to read?

---

[3] https://pytorch.org

Compared models. We compare the two variants of our model as described in Section 3.4 with two following state-of-the-art systems:

Mesgar and Strube (2016). This is a graph-based coherence model, in which nodes of a graph indicate sentences of a text, and an edge between two sentence nodes represents the existence of a lexico-semantic relation between two words in the sentences. Semantic relations between words are measured by the absolute value of the cosine function over their corresponding pre-trained word embeddings. If the similarity value for two word vectors is below a certain threshold[4] then the connection between these two words is omitted. Given the graph representation of a text, its coherence is encoded as a vector whose elements are frequencies of different subgraphs in the graph. The size of subgraphs is defined by the number of their nodes and is set to five. Subgraphs are extracted by a random sampling approach. We choose this model for comparison because its intuition is similar to our model. However, this model suffers from the following limitations: word embeddings are considered independently, not in their current context; and a manual threshold is used for connection filtering. We overcome these two weaknesses using the RNN and CNN layers in our model, respectively.

De Clercq and Hoste (2016). This is the state-of-the-art readability system on the examined dataset. It uses a rich set of readability features ranging from surface to semantic text features. The ranking is performed by LibSVM in their model. We report their best performance that is achieved by extensive feature engineering and SVM's parameter optimization.

Experimental setup. In Section 3, we formulated our model as $\vec{p} = L_\theta(d)$ where θ represents parameters of the neural modules (i.e. the CNN and RNN layers) in our model. For this task, we use an output layer to map coherence vector $\vec{p}$ to score s which quantifies the degree of the perceived coherence of document d. Formally, the output layer is $s_d = \vec{u} \cdot \vec{p} + b$ where $\vec{u}$ and b are the weight vector and bias, respectively. Let document d be more readable than document d', then the model should ideally produce $s_d > s'_d$. We train the parameters of the model by a pairwise ranking approach and define the loss function as:

$$loss = \max\{0, 1 - s_d + s_{d'}\}.$$

The parameters of the model are shared to obtain the scores for texts in pair (d, d').

Data. We use the readability dataset proposed by De Clercq et al. (2014). It consists of 105 texts collected from the British National Corpus and Wikipedia in four different genres: administrative (e.g. reports and surveys), informative (e.g. articles of newspapers and Wikipedia entries), instructive (e.g. user manuals and guidelines), and miscellaneous (e.g., very technical texts and children's literature). The average number of sentences is about 12 per text. $10,907$ pairs of texts are labeled with five fine-grained categories: $\{-100, -50, 0, 50, 100\}$ indicating that the first text in a pair is respectively *much easier*, *somewhat easier*, *equally difficult*, *somewhat difficult*, *more difficult* to read than the second text in the pair. Labels of text-pairs are assigned by human judges. Similar to De Clercq and Hoste (2016), we evaluate on the positive and negative labels as two sets of classes resulting in $6,290$ text-pairs in total. The original readability dataset does not provide any standard training/validation/test sets. We apply 5-fold cross-validation over this dataset.

Evaluation metric. The quality of a model is measured in terms of accuracy, which is the fraction of pairs that are correctly ranked by a model divided by the total number of document-pairs. We report the average accuracy over all runs of cross-validation as the final result. We perform a paired t-test to determine if improvements are statistically significant ($p < .05$).

Results. Table 1 summarizes the results of different systems for the readability assessment task.

Model	**Accuracy (%)**
Mesgar and Strube (2016)	85.70*
CohEmb	92.17*
CohLSTM	**97.77**
De Clercq and Hoste (2016)	96.88

Table 1: Results on readability assessment. The first system is the state-of-the-art coherence model on this dataset. The last one is a full readability system. "$*$" indicates statistically significant difference with the bold result.

CohEmb significantly outperforms the graph-based coherence model proposed by

---

[4] Like Mesgar and Strube (2016), we set this threshold to 0.9.

Mesgar and Strube (2016) by a large margin (6%), showing that our model captures coherence better than their model. In our model, the CNN layer automatically learns which connections are important to be considered for coherence patterns, whereas this is performed in Mesgar and Strube (2016) by defining a threshold for eliminating connections.

CohLSTM significantly outperforms both the coherence model proposed by Mesgar and Strube (2016) and the CohEmb model by 11% and 5%, respectively, and defines a new state-of-the-art on this dataset. CohLSTM, unlike Mesgar and Strube (2016)'s model and CohEmb, considers words of sentences in their sentence context. This supports our intuition that actual context information of words contributes to the perceived coherence of texts.

CohLSTM, which captures exclusively local coherence, even outperforms the readability system proposed by De Clercq and Hoste (2016), which relies on a wide range of lexical, syntactic and semantic features.

5.2 Essay Scoring

One part of the student assessment process is essay writing where students are asked to write an essay about a given topic known as a prompt. An essay scoring system assigns an essay a score reflecting the quality of the essay. The quality of an essay depends on various factors including coherence. Following previous studies (Miltsakaki and Kukich, 2004; Lei et al., 2014; Somasundaran et al., 2014; Zesch et al., 2015), we approach this task by combining the coherence vector produced by our model and the feature vector developed by an open-source essay scorer to represent an essay by a vector. The final vector representation of an essay, $\vec{x}$, is mapped to a score by a simple neural regression method as follows:

$$s = sigmoid(\vec{u} \cdot \vec{x} + b),$$

where $\vec{u}$ and b are the weight vector and the bias, respectively. We exactly define vector $\vec{x}$ for different examined systems, where we explain compared models for essay scoring.

Compared models. We compare variations of our model (Section 3.4) with the following models:

EASE (BLRR). As a baseline we use an open-source essay scoring system, Enhanced AI Scoring Engine[5] (EASE) (Phandi et al., 2015). This system was ranked third among all 154 participating teams in the Automated Student Assessment Prize (ASAP) competition and is the best among all open-source participating systems. It employs Bayesian Linear Ridge Regression (BLRR) as its regression method applied to a set of linguistic features grouped in four categories: *(i) Frequency-based features*: such as the number of characters, the number of words, the number of commas, etc; *(ii) POS-based features*: the number of POS n-grams; *(iii) Word overlap with prompt*; *(iv) Bag of n-grams*: the number of uni-grams and bi-grams.

EASE. The difference between this system and *EASE (BLRR)* is in the employed regression method. This system uses a neural regression method as described above. In order to have a similar experimental settings for this task, here, we use feature vectors generated by Phandi et al. (2015) to train our neural regression system. The input of the neural regression function is a nonlinear transformation of the feature vector produced by EASE, $\vec{f}$. Therefore $\vec{x} = tanh(\vec{w} \cdot \vec{f} + b)$.

EASE & CohEmb. This model combines the feature vector computed by EASE, $\vec{f}$, and the coherence vector produced by CohEmb, $\vec{p}$, to have a more reliable representation of an essay. More concretely, the input to our regression function, $\vec{x}$, is obtained as follows:

$$\vec{h}_1 = tanh(\vec{w}_1 \cdot \vec{f} + b_1),$$
$$\vec{h}_2 = \vec{h}_1 \oplus \vec{p},$$
$$\vec{x} = tanh(\vec{w}_2 \cdot \vec{h}_2 + b_2),$$

where $\oplus$ indicates the concatenation operatation.

EASE & CohLSTM. The structure of this model is the same as the *EASE & CohEmb* structure. But the input coherence vector, $\vec{p}$, is produced by CohLSTM.

Dong et al. (2017). It is a sentence-document model, which is especially designed for this task. It first encodes each sentence by a vector, which represents whole sentence meanings, and then use an RNN to embed vectors of sentences into a document vector.

Experimental setup. The size of the input vector for the regression method, $\vec{x}$, is fixed to 100 and its output size is fixed to 1. Dimensions of other parameters, $\vec{w}_1$ and $\vec{w}_2$, are set accordingly. The

---

[5] `https://github.com/edx/ease`

loss function is the Mean Squared Error (MSE) between human scores, $\vec{H}$, and scores predicted by our system, $\vec{S}$:

$$MSE(\vec{H}, \vec{S}) = \frac{1}{N} \sum (\vec{H} - \vec{S})^2.$$

The models are compared for each prompt by running 5-fold cross-validation (Dong et al., 2017).

Data. We apply our model to a dataset used in the Automated Student Assessment Prize (ASAP) competition run by Kaggle[6]. The essays are associated with scores given by humans and categorized in eight prompts. Each prompt can be interpreted as a different essay topic along with different genres. Table 2 summarizes some properties of this dataset.

Prompt	# Essays	Genre	Avg. Len.
1	1783	argumentative	350
2	1800	argumentative	350
3	1726	response	150
4	1772	response	150
5	1805	response	150
6	1800	response	150
7	1569	narrative	250
8	723	narrative	650

Table 2: Some properties of the dataset used for the essay scoring experiment.

Evaluation metric. ASAP adopted Quadratic Weighted Kappa (QWK) as the official evaluation metric. This metric measures the agreement between scores predicted by a system and scores assigned by humans. QWK considers chance agreements and penalizes large disagreements more than small agreements. We use an implementation of QWK that is described in Taghipour and Ng (2016). The formulation of QWK are explained in Appendix D. The final reported QWK is the average over QWKs of all prompts. We perform a paired t-test to determine if improvements are statistically significant ($p < .05$).

Results. Table 3 shows the results of different systems for the essay scoring task.

Both EASE & CohEmb, and EASE & CohLSTM significantly improve EASE, confirming that our proposed representation for coherence is beneficial for essay scoring and improves the performance of the examined essay scoring system. Our model does not beat the state-of-the-art essay scoring system (Dong et al., 2017), which is especially designed for this task and is tuned on this dataset. This model learns a vector representation for an input essay so that the vector performs the best for this regression task. In contrast, the core of our best performing essay scoring system, i.e. EASE & CohLSTM, is the feature vector generated by EASE, which has less modeling capacity than a deep learning model like the model proposed by Dong et al. (2017). The reason that we combine our coherence model with EASE, rather than the model proposed by Dong et al. (2017), is that EASE has no notion of coherence. By combining our coherence model with it, we examine if our coherence vector improves its performance or not.

Surprisingly, EASE & CohLSTM works on par with EASE & CohEmb. To gain a better insight, we ablate EASE feature vectors and compare the performance of the coherence models, i.e., CohLSTM, and CohEmb. Of course, coherence vectors on their own are not sufficient for predicting essay scores but this setup shows how much each variant of our model contributes to this task. The two last rows in Table 3 show the results.

CohLSTM outperforms CohEmb on all prompts, which matches the results for readability assessment. This confirms our intuition that integrating the information of the current context of words contributes to coherence measurement.

In terms of average QWK, CohLSTM works similar to EASE; however they behave differently on different prompts. The largest improvement for CohLSTM, with respect to EASE, is obtained on prompt 7 and 8. These two prompts ask for stories about *laughter* and *patience*, so corresponding essays can be categorized in the narrative genre (see Table 2). The guidelines of these two prompts, which are publicly available in the Kaggle data, ask human annotators to assign the highest score to essays that are coherent and hold the attention of readers through an essay. This is what our model captures: the sequence of semantic changes in a text, or coherence.

On prompt 5, in contrast, we see the largest deterioration in performance of CohLSTM in comparison to EASE. This prompt asks students to describe the mood created by the author of a memoir. Essays are expected to contain specific infor-

CohLSTM	0.669	0.634	0.591	0.710	0.639	0.716	0.729	0.641	0.666

Table 3: Results on essay scoring. "$*$" shows significant improvements with respect to the underlined score ($p < .05$). Bold numbers show the best results among different variants of our model.

mation from the memoir so that an essay with the highest score has the highest coverage of all relevant and specific information from the memoir. Therefore, mentioning the details of the memoir in essays of prompt 5 is more important than coherence for this prompt. This also shows that our model exclusively captures the coherence of a text, which is the goal of this paper.

6 Conclusions

We developed a local coherence model that encodes patterns of changes in what semantically relates adjacent sentences. The main novelty of our approach is that it defines sentence connections based on any semantic concept in sentences. In this sense, our model goes beyond entity-based coherence models, which need extra dependencies such as coreference resolution systems. Moreover, in contrast to lexical cohesion models, which take words individually, our model encodes words in their sentence context. Our model relates sentences by means of distant relations between word representations. The most similar LSTM states in two adjacent sentences are selected to encode the salient semantic concept that relates the sentences. The model finally employs a convolutional layer to extract and represent patterns of topic changes across sentences in a text as a coherence vector.

We evaluate coherence vectors generated by our model on the readability assessment and essay scoring tasks. On the former, our model achieves new state-of-the-art results. On the latter, it significantly improves the performance of a strong essay scorer. We believe the reason that our system works is that it learns which semantic concepts of sentences should be used to relate sentences, and which information about concepts is required to model sentence-to-sentence transitions. In future work we intend to run qualitative experiments on patterns that are extracted by our model to see if they are also linguistically interpretable.

Acknowledgments

This work has been supported by the German Research Foundation (DFG) as part of the Research Training Group Adaptive Preparation of Information from Heterogeneous Sources (AIPHES) under grant No. GRK 1994/1 and the Klaus Tschira Foundation, Heidelberg, Germany. We thank Mohammad Taher Pilehvar, Ines Rehbein, and Mark-Christoph Müller for their valuable feedback on earlier drafts of this paper. We also thank anonymous reviewers for their useful suggestions for improving the quality of the paper.

Abstract

In this paper, we propose a novel deep attentive sentence ordering network (referred as ATTOrderNet) which integrates self-attention mechanism with LSTMs in the encoding of input sentences. It enables us to capture global dependencies among sentences regardless of their input order and obtains a reliable representation of the sentence set. With this representation, a pointer network is exploited to generate an ordered sequence. The proposed model is evaluated on Sentence Ordering and Order Discrimination tasks. The extensive experimental results demonstrate its effectiveness and superiority to the state-of-the-art methods.

1 Introduction

Modeling a coherent text is one of the key problems in natural language processing. A well-organized text with a logical structure is much easier for people to read and understand. Sentence ordering task (Barzilay and Lapata, 2008) has been proposed to cope with this problem. It aims to organize a set of sentences into a coherent text with a logically consistent order and has wide applications in natural language generation such as concept-to-text generation (Konstas and Lapata, 2012a,b, 2013), retrieval-based question answering (Yu et al., 2018; Verberne, 2011), and extractive multi-document summarization (Barzilay and Elhadad, 2002; Galanis et al., 2012; Nallapati et al., 2017), where the improper ordering of sentences would introduce ambiguity and degrade readability. An example of this task is shown in Table 1.

A set of sentences		An ordered text

3	Then we present our parser.	3	Then we present our parser.
2	We first describe the older one.	4	Finally, the parser is evaluated.

Table 1: An example to illustrate the sentence ordering task. The set of sentences is confusing in its current order. We aim to reorganize them with a more coherent order.

Traditional methods developed for this task employ handcrafted linguistic features to model the document structure such as Entity Grid (Barzilay and Lapata, 2008), Content Model (Barzilay and Lee, 2004), and Probabilistic Model (Lapata, 2003). However, manual feature engineering heavily relies on linguistic knowledge and also limits these systems to be domain specific. Inspired by the success of deep learning, data-driven approaches based on neural networks have been proposed including Pairwise Ranking Model (Chen et al., 2016) which learns the relative order of sentence pairs to predict the pairwise ordering of sentences, and Window network (Li and Hovy, 2014) sliding a window over the text to evaluate the coherence.

Recently, hierarchical RNN-based approaches (Gong et al., 2016; Logeswaran et al., 2018) have been proposed to deal with this task. Such methods exploit LSTMs based paragraph encoder to compute a context representation for the whole sequential sentences and then adopt a pointer network (Vinyals et al., 2015) as the decoder to predict their order. However, since LSTM works sequentially, paragraph encoder only based on LSTMs suffers from the incorrect input sentence order and has difficulty in capturing a logically reliable representation through the recurrent connections, which makes trouble for the decoder to find the correct order.

To overcome the above limitation, in this work, we develop a novel deep attentive sentence ordering network (referred as ATTOrderNet) by inte-

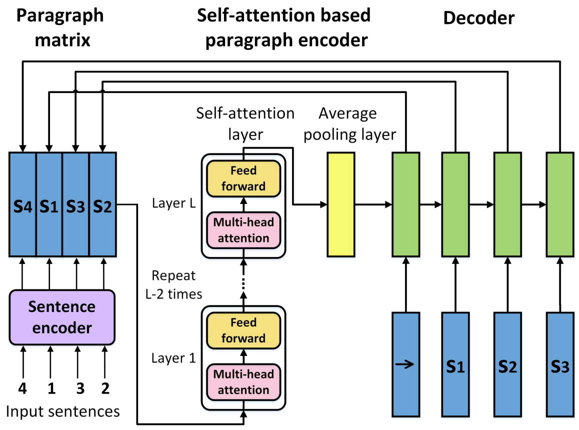

Figure 1: Architecture of deep attentive Sentence Ordering Network.

grating self-attention mechanism (Vaswani et al., 2017) with LSTMs to learn a relatively reliable paragraph representation for subsequent sentence ordering. In particular, the bidirectional LSTM is first adopted as a sentence encoder to map the input sentences to the corresponding distributed vectors, and then a self-attention based paragraph encoder is introduced to capture structural relationships across sentences and to obtain a hierarchical context representation of the entire set of sentences. Consequently, based on the learned paragraph vector, a pointer network is applied to perform sentence ordering by decoding an ordered sequence. Figure 1 shows the architecture of ATTOrderNet, where self-attention mechanism is introduced to capture the dependencies among sentences.

In contrast to the previous paragraph encoders with LSTMs, self-attention mechanism is less sensitive to the input order of sentence sequence and is effective in modeling the accurate relationships across sentences, which reduces the influence of the original order of the input sentences and perfectly meets the requirement of our task. Further, unlike Transformer (Vaswani et al., 2017), we do not add any positional encodings in our model to minimize the influence of the unclear order information.

Extensive evaluations are conducted on the sentence ordering task and order discrimination task to investigate the performances of ATTOrderNet. The experimental results on seven public sentence ordering datasets show the superior performances of the framework to the competing models. Meanwhile, the visualization of the attention layer in paragraph encoder is provided for better understanding of the effectivity of self-attention mechanism. Besides, in the Order Discrimination task, our model also achieves the state-of-the-art performance with remarkable improvements on two benchmark datasets.

2 Deep Attentive Sentence Ordering Network

In this section, we first formulate the sentence ordering problem and then describe the proposed model ATTOrderNet, which is based on the encoder-decoder architecture applying self-attention mechanism as paragraph encoder and a pointer network as the decoder. This combination effectively captures the intrinsic relations across a set of sentences with the desirable property of being invariant to the sentence order, which directly helps address the difficulty of this task.

2.1 Problem formulation

The sentence ordering task aims to order a set of sentences as a coherent text. Specifically, a set of n sentences with the order $\mathbf{o} = [o_1, o_2, \cdots, o_n]$ can be described as $\mathbf{s} = [s_{o_1}, s_{o_2}, \cdots, s_{o_n}]$. The goal is to find the correct order $\mathbf{o}^*$ for them, $\mathbf{o}^* = [o_1^*, o_2^*, \cdots, o_n^*]$, with which the whole sentences have the highest coherence probability:

$$P(\mathbf{o}^*|\mathbf{s}) > P(\mathbf{o}|\mathbf{s}), \forall \mathbf{o} \in \psi \qquad (1)$$

where $\mathbf{o}$ indicates any order of these sentences and ψ denotes the set of all possible orders. For instance, in Table 1, the current order $\mathbf{o}$ is $[4, 1, 3, 2]$ and $\mathbf{o}^* = [1, 2, 3, 4]$ is the correct order for these sentences.

2.2 Intuition and Model architecture

Given a set of sentences, the existing hierarchical RNN-based models first transform each sentence into a distributed vector with a sentence encoder and then these sentence embeddings are fed to a LSTMs-based paragraph encoder. Consequently, based on the learned paragraph vector, a pointer network is exploited to decode the order of the input sentences. However, since LSTM works sequentially while the order of these sentences is unknown and quite possibly wrong in this problem, LSTMs-based paragraph encoder has difficulty in capturing a convincing representation through the recurrent connections, which influences the performance of sentence ordering.

In this paper, we use self-attention mechanism for paragraph encoder instead. In particular, we employ this mechanism without encoding any positional information of the sentences. Ignoring the current order of the sentences, self-attention based paragraph encoder perfectly meets the requirement of the sentence ordering task and learns a logically reliable representation of the whole paragraph by globally capturing the relationships across sentences. With this learned representation vector, a decoder is then designed to generate a coherent order assignment for the input sentences.

In the following, we elaborate on the main building blocks of our ATTOrderNet in details: a sentence encoder, a self-attention mechanism based paragraph encoder, and a decoder.

2.3 Sentence Encoder

For a sentence, we first apply word embedding matrix to translate the raw words in the sentence into distributional representations, and then adopt bidirectional LSTMs to learn a sentence-level representation for summarizing its high level semantic concepts.

Specifically, assume that a sentence s_{o_i} containing n_w raw words as $s_{o_i} = [w_1, \cdots, w_{n_w}]$, these words are transformed to dense vectors through a word embedding matrix $\mathbf{W}_e$: $\mathbf{x}_t = \mathbf{W}_e w_t$, $t \in [1, n_w]$. The sequence of vectors $[\mathbf{x}_1, \cdots, \mathbf{x}_{n_w}]$ is then fed into bidirectional LSTMs sequentially to compute a semantic representation of the sentence.

Long Short-term Memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997) is capable of learning long-term dependencies and alleviating the problems of gradient vanishment and exploding. Here, we adopt bidirectional LSTMs (Bi-LSTMs) to take full advantages of additional backward information and enhance the memory capability. In particular, the Bi-LSTMs contain the forward LSTMs which process the sentence s_{o_i} from w_1 to w_{n_w} and backward LSTMs which read s_{o_i} in the reversed direction:

$$\begin{aligned} \overrightarrow{\mathbf{h}}_t, \overrightarrow{\mathbf{c}}_t &= \mathrm{LSTM}(\overrightarrow{\mathbf{h}}_{t-1}, \overrightarrow{\mathbf{c}}_{t-1}, \mathbf{x}_t) \\ \overleftarrow{\mathbf{h}}_t, \overleftarrow{\mathbf{c}}_t &= \mathrm{LSTM}(\overleftarrow{\mathbf{h}}_{t+1}, \overleftarrow{\mathbf{c}}_{t+1}, \mathbf{x}_t) \\ \mathbf{h}_t &= [\overrightarrow{\mathbf{h}}_t, \overleftarrow{\mathbf{h}}_t] \end{aligned} \tag{2}$$

where $\mathbf{h}_t$ denotes the representation of position t by concatenating the forward hidden state $\overrightarrow{\mathbf{h}}_t$ and backward hidden state $\overleftarrow{\mathbf{h}}_t$ together. The output of the last hidden state of the Bi-LSTMs is taken to be the sentence representation vector as $\mathbf{s}_{o_i} = \mathbf{h}_{n_w}$, which incorporates the contextual information from both directions in the sentence.

So far, we have obtained a syntactic and semantic representation for a single sentence. In the following, a self-attention based paragraph encoder is proposed to obtain a high level representation for all given sentences by capturing sequential structures and logical relationships among them.

2.4 Paragraph Encoder

2.4.1 Self-attention mechanism

We start by introducing the scaled dot-product attention, which is the foundation of self-attention mechanism used in ATTOrderNet. Given a matrix of n query vectors $\mathbf{Q} \in \mathbb{R}^{n \times d}$, keys $\mathbf{K} \in \mathbb{R}^{n \times d}$, and values $\mathbf{V} \in \mathbb{R}^{n \times d}$, the scaled dot-product attention computes the output matrix as:

$$\mathrm{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}(\frac{\mathbf{Q}\mathbf{K}^{\mathrm{T}}}{\sqrt{\mathrm{d}}})\mathbf{V} \tag{3}$$

The multi-head attention with h parallel heads is employed, where each head is an independent scaled dot-product attention. The mathematical formulation is shown below:

$$\mathbf{M}_i = \mathrm{Attention}(\mathbf{Q}\mathbf{W}_{\mathrm{i}}^{\mathrm{Q}}, \mathbf{K}\mathbf{W}_{\mathrm{i}}^{\mathrm{K}}, \mathbf{V}\mathbf{W}_{\mathrm{i}}^{\mathrm{V}}) \tag{4}$$

$$\mathrm{MH}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{Concat}(\mathbf{M}_1, \cdots, \mathbf{M}_h)\mathbf{W} \tag{5}$$

where $\mathbf{W}_i^Q, \mathbf{W}_i^K, \mathbf{W}_i^V \in \mathbb{R}^{d \times d_a}$ with $d_a = d/h$ are the projection matrices for the i-th head and $\mathbf{W} \in \mathbb{R}^{hd_a \times d}$.

Self-attention (Vaswani et al., 2017; Tan et al., 2017; Shen et al., 2017) is a special case of attention mechanism that only requires a single sequence to compute its representation where queries, keys, and values are all from the same place.

2.4.2 Self-attention based Paragraph Encoder

The paragraph encoder is composed of multiple self-attention layers followed by an average pooling layer.

Sentence vectors encoded by the sentence encoder are first packed together into a paragraph matrix $\mathbf{S} = [\mathbf{s}_{o_1}, \mathbf{s}_{o_2}, \cdots, \mathbf{s}_{o_n}]$ as $\mathbf{E}^0$. This paragraph matrix $\mathbf{S} \in \mathbb{R}^{n \times d}$ is then fed forward to L self-attention layers, where each layer learns a representation $\mathbf{E}^{l+1} = \mathrm{U}(\mathbf{E}^l)$ by taking the output from the previous layer l:

$$\mathrm{U}(\mathbf{E}^l) = \Phi(\mathrm{FN}(\mathrm{D}(\mathbf{E}^l)), \mathrm{D}(\mathbf{E}^l)) \quad (6)$$

$$\mathrm{D}(\mathbf{E}^l) = \Phi(\mathrm{MH}(\mathbf{E}^l, \mathbf{E}^l, \mathbf{E}^l), \mathbf{E}^l) \quad (7)$$

$$\Phi(\mathbf{v}, \mathbf{w}) = \mathrm{LayerNorm}(\mathbf{v} + \mathbf{w}) \quad (8)$$

$$\mathrm{FN}(\mathbf{x}) = \mathrm{ReLU}(\mathbf{x}\mathbf{W}_1^l + \mathbf{b}_1^l)\mathbf{W}_2^l + \mathbf{b}_2^l \quad (9)$$

where $\Phi(\cdot)$ performs layer normalization (Ba et al., 2016) on the residual output to preserve the auto-regressive property, and $\mathrm{FN}(\cdot)$ represents the fully connected feed-forward networks which consists of two linear layers with ReLU nonlinearity in the middle. $\mathbf{W}_1^l \in \mathbb{R}^{d \times d_f}$, $\mathbf{b}_1^l \in \mathbb{R}^{d_f}$, $\mathbf{W}_2^l \in \mathbb{R}^{d_f \times d}$, and $\mathbf{b}_2^l \in \mathbb{R}^d$ are trainable parameters. We set $d_f = 1024$ in all our experiments.

Self-attention mechanism adopted in the paragraph encoder directly relate sentences at different positions from the text by computing the attention score (relevance) between each pair of sentences. This allows each sentence to build links with all other sentences in the text, which enables the encoder to exploit latent dependency relationships among sentences without regarding to their input order. Then, attention mechanism uses weighted sum operation to establish a higher level representation for the entire sentence set. As we see, there is no order information used in the encoding process which prevents the model from being affected by the incorrect sentence order. Therefore, self-attention based paragraph encoder is efficient in modeling of dependencies while being invariant to the sentence order.

The final paragraph representation $\mathbf{v}$ is obtained in the average pooling layer by averaging the output matrix $\mathbf{E}^L \in \mathbb{R}^{n \times d}$ from the last self-attention layer: $\mathbf{v} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{e}^{L_i}$, where n is the number of sentences and $\mathbf{e}^{L_i}$ denotes the i-th row in $\mathbf{E}^L$. This learned representation vector can be viewed as a hierarchical encoding of the entire set of sentences which will then be used as the input of the decoder to perform sentence ordering.

2.5 Decoder

The aim of decoder is to predict a consistent order for the input set of sentences.

Following the previous approaches (Gong et al., 2016; Logeswaran et al., 2018), the coherence probability of given sentences $\mathbf{s}$ with the order $\mathbf{o}$ is formalized as:

$$P(\mathbf{o}|\mathbf{s}) = \prod_{i=1}^{n} P(o_i|o_{i-1}, \cdots, o_1, \mathbf{s}) \quad (10)$$

The higher the probability, the more coherent sentences assignment is.

To calculate $P(\mathbf{o}|\mathbf{s})$, we employ the pointer network architecture (Vinyals et al., 2015) as our decoder which consists of LSTMs cells (Equation 11-13). The LSTM takes the embedding of the previous sentence as the input to decoder step. During training, the correct order of sentences $\mathbf{o}^*$ is known, so the input sequence $[\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n] = [\mathbf{s}_{o_1^*}, \mathbf{s}_{o_2^*}, \cdots, \mathbf{s}_{o_n^*}]$. For step i, the input to the decoder is $\mathbf{x}_{i-1} = \mathbf{s}_{o_{i-1}^*}$. At test time, the predicted sentence assignment $\mathbf{s}_{\hat{o}_{i-1}}$ is used instead.

The initial state of the decoder LSTM is initialized with the final paragraph vector from the encoder: $\mathbf{h}_0 = \mathbf{v}^T$. And the input at the first step in decoder $\mathbf{x}_0 \in \mathbb{R}^d$ is a vector of zeros. The mathematical formulation for the i-th step in decoder is as follows:

$$\mathbf{h}_i, \mathbf{c}_i = \mathrm{LSTM}(\mathbf{h}_{i-1}, \mathbf{c}_{i-1}, \mathbf{x}_{i-1}) \quad (11)$$

$$\mathbf{u}_j^i = \mathbf{g}^T \tanh(\mathbf{W}_1 \mathbf{s}_{o_j} + \mathbf{W}_2 \mathbf{h}_i) \quad (12)$$

$$P(o_i|o_{i-1}, \cdots, o_1, \mathbf{s}) = \mathrm{softmax}(\mathbf{u}^i) \quad (13)$$

where $\mathbf{g} \in \mathbb{R}^d$, $\mathbf{W}_1 \in \mathbb{R}^{d \times d}$, and $\mathbf{W}_2 \in \mathbb{R}^{d \times d}$ are learnable parameters and $j \in (1, \cdots, n)$. The softmax function normalizes the vector $\mathbf{u}^i \in \mathbb{R}^n$ to produce an output distribution over all input sentences. And $P(o_i|o_{i-1}, \cdots, o_1, \mathbf{s})$ can be interpreted as the coherence probability for the current output sequence when s_{o_i} being the sentence choice at position i conditioned on the previous sentences assignment.

Order Prediction: The predicted order $\hat{\mathbf{o}} = [\hat{o}_1, \hat{o}_2, \cdots, \hat{o}_n]$ is the one with the highest coherence probability:

$$\hat{\mathbf{o}} = \underset{\mathbf{o}}{\mathrm{argmax}}\, P(\mathbf{o}|\mathbf{s}) \quad (14)$$

In this work, we use beam search strategy to find a sub optimal result.

2.6 Training

For each ordered document, we use one random permutation of sentences as the input sample at each epoch during the training and testing process. Assume that there are K documents in the training set. We define $(q_j, y_j)_{j=1}^K$, where y_j is in the correct order $\mathbf{o}^*$ of original document j and q_j denotes the set of sentences with a specific permutation of y_j. $P(y_j|q_j) = P(\mathbf{o}^*|\mathbf{s} = q_j)$ can be interpreted as the probability that sentences are assigned in the correct order when given sentences q_j.

Dataset	Length statistics			Data split			Vocabulary

SIND caption	5	5	5	40155	4990	5055	30861

Table 2: Statistics of seven datasets used in our experiments.

We aim to train the overall model to maximize this probability by minimizing the loss function:

$$L = -\frac{1}{K}\sum_{j=1}^{K} \log P(y_j|q_j;\theta) + \frac{\lambda}{2}||\theta||_2^2 \qquad (15)$$

where θ represents all trainable parameters in the networks and λ is a regularization parameter.

3 Experiments

3.1 Datasets

Accident, Earthquake: two datasets obtained from (Barzilay and Lapata, 2008). The first one is a collection of aviation accident reports from the National Transportation Safety Board and the second one comprises Associated Press articles related to earthquake. Since the original datasets do not provide validation samples, we follow the setup in (Louis and Nenkova, 2012; Li and Hovy, 2014) and use 10-fold cross validation on the training data.

NIPS abstract, AAN abstract, NSF abstract: these three datasets are from (Logeswaran et al., 2018) containing abstracts from NIPS papers, ACL papers, and the NSF Research Award Abstracts dataset respectively.

arXiv abstract, SIND caption: we further consider two datasets used in (Gong et al., 2016). The former consists of abstracts from papers on arXiv website (Chen et al., 2016) and the other contains captions from SIND dataset (Huang et al., 2016).

Further statistics about seven datasets are illustrated in Table 2.

3.2 Training setup

We use pre-trained 100 dimensional GloVe word embeddings (Pennington et al., 2014). And all the out-of-vocabulary words are replaced with <UNK>, whose embeddings are updated during training process. The nltk sentence tokenizer is used for word tokenization.[1] Parameter optimization is performed using stochastic gradient descent. We adopt Adadelta (Zeiler, 2012) as the optimizer with $\epsilon = 10^6$ and $\rho = 0.95$. The learning rate is initialized to 1.0, the batch size is 16, and the beam size is set to 64. The hidden layer size of LSTMs in sentence encoder is 256, and is 512 in the decoder. The number of attention layers in the paragraph encoder is 6 for AAN abstract, 4 for NSF abstract and arXiv abstract, and 2 for the rest of datasets. We employ 8 parallel heads throughout all self-attention layers and use L2 weight decay on the trainable variables with regularization parameter $\lambda = 10^{-5}$. The model is implemented with TensorFlow[2]. Hyperparameters are chosen using the validation set.

3.3 Sentence Ordering

We first evaluate our model on the sentence ordering task, as proposed by Barzilay and Lapata (2008). Given a set of permuted sentences, our goal is to return the original order for them which is considered to be the most coherent.

3.3.1 Baselines

We compare ATTOrderNet against a random baseline and all the competing models. These baseline methods can be categorized into three classes and results are reported in (Soricut and Marcu, 2006; Gong et al., 2016; Logeswaran et al., 2018).

(1) Traditional approaches: Probabilistic Model (Lapata, 2003); Content Model (Barzilay and Lee, 2004); Utility-Trained model (Soricut and Marcu, 2006); Entity Grid (Barzilay and Lapata, 2008). These four methods employ handcrafted features in modeling the document structure.

(2) Data-driven methods: Window network (Li and Hovy, 2014); Seq2seq (Li and Jurafsky,

Table 3: Experimental results for different methods on the Sentence Ordering task.

2017); Pairwise Ranking Model (Chen et al., 2016). These three approaches capture the local coherence of text based on the neural networks.
(3) Hierarchical RNN-based models: Varient-LSTM+PtrNet, RNN Decoder (Logeswaran et al., 2018); CNN+PtrNet, LSTM+PtrNet (Gong et al., 2016). These architectures adopt RNN based approaches to obtain the representation for the input set of sentences and employ the pointer network as the decoder to predict order. The main difference between ATTOrderNet and these models lies in the design of paragraph encoder.

For thorough comparison, besides the models proposed in the existing literature, we further implement two variants of ATTOrderNet.

ATTOrderNet (ATT): The sentence encoder in this model is also entirely based on self-attention mechanism with 4 self-attention layers and 5 heads. Different from the paragraph encoder, the positional encoding method proposed by Vaswani et al. (2017) is applied here to encode temporal information of each input word.

ATTOrderNet (CNN): This model employs convolutional neural networks to model sentences. In experiment, the number of feature maps is set to 512 and the width of convolution filter is 4.

3.3.2 Evaluation Metrics

To provide assessments on the quality of the orderings we predict in this task, we use the following three metrics:

Kendall's tau (τ): Kendall's tau is one of the most frequently used metrics for the automatic evaluation of document coherence (Lapata, 2003; Logeswaran et al., 2018; Li and Jurafsky, 2017). It could be formalized as: $\tau = 1 - 2\times$ (number of inversions) $/\binom{n}{2}$, where n is the length of the sequence and the number of inversions denotes the number of pairs in the predicted sequence with incorrect relative order. This metric ranges from -1 (the worst) to 1 (the best).

Accuracy (Acc): We follow (Logeswaran et al., 2018) in employing Accuracy to measure how often the absolute position of a sentence was correctly predicted. Compared to τ, it penalizes correctly predicted subsequences that are shifted.

Perfect Match Ratio (PMR): Perfect match ratio (Gong et al., 2016) is the most stringent measurement in this task. It calculates the radio of exactly matching orders: PMR=$\frac{1}{K}\sum_{i=1}^{K}\mathbf{1}(\widehat{\mathbf{o}}^i = \mathbf{o}^{i*})$, where $\widehat{\mathbf{o}}^i$ and $\mathbf{o}^{i*}$ are predicted and correct orders of the i-th text respectively.

3.3.3 Results

The experimental results on all datasets are reported in Table 3. Results show that ATTOrderNet gives the best performance across most datasets and under most evaluation measurements.

The improvement is regardless of data sizes. In particular, for smaller datasets such as Accident and Earthquake datasets, ATTOrderNet outperforms the previous best baseline methods by 6% and 7% tau score respectively. As for medium size datasets including NIPS abstract and AAN abstract, ATTOrderNet shows absolute improvements of 4.54% and 5.03% accuracy score over the previous state-of-the-art. Such finding is consistent across larger datasets. ATTOrderNet outperforms the previous state-of-the-art systems by 4.50% accuracy score with 3% tau score on NSF abstract, 1.75% PMR score with 1% tau score on arXiv abstract, and 1.67% PMR score with 1% tau score on SIND caption. Interestingly, ATTOrderNet reaches 42.19% PMR score on arXiv abstract, which means that more than 2/5 texts in the test set can be ordered exactly right. This performance clearly demonstrates the adaptability and flexibility of the proposed model.

As shown in Table 3, ATTOrderNet performs much better than data-driven methods by a significant margin on all corresponding datasets. It proves the importance of exploiting the context by self-attention mechanism as these competing models only consider the local coherence in the text. Among the traditional ordering approaches, Content Model (Barzilay and Lee, 2004) representing topics as states and capturing possible orderings for global coherence performs better than other methods with the tau score of 0.81 on Earthquake dataset, which also demonstrates that global context is important to sentence ordering. However, Content Model requires manual feature engineering that costs great human efforts. In contrast, the self-attention mechanism used in ATTOrderNet directly captures the global dependences for the whole text while requiring no linguistic knowledge anymore and enables ATTOrderNet to further improve tau score to 0.92 on the same dataset.

In addition, hierarchical RNN-based models capture the global coherence among sentences with LSTMs and outperform the traditional methods and data-driven approaches in most cases. However, these models still suffer from the permutation of sentences within the document since LSTM works sequentially. ATTOrderNet achieves superior performances to them by adopting the self-attention mechanism to reduce the influence of the permutation of sentences.

Further, ATTOrderNet (CNN) has better performances than ATTOrderNet (ATT) on most of the datasets. We conjecture that this is due to the limitation of data size. Since ATTOrderNet (ATT) applies self-attention mechanism in both sentence and paragraph encoders requiring more data to train the model, however the size of the datasets used in this task is smaller than those in other tasks such as document classification (Yang et al., 2016). Given larger datasets in the future, we believe ATTOrderNet (ATT) would perform much better. Among three sentence encoders, ATTOrderNet presents a superior performance across the board. This indicates that LSTM is more efficient in learning semantic representation for sentence level in this task. ATTOrderNet becomes more competitive through combining both advantages of LSTMs and self-attention mechanism.

Models	arXiv abstract		SIND caption	
	head	tail	head	tail
Random	23.06	23.16	22.78	22.56
Pairwise Ranking Model	84.85	62.37	-	-
CNN+PtrNet	89.43	65.36	73.53	53.26
LSTM+PtrNet	90.47	66.49	74.66	53.30
ATTOrderNet (ATT)	89.68	65.75	75.88	54.30
ATTOrderNet (CNN)	90.86	67.85	75.95	54.37
ATTOrderNet	**91.00**	**68.08**	**76.00**	**54.42**

Table 4: The performance of correctly predicting the first and the last sentences on arXiv abstract and SIND caption datasets.

Since the first and the last sentences of the text are more special to discern (Chen et al., 2016; Gong et al., 2016), we also evaluate the ratio of correctly predicting the first and the last sentences. Table 4 summarizes our performances on arXiv abstract and SIND caption. As we see, all models show fair well in predicting the first sentence, and the prediction accuracy declines for the last one. It is observed that ATTOrderNet still achieves a boost in predicting two positions compared to the previous state-of-the-art system on both datasets.

3.3.4 Visualization of attention

The aim of this section is to visualize the relationship between sentences captured by self-attention mechanism and understand how it helps perform the sentence ordering task. A technique for visualizing attention mechanism in neural networks is proposed by Vaswani et al. (2017) [3]. Inspired by this work, we select a text from AAN abstract dataset to visualize the hierarchical attention layer from the paragraph encoder of ATTOrderNet in Figure 2. Different from visualizing the dependencies of one word with the other words in the sentence (Vaswani et al., 2017), our visualization

---

[3] https://github.com/tensorflow/tensor2tensor

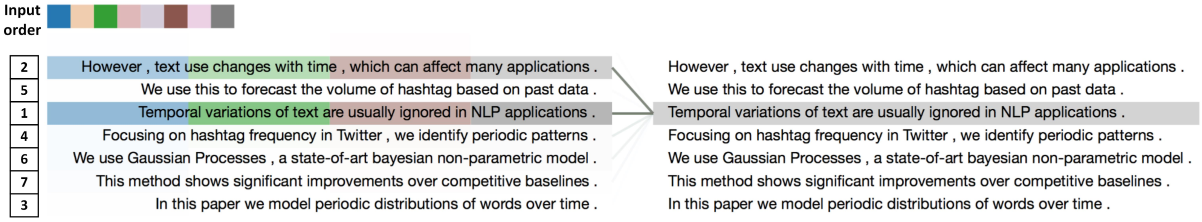

Figure 2: An example of the attention mechanism describing sentence dependencies in the encoder self-attention in layer 5 of 6 for the text from AAN abstract. Four attention heads attend to a dependency of the selected sentence *"Temporal variations of text are ..."*, providing important clues for the correct order prediction. Attention here shown is only for this sentence. Different color indicate different heads. Best viewed in color.

shows the dependencies between each sentence and all other sentences in the text.

For the example in Figure 2, the left text is the input sample to our model which contains a set of permuted sentences with the correct order besides it. The right side is a copy of the input text, which is presented for showing the relevance between each pair of sentences more clearly. The line with grey color on the right text is an example sentence chosen to visualize the attention weights with other sentences. On the top of the text are 8 colored squares representing 8 different attention heads used in the paragraph encoder. Colored columns on the left text show the performance of their corresponding heads. The darkness of the color in column denotes the normalized distribution of the attention weight for the example sentence in the head. Sentences in darker shades show more attention weight which reflects stronger links they have with the example sentence.

In particular, Figure 2 shows the attention distribution for the first sentence in the original document. We present the weight distribution in four heads as an instance. It is interesting to see that all of them showing significant higher attention weights on the true second sentence *"However, text use changes ..."* than other sentences in the text. This indicates that these heads are able to learn the latent dependency relationships from sentences and can successfully distinguish which one is the true next following among all sentence candidates. These heads build much stronger links between this sentence with the chosen one in order to keep structural information for higher level representation, such as paragraph representation.

3.4 Order Discrimination

In this section, we assess ATTOrderNet on another common evaluation task which is usually adopted in the existing literature: order discrimination task.

Order discrimination (Barzilay and Lapata, 2008; Elsner and Charniak, 2011, 2008) aims to compare a document to a randomly permuted version of it. Models are evaluated with Pairwise Accuracy: the ratio of correctly identifying the original document with higher coherence probability (defined in Equation 10) than the probability of its permutation.

Among seven datasets mentioned above, we use two of them to assess the performance of ATTOrderNet on the order discrimination task: Accident and Earthquake datasets. These two have been widely used for this task in the previous literature (Li and Hovy, 2014; Logeswaran et al., 2018). This gives us the convenience of directly comparing the result of the proposed model against the reported results. Following the setup in (Barzilay and Lapata, 2008), a maximum of 20 random permutations were generated for each training and testing article to create the pairwise data. There are 1986 and 1956 test pairs in Accident and Earthquake datasets respectively.

3.4.1 Baselines

To demonstrate that ATTOrderNet truly improves the order discrimination performance, we compare ATTOrderNet with the following representative models: Graph from (Guinaudeau and Strube, 2013), HMM and HMM+Entity from (Louis and Nenkova, 2012), Entity Grid from (Barzilay and Lapata, 2008), Recurrent and Recursive from (Li and Hovy, 2014), Discriminative model from (Li and Jurafsky, 2017), Varient-LSTM+PtrNet from (Logeswaran et al., 2018), CNN+PtrNet and LSTM+PtrNet from (Gong et al., 2016). The results of the last two methods were obtained by training their models on two datasets.

Models	Accident	Earthquake
Random	50.0	50.0
Graph	84.6	63.5
HMM+Entity	84.2	91.1
HMM	82.2	93.8
Entity Grid	90.4	87.2
Recurrent	84.0	95.1
Recursive	86.4	97.6
Discriminative Model	93.0	99.2
Varient-LSTM+PtrNet	94.4	99.7
CNN+PtrNet	93.5	99.4
LSTM+PtrNet	93.7	99.5
ATTOrderNet (ATT)	95.4	99.6
ATTOrderNet (CNN)	95.8	99.7
ATTOrderNet	**96.2**	**99.8**

Table 5: Experimental results of Pairwise Accuracy for different approaches on two datasets in the Order Discrimination task.

3.4.2 Results

Table 5 reports the results of ATTOrderNet and currently competing architectures in this evaluation task. ATTOrderNet also achieves the state-of-the-art performance, showing a remarkable advancement of about 1.8% gain on Accident dataset and further improving the pairwise accuracy to 99.8 on Earthquake dataset.

LSTM+PtrNet and CNN+ PtrNet (Gong et al., 2016) fall short of Varient-LSTM+PtrNet (Logeswaran et al., 2018) in performance. This could also be blamed for their paragraph encoder. Documents in both datasets are much longer than those in others, which brings more trouble for LSTMs in paragraph encoder to build logical representations. Compared to the result in the sentence ordering task, Entity Grid (Barzilay and Lapata, 2008) achieves a good performance in this task and even outperforms Recurrent neural networks and Recursive neural networks (Li and Hovy, 2014) on Accident dataset. However, Entity Grid requires hand-engineered features and heavily relies on linguistic knowledge which restrain the model to be adapted to other tasks.

4 Conclusion

In this paper, we develop a novel deep attentive sentence ordering model (referred as ATTOrderNet) integrating self-attention mechanism with LSTMs. It enables us to directly capture logical relationships among sentences regardless of their input order and obtain a reliable representation of the sentence set. With this representation, a pointer network is applied to generate an ordered sequence. ATTOrderNet is evaluated on Sentence Ordering and Order Discrimination tasks. The experimental results demonstrate its effectiveness and show promising improvements over existing models across most datasets.

Getting to “Hearer-old”: Charting Referring Expressions Across Time

Abstract

When a reader is first introduced to an entity, its referring expression must describe the entity. For entities that are widely known, a single word or phrase often suffices. This paper presents the first study of how expressions that refer to the same entity develop over time. We track thousands of person and organization entities over 20 years of *New York Times* (NYT). As entities move from *hearer-new* (first introduction to the NYT audience) to *hearer-old* (common knowledge) status, we show empirically that the referring expressions along this trajectory depend on the type of the entity, and exhibit linguistic properties related to becoming common knowledge (e.g., shorter length, less use of appositives, more definiteness). These properties can also be used to build a model to predict how long it will take for an entity to reach hearer-old status. Our results reach 10-30% absolute improvement over a majority-class baseline.

1 Introduction

While today the company Google is so well known that its name can even be used as a verb, in 2002, it was referred to in *The New York Times*[1] as “Google, the company behind the popular Web search engine”. The appositive told the readers what the company does, whereas now such elaboration is needed rarely, if at all. This paper presents a first computational study that relates the form of an entity’s referring expressions (RE) in articles written at different times to the entity’s changing information status.[2]

Previous work has focused on predicting how REs for an entity vary *within a single text*. This type of information status can improve coreference resolution (Recasens et al., 2013) and help generate references in automatic summaries (Nenkova and McKeown, 2003). But there has been little exploration of the change in REs to an entity *over time* and *across articles*, as the entity is accepted into common knowledge. The current work is driven by linguistic interest in characterizing REs over time. In addition, knowing the current acceptance of an entity can help in generating time-appropriate expressions. From a social science perspective, there is also great interest in capturing the birth, acceptance into common parlance, but also possible death, and subsequent reintroductions of entities.

In this paper, we disambiguate and track thousands of person (PER) and organization (ORG) entities in the *New York Times Annotated Corpus* (Sandhaus, 2008) across 20 years of news. We extract and analyze hundreds of thousands of REs for these entities, and provide the first empirical evidence that the expressions used to refer to an entity grow shorter over time, and that properties such as definiteness increase. The properties of RE form are also not uniform over entities, and we identify systematic differences between PER and ORG.

We also present a model that predicts the future information status of an entity. The model takes the REs in a small snapshot (a month’s span) from anywhere in an entity’s timeline, and predicts how long it will take the entity to reach hearer-old (common knowledge) status. Features related to mention frequency, and content, syntax, and topic of the REs are highly predictive, giving accuracies in the 60-80% range. We also make our corpus available for future work on REs over time.

2 Background

The choice of an RE depends on the availability and novelty of an entity (Prince, 1992). A mention may be first or later *within a text* (discourse-new

---

[1] article 1386221 from Sandhaus (2008)

[2] Corpus available at `http://groups.inf.ed.ac.uk/cup/ref/`

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4350–4359
Brussels, Belgium, October 31 - November 4, 2018.

and discourse-old respectively), or either newly introduce the entity to an audience (hearer-new) or be part of common knowledge (hearer-old). According to Prince (1992), hearer-old entities are more often mentioned with definite expressions, since the hearer can pick out the unique referent based on background knowledge. Corpus studies (Nenkova and McKeown, 2003; Yoshida, 2011) have corroborated similar trends that subsequent mentions to established entities *within a discourse* tend to be reduced or definite noun phrases.

In computational work, many studies (Nissim, 2006; Rahman and Ng, 2011; Markert et al., 2012) classify entities in a text as discourse-new/old. Here, hearer-old entities are a separate *mediated* class (not introduced in the text but which readers infer based on common knowledge), and predicted using features such as definiteness and the entity name itself. In the context of text summarization, the system of Siddharthan et al. (2011) classifies entities in source documents as hearer-old or not, based on frequency, syntax, and coreference (within the documents). The predicted status is then used in a rule-based algorithm to generate references in summaries of the source. Earlier work (Radev, 1998) modeled the choice of the best expression (from a lexicon) to fit the specific semantic context during text generation. Supplementing these efforts, we model the *progression* of entities' status from hearer-new to hearer-old as it changes across, rather than within, documents.

In the social sciences, Graus et al. (2017) analyzed distributions of entity mentions, and intervals between mentions, to identify patterns of entities becoming common knowledge, but without looking at the content of the REs. The coinage and subsequent acceptance/extinction of lexical innovations is another domain that models expressions over time, often by mapping properties of the speakers who use them within a community (see Tredici and Fernandez, 2018 and work reviewed therein). Our focus here is on REs specifically.

In what follows, we explain our RE extraction (Section 3) and linguistic features (Section 4). Analysis of the REs and the model for information status prediction are in Sections 5 and 6.

3 Extracting REs over time

We use the *New York Times Annotated Corpus* (NYTAC) (Sandhaus, 2008), containing the 1.8M articles published in the *New York Times* over the period 1987–2007 (20 years).

Given the complexity in identifying potentially interesting entities and disambiguating references to them over time, we limited our scope to person (PER) and organization (ORG) entities, which we could disambiguate with high accuracy. We also set aside years 2003–2007 for future validation, and used 1990–2002 for all our training, validation, and testing. Across these 13 years[3], we collected 52,338 unique entities (74% PER and 26% ORG) that were mentioned 284,064 times (65% PER mentions and 35% ORG).

3.1 RE span detection

We used the Stanford CoreNLP toolkit (Manning et al., 2014) (version 2018-01-31) to obtain constituency parse trees, and perform coreference resolution on the articles.[4]

We then extract all noun phrases (NP), including NPs that are nested in other NPs. For each NP, we identify if it is a *proper name* RE by matching the structure of its children to a set of six patterns (Table 1) of syntactic structures that can be used in describing an entity: *pre-modifier, relative clause, appositive, participle clause, adjective/adverb clause and prepositional phrase.*

Pattern 1 (pre-modifier) is used to identify NPs which are headed (rightmost leaf, except for possessives) by a proper noun (NNP). If an NP matches pattern 1, we have found a proper noun RE. Otherwise, if the NP matches one of the other patterns, we recursively match the patterns for the head NP phrase (bolded in Table 1) until one of them matches pattern 1. For *appositives*, there is no consensus about which NP should be the head of the phrase, as the entity name can be syntactically realized as the first or the second NP. Here we process both NPs. If there is no match for pattern 1 in this process, we discard the RE because the entity name is not a proper noun phrase. If we find multiple overlapping RE spans headed by the same noun, we only keep the largest NP.

After identifying a proper noun NP, the sequence of NNP children in the component NP span that matched pattern 1 is treated as the *base expression* (the entity name). The rest of the RE is the *descriptor* (description of the entity). For example, the phrase 'the pilot, First Lieut. Kelly Flinn' matches the *appositive* pattern.

---

[3] Our corpus contains trajectories for 20 years.

[4] The shift-reduce parser (Zhu et al., 2013) has an F1 score of 90% on the Wall Street Journal corpus (results from 2014).

Type	**Pattern for the children of an NP**	**Example NP**	**Base expression**
1. Pre-modifier	DT? (JJ | JJR | JJS | VBG | CD | QP | NP | NN | NNS | NNP | NNPS | PRP | , | CC | HYPH | SYM)* POS? *NNP*+ POS?	The tedious, complicated ABC	ABC
2. Relative clause	**NP** ,? SBAR ,?	The International Business Machines Corporation, which is the second-biggest advertiser on the Internet	International Business Machines
3. Appositive	**NP** (, | :)? **NP** (, | :)?	International Business Machines Corporation, the worlds largest computer company	International Business Machines Corporation
4. Participle clause	**NP** ,? VP ,?	International Business Machines Corporation, based in Armonk, N.Y.	International Business Machines Corporation
5. Adjective or adverb clause	**NP** ,? (ADJP | ADVP) ,?	Western Resources Inc., worth $1.7 billion	Western Resources Inc.
6. Prepositional phrase	**NP** ,? PP ,?	The National Basketball Association in New York	National Basketball Association

Table 1: Regular expressions (regex) for finding RE spans within an NP. The regex use Penn Treebank (Marcus et al., 1993) tags.

The full phrase is the RE, the string of NNPs ‘First Lieut. Kelly Flinn’ that comprise the embedded NP is the base expression, and the remaining NP ‘the pilot’ is the descriptor.

Certain adjustments had to be made. For example, NPs of the form ‘NNP of NNP’ (e.g. “University of Virginia”) are treated as base expressions. In addition, some connectives and symbols were included in the base to accommodate names such as “Food and Drug Administration”. These adjustments lead to their own errors. For instance, for “Dan Zegart of Titusville”, our exception rule will mark the full expression as the base, while we would prefer just the name. As expected, our RE spans are also subject to parsing errors.

But we found that the REs mined are largely robust. We manually annotated 100 randomly selected REs for correctness of the full RE span and base expression. 92 were correctly identified. Most errors involve prepositional phrase (PP) attachment, so PP modifiers are ignored in further analysis (except PPs within base expressions).

3.2 Finding cross-document entity chains

We next identify ORG and PER entities, and link the REs for the same entities over the entire span of the NYTAC. While cross-document coreference is usually a hard problem, we took advantage of NYTAC metadata to identify and link mentions to the same ORG and PER entity with high precision.

STEP 1: Our analysis focuses on salient and repeatedly appearing entities in the news. Therefore using position in the lead paragraph as a proxy for salience, we only include entities mentioned at least once in the first three sentences of each article. We also filter out entities that appear in fewer than two documents in our corpus.

Then within an article, we extract coreference chains to identify unique entities and their REs. For each entity, we then identify a *single RE* in the article which is indicative of its hearer-old/new status. One would expect the first mention to be performing this task as later mentions are discourse-old, which itself affects the form of the REs. But we found that entities are not necessarily introduced in the first mention, hence for each entity we take the *longest descriptor* among the first three mentions in an article.

STEP 2: Next we link mentions across articles. Each NYTAC article has metadata tags which *inter alia* name *salient* people and organizations appearing in the article. These tags uniquely identify an entity every time it appears in the corpus.

We match these tags to the article REs. The tags contain normalized entity names which may not match the article’s REs (from STEP 1) exactly. So we perform matches at the level of coreference chains. A chain is matched to a tagged name if the words from the base expressions in that chain overlap highly with the tag. In the case of people, the last name of the tagged person had to match the last proper noun in one of the base expressions. For ORG, at most one word in the base expression could be missing in the tag, unless an acronym of the tagged name was used as the base expression. We manually annotated the correctness of tag matches for a random sample of 25 each of PER and ORG entities. 88% of PER and 96% of ORG matches were accurate indicating high precision. All the PER match mistakes involved two people with the same last name mentioned in same article, e.g. Bill Clinton and Hillary Clinton.[5] As an estimate of recall, we find that 61.1% of all PER metadata tags, and 59.5% of ORG tags were matched to an entity, which is reasonable. Note also that we only match when an entity is mentioned within the first three sentences of an article.

Once tags are matched to article REs, the linking of REs across the corpus is also complete since the tags are already linked. The extracted REs for each entity are ordered by the publication date of the article, creating a chain of time-ordered REs for that entity across the entire corpus.

For an example of the result of our complete timeline extraction method, consider the entity Boris Yeltsin. Mr. Yeltsin became leader of the Russian parliament in May 1990, and subsequently the President in June 1991. Both events are within the timeframe of our corpus. Below we list some expressions taken from different timepoints in Mr. Yeltsin's path to presidency and later.

Spring 1990	Mr. Yeltsin, the popular chairman of the Russian Parliament who has emerged as the champion of radical reform and decentralization and as the prime political rival to the Soviet President, Mikhail S. Gorbachev
Fall 1990	Boris Yeltsin, champion of the slender insurgent minority at the Communist Party congress
Spring 1991	Boris Yeltsin, the president of the Russian federated republic and chief opposition critic of Mr. Gorbachev
Fall 1991	Boris Yeltsin, the president of the Russian republic
Spring 1992	President Boris Yeltsin
Spring 1993	Mr. Yeltsin
Spring 2000	Former Russian President Boris Yeltsin

Figure 1 shows the average length of descriptors for Mr. Yeltsin: 5 or 6 words up until Spring 1991, after which the average length is 1 word or below, indicating a significant shift in information status.

3.3 Defining hearer-old status

Next we designate an entity's mentions as hearer-new, mentions which are hearer-old, and those whose information status lies in between.

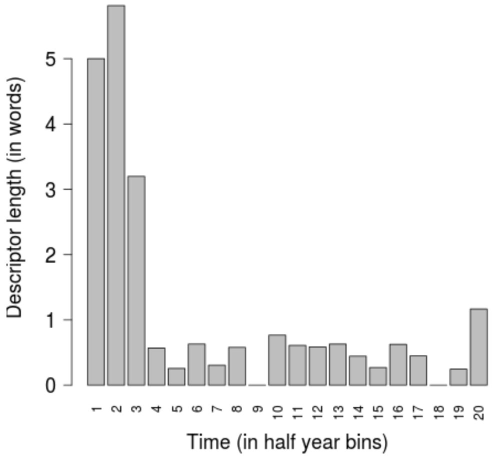

Figure 1: Descriptor lengths for Mr. Boris Yeltsin starting Spring 1990

Hearer-new mention. The NYTAC spans the years 1987–2007. To identify entities which are new, we treat the years 1987 to 1989 as a prior background corpus. When an entity is mentioned in the news from 1990 onwards but which never appeared in the prior corpus, the entity is considered as 'hearer-new' at the first mention.[6]

Mr. Yeltsin (our previous example) in fact resigned from the Politburo in 1987 before emerging again as leader of Parliament in 1990. Interestingly, our method (possibly) correctly identifies Mr. Yeltsin as hearer-new in 1990 based on comparison with the prior corpus of 1987-89.

Entity mention trajectories. From the previous section, we have the trajectories of REs for any identified hearer-new entity up to the end of our data (2002). We exclude entities that have a gap of more than 6 months between consecutive mentions, because such long gaps require the author to reintroduce an entity in case readers had forgotten it. Figure 2 shows how the length of descriptors tends to increase with greater time gaps.

Also, different entities are introduced at different times in the span from 1990 to 2002. To normalize their introduction time, we define the idea of *age* for an entity at a certain time point, so

---

[5] Coreference chains are also noisy in these cases.

[6] We noticed that sometimes multiple unique metadata tags exist for the same entity, mostly reflecting major changes in what the entity is known for, for example an entity before and after becoming a President. This pattern is not consistent in the editorial conventions however, so we leave improvements to cross-document coreference for future work.

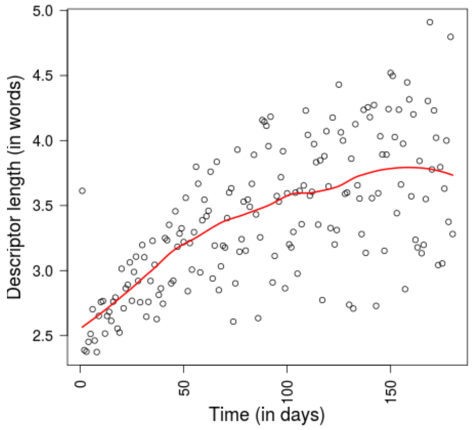

Figure 2: Mean descriptor length vs. time since previous mention

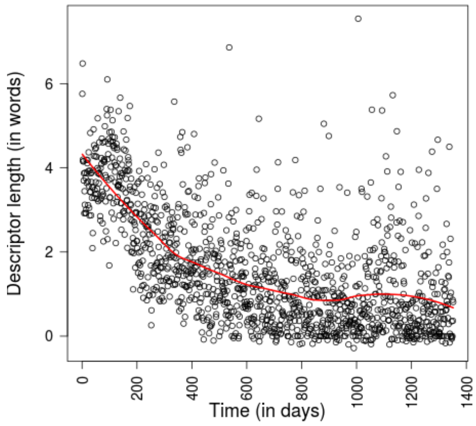

Figure 3: Mean descriptor length vs 'age' of entity

that all entities start out at time zero. For every later mention of the entity, we record the *age* as the number of days since first mention. Figure 3 shows a clear decrease in length of descriptors with increasing age of the entity.

Hearer-old mentions. We hypothesize that hearer-old entities are referred to by bare names only, and only occasionally by longer REs. Thus, we define *acceptance* of a hearer-old entity as the time after which its descriptors (the additional words besides the base expression) do not exceed a length of n words on average. Also rather than define this time point based on a single mention (which would be fragile), we bin the age values into month spans. The information status of an entity will undergo little change within a month.

First, we calculate the average length of all descriptors (entire timeline) for a given entity. If it is less than n words, then we designate the entity as hearer-old within the first month. Otherwise, we find the first month in the timeline after which the average length of descriptors of all remaining mentions is below n, and use it as time of acceptance. If the entity never reaches the threshold, we conclude that it is not accepted in the time span of the corpus. We tested values for n of 0.5 words, 1 word, and 2 words, and chose the 1-word threshold which performed best (in our linear model and classification experiments which follow).

Table 2 shows the distribution of the acceptance age for entities in our corpus. While PERs are accepted faster, more of the PER entities are also never accepted within the corpus timespan.

Below we list some examples, and qualitative observations of PER entities from each bin. The frequency of mentions is indicated within [].

1 month bin involves prominent public figures:

Bill Clinton [6005]; Michael Jordan [8]; Michael Bloomberg [546]; Nelson Mandela [3]

within 1 year are authors, journalists, local politicians (senators, mayors):

Judith Kaye (a centrist on the New York State Court of Appeals) [6]; (Senator-elect) Hillary Rodham Clinton [86]; Jurate Kazickas (a freelance writer) [2]

1-13 years involve politicians and their families, people linked to famous criminal cases:

Lisa Olson (a reporter for the Boston Herald) [14]; Laura Bush (the wife of president-elect George W. Bush) [47]; Boris Yeltsin (President of the powerful Russian Republic, whom Mr. Gorbachev portrayed as a destructive opportunist) [1229]; Joseph Gambino (a convicted heroin trafficker) [9]; Abner Louima (the Haitian immigrant who the prosecutors say was tortured by New York City police officers in a Brooklyn station house) [276]

longer than timespan involves those mentioned along a longer period but not famous (lawyers, economists, doctors), or people mentioned a lot within a short period (wedding announcements, serial killers, accident victims) and people reintroduced from the past:

Mildred Natwick (a versatile actress who created an engaging gallery of eccentric, whimsical and spunky characters in plays, films and television for more than 60 years) [2], Irene Neal (a 53 year old sculptor and painter) [2]

4 Features to characterize REs

We group the mentions of an entity within each month, and treat the *group* as one example. In this

Accepted after	less than 1 month	1 to 12 months	1 to 13 years	longer than timespan of corpus
People (entity level)	48.39%	6.42%	0.24%	44.95%
Organizations (entity level)	57.61%	8.66%	0.86%	32.89%
People (RE level)	46.92%	7.59%	2.47%	43.02%
Organizations (RE level)	49.71%	10.77%	6.67%	32.85%

Table 2: Distribution of acceptance ages. The 'entity level' rows record *one age* for each entity since its first mention. 'RE level' is the distribution when the remaining age is calculated from each RE mention. The timelines are truncated at year 2002. The later years are kept as a test set.

ORGANIZATION	**PERSON**
Positive indefinite article, length 0, length 0-3, length 3-10, length 10-20, average length, gap between mentions, topic:transport	**Positive** definite article, pre-modifier, age, length 0-3, length 3-10, length 10-20, average length, section:cars and lifestyle, topic:sports, topic: entertainment
Negative relative clause, definite article, named entity, topic:international relations, topic:military and politics	**Negative** relative clause, appositive, possessive, named entity, length 0, topic:transport, topic:religion, topic:awards

Table 3: Significant main effects in linear model

way, the example contains RE choices for the entity at *a certain snapshot in time*. A set of 61 features are computed for each example to characterize the REs (descriptor part only) it contains. *None* of the features involve the identity of the entity.

Descriptor contents: include the number of PER and ORG named entities if any in the descriptor text, type/token ratio, the counts of date and money, adjectives, superlative adjectives, verbs, and honorifics (based on a list with words such as Judge, President, Dr. etc). All counts are normalized by the number of REs in the example.

Syntactic form: They include average number per RE of definite articles, indefinite articles and possessive constructions, appositives, participle clauses, relative clauses, adjective or adverb clauses, and pre-modification. We also record the length of the descriptors using 5 bins (0 words, 1-3, 3-10, 10-20 and >20 words). The feature value is the proportion of REs in a bin. A binary feature also indicates whether the average length of descriptors is below 0.5 words.

Frequency of mentions: We include the number of mentions within the one month bin, and the average time gap between consecutive mentions (multiplied by the $\log$ of number of mentions to compensate for frequency). We also include the entity's current age (time since introduction).

Context: We employ the topic metadata from NYTAC to capture a notion of world context of an entity's mentions. Every article has topic tags (sports, finance, technology, politics, etc.) and also a section label (travel, economics, culture, etc.). We clustered the thousands of topic tags into 20 broad topics by using the Glove word embeddings (Pennington et al., 2014), and K-means clustering. A small set of 17 clusters were also created for the newspaper sections. The count of mentions belonging to articles in each cluster is a feature.

5 Features versus acceptance time

We built a linear model (LM) to test which features are significantly predictive of time to acceptance.

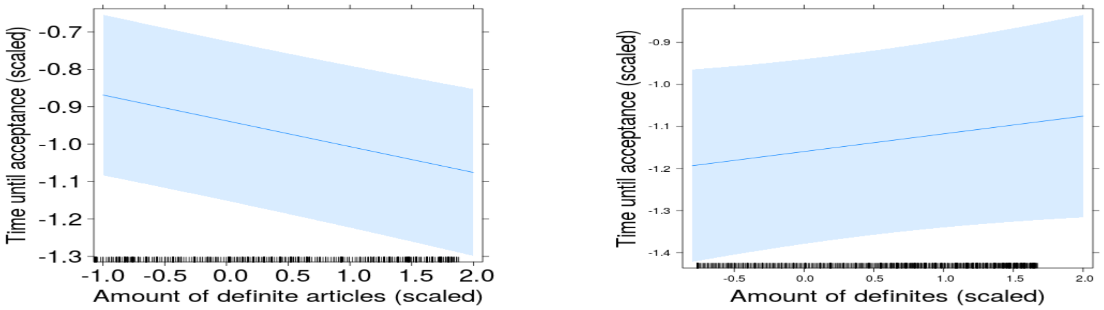
An example is the set of REs for an entity from a one month bin. The dependent variable is the *time left until acceptance*, i.e. the value (in months) from the current age of the entity (month were the mentions were taken from) until the acceptance age. For our corpus, the possible values are 0 to 156. Entities that do not become well known within the span of our dataset are given a label of 160 months. Entities which fall out of use (never mentioned in the corpus after a certain time point but also have not reached acceptance threshold at their found last mentions) have a label of 161.[7]

We also performed a variance analysis over the LM with ANOVA to account for possible correlation between variables. We scale the feature values into z-scores which show how many standard deviations each example is away from the mean.

We used *lm* and *Anova* (Fox and Weisberg, 2011) functions within R (R Core Team, 2013). The adjusted R^2 value is 43% for PER and 37%

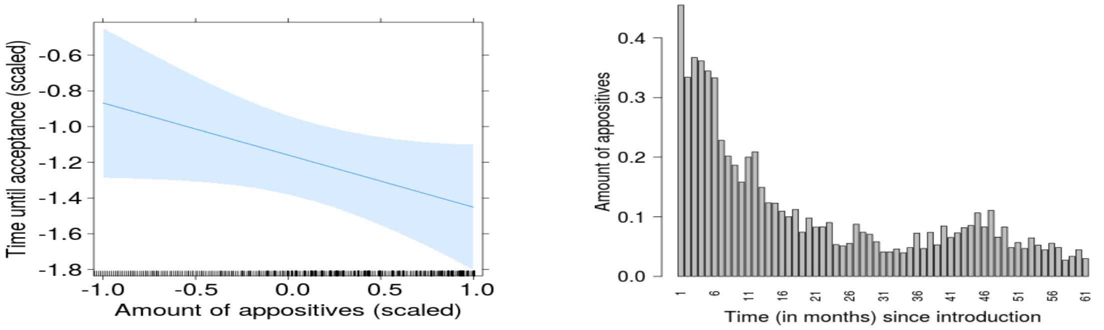
---

[7] One could also perform survival analysis for this problem, we have not explored it yet.



(a) Definite articles in ORG descriptors

(b) Definite articles in PER descriptors



(c) Appositives in PER descriptors

(d) Proportion of PER mentions with appositive descriptors, at different ‘ages’ of an entity (within the first 5 years)

Figure 4: Main effects for definite articles and appositives

for ORG entities. The significant features ($p < 0.05$) from the ANOVA are in Table 3. The features are divided into positive and negative ones, reflecting whether a higher value of the feature was predictive of a higher (positive) or lower (negative) value of the time until acceptance. More features are significant for PER (18) compared to ORG (13) expressions. Also for persons, the significant features are more varied compared to ORG, indicating that people may have more varied roles and characterizations presented in the media. Note also that we have more data for PER entities.

Below we describe some of the most interesting findings from the model.

5.1 Main effects

Definite articles are a significant feature for both PER and ORG entities. In Figures 4a and 4b, we plot the variation in *time until acceptance* versus number of definite articles, holding other variables at their means. The bands show the 0.95 level confidence interval. We used the *effects* package (Fox, 2003) in R, and the graphs show scaled values.

Assuming that the use of definite articles indicates definite expressions roughly, for ORG entities, the results confirm the hypothesis that REs become more definite the longer the entity is in use. REs such as “Ebay, an online auction site” become “Ebay, the largest of the auction sites” and “Ebay, the auction site” before settling to “Ebay”.

The pattern for people is opposite, with more definite articles used with early mentions. Upon closer observation, we found that in fact, the expressions are more often definite when they are closer to acceptance, but with definiteness not expressed by the article. The definite article is excluded, and the possessive is used to produce a concise phrase e.g. “Russia’s acting president” instead of “the acting president of Russia”. The possessive phrase is short and also has fewer function words, which is consistent with psycholinguistic findings that people tend to reduce highly predictable phrases by dropping function words (Jaeger and Levy, 2007). Moreover, we observed that for ORG, an article may still describe the entity after acceptance e.g. “The FDA”, and understandably this pattern does not exist for persons.

Appositives are not significant predictors for ORG; for PER, more appositives is associated with closeness to acceptance (Figure 4c). Yet early mentions involve more appositives than later ones (Figure 4d). One interpretation of these contrast-

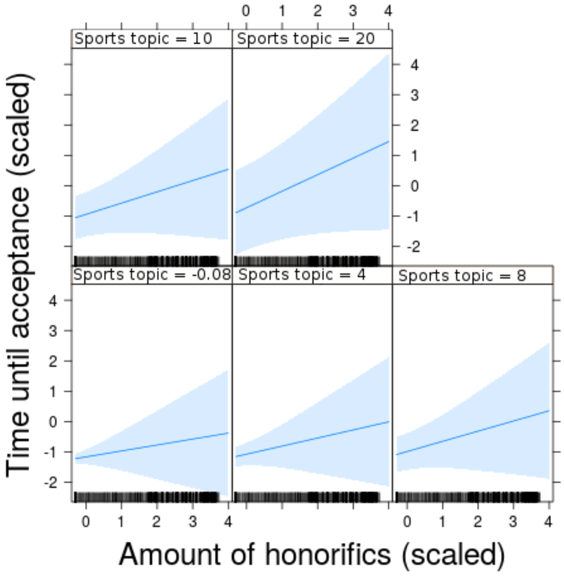


Figure 5: Interaction between the effect of sports topic and honorifics (both scaled). Sub-figures represent proportions of mentions in sports topics.

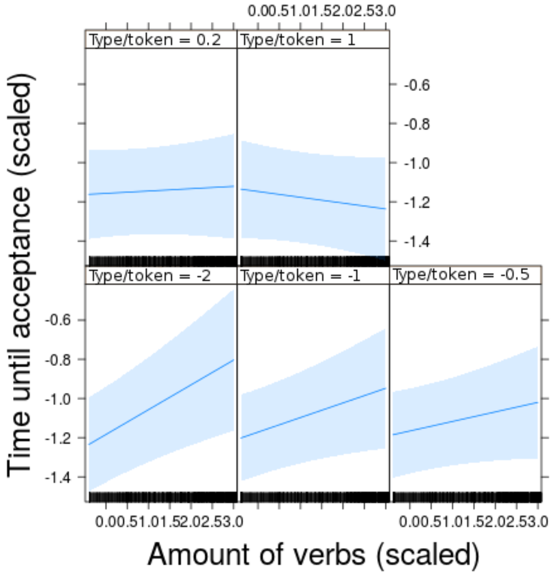

Figure 6: Interaction between the effect of type/token ratio and verb use (both scaled). Sub-figures represent values of the type/token ratio.

ing tendencies could be that there are two types of entities. The first are those important enough to be introduced with lots of appositives at the beginning of their 'lifespan'. These entities could be accepted quickly, and this behavior may manifest as having more appositives close to acceptance. The other set is that of non-salient entities which are probably not introduced with appositives anyway, and show slow acceptance. This analysis is supported by our observations that entities which are not as important as the context they appear in, such as a lesser known football player who scores a goal or an architect of a famous building, are often introduced without an appositive.

5.2 Interactions

We also found significant interactions in the model highlighting differences between various types of entities. For example, there is no main effect for honorifics but there is a significant positive effect when sports entities are involved (Figure 5). It is possible that REs such as "the number one player" indicate closeness to acceptance more than "the president of the National Hockey League", as honorifics (e.g. 'president') are not used with most known people in the sports domain.

The presence of verbs (in the descriptor) also does not have a main effect, but becomes meaningful when the type/token ratio of descriptors of a person is low (see Figure 6). We consider the type/token ratio as reflecting the different guises that a person is mentioned with, and verbs in the descriptor as associating the person with an event rather than their role in society. When the type/token ratio is low, it suggests the person is known for one or a few aspects. Here acceptance time and verbs are positively related, implying that when the few aspects are events (more verbs), the entities have a slower path to hearer-old. Whereas, if the aspects were titles such as CEO (less verbs), the entity is closer to acceptance.

6 Predicting future information-status

Given the significant correlations between our features and the time to acceptance, we now build a predictive model to identify acceptance time given a snapshot of REs for an entity. Every example contains a certain entity's mentions over a month's span, similar to the linear model. The target class indicates whether or not the entity was accepted within a period, x years from the sample time.

The classification models were built separately for PER and ORG expressions. We divide the data into 70% training, 10% validation and 20% test. For number of data points for training/validation/test, ORG has 8,768/1,252/2,506 data points; PER has 26,190/3,742/7,483. Note that examples are month-sized bins of each en-

ENTITY	Baseline (%) (majority-class)	SVM			MLP			
		C	Gamma	Accuracy (%)	Layers	Units	Alpha	Accuracy (%)
4-CLASS								
Org	35.17	10	0.01	62.69	2	400	100	68.36
People	42.01	100	0.01	70.77	3	300	100	74.18
BINARY								
Org	69.80	10	0.01	78.41	3	100	100	79.41
People	59.16	10	0.01	79.14	3	300	100	80.66

Table 4: Results of the SVM and MLP classifiers. C and Alpha are regularization parameters, Gamma parameterizes the RBF kernel. Hidden layers and hidden units in the MLP are also shown.

tity's REs, rather than unique entities. We explore both an SVM classifier with an RBF kernel, and a Multi Layer Perceptron (MLP) classifier. The MLP uses a BFGS solver with ReLU activation function. We used implementations from scikit-learn (Pedregosa et al., 2011), and the parameters of both classifiers were tuned on the development set using grid search.

We build two types of classifiers (results in Table 4). The baseline is majority-class assignment.

4-CLASS is a four-label classifier for predicting *when* an entity will become hearer-old. The four classes reflect the distribution of acceptance ages (see Table 2—RE level): already accepted (at the sample month), will be accepted within the year, between 1 and 13 years from the sample, and will not be accepted within the time frame we have.

BINARY is a classifier performing a simpler binary division of whether an entity is hearer-old or hearer-new *after 2 years* from the sampling time. About half of both entities in our data are accepted within 2 years after introduction.

The 4-CLASS MLP model is better than SVM reaching 68% accuracy for ORG and 74% for people. The improvement is over 30% absolute value, indicating the significant effect of the model and features. Still there is scope for improvement, given that the performance is less than 75%.

Both SVM and MLP perform similarly for the binary tasks. The overall binary classification accuracy is 80% for both PER and ORG entities, a 10% increase for ORG and 20% for PER.

We also performed an ablation study to identity the most useful individual classes of features. Syntax features (Section 4) had the biggest impact when removed, lowering performing by 5-8% for all models. But since both our classifiers are non-linear, they can capture useful interactions between all our feature classes.[8]

7 Conclusion

In this work, we have shown empirically that the path to hearer-old status displays detectable and interesting linguistic features, and that entities of a certain type exhibit distinctive properties. These significant differences have allowed for a first model which predicts how long it will take for an entity to be accepted as common knowledge.

There are a number of directions which we plan to explore. While we have focused on predicting whether an entity will be accepted after a certain period of time has passed, we have not modeled the RE tokens themselves, or their generation. During our analysis, it was clear that the REs of a (named) entity may also change semantically over time, reflecting current interest in it, rather than the same RE content just growing shorter over time. We have also not explored the RE timelines of common noun entities such as *organic food* or *cryptocurrency*. It is possible that they follow a different trend than named entities, and require a different set of feature indicators. We also plan to improve upon our current models and assumptions. Currently, we have ignored entities with long time gaps and requiring reintroduction to an audience. Learning to predict when an entity will go out of use, and indicators for reintroduction will add strength to our analyses. The definition of acceptance and fine-grained models for prediction will also be developed. We are also releasing a corpus of chained REs from the NYTAC (represented as byte-span sets) to enable other researchers to study these aspects of REs.

Making “fetch” happen: The influence of social and linguistic context on nonstandard word growth and decline

Ian Stewart and Jacob Eisenstein
School of Interactive Computing
Georgia Institute of Technology
Atlanta, GA 30318
{istewart6, jacobe}@gatech.edu

Abstract

In an online community, new words come and go: today’s *haha* may be replaced by tomorrow’s *lol*. Changes in online writing are usually studied as a social process, with innovations diffusing through a network of individuals in a speech community. But unlike other types of innovation, language change is shaped and constrained by the grammatical system in which it takes part. To investigate the role of social and structural factors in language change, we undertake a large-scale analysis of the frequencies of nonstandard words in Reddit. Dissemination across many linguistic contexts is a predictor of success: words that appear in more linguistic contexts grow faster and survive longer. Furthermore, social dissemination plays a less important role in explaining word growth and decline than previously hypothesized.

1 Introduction

Stop trying to make “fetch” happen! It’s not going to happen! – Regina George (*Mean Girls*, 2005)

With the fast-paced and ephemeral nature of online discourse, language change in online writing is both prevalent (Androutsopoulos, 2011) and noticeable (Squires, 2010). In social media, new words emerge constantly to replace even basic expressions such as laughter: today’s *haha* is tomorrow’s *lol* (Tagliamonte and Denis, 2008). Why do some nonstandard words, like *lol*, succeed and spread to new contexts, while others, like *fetch*, fail to catch on? Can a word’s growth be predicted from patterns of usage during its early days?

Language change can be treated like other social innovations, such as the spread of hyperlinks (Bakshy et al., 2011) or hashtags (Romero et al., 2011; Tsur and Rappoport, 2015). A key aspect of the adoption of a new practice is its *dissemination*: is it used by many people, and in many social contexts? High dissemination enables words to achieve greater exposure among social groups (Altmann et al., 2011), and may signal that the innovation is positively evaluated.

In addition to social constraints, language change is also shaped by grammatical constraints (D’Arcy and Tagliamonte, 2015). New words and phrases rarely change the rules of the game but must instead find their place in a competitive ecosystem with finely-differentiated linguistic roles, or “niches” (MacWhinney, 1989). Some words become valid in a broad range of linguistic contexts, while others remain bound to a small number of fixed expressions. We therefore posit a structural analogue to social dissemination, which we call *linguistic dissemination*.

We compare the fates of such words to determine how linguistic and social dissemination each relate to word growth, focusing on the adoption of nonstandard words in the popular online community Reddit. The following hypotheses are evaluated:

- **H1: Nonstandard words with higher initial social dissemination are more likely to grow.** Following the intuition that words require a large social base to succeed, we hypothesize a positive correlation between social dissemination and word growth.
- **H2-weak: Nonstandard words with higher linguistic dissemination in the early phase of their history are more likely to grow.** This follows from work in corpus linguistics showing that words and grammatical patterns with a higher diversity of collocations are more likely to be adopted (Ito and Tagliamonte, 2003; Partington, 1993).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4360–4370
Brussels, Belgium, October 31 - November 4, 2018.

- **H2-strong: Nonstandard words with higher linguistic dissemination are more likely to grow, even after controlling for social dissemination.** This follows from the intuition that linguistic context and social context contribute differently to word growth.

To address H2, we develop a novel metric for characterizing linguistic dissemination, by comparing the observed number of n-gram contexts to the number of contexts that would be predicted based on frequency alone. Our analysis of word growth and decline includes: (1) prediction of frequency change in growth words (as in prior work); (2) causal inference of the influence of dissemination on probability of word growth; (3) binary prediction of future growth versus decline; and (4) survival analysis, to determine the factors that predict when a word's popularity begins to decline. All tests indicate that linguistic dissemination plays an important role in explaining the growth and decline of nonstandard words.

2 Related Work

Lexical change online Language changes constantly, and one of the most notable forms of change is the adoption of new words (Metcalf, 2004), sometimes referred to as lexical entrenchment (Chesley and Baayen, 2010). New nonstandard words may arise through the mutation of existing forms by processes such as truncation (e.g, *favorite* to *fave*; Grieve et al., 2016) and blending (e.g., *web+log* to *weblog* to *blog*; Cook and Stevenson, 2010). The fast pace and interconnected nature of online communication is particularly conducive to innovation, and social media provides a "birds-eye view" on the process of change (Danescu-Niculescu-Mizil et al., 2013; Kershaw et al., 2016; Tsur and Rappoport, 2015).

The most closely related work is a contemporaneous study that explored the role of weak social ties in the dissemination of linguistic innovations on Reddit, which also proposed the task of quantitatively predicting the success or failure of lexical innovations (Tredici and Fernández, 2018). One distinguishing feature of our work is the emphasis on *linguistic* (rather than social) context in explaining these successes and failures. In addition to predicting the binary distinction between success and failure, we also take on the more fine-grained task of predicting the length of time that each nonstandard word will survive.

Social dissemination Language changes as a result of transmission across generations (Labov, 2007) as well as diffusion across individuals and social groups (Bucholtz, 1999). Such diffusion can be quantified with *social dissemination*, which Altmann et al. (2011) define as the count of social units (e.g., users) who have adopted a word, normalized by the expected count under a null model in which the word is used with equal frequency across the entire population. Altmann et al. (2011) use dissemination of words across forum users and threads to predict the words' change in frequency in Usenet, finding a positive correlation between frequency change and both kinds of social dissemination. In contrast, Garley and Hockenmaier (2012) use the same metric to predict the growth of English loanwords on German hip-hop forums, and find that social dissemination has less predictive power than expected. We seek to replicate these prior findings, and to extend them to the broader context of Reddit.

Linguistic dissemination In historical linguistics, the distribution of a new word or construction across lexical contexts can signal future growth (Partington, 1993). Furthermore, grammatical and lexical factors can explain a speaker's choice of linguistic variant (Ito and Tagliamonte, 2003; Cacoullos and Walker, 2009) and can provide more insight than social factors alone. Our study proposes a generalizable method of measuring the dissemination of a word across lexical contexts with *linguistic* dissemination and compares social and linguistic dissemination as predictors of language change.

3 Data

Our study examines the adoption of words on social media, and we focus on Reddit as a source of language change. Reddit is a social content sharing site separated into distinct sub-communities or "subreddits" that center around particular topics (Gilbert, 2013). Reddit is a socially diverse and dynamic online platform, making it an ideal environment for research on language change (Kershaw et al., 2016). Furthermore, because Reddit data is publicly available we expect that this study can be more readily replicated than a similar study on other platforms such as Facebook or Twitter, whose data is less easily obtained.

	Total	Monthly mean
Comments	1,625,271,269	45,146,424
Tokens	56,674,728,199	1,574,298,006
Subreddits	333,874	48,786
Users	14,556,010	2,302,812
Threads	102,908,726	3,079,780

Table 1: Data summary statistics.

We analyze a set of public monthly Reddit comments[1] posted between 1 June 2013 and 31 May 2016, totalling $T = 36$ months of data. This dataset has been analyzed in prior work (Hessel et al., 2016; Tan and Lee, 2015) and has been noted to have some missing data (Gaffney and Matias, 2018), although this issue should not affect our analysis. To reduce noise in the data, we filter all comments generated by known bots and spam users[2] and filter all comments created in well-known non-English subreddits.[3] The final data collected is summarized in Table 1.

We replace all references to subreddits and users (marked by the convention *r/subreddit* and *u/user*) with *r/SUB* and *u/USER* tokens, and all hyperlinks with a *URL* token. We also reduce all repeated character sequences to a maximum length of three (e.g., *loooool* to *loool*). The final vocabulary includes the top 100,000 words by frequency.[4] We replace all OOV words with UNK tokens, which comprise 3.95% of the total tokens.

3.1 Finding growth words

Our work seeks to study the growth of nonstandard words, which we identify manually instead of relying on pre-determined lists (Tredici and Fernández, 2018).To detect such words, we first compute the Spearman correlation coefficient between the time steps $\{1...T\}$ and each word w's frequency time series $f^{(w)}_{(1:T)}$ (frequency normalized and log-transformed). The Spearman correlation coefficient captures monotonic, gradual growth that characterizes the adoption of nonstandard words (Grieve et al., 2016; Kershaw et al., 2016).

The first set of words is filtered by a Spearman correlation coefficient above the 85th percentile ($N = 15,017$). From this set of words, one of the authors manually identified 1,120 words in set $\mathcal{G}$ ("growth") that are neither proper nouns (*berniebot, killary, drumpf*) nor standard words (*election, voting*).[5] These words were removed because their growth may be due to exogenous influence. A "standard" word is one that can plausibly be found in a newspaper article, which follows from the common understanding of newspaper text as a more formal and standard register. Therefore, a "nonstandard" word is one that cannot plausibly be found in a newspaper article, a judgment often used by linguists to determine what counts as slang (Dumas and Lighter, 1978). In ambiguous cases, one of the authors inspected a sample of comments that included the word. We validate this process by having both authors annotate the top 200 growth candidates for standard/proper versus nonstandard (binary), obtaining inter-annotator agreement of κ=0.79.

3.2 Finding decline words

To determine what makes the growth words successful, we need a control group of "decline" words, which are briefly adopted and later abandoned. Although these words may have been successful before the time period investigated, their decline phase makes them a useful comparison for the growth words. We find such words by fitting two parametric models to the frequency series.

Piecewise linear fit We fit a two-phase piecewise linear regression on each word's frequency time series $f_{(1:T)}$, which splits the time series into $f_{(1:\hat{t})}$ and $f_{(\hat{t}+1:T)}$. The goal is to select a split point $\hat{t}$ to minimize the sum of the squared error between observed frequency f and predicted frequency $\hat{f}$:

$$\hat{f}(m_1, m_2, b, t) = \begin{cases} b + m_1 t & t \leq \hat{t} \\ b + m_1\hat{t} + m_2(t - \hat{t}) & t > \hat{t}, \end{cases} \tag{1}$$

where b is the intercept, m_1 is the slope of the first phase, and m_2 is the slope of the second phase. Decline words $\mathcal{D}_p$ ("piecewise decline") display

[2] The same list used in Tan and Lee (2015): `https://chenhaot.com/data/multi-community/README.txt` (Accessed 1 October 2016).

[3] We randomly sampled 100 posts from the top 500 subreddits and labelled a subreddit as non-English if fewer than 90% of its posts were identified by `langid.py` (Lui and Baldwin, 2012) as English.

[4] We restricted the vocabulary because of the qualitative analysis required to identify nonstandard words.

[5] Code and word lists available at: `https://github.com/ianbstewart/nonstandard_word_dissemination`.

Word set	Examples
$\mathcal{G}$	*idk, lmao, shitpost, tbh, tho*
$\mathcal{D}_l$	*atty, eyebleach, iifym, obeasts, trashy*
$\mathcal{D}_p$	*brojob, nparent, rekd, terpers, wot*

Table 2: Examples of nonstandard words in all word sets: growth ($\mathcal{G}$), logistic decline ($\mathcal{D}_l$) and piecewise decline ($\mathcal{D}_p$).

growth in the first phase ($m_1 > 0$), decline in the second phase ($m_2 < 0$), and a strong fit between observed and predicted data, indicated by $R^2(f, \hat{f})$ above the 85^{th} percentile (36.1%); this filtering yields 14,995 candidates.

Logistic fit To account for smoother growth-decline trajectories, we also fit the growth curve to a logistic distribution, which is a continuous unimodal distribution with support over the non-negative reals. We identify the set of candidates $\mathcal{D}_l$ ("logistic decline") as words with a strong fit to this distribution, as indicated by R^2 above the 99^{th} percentile (82.4%), yielding 998 candidates. The logistic word set partially overlaps with the piecewise set, because some words' frequency time series show a strong fit to both the piecewise function and the logistic distribution.

Combined set We combine the sets $\mathcal{D}_p$ and $\mathcal{D}_l$ to produce a set of decline word candidates ($N = 15,665$). Next, we filter this combined set to exclude standard words and proper nouns, yielding a total of 530 decline words in set $\mathcal{D}$. Each word is assigned a split point $\hat{t}$ based on the estimated time of switch between the growth phase and the decline phase, which is the split point $\hat{t}$ for piecewise decline words and the center of the logistic distribution $\hat{\mu}$ for the logistic decline words.

Examples of both growth and decline words are shown in Table 2. The growth words include several acronyms (*tbh*, "to be honest"; *lmao*, "laughing my ass off"), while the decline words include clippings (*atty*, "atomizer"), respellings (*rekd*, "wrecked"; *wot*, "what") and compounds (*nparent*, "narcissistic parent").

We also provide a distribution of the words across word generation categories in Table 3, including compounds and clippings in similar proportions to prior work (Kulkarni and Wang, 2018). Because the growth and decline words exhibit similar proportions of category counts, we do not expect that this will be a significant confound in differentiating growth from decline.

	Clipping	Compound	Respelling	Other	Total
$\mathcal{G}$	198 (17.7%)	334 (29.8%)	83 (7.4%)	505 (45.1%)	1,120
$\mathcal{D}$	53 (10.0%)	100 (18.9%)	108 (20.4%)	269 (50.8%)	530

Table 3: Word formation category counts in growth ($\mathcal{G}$) and decline ($\mathcal{D}$) word sets.

4 Predictors

We now outline the predictors used to measure the degree of **social** and **linguistic** dissemination in the growth and decline words.

4.1 Social dissemination

We rely on the dissemination metric proposed by Altmann et al. (2011) to measure the degree to which a word occupies a specific social niche (e.g., low dissemination implies limited niche). To compute user dissemination D^U for word w at time t, we first compute the number of individual users who used word w at time t, written $U_t^{(w)}$. We then compare this with the expectation $\tilde{U}_t^{(w)}$ under a model in which word frequency is identical across all users. The user dissemination is the log ratio,

$$\log \frac{U_t^{(w)}}{\tilde{U}_t^{(w)}} = \log U_t^{(w)} - \log \tilde{U}_t^{(w)}. \qquad (2)$$

Following Altmann et al. (2011), the expected count $\tilde{U}_t^{(w)}$ is computed as,

$$\tilde{U}_t^{(w)} = \sum_{u \in \mathcal{U}_t} (1 - e^{-f_t^{(w)} m_t^{(u)}}), \qquad (3)$$

where $m_t^{(u)}$ equals the total number of words contributed by user u in month t, and $\mathcal{U}_t$ is the set of all users active in month t. This corresponds to a model in which each token from a user has identical likelihood $f_t^{(w)}$ of being word w. In this way, we compute dissemination for all users (D^U), subreddits (D^S) and threads (D^T) for each month $t \in \{1...T\}$.

4.2 Linguistic dissemination

Linguistic dissemination captures the diversity of linguistic contexts in which a word appears, as measured by unique n-gram counts. We compute

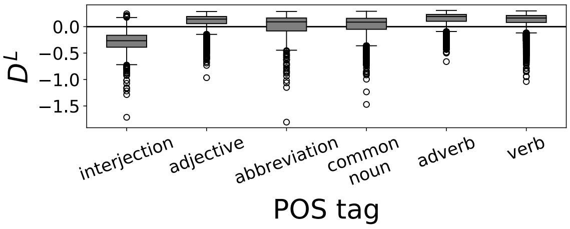

Figure 1: Distribution of mean linguistic dissemination (D^L) across part of speech groups.

the log count of unique trigram[6] contexts for all words (C^3) using all possible trigram positions: in the sentence "*that's cool af haha*", the term *af* appears in three unique trigrams, *that's cool af, cool af haha, af haha <END>*.

The unique log number of trigram contexts is strongly correlated with log word frequency ($\rho(C^3, f) = 0.904$), as implied by Heaps' law (Egghe, 2007). We therefore adjust this statistic by comparing with its expected value $\tilde{C}^3$. At each timestep t, we fit a linear regression between log-frequency and log-unique n-gram counts, and then compute the residual between the observed log count of unique trigrams and its expectation, $D^L = C^3_t - \tilde{C}^3_t$. The residual D^L, or *linguistic dissemination*, identifies words with a higher or lower number of lexical contexts than expected.

Linguistic dissemination can separate words by grammatical category, as shown in Figure 1 where the mean D^L values are computed for words across common part-of-speech categories. Part-of-speech tags were computed over the entire corpus using a Twitter-based tagger (Gimpel et al., 2011), and each word type was assigned the most likely POS tag to provide an approximate distribution of tags over the vocabulary. Interjections have a lower median D^L than other word categories due to the tendency of interjections to occur in limited lexical contexts. Conversely, verbs have a higher median D^L due to the flexibility of verbs' arguments (e.g., subject and object may both be open-class nouns).

5 Results

The hypotheses about social and linguistic dissemination are tested under four analyses: correlation against frequency change in growth words; causal inference on probability of word growth; binary prediction of word growth; and survival analysis of decline words.

	Variance explained	Lower, upper 95%
f_{t-12}	10.8%	[10.2%, 11.5%]
D^L_{t-12}	0.584%	[0.461%, 0.777%]
D^U_{t-12}	0.307%	[0.251%, 0.398%]
D^S_{t-12}	0.120%	[0.0852%, 0.191%]
D^T_{t-12}	0.246%	[0.171%, 0.379%]
f_{t-24}	21.4%	[20.4%, 22.4%]
D^L_{t-24}	1.29%	[1.05%, 1.64%]
D^U_{t-24}	0.400%	[0.346%, 0.493%]
D^S_{t-24}	0.287%	[0.201%, 0.392%]
D^T_{t-24}	0.272%	[0.226%, 0.380%]

Table 4: Percent of variance explained in frequency change, computed over all growth words $\mathcal{G}$. $N = 26,880$ for $k = 12$, $N = 13,440$ for $k = 24$.

5.1 Correlational analysis

To test the relative importance of the linguistic and social context on word growth, we correlate these metrics with frequency change ($\Delta_{f_t} = f_t - f_{t-k}$) across all growth words. This replicates the methodology in prior work by Altmann et al. (2011) and Garley and Hockenmaier (2012), who analyzed different internet forums. Focusing on long-term change with $k = 12$ (one year) and $k = 24$ (two years), we compute the proportion of variance in frequency change explained by the covariates using a relative importance regression (Kruskal, 1987).[7]

The results of the regression are shown in Table 4. All predictors have relative importance greater than zero, according to a bootstrap method to produce confidence intervals (Tonidandel et al., 2009). Frequency is the strongest predictor (f_{t-12}, f_{t-24}), because words with low initial frequency often show the most frequency change. In both short- and long-term prediction, linguistic dissemination (D^L_{t-12}, D^L_{t-24}) has a higher relative importance than each of the social dissemination metrics. The social dissemination metrics have less explanatory power, in comparison with the other predictors and in comparison to the prior results of Garley and Hockenmaier (2012), who found 1.5% of variance explained by D^U and 1.9% for D^T at $k = 24$. Our results were robust to the exclusion of the predictor D^L, meaning that

---

[6] Pilot analysis with bigram contexts gave similar results.

[7] Relative importance regression implemented in the *relaimpo* package in R: `https://cran.r-project.org/package=relaimpo`

a model with only the social dissemination metrics as predictors resulted in a similar proportion of variance explained. The weakness of social dissemination could be due to the fragmented nature of Reddit, compared to more intra-connected forums. Since users and threads are spread across many different subreddits, and users may not visit multiple subreddits, a higher social dissemination for a particular word may not lead to immediate growth.

5.2 Causal analysis

While correlation can help explain the relationship between dissemination and frequency change, it only addresses the weak version of H2: it does not distinguish the causal impact of linguistic and social dissemination. To test the strong version of H2, we turn to a causal analysis, in which the *outcome* is whether a nonstandard word grows or declines, the *treatment* is a single dissemination metric such as linguistic dissemination, and the *covariates* are the remaining dissemination metrics. The goal of this analysis is to test the impact of each dissemination metric, while holding the others constant.

Causal inference typically uses a binary treatment/control distinction (Angrist et al., 1996), but in this case the treatment is continuous. We therefore turn to an adapted model known as the *average dose response function* to measure the causal impact of dissemination (Imbens, 2000). To explain the procedure for estimating the average dose response, we adopt the following terminology: Z for treatment variable, X for covariates, Y for outcome.[8]

1. A linear model is fit to estimate the treatment from the covariates,

$$Z_i \mid X_i \sim \mathcal{N}(\beta^\top X_i, \sigma^2). \tag{4}$$

The output of this estimation procedure is a vector of weights $\hat{\beta}$ and a variance $\hat{\sigma}^2$.

2. The generalized propensity score (GPS) R is the likelihood of observing the treatment given the covariates, $P(Z_i \mid X_i)$. It is computed from the parameters estimated in the previous step:

$$\hat{R}_i = \frac{1}{\sqrt{2\pi\hat{\sigma}^2}} \exp\left(-\frac{(Z_i - \hat{\beta}^\top X_i)^2}{2\hat{\sigma}^2}\right). \tag{5}$$

3. A logistic model is fit to predict the outcome Y_i using the treatment Z_i and the GPS $\hat{R}_i$:

$$\hat{Y}_i = \text{Logistic}(\hat{\alpha}_0 + \hat{\alpha}_1 Z_i + \hat{\alpha}_2 \hat{R}_i). \tag{6}$$

This involves estimating the parameters $\{\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2.\}$ By incorporating the generalized propensity score $\hat{R}_i$ into this predictive model over the outcome, it is possible to isolate the causal effect of the treatment from the other covariates (Hirano and Imbens, 2004).

4. The range of treatments is divided into levels (quantiles). The *average dose response* for a given treatment level s_z is the mean estimated outcome for all instances at that treatment level,

$$\hat{\mu}(s_z) = \frac{1}{|s_z|} \sum_{z_i \in s_z} \hat{Y}_i. \tag{7}$$

The average dose response function is then plotted for all treatment levels.

Each dissemination metric is considered separately as a treatment. We consider all other dissemination metrics and frequency as covariates: e.g., for treatment variable D^L, the covariates are set to $[f, D^U, D^S, D^T]$. We bootstrap the above process 100 times with different samples to produce confidence intervals. To balance the outcome classes, we sample an equal number of growth and decline words for each bootstrap iteration.

The average dose response function curves in Figure 2 show that linguistic dissemination (D^L) produces the most dramatic increase in word growth probability. For linguistic dissemination, the lowest treatment quantile (0%-10%) yields a growth probability below 40% (significantly less than chance), as compared to the highest treatment quantile (90-100%), which yields a growth probability nearly at 70% (significantly greater than chance). This supports the strong form of H2, which states that linguistic dissemination is predictive of growth, even after controlling for the frequency and the other dissemination metrics. Subreddit dissemination also shows a mild causal effect on word growth, up to 60% in the highest treatment quantile. The other social dissemination metrics prove to have less effect on word growth.

---

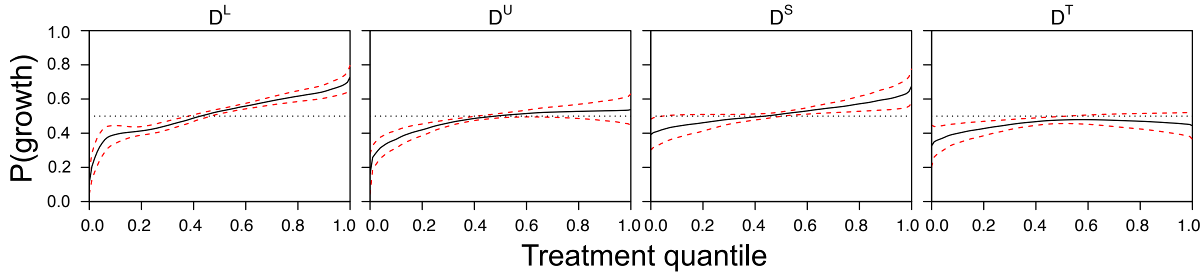

Figure 2: Average dose response function for all treatment variables, where outcome is probability of word growth. 95% confidence intervals plotted in red, chance rate of 50% marked with dotted black line.

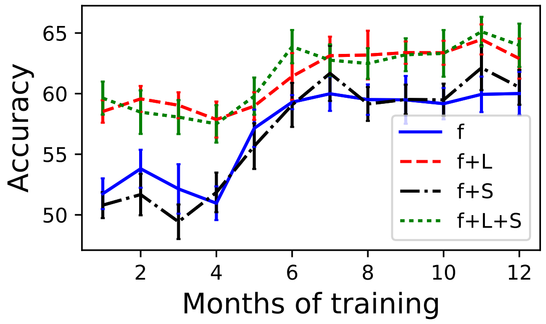

Figure 3: Prediction accuracy for different feature sets using $k = 1...12$ months of training data. f indicates frequency-only, $f+L$ frequency plus linguistic dissemination, $f+S$ frequency plus social dissemination, $f+L+S$ all features.

5.3 Predictive analysis

We now turn to prediction to determine the utility of linguistic and social dissemination: using the first k months of data, can we predict whether a word will grow or decline in popularity? This is similar to previous work in predicting the success of lexical innovations (Kooti et al., 2012), but our goal is to compare the relative predictive power of various dissemination metrics, rather than to maximize accuracy.

We use logistic regression with 10-fold cross-validation over four different feature sets: frequency-only (`f`), frequency plus linguistic dissemination (`f+L`), frequency plus social dissemination (`f+S`) and all features (`f+L+S`). Each fold is balanced for classes so that the baseline accuracy is 50%. Figure 3 shows that linguistic dissemination provides more predictive power than social dissemination: the accuracy is consistently higher for the models with linguistic dissemination than for the frequency-only and social dissemination models. The accuracies converge as the training data size increases, which suggests that frequency is a useful predictor if provided sufficient historical trajectory.

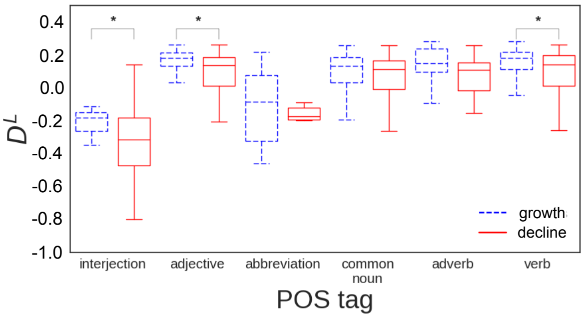

Figure 4: Distribution of D^L values across growth and decline words, grouped by part of speech tag. * indicates $p < 0.05$ in one-tailed t-test between growth and decline D^L values.

Part-of-speech robustness check Considering the uneven distribution of linguistic dissemination across part-of-speech groups (Figure 1), the prediction results may be explained by an imbalance of word categories between the growth and decline words. This issue is addressed through two robustness checks: within-group comparison and prediction.

First, we compare the distribution of linguistic dissemination values between growth and decline words, grouped by the most common POS tags (computed in § 4.2). Each decline word is matched with a growth word based on similar mean frequency in the first $k = 12$ months, and their mean linguistic dissemination values during that time period are compared, grouped within POS tag groups. The differences in Figure 4 show that across all POS tags, the growth words show a tendency toward higher linguistic dissemination with significant ($p < 0.05$) differences in the interjections, adjectives and verbs.

Next, we add POS tags as additional features to the frequency-only model in the binary prediction task. The accuracy of a predictive model with access to frequency and POS features at $k = 1$ is 54.8%, which is substantially lower than the accuracy of the model with frequency and linguistic dissemination (cf. Figure 3).[9] Thus, linguistic dissemination thus contributes predictive power beyond what is contributed by part-of-speech alone.

5.4 Survival analysis

Having investigated what separates growth from decline, we now focus on the factors that precede a decline word's "death" phase (Drouin and Dury, 2009).

Predicting the time until a word's decline can be framed as survival analysis (Klein and Moeschberger, 2005), in which a word is said to "survive" until the beginning of its decline phase at split point $\hat{t}$. In the Cox proportional hazards model (Cox, 1972), the hazard of death λ at each time t is modeled as a linear function of a vector of predictors,

$$\lambda_i(t) = \lambda_0(t) \exp(\beta \cdot \mathbf{x}_i), \tag{8}$$

where $\mathbf{x}_i$ is the vector of predictors for word i, and β is the vector of coefficients. Each cell $x_{i,j}$ is set to the mean value of predictor j for word i over the training period $t = \{1...k\}$ where $k = 3$.

For words which begin to decline in popularity in our dataset, we treat the point of decline as the "death" date. The remaining words are viewed as *censored* instances: they may begin to decline in popularity at some point in the future, but this time is outside our frame of observation. We use frequency, social dissemination and linguistic dissemination as predictors in a Cox regression model.[10]

The estimated coefficients from the regression are shown in Table 5. We find a negative coefficient for linguistic dissemination ($\beta = -0.330, p < 0.001$), which mirrors the results from § 5.2: higher D^L indicates a lower hazard of word death, and therefore a higher likelihood of survival. We also find that higher subreddit dissemination has a weak but insignificant correlation with a lower likelihood of word death ($\beta = -0.156, p > 0.05$). Both of these results lend additional support to the strong form of the hypothesis H2.

Predictor	β	std. error	Z	p
f	-0.207	0.0492	-4.21	***
D^{L}	-0.330	0.0385	-8.56	***
D^{U}	0.0053	0.0518	0.102	
D^{S}	-0.156	0.0807	-1.928	
D^{T}	0.0825	0.0662	1.25	

Table 5: Cox regression results for predicting word death with all predictors (`f+L+S`) averaged over first $k = 3$ months. *** indicates $p < 0.001$, otherwise $p > 0.05$.

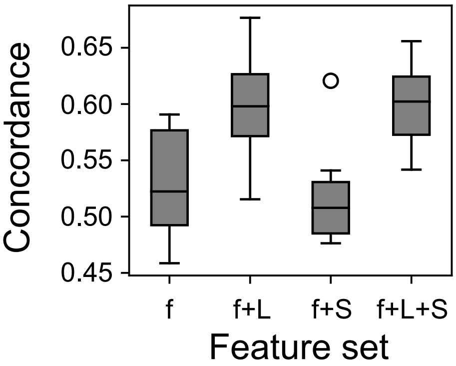

Figure 5: Distribution of concordance scores (10-fold cross-validation) of the Cox regression models across feature sets.

The predictive accuracy of survival analysis can be quantified by a *concordance score*. A score of 1.0 on heldout data indicates that the model perfectly predicts the order of death times; a score of 0.5 indicates that the predictions are no better than a chance ordering. We perform 10-fold cross-validation of the survival analysis model, and plot the results in Figure 5. The model with access to linguistic dissemination (`f+L`) consistently achieves higher concordance than the baseline frequency-only model (`f`), ($t = 4.29, p < 0.001$), and the model with all predictors `f+L+S` significantly outperforms the model with access only to frequency and social dissemination `f+S` ($t = 4.64, p < 0.001$). The result is reinforced by testing the goodness-of-fit for each model with model *deviance*, or difference from the null model. The `f+L` model has lower deviance, i.e. better fit, than the null model ($\chi^2 = 93.3, p < 0.01$), and the `f+L+S` does not have a significantly lower deviance than the `f+L` model ($\chi^2 = 4.6, p = 0.80$),

---

[9] Higher k values yield similar results.

[10] Cox regression implemented in the *lifelines* package in Python: `https://lifelines.readthedocs.io/en/latest/`.

suggesting that adding social dissemination does not significantly improve model fit.

6 Discussion

All four analyses support H2: linguistic dissemination was the strongest predictor of monthly frequency changes in growth words, the best differentiator of growth and decline words in causal and predictive tasks, and the most effective warning sign that a word is about to decline. Linguistic dissemination can be related to theories such as the FUDGE factors (Chesley and Baayen, 2010; Cook, 2010; Metcalf, 2004), in which a word's growth depends on frequency (F), unobtrusiveness (U), diversity of users and situations (D), generation of other forms and meanings (G), and endurance (E). Linguistic dissemination provides an example of "diversity of situation."

The effectiveness of linguistic dissemination is exemplified in pairs of semantically similar growth and decline words. In the first $k = 3$ months of growth, the growth word *kinda* has a relatively high ratio of linguistic to frequency ($\frac{D^L}{f} = 0.270$) as compared with the semantically similar decline word *sorta* (0.055). This pattern holds for other pairs of semantically similar growth/decline words: *fuckwit* and *fuckboy*; *lolno* and *lmao*; *yup* and *yas*. While not exhaustive, such a trend suggests that the growth words were able to reach a wider range of lexical contexts and therefore succeed where the decline words failed.

Regarding H1, we generally found a positive role for social dissemination as well, although these results were not consistent across all metrics and tests, particularly in the survival analysis. This matches the conclusion from Garley and Hockenmaier (2012), who argued that social dissemination is less predictive of word adoption than Altmann et al. (2011) originally suggested. One possible explanation is the inclusion of word categories such as proper nouns in the analysis of Altmann et al. (2011); the adoption of such terms may rely on social dynamics more than the adoption of nonstandard terms. The lower predictive power of thread and user dissemination is also interesting and suggests that subreddits are more socially salient in terms of exposing nonstandard words to potential adopters.

Limitations One limitation in the study was the exclusion of orthographic and morphological features such as affixation, which has been noted as a predictor of word growth (Kershaw et al., 2016). Future work should incorporate these features as additional predictors. Our study also omitted borrowings, unlike prior work in word adoption that has focused on borrowings (Chesley and Baayen, 2010; Garley and Hockenmaier, 2012). Our early language-filtering steps eliminated most non-English words from the vocabulary, although it would have been interesting to examine loanword use in English-language posts. Finally, our study was limited by the focus on nonstandard words rather than memetic phrases (e.g., *like a boss*) which may show a similar correlation between dissemination, growth and decline (Bybee, 2006).

Future work We approximate linguistic dissemination using trigram counts, because they are easy to compute and they generalize across word categories. In future work, a more sophisticated approach might estimate linguistic dissemination with syntactic features such as appearance across different phrase heads (Kroch, 1989; Ito and Tagliamonte, 2003) or across nouns of different semantic classes (D'Arcy and Tagliamonte, 2015). Future work should also investigate more semantically-aware definitions of linguistic dissemination. The existence of semantic "neighbors" occurring in similar contexts (e.g., the influence of standard intensifier *very* on nonstandard intensifier *af*) may prevent a new word from reaching widespread popularity (Grieve, 2018).

Acknowledgments

Analyzing Correlated Evolution of Multiple Features Using Latent Representations

Abstract

Statistical phylogenetic models have allowed the quantitative analysis of the evolution of a single categorical feature and a pair of binary features, but correlated evolution involving multiple discrete features is yet to be explored. Here we propose latent representation-based analysis in which (1) a sequence of discrete surface features is projected to a sequence of independent binary variables and (2) phylogenetic inference is performed on the latent space. In the experiments, we analyze the features of linguistic typology, with a special focus on the order of subject, object and verb. Our analysis suggests that languages sharing the same word order are not necessarily a coherent group but exhibit varying degrees of diachronic stability depending on other features.

1 Introduction

Research on structural properties (typological features) of language, such as the order of subject, object and verb (examples are `SOV` and `SVO`) and the presence or absence of tone, is largely synchronic in nature. Since languages of the world exhibit an astonishing diversity, the sample of languages used in a typical typological study is selected from a diverse set of language families and from various geographical regions. Not surprisingly, most of them lack historical documentation that allows us to directly trace their evolutionary history.

At the same time, however, typologists have long struggled to *dynamicize* synchronic typology, or to infer diachronic universals of change from current cross-linguistic variation (Greenberg, 1978; Nichols, 1992; Maslova, 2000; Bickel, 2013). They have also tried to uncover deep historical relations between languages (Nichols, 1992).

One of the main developments in diachronic typology in the last decade has been the application of powerful statistical tools borrowed from the field of evolutionary biology (Dediu, 2010; Greenhill et al., 2010; Dunn et al., 2011; Maurits and Griffiths, 2014; Greenhill et al., 2017). As illustrated in Figure 1, the key idea is that if a phylogenetic tree is given, we can infer the ancestral states with varying degrees of confidence, and by extension, can induce diachronic universals of change. To perform statistical inference, we assume that each feature evolves along the branches of the tree according to a continuous-time Markov chain (CTMC) model, which is controlled by a *transition rate matrix* (TRM). Once TRMs are estimated, we can gain insights from them, for example, by simulating language evolution (Maurits and Griffiths, 2014).

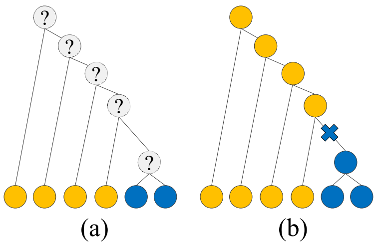

Figure 1: Phylogenetic comparative methods. Each node denotes a language with its state, or the value of its feature, indicated by color. (a) The task settings. A tree and the states of the leaf nodes are observed. The states of the internal nodes are latent variables to be inferred. (b) A result of inference. The cross sign on the branch indicates a change of the state.

One problem in previous studies is that they do not adequately model a characteristic of typological features that has been central to linguistic typology, that is, the fact that these features are not independent but depend on each other (Greenberg, 1963; Daumé III and Campbell, 2007). For example, if a language takes a verb before an object (`VO`), then it takes postnominal relative clauses

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4371–4382
Brussels, Belgium, October 31 - November 4, 2018.

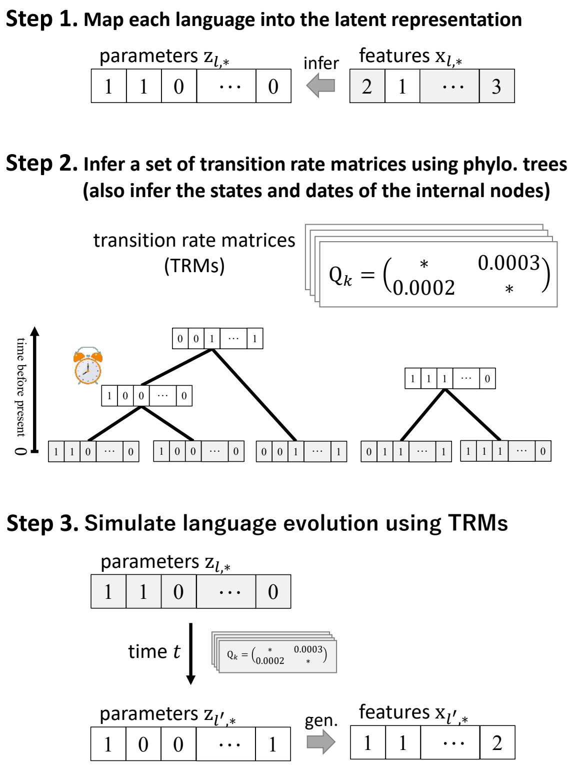

Figure 2: Overview of our framework. Observed and latent variables are marked in gray and white, respectively.

(`NRel`) (`VO` → `NRel`, in shorthand), and a related universal, `RelN` → `OV`, also holds (Dryer, 2011). Despite the long-standing interest in inter-feature dependencies, most statistical models assume independence between features (Daumé III, 2009; Dediu, 2010; Greenhill et al., 2010, 2017; Murawaki, 2016; Murawaki and Yamauchi, 2018). A rare exception is Dunn et al. (2011), who extended Greenberg's idea by applying a phylogenetic model of correlated evolution (Pagel and Meade, 2006). However, the model adopted by Dunn et al. (2011) can only handle the dependency between a pair of binary features. Typological features have two or more possible values in general, and more importantly, the dependencies between features are not limited to a pair (Itoh and Ueda, 2004). For example, the order of relative clauses has connections to the order of adjective and noun (`AdjN` or `NAdj`), in addition to the order of object and verb, as two universals, `RelN` → `AdjN` and `NAdj` → `NRel`, are known to hold well (Dryer, 2011).

In this paper, we propose latent representation-based analysis of diachronic typology. Figure 2 shows an overview of our framework. Following Murawaki (2017), we assume that a sequence of discrete surface features that represents a language is generated from a sequence of binary latent variables called *parameters* (Step 1). Parameters are, by assumption, independent of each other and switching one parameter entails multiple changes of surface features in general. Thus, by performing phylogenetic inference on the latent space, we can handle the dependencies of all available features in an implicit manner (Step 2). The latent parameter representation can be projected back to the surface feature representation when needed for analysis. Like Maurits and Griffiths (2014), we run simulation experiments to interpret the estimated model parameters (Step 3).

What we propose is a general framework with which we can analyze any discrete feature, but as a proof-of-concept demonstration, we follow Maurits and Griffiths (2014) in focusing on the order of subject, object and verb (hereafter simply referred to as basic word order or BWO).[1] In the dataset we use, the BWO feature has 7 possible values, 6 logically possible orders plus the special value `No dominant order` (Dryer, 2013b), meaning that it cannot be analyzed directly with Dunn et al.'s model. We show that languages sharing the same word order are not a coherent group but exhibit varying degrees of diachronic stability depending on other features.

2 Related Work

2.1 Statistical Diachronic Typology

The building block of statistical phylogenetic models[2] is a *time-tree*, which places nodes on an axis of time. In their standard applications to language (Gray and Atkinson, 2003; Bouckaert et al., 2012), time-trees are inferred from cognate

---

[1] We chose the BWO feature because it is appealing to a wider audience. We are aware that Matthew S. Dryer, who provided language data for the BWO feature, favors binary classifications (`OV` vs. `VO` and `SV` vs. `VS`) over the six-way classification (Dryer, 1997, 2013a). He argues that the binary classifications are more fundamental than the six-way classification, but our latent representation-based analysis does not require feature values to be primitive in nature because it reorganizes feature values into various latent parameters.

[2] Statistical phylogenetic models can be either distance-based and character-based. Character-based models are classified into parsimony-based and likelihood-based. In this paper, we focus on likelihood-based Bayesian models for their ability to date internal nodes. However, it is worth noting that attempts to overcome the limitations of the tree model mostly rely on non-likelihood-based models (Nakhleh et al., 2005; Nelson-Sathi et al., 2010).

	Dep.	# of language families	Tree sources	Dating	Abs.
Dediu (2010)	single	1	experts	yes	no
Greenhill et al. (2010)	single	1	cognates	no	yes
Maurits and Griffiths (2014)	single	1 or 7 combined	other	no	yes
Dunn et al. (2011)	bin. pair	1	cognates	no	yes
Ours	all	309 incl. 154 isolates	experts	yes	yes

Table 1: A comparison of time-tree-based approaches to diachronic typology. (1) Feature dependencies modeled: independent (single), a pair of binary features (bin. pair) or all dependencies considered (all). (2) The number of language families (i.e., trees) used for each run of phylogenetic inference. (3) The sources of the trees used in inference: tree topologies established by historical linguists (experts), time-trees reconstructed by phylogenetic models using cognate data (cognates), or time-trees obtained by distance-based clustering based on geographical coordinates or others (other). (4) Whether the dates of internal nodes are inferred (yes) or given a priori (no). (5) Whether absolute dates are obtained. If no, only dates relative to the root node are inferred.

data (Dyen et al., 1992; Greenhill et al., 2008).[3] However, if a tree is given a priori, phylogenetic models can also be used to estimate the parameters of a TRM, which controls how languages change their feature values over time. This is how typological features are analyzed in previous studies.

Dediu (2010) aggregated TRMs taken from various families to measure the stability of features. Greenhill et al. (2010) compared typological data with cognate data in terms of stability. Maurits and Griffiths (2014) focused on the BWO feature and analyzed how it had changed in the past and was likely to change in the future. Dunn et al. (2011) estimated TRMs for pairs of binary features and found that perceived correlated evolution was mostly lineage-specific rather than universal.

Taking a closer look at these studies, we can see that they vary as to how to prepare trees, as summarized in Table 1. Leaf nodes are assumed to be at the present date $t = 0$, but how can we assign backward dates t to internal nodes? A popular approach (Greenhill et al., 2010; Dunn et al., 2011) is to construct a time-tree with absolute (calendar) dates, using binary-coded lexical cognate data, and then to fit each trait of interest independently on the time-tree.[4]

However, cognate data are available only for a handful of language families such as Indo-European, Austronesian and Niger-Congo (or its mammoth Bantu branch). Moreover, phylogenetic inference was performed separately one after the other. This marks a sharp contrast with the long tradition of testing against a worldwide sample. In fact, it is suggested that sample diversity and aggregate time depth are not large enough to draw meaningful conclusions (Croft et al., 2011; Levy and Daumé III, 2011).

For this reason, we take another approach, which was employed by Dediu (2010). He used language families established by historical linguists. Because such tree topologies are not associated with dates, he inferred the dates of internal nodes together with the states of internal nodes and TRMs. This was possible because he jointly fitted a sequence of traits, instead of fitting each trait independently. If multiple traits are combined, they provide considerable information on a branch length, or the time elapsing from a parent to a child, because the elapsed time is roughly inversely proportional to the similarity between the two nodes.[5]

Our approach differs from Dediu's mainly in two points. First, whereas Dediu (2010) performed posterior inference separately for each language family, we tie a single set of TRMs to all available language families. Second, Dediu (2010) only inferred relative dates because he did not perform *calibration* (Drummond and Bouckaert, 2015). In order to assign calendar dates to nodes, we use multiple calibration points (the clock in Figure 2 indicates a calibration point). As is com-

---

[3] See Pereltsvaig and Lewis (2015) for a criticism of computational approaches to historical linguistics and Chang et al. (2015) for an elegant solution to a set of problems commonly found in inferred time-trees.

[4] To be precise, a set of tree *samples* given by MCMC sampling is usually employed to account for uncertainty.

[5] Although some previous studies adopted relaxed clock models, in which different branches have different rates of evolution (Drummond and Bouckaert, 2015), we use the simple strict clock model because our calibration points are not large enough in number to harness the very flexible models.

monly done in the cognate-based reconstruction of a time-tree (Bouckaert et al., 2012), we set the Gaussian, Gaussian mixture, log-normal and uniform distributions as priors on the dates of the corresponding internal nodes.

2.2 Latent Representations of Languages

While previous studies analyzed the evolution of a single categorical feature (Dediu, 2010; Greenhill et al., 2010; Maurits and Griffiths, 2014) or a pair of binary features (Dunn et al., 2011), we capture the dependencies of all available features by mapping each language to a sequence of independent latent variables. To our knowledge, Murawaki (2015) was the first to introduce latent representations to typological features. Pointing out several critical problems, however, Murawaki (2017) superseded the earlier model. The present study is built on top of a slightly modified version of the Bayesian model presented by Murawaki (2017).

Like the present study, Murawaki (2015) performed phylogenetic inference on the latent space. However, since this model lacks the notion of time, it does not have descriptive power beyond clustering. Borrowing statistical models from the field of evolutionary biology, we perform time-aware inference.

3 Proposed Method

3.1 Latent Representations of Languages

Central to our framework of diachronic analysis are the latent representations of languages (Murawaki, 2017). Each language l is represented as a sequence of N discrete features $\mathrm{x}_{l,*} = (x_{l,1}, \cdots, x_{l,N}) \in \mathbb{N}_0^N$. $x_{l,n}$ can take a binary value ($x_{l,n} \in \{0,1\}$) or categorical value ($x_{l,n} \in \{1, 2, \cdots, F_n\}$, where F_n is the number of distinct values). We assume that $\mathrm{x}_{l,*}$ is stochastically generated from its latent representation, $\mathrm{z}_{l,*} = (z_{l,1}, \cdots, z_{l,K}) \in \{0,1\}^K$, where K is the number of binary parameters, which is given a priori.

Dependencies between surface features are captured by weight matrix $W \in \mathbb{R}^{K \times M}$. M will be described below. In the generative story, we first calculate feature score vector $\tilde{\theta}_{l,*} = (\mathrm{z}_{l,*}^{\mathrm{T}} W)^{\mathrm{T}} \in \mathbb{R}^M$. We then obtain model parameter vector $\theta_{l,*} \in (0,1)^M$ by normalizing $\tilde{\theta}_{l,*}$ for each feature type n. We use the sigmoid function for binary features,

$$\theta_{l,f(n,1)} = \frac{1}{1 + \exp(-\tilde{\theta}_{l,f(n,1)})}, \tag{1}$$

and the softmax function for categorical features,

$$\theta_{l,f(n,i)} = \frac{\exp(\tilde{\theta}_{l,f(n,i)})}{\sum_{i'=1}^{F_n} \exp(\tilde{\theta}_{l,f(n,i')})}. \tag{2}$$

Note that while a binary feature corresponds to one model parameter, categorical feature n is tied to F_n model parameters. We use function $f(n,i) \in \{1, \cdots, m, \cdots, M\}$ to map feature n to the corresponding model parameter index. Finally, we draw a binary feature from $\mathrm{Bernoulli}(\theta_{l,f(n,1)})$, and a categorical feature from $\mathrm{Categorical}(\theta_{l,f(n,1)}, \cdots, \theta_{l,f(n,F_n)})$.

To gain an insight into how W captures inter-feature dependencies, suppose that for parameter k, a certain group of languages take $z_{l,k} = 1$. If two categorical feature values (n_1, i_1) and (n_2, i_2) have large positive weights (i.e., $w_{k,f(n_1,i_1)} > 0$ and $w_{k,f(n_2,i_2)} > 0$), then the pair must often co-occur in these languages because W raises both $\theta_{l,f(n_1,i_1)}$ and $\theta_{l,f(n_2,i_2)}$. Likewise, the fact that two feature values do not co-occur can be encoded as a positive weight for one value and a negative weight for the other.

The remaining question is how $z_{l,k}$ is generated. We draw $\mathrm{z}_{*,k} = (z_{1,k}, \cdots, z_{L,k})$ from an autologistic model (Besag, 1974) that incorporates the observation that phylogenetically or areally close languages tend to take the same value.

To complete the generative story, let X and Z be the matrices of languages in the surface and latent representations, respectively, and let A be a set of latent variables controlling K autologistic models. The joint distribution is defined as

$$P(A, Z, W, X) = P(A)P(Z|A)P(W)P(X|Z, W),$$

where hyperparameters are omitted for brevity. For prior probabilities $P(A)$ and $P(W)$, please refer to Murawaki (2017).

Even if less than 30% of the items of X are present, this model has been demonstrated to recover missing values reasonably well. Also, when plotted on a world map, some parameters appear to retain phylogenetic and areal signals observed for surface features, indicating that they are not mere statistical artifacts (Murawaki, 2017).

3.2 Transition Rate Matrices (TRMs)

We assume that each parameter k independently evolves along the branches of trees according to a continuous-time Markov chain (CTMC) model (Drummond and Bouckaert, 2015). The CTMC is a continuous extension to the more familiar discrete-time Markov chain. It is is controlled by a TRM Q_k. If the number of states (possible values) is 2, then Q_k is a 2×2 matrix:

$$Q_k = \begin{pmatrix} -\alpha_k & \alpha_k \\ \beta_k & -\beta_k \end{pmatrix}.$$

We set Gamma priors on $\alpha_k, \beta_k > 0$.

Q_k can be used to calculate the *transition probability*, or the probability of language l taking value b for parameter k conditioned on l's parent $\pi(l)$ and t, the time span between the two:

$$P(z_{l,k} = b | z_{\pi(l),k} = a, t) = \exp(tQ_k)_{a,b}. \quad (3)$$

The matrix exponential $\exp(tQ_k)$ can be solved analytically if Q_k is a 2×2 matrix:

$$\exp(tQ_k) = \begin{pmatrix} \frac{\beta_k + \alpha_k e^{-(\alpha_k+\beta_k)t}}{\alpha_k+\beta_k} & \frac{\alpha_k - \alpha_k e^{-(\alpha_k+\beta_k)t}}{\alpha_k+\beta_k} \\ \frac{\beta_k - \beta_k e^{-(\alpha_k+\beta_k)t}}{\alpha_k+\beta_k} & \frac{\alpha_k + \beta_k e^{-(\alpha_k+\beta_k)t}}{\alpha_k+\beta_k} \end{pmatrix}.$$

As t approaches to infinity, we obtain the *stationary probability* $(\frac{\beta_k}{\alpha_k+\beta_k}, \frac{\alpha_k}{\alpha_k+\beta_k})^{\mathrm{T}}$. We can see that α_k and β_k control both the speed of change (the larger the higher) and the stationary distribution.

A root node has no parent by definition. We draw the state of a root node from the stationary distribution. Thus, language isolates do have impact on posterior inference of TRMs.

3.3 Posterior Inference of Time-trees

To estimate TRMs, we need to specify the generative model of time-trees and an inference algorithm. In the generative story, each tree topology is drawn from some uniform distribution. The dates of its nodes are determined next. If the node in question is not a calibration point, its date is drawn from some uniform distribution, subject to the ancestral ordering constraint: a node must be older than its descendants. If the node is a calibration point, its date is drawn from the corresponding prior distribution.[6] TRM parameters, α_k and β_k, are generated from Gamma priors. For the root node, the value of parameter k is drawn from the corresponding stationary distribution. The states of the non-root nodes are generated using Eq. (3).

Given tree topologies, the states of the leaf nodes and calibration points, we need to infer (1) the dates of the internal nodes, (2) the states of the internal nodes, and (3) TRM parameters, α_k and β_k, for each latent parameter k. Gibbs sampling updates of these variables are as follows:

Update dates We update the dates of the internal nodes one by one. The time span in which the target node can move is bound by its parent (if there is) and its eldest child. We use slice sampling (Neal, 2003) to update the date. In addition, we use a Metropolis-Hastings operator that multiplies the dates of all the internal nodes of a tree by a rate drawn from a log-normal distribution.

Update states For each parameter k, we block-sample a whole given tree. Specifically, we implement a Bayesian version of Felsenstein's tree-pruning algorithm, which is akin to the forward filtering-backward sampling algorithm for Bayesian hidden Markov models.

Update α_k and β_k We jointly sample α_k and β_k for each k. Since both the transition and stationary probabilities can be obtained analytically for binary traits, we use Hamiltonian Monte Carlo to exploit gradient information (Neal, 2011).

3.4 Three-Step Analysis

Now we are ready to elaborate on the proposed framework of diachronic analysis (Figure 2).

Step 1 We map each language, represented as a sequence of N discrete surface features, to a sequence of K binary latent parameters. Let feature matrix X be decomposed into observed and missing portions, X_{obs} and X_{mis}, respectively. Given X_{obs}, we use Gibbs sampling to infer A, parameter matrix Z, weight matrix W, and X_{mis} (Murawaki, 2017).[7]

In the present study, we set $K = 100$. We run 5 independent MCMC chains. For each chain, we start with 1,000 burn-in iterations. We then obtain 10 samples with an interval of 10 iterations. Note that after burn-in iterations, we fix W and only sample A, Z, and X_{mis} to avoid the identifiability problems (e.g., label-switching). For each item of Z and X_{mis}, we output the most frequent value among the 10 samples. We do this to reduce uncertainty.

---

[6] This model is slightly leaky because some priors (e.g., Gaussian) assign non-zero probabilities to illogical time-trees that violate the ancestral ordering constraint.

[7] We employ a slightly modified Metropolis-Hastings operator to improve the mobility of Z.

Step 2 We fit a set of K TRMs on family trees around the world. Formally, what are observed are tree topologies, the states of the leaf nodes (i.e., sequences of latent parameters), and multiple calibration points. Given these, we infer TRM parameters, α_k and β_k, for each latent parameter k, as well as the dates and states of the internal nodes. We, again, use Gibbs sampling as explained in Section 3.3.

We collect 10 samples with an interval of 10 iterations after 1,000 burn-in iterations. We do this for each of the 5 samples obtained in Step 1. As a result, we obtain 50 samples in total.

Step 3 We analyze the TRMs by simulating language evolution. Given the latent representation of language l, we stochastically generate its descendant l' after some time span t. Specifically, we draw $z_{l',k}$ according to the transition probability of Eq. (3) for each parameter k. Using weight matrix W, we then project the latent representation $\mathrm{z}_{l',*}$ back to the surface representation $\mathrm{x}_{l',*}$. To be precise, we use model parameter vector $\theta_{l',*}$, instead of $\mathrm{x}_{l',*}$, for further analysis. For each of the 50 samples obtained in Step 2, we simulate the evolution of a given language 100 times (5,000 samples in total).

4 Experiments

4.1 Data and Preprocessing

The database of typological features we used is the online edition[8] of the *World Atlas of Language Structures* (WALS) (Haspelmath et al., 2005). We preprocessed the database as was done in Murawaki (2017), with different thresholds. As a result, we obtained a language–feature matrix consisting of $L = 2{,}607$ languages and $N = 152$ features. Only 19.98% of items in the matrix were present. We manually classified features into binary and categorical ones. The number of model parameters, M, was 760.

We used Glottolog 3.2 (Hammarström et al., 2018) as the source of family trees. Glottolog has three advantages over Ethnologue (Lewis et al., 2014), another commonly-used catalog of the world's languages. (1) Glottolog makes explicit that it adopts a genealogical classification, rather than hierarchical clusterings of modern languages. (2) It reflects more recent research. (3) Mapping between Glottolog and WALS is easy because WALS provides Glottolog's language codes (glottocodes) when available.

After Step 1 of Section 3.4, we dropped languages from WALS that could not be mapped to Glottolog. As a result, 2,557 languages remained. We subdivided a Glottolog node if multiple languages from WALS shared the same glottocode. We removed leaf nodes that were not present in WALS and repeatedly dropped internal nodes that had only one child. We obtained 309 language families among which 154 had only one node (i.e., language isolates).

We collected 50 calibration points from secondary literature (Holman et al., 2011; Bouckaert et al., 2012; Gray et al., 2009; Maurits and Griffiths, 2014; Grollemund et al., 2015). For example, we set a Gaussian prior with mean 2,500 BP (before present) and standard deviation 500 on the date of (Proto-)Hmong-Mien. See Table S.1 of the supplementary materials for details. Our calibration points are by no means definitive or exhaustive but should be seen as a first step toward world-scale dating.

4.2 Case Study: Basic Word Order (BWO)

As a proof-of-concept demonstration of the proposed framework, we investigate the BWO feature, or WALS's Feature 81A (Dryer, 2013b). The cross-linguistic variation of BWO attracts attention not only from typologists but from psycholinguists (see Maurits and Griffiths (2014) for a brief review). Some claim that the fact that `SOV` is the most frequent order indicates its optimality, presumably in terms of functionality. Some others point to an apparent historical trend of `SOV` changing to `SVO`, but not vice versa (Gell-Mann and Ruhlen, 2011), which might imply (1) the functional superiority of `SVO` over `SOV` and (2) an even higher prevalence of `SOV` in the past. `SOV` preferences in emerging sign languages (Sandler et al., 2005) and in elicited pantomime (Goldin-Meadow et al., 2008) are also reported.

Maurits and Griffiths (2014) fitted a 6 × 6 TRM[9] on large language families. However, we suspect that singling out BWO is oversimplification. Given its profound effect on the whole grammatical system, a BWO change can hardly occur independently of other features. In fact, Mithun (1995) lists a variety of morphological factors that have

---

[8] `http://wals.info/`

[9] The special value `No dominant order` was removed in their experiments.

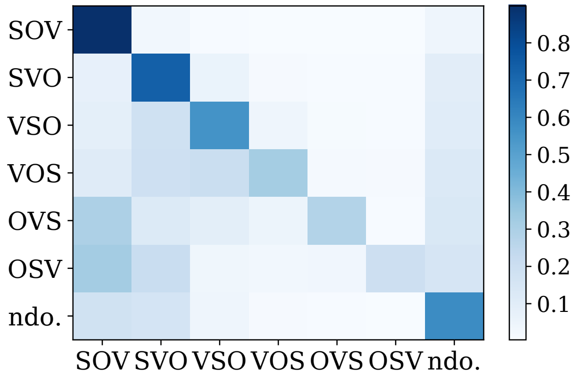

Figure 3: Transition probability of BWO. An item of the matrix (a, b) indicates how probable a language with word order a will take word order b after 2,000 years. Note that this covers the scenario in which the language switches to another word order c before changing to b.

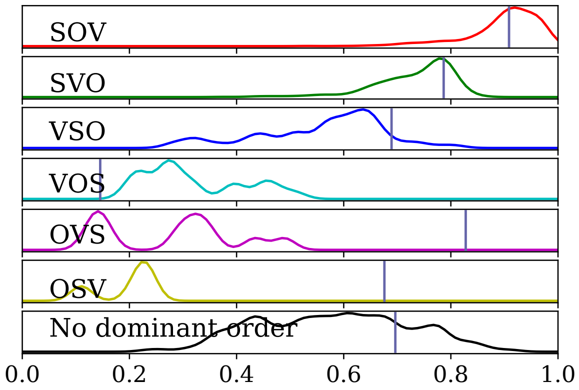

Figure 4: Variability in the probability of keeping the same word order. For word order i, the x-axis indicates the average of $\theta_{l',f(n,i)}$, the probability of taking word order i after 2,000 years. The y-axis indicates the relative frequency of the corresponding probability among the languages with word order i. Kernel density estimation is used for smoothing. The pulse in each box shows the corresponding probability estimated by directly fitting the 7 × 7 TRM of the surface feature.

diachronically reduced the rigidity of `SOV` order in Native American languages. Her analysis suggests that languages sharing the same word order might not be a monolithic group.

Here, we use latent representation-based analysis to answer questions: how variable language sharing the same BWO are with respect to diachronic stability, and what kind of features are correlated with BWO stability?

4.3 Variability of Diachronic Stability

Among the 2,557 modern languages, we chose 1,357 languages for which the BWO feature was present. We simulated evolution with $t = 2{,}000$, as described in Section 3.4. Let n be the index of the BWO feature. For the 5,000 samples of each simulated language l', we averaged the BWO probability vectors, $\theta_{l',f(n,1)}, \cdots, \theta_{l',f(n,F_n)}$.

Before going into inter-language variability, let us take a look at the overall trend. We took the average of the BWO probability vectors for each word order. The result is shown in Figure 3. Our findings largely agree with those of Maurits and Griffiths (2014): (1) `SOV` is the most diachronically stable word order, which is followed by `SVO`, (2) `SOV` prefers changing to `SVO` over `VSO` (although hardly visually recognizable), and (3) `VSO` is more likely to change to `SVO` than to `SOV`, just to name a few.

Next, the variability is visualized in Figure 4. We can see that languages sharing the same word order differ considerably in terms of diachronic stability. For comparison, we fitted the 7 × 7 TRM of the BWO feature on the samples of time-trees obtained in Step 2 of Section 3.4. For `SOV` and `SVO`, the probabilities based on the surface feature pointed to the modal probabilities based on the latent representations. This is somewhat surprising because we anticipated that the combination of the stochastic surface-to-latent and latent-to-surface mappings would amplify uncertainty of estimation.

The two least common word orders, `OVS` (0.8%) and `OSV` (0.3%) exhibited huge gaps between the two types of probabilities. The probabilities based on the surface feature were consistently larger (i.e., more stable). Surface feature-based estimation had no other way to explain the presence of these uncommon word orders than slowing down the convergence to the stationary distribution (otherwise they go extinct). Maurits and Griffiths (2014) also reported some counter-intuitive results regarding `OVS` and `OSV`. By contrast, latent parameter-based estimation appears to have explained the low frequencies partly with the stochasticity of observation associated with the latent-to-surface mapping.

Now we attempt to explain the variability of diachronic stability. Although we have all model parameters in hand, it is not easy to manually ana-

Weight	Explanatory variable (feature: value)
0.01527	59A Possessive Classification: More than five classes
0.01297	90A Order of Relative Clause and Noun: Relative clause-Noun

−0.01974	57A Position of Pronominal Possessive Affixes: Possessive suffixes
−0.03226	51A Position of Case Affixes: Case suffixes

Table 3: Regression analysis of variability for `SVO`. 10 among 52 variables are shown.

Prob.	Language	Family	Aff.
0.854	Fyam	Atlantic-Congo	`WS`
0.828	Younuo Bunu	Hmong-Mien	`LA`
0.825	Czech	Indo-European	`WS`
0.825	Tetum	Austronesian	`LA`
0.824	Stieng	Austroasiatic	`LA`
0.824	Alune	Austronesian	`EQ`
0.822	Berom	Atlantic-Congo	`SP`
0.822	Paulohi	Austronesian	`EQ`
0.821	South-Central Kikongo	Atlantic-Congo	`SP`
0.820	Abun	(isolate)	`LA`

Table 4: Some of the most stable `SVO` languages with the values of the affixation feature (Dryer, 2013c). The first column indicates the probabilities of keeping the `SVO` order after 2,000 years. Names of languages and language families are taken from Glottolog. The values of the affixation feature are `EQ` (Equal prefixing and suffixing), `LA` (Little affixation), `SP` (Strong prefixing), and `WS` (Weakly suffixing).

lyze their complex dependencies. The approach we adopt in the present study is to let a simpler model explain the model's complex behavior. Specifically, we used linear regression with L1 regularization (i.e., lasso). The hyperparameter was tuned using 3-fold cross-validation. For each word order i, the target variable was the average of $\theta_{l',f(n,i)}$ while explanatory variables were the current surface features, $x_{l,1}, \cdots, x_{l,N}$. For better interpretability, we excluded from explanatory variables surface features that trivially depended on the BWO feature (Takamura et al., 2016). Note that missing values were imputed in Step 1 of Section 3.4.

Tables 2 and 3 show the results of regression analysis for `SOV` and `SVO` languages, respectively. As expected, feature values typically associated with the specified word order had positive weights while negative weights indicate inconsistency. A stable `SOV` language may use prenominal relative clauses, postpositions and/or case suffixes. The trend was less clear for `SVO` languages, but those characterized by heavy use of prefixes were stable too. Interestingly, Feature 85A (Order of Adposition and Noun Phrase) had two positively weighted values: `Prepositions` and `No adpositions`. We speculate that `SVO` order is suitable for analytic languages that rely heavily on word ordering to encode syntactic structure (e.g., English and languages of Mainland Southeast Asia) but is not necessarily so for languages with rich morphological devices for marking syntactic structure so that word ordering can relatively freely convey information structure.

4.4 Language-Specific Analysis

In Section 4.3, we suggested that stable `SVO` languages do not form a coherent group but can be grouped into at least two clusters. This can be confirmed in Table 4, where most of the most stable `SVO` languages exhibit either (1) little affixation or (2) strong prefixation. To analyze these languages in detail, we performed language-specific simulations. We chose Tetum and South-Central Kikongo as the examples of analytic and strongly prefixing languages, respectively.

Figure 5 shows the word order probabilities of

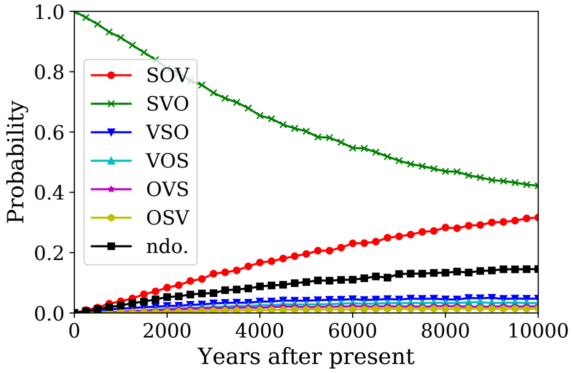

Figure 5: Simulated evolution of Tetum BWO.

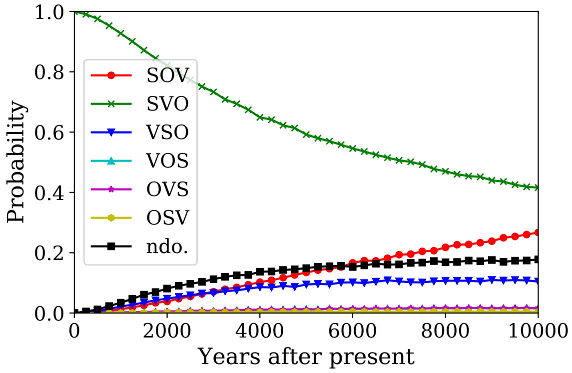

Figure 6: Simulated evolution of South-Central Kikongo BWO.

Tetum as a function of time. For each time t, we performed simulation 500 times for each of the 50 samples and took the average of the BWO probability vectors, $\theta_{l',f(n,1)}, \cdots, \theta_{l',f(n,F_n)}$. According to our analysis, Tetum will remain `SVO` with a probability of 81.1% at $t = 2{,}000$. `SVO` was followed by `SOV` (8.4%) and `No dominant order` (5.3%).

What will the Austronesian language of East Timor look like in the future, if it switches to `SOV`? To answer this question, we performed regression analysis again with $t = 2{,}000$. For each word order i, the target variable was $\theta_{l',f(n,i)}$ of each sample of simulated language l' whereas explanatory variables were the items of the probability vector $\theta_{l',*}$. In other words, we aimed at finding out features that were characteristic of the specified word order. As before, we removed surface features with trivial dependencies on the BWO feature (Takamura et al., 2016) as well as the BWO feature itself.

Table 5 shows the result of regression analysis. If the relatively analytic language switches to `SOV`, Tetum will be characterized by a holistic reconfiguration. It is likely to develop suffixes and to replace prepositions with postpositions. South-Central Kikongo is analyzed in the same manner, as shown in Figure 6 and Table 6. The Bantu language of Africa is markedly different from Tetum as it is characterized by a higher tendency to switch to `No dominant order`.

Weight	Explanatory variable (feature: value)
0.1256	85A Order of Adposition and Noun Phrase: Postpositions
0.1086	16A Weight Factors in Weight-Sensitive Stress Systems: Coda consonant

5 Conclusion

In this paper, we presented a new framework of latent representation-based analysis of diachronic typology, which enables us to investigate correlated evolution of multiple surface features in an exploratory manner. We focused on the order of subject, object and verb as a proof-of-concept demonstration, but investigating other features would be fruitful too. We analyzed the estimated model parameters with simulation experiments. In the future, we would like to investigate the inferred trees in detail.[10] The source code is publicly available at `https://github.com/murawaki/lattyp`.

Capturing Regional Variation with Distributed Place Representations and Geographic Retrofitting

Abstract

Dialects are one of the main drivers of language variation, a major challenge for natural language processing tools. In most languages, dialects exist along a continuum, and are commonly discretized by combining the extent of several preselected linguistic variables. However, the selection of these variables is theory-driven and itself insensitive to change. We use Doc2Vec on a corpus of 16.8M anonymous online posts in the German-speaking area to learn continuous document representations of cities. These representations capture continuous regional linguistic distinctions, and can serve as input to downstream NLP tasks sensitive to regional variation. By incorporating geographic information via retrofitting and agglomerative clustering with structure, we recover dialect areas at various levels of granularity. Evaluating these clusters against an existing dialect map, we achieve a match of up to 0.77 V-score (harmonic mean of cluster completeness and homogeneity). Our results show that representation learning with retrofitting offers a robust general method to automatically expose dialectal differences and regional variation at a finer granularity than was previously possible.

1 Introduction

People actively use dialects to mark their regional origin (Shoemark et al., 2017a,b), making them one of the main drivers of language variation. Accounting for this variation is a challenge for NLP systems (see for example the failed attempts of people with accents trying to use dialogue systems. Accounting for variation can significantly improve performance in machine translation (Mirkin and Meunier, 2015; Östling and Tiedemann, 2017), geolocation (Rahimi et al., 2017a,b) and help personalize applications and search.

However, regional variation involves a complex set of grammatical, lexical, and phonological features, all of them continuously changing. Consequently, dialects are not static discrete entities, but exist along a continuum in most languages. Variational linguistics and dialectology typically discretize this continuum by using a set of preselected features (Trudgill, 2000), often including outdated vocabulary. The resulting dialect areas are highly accurate, but extremely time-consuming to construct and inflexible (the largest and to date most comprehensive evaluation of German dialects, the Wenker-Atlas (Rabanus et al., 2010) is almost 150 years old and took decades to complete). Work in dialectometry has shown that computational methods, such as clustering (Nerbonne and Heeringa, 1997; Prokić and Nerbonne, 2008; Szmrecsanyi, 2008, inter alia) and dimensionality reduction (Nerbonne et al., 1999; Shackleton Jr, 2005) can instead be used to identify dimensions of variation in manually constructed discrete feature vectors. However, the success of such approaches depends on precise prior knowledge of variation features (Lameli, 2013).

Distributed representations, as unsupervised methods, can complement these methods by capturing similarities between words and documents (here: cities) along various latent dimensions, including syntactic, semantic, and pragmatic aspects. These representations are therefore more compact, less susceptible to data sparsity than latent variable models, and allow us to represent a large number of possible clusters than feature-based representations (cf. Luong et al. (2013)). These properties also allow us to measure similarities on a continuous scale, which makes represen-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4383–4394
Brussels, Belgium, October 31 - November 4, 2018.

tation learning especially useful for the study of regional language variation along several linguistic dimensions.

We use a corpus of 16.8 million anonymous German online posts, cast cities as document labels, and induce document embeddings for these cities via Doc2Vec (Le and Mikolov, 2014). We first show that the resulting city embeddings capture regional linguistic variation at a more fine-grained, continuous regional distinction than previous approaches (Bamman et al., 2014; Östling and Tiedemann, 2017), which operated at a state or language level.[1] We also show that the embeddings can serve as input to a geolocation task, outperforming a bag-of-words model, and producing competitive results.

However, such representations are susceptible to linguistic data bias, ignore geographic factors, and are hard to evaluate with respect to their fit with existing linguistic distinctions. We address these problems by including geographic information via retrofitting (Faruqui et al., 2015; Hovy and Fornaciari, 2018): we use administrative region boundaries to modify the city embeddings, and evaluate the resulting vectors in a clustering approach to discover larger dialect regions.

In contrast to most dialectometric approaches (Nerbonne et al., 1999; Prokić and Nerbonne, 2008), and in line with common NLP practice (Doyle, 2014; Grieve, 2016; Huang et al., 2016; Rahimi et al., 2017a), we also evaluate the clustered dialect areas quantitatively. Rather than testing the geographic extent of individual words against known dialect areas (Doyle, 2014), we compare the match of entire geographic regions to a recent German dialect map (Lameli, 2013). We use cluster evaluation metrics to measure how well our clusters match the known dialect regions.

The results show that our method automatically captures existing (manually determined) dialect distinctions well, and even goes beyond them in that it also allows for a more fine-grained qualitative analysis. Our research shows that representation learning is well suited to the study of language variation, and demonstrates the potential of incorporating non-linguistic information via retrofitting. For an application of our methodology to a larger Twitter data set over multiple languages, see (Hovy et al., In Preparation).

Contributions In this paper, we make the following contributions to linguistic insights, performance improvements, and algorithmic contributions. We show:

1. how Doc2Vec can be used to learn distributed representations of cities that capture continuous regional linguistic variation. The approach is general and can be applied to other languages and data sets;
2. that the city representations capture enough distinction to produce competitive results in geolocation, even this was not the main focus;
3. that retrofitting can be used to incorporate geographic information into the embeddings, extending the original algorithm's applications;
4. that the clusterings match with a sociolinguistic dialect map (Lameli, 2013), measuring their homogeneity, completeness, and their harmonic mean (V-measure), and reach a V-measure of 0.77, beating an informed baseline;

We publicly release the data, code, and map files for future research at https://github.com/Bocconi-NLPLab.

2 Data

2.1 Source

We use data from the social media app Jodel,[2] a mobile chat application that lets people anonymously talk to other users within a 10km-radius around them. The app was first published in 2014, and has seen substantial growth since its beginning. It has several million users in the German-speaking area (GSA), and is expanding to France, Italy, Scandinavia, Spain, and lately the United States. Users can post and answer to posts within the radius around their own current location. All users are anonymous. Answers to an initial post are organized in threads. The vast majority of posts in Jodel are written in standard German, but since it is conceptually spoken langauge (Koch and Oesterreicher, 1985; Eisenstein, 2013), regional and dialectal forms are common, especially in Switzerland, Austria, and rural areas in Southern Germany. The data therefore reflects current

---

[1] Han et al. (2014) has used city-level representations, but have not applied them to the identification of dialect areas.

[2] `https://jodel.com/`

developments in language dynamics to mark regionality (Purschke, 2018).

We used a publicly available API to collect data between April and June 2017 from 123 initial locations: 79 German cities with a population over 100k people, all 17 major cities in Austria ("Mittel- und Oberzentren"), and 27 cities in Switzerland (the 26 cantonal capitals plus Lugano in the very south of the Italian-speaking area). Due to the 10km radius, posts from other nearby cities get collected as well. We include these additional cities if they have more than 200 threads, thereby growing the total number of locations.[3] Ultimately, this results in 408 cities (333 in Germany, 27 in Austria, 48 in Switzerland). The resulting locations are spread relatively evenly across the entire GSA, albeit with some gaps in parts of Germany with low population density. In total, we collect 2.3 million threads, or 16.8 million posts.

We treat each thread as a document in our representation learning setup, labeled with the name of the city in which the thread took place.

2.2 Preprocessing

We preprocess the data to minimize vocabulary size, while maintaining regional discriminative power. We lowercase the input and restrict ourselves to content words, based on the part-of-speech (nouns, verbs, adjectives, adverbs, and proper names), using the `spacy`[4] tagger.

Prior studies showed that many regionally-distributed content words are topically driven (Eisenstein et al., 2010; Salehi et al., 2017). People talk more about their own region than about others, so the most indicative words include place names (the own city, or specific places within that city), and other local culture terms, such as sports teams. We try to minimize the effect of such regional topics, by excluding all named entities, as well as the names of all cities in our list, to instead focus on dialectal lexical variation.

We use `NLTK`[5] to remove German stop words, and to lemmatize the words. While this step removes the inflectional patterns found in German, which could have regional differences, we focus here on lexical differences, and lemmatization greatly reduces vocabulary size, leading to better representations. While both POS-tagging and NER can introduce noise, they are more flexible and exhaustive than pre-defined word lists.[6] Finally, we concatenate collocations based on the PMI of the adjacent words in the cleaned corpus. The average instance length is about 40 words after cleaning.

2.3 Data Statement

The corpus was selected to represent informal, everyday online speech across the German-speaking area in Europe, and to capture regional distinctions. The data was acquired via the publicly available API. The language is mainly standard German, but with a substantial amount of dialectal entries, mainly from southern German varieties, as well as some French and Italian, which could not be removed without losing dialect. The platform is anonymous, but mainly used by young people, as indicated by a prevalence of college-related topics. It contains spontaneous, written, asynchronous interactions in a chat platform organized by threads. Anonymous reference to prior interlocutors is possible. The app is mainly used to discuss everyday topics, entertainment, flirting, venting, and informal surveys.

3 Methodology

3.1 Representation Learning

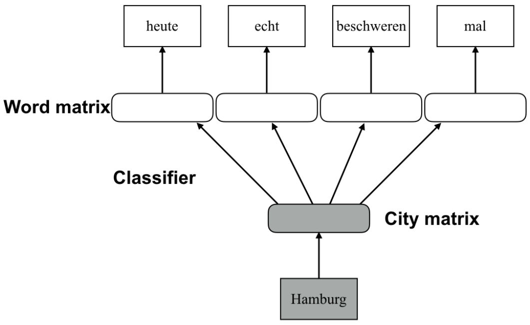

Figure 1: Doc2vec model example for window size 4.

To learn both word and city representations, we use the Doc2Vec implementation of para-

---

[3] The number of threads differs widely even between cities, ranging from dozens to over 40k in cities like Munich, Vienna, or Berlin.

[4] https://spacy.io/

[5] http://www.nltk.org/

[6] Note that stopwords and place names are more reliably detected in their standard form than in regional variants of abbreviations, meaning the standard forms are more reliably excluded if posts are written in High German, than if posts are written in dialect. This may lead to higher coherence for regions with a higher amount of non-standard tokens (as in Switzerland), thereby actually supporting our goal of detecting regional variation.

graph2vec (Le and Mikolov, 2014) in `gensim`.[7] The model is conceptually similar to `word2vec` (Mikolov et al., 2013), but also learns document label representations (in our case city names), embedded in the same space as the words. We use distributed bag-of-words (DBOW) training. The model parameters are fitted by predicting randomly sampled context words from a city vector. The objective is to maximize the log probability of the prediction,

$$y = \arg\max_{W} \log \sum_{i=1}^{N} log(p(w_i|k))$$

where k is a city, and $W = w_{i...N}$ a sequence of N randomly sampled words from the thread (see Figure 1 for a schematic representation).

During training, semantically similar words end up closer together in vector space, as do words "similar" to a particular city, and cities that are linguistically similar to each other.

Due to the nature of our task, we unfortunately do not have gold data (i.e., verified cluster labels) to tune parameters.We therefore follow the settings described in (Lau and Baldwin, 2016) for the parameters, and set the vector dimensions to 300, window size to 15, minimum frequency to 10, negative samples to 5, downsampling to 0.00001, and run for 10 iterations.

3.2 Visualization

In order to examine whether the city embeddings capture the continuous nature of dialects, we visualize them. If our assumption holds, we expect to see gradual continuous change between cities and regions.

We use non-negative matrix factorization (NMF) on the 300-dimensional city representation matrix to find the first three principal components, normalize them each to values 0.0–1.0 and interpret those as RGB values.[8] I.e., we assume the first principal component signals the amount of red, the second component the amount of green, and the third component the amount of blue. This triple can be translated into a single color value. E.g., 0.5 red, 0.5 green, and 0.5 blue translates into medium gray. This transformation translates city representations into color values that preserve linguistic similarities. Similar hues correspond to similar representations, and therefore, by extension, linguistic similarity.

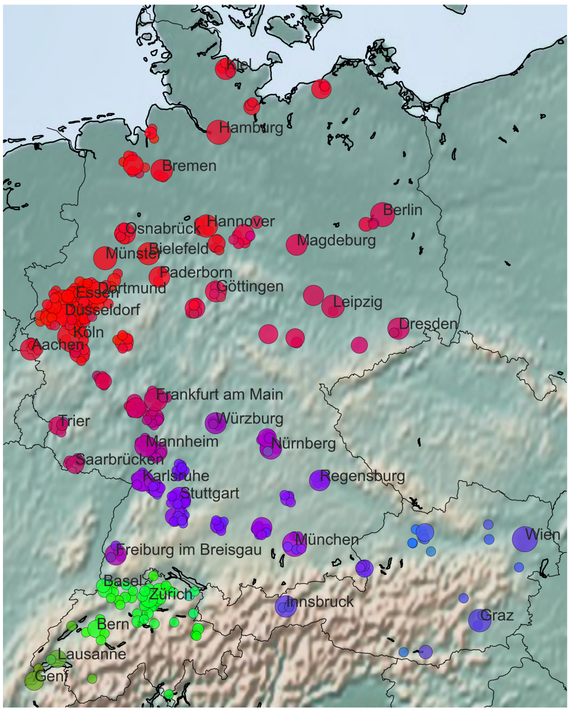

Figure 2: Gradient color map of first three components of city embeddings, interpreted as RGB, for all cities above 200 threads. Color reflects linguistic similarity.

NMF tries to find a decomposition of a given i-by-k matrix W into d components by a i-by-d row-representation V and a d-by-k column representation H. In our case, $d = 3$. Since we are only interested in a reduced representation of the cities, V, we discard H.

The result is indeed a continuous color gradient over the cities over 200 threads, see Figure 2. The circle size for every city indicates the relative number of threads per location.

In order to get reliable statistics, we restrict ourselves to cities with more than 200 observed conversations (about 2.1M conversations: 1.82M in Germany, 173k in Austria, and 146k in Switzerland). Including cities with fewer conversations adds more data points, but induces noise, as many of those representations are based on too little data, resulting in inaccurate vectors.

Even without in-depth linguistic analysis, we can already see differences between Switzerland (green color tones) and the rest of the GSA. Within

---

[7] `https://radimrehurek.com/gensim/models/doc2vec.html`

[8] Note that instead learning 3-dimensional embeddings would not amount to the same, as those are likely *not* equivalent of the three first principal components, and thus not as useful. 300 dimensions capture other degrees of variation, increasing the chance to capture meaningful latent dimensions.

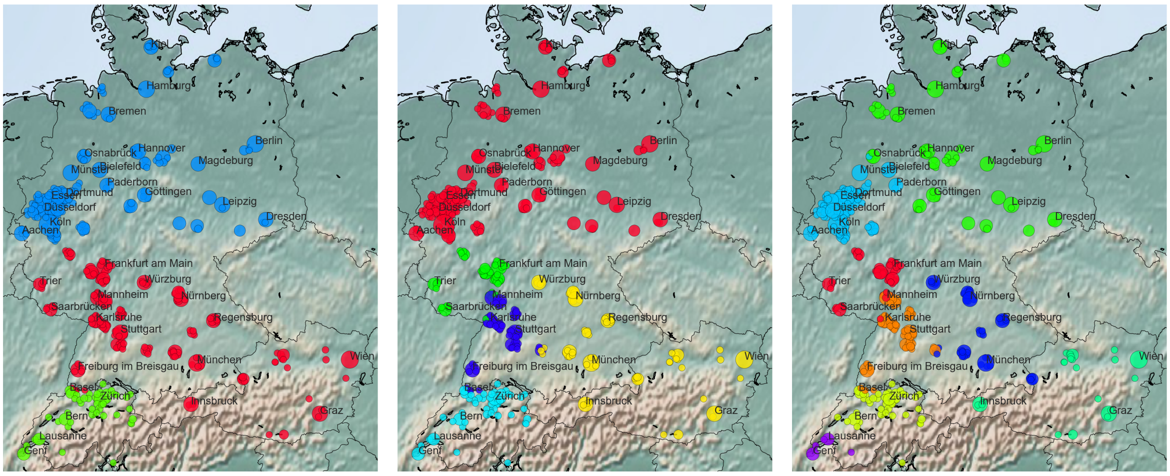

Figure 3: Clustering solutions of retrofit city embeddings for entire GSA with 3, 5, and 8 clusters. Colors denote clusters, assigned randomly.

Switzerland, we see a distinction between the German (lighter green) and the French-speaking area around Lausanne and Geneva (darker tones). On the other hand, we find a continuous transition from red over purple to bluish colors in Germany and Austria. These gradients largely correspond to the dimensions North→South(East): red→blue and West→East: intense tones →pale tones. These dimensions mirror the well-known strong linguistic connection between the southeast of Germany and Austria, and between most cities in the north of Germany.

3.3 Clustering

The visualization in the last section already suggests that we capture the German dialect continuum, and the existence of larger dialect areas. However, in order to evaluate against existing dialect maps, we need to discretize the continuous representation. We use hierarchical agglomerative clustering (Ward Jr, 1963) with Ward linkage, Euclidean affinity, and structure to discover dialect areas. We compare the agglomerative clustering results to a k-means approach.

Agglomerative clustering starts with each city in its own cluster, and recursively merges pairs into larger clusters, until we have reached the required number. Pairs are chosen to minimize the increase in linkage distance (for Ward linkage, this measure is the new cluster's variance). We use cities with 50–199 threads (66 cities) to tune the clustering parameters (linkage function and affinity), and report results obtained on cities with more than 200 threads.

Since the city representations are indirectly based on the words used in the respective cities, the clustering essentially captures regional similarity in vocabulary. If the clusters we find in our data match existing dialect distinctions, this provides a compelling argument for the applicability of our methodology.

3.4 Including geographic knowledge

While we capture regional variation by means of linguistic similarities here, it does include a geographic component as well. The embeddings we learn do not include this component, though. This can produce undesirable clustering results. Large cities, due to their "melting-pot" function, often use similar language, so their representations are close in embedding space. This is an example of Galton's problem (Naroll, 1961): Munich and Berlin are not linguistically similar because they belong to the same dialect, but due to some outside factor (in this case, shared vocabulary through migration).

To address geography, we experiment with two measures: clustering with structure, and retrofitting (Faruqui et al., 2015; Hovy and Fornaciari, 2018).

Structure To introduce geographic structure into clustering, we use a connectivity matrix over the inverse distance between cities (i.e., geographically close cities have a higher number), which is used as weight during the merging. This weight makes close geographic neighbors more likely to be merged before distant cities are.

Note, though, that this geographic component does *not* predetermine the clustering outcome: geographically close cities that are linguistically different still end up in separate clusters, as we will see. The Spearman ρ correlation between the geographic distance and the cosine-similarity of cities is positive, but does not fully explain the similarities (Austria 0.40, Germany 0.42, Switzerland 0.72). The stronger correlation for Switzerland suggests a localized effect of regional varieties. Geographic structure in clustering does, however, provide speedups, regional stability, and more stable clustering solutions than unstructured clustering. We will see this in comparison to k-means.

Retrofitting Faruqui et al. (2015) introduced retrofitting of vectors based on external knowledge. We take the idea proposed for word vectors and semantic resources and extend it following Hovy and Fornaciari (2018) to apply it to city representations and membership in geographic regions. We construct a set Ω with tuples of cities (c_i, c_j) such that there exists a region R where $c_i \in R$ and $c_j \in R$. We use the NUTS2 regions (Nomenclature of Territorial Units for Statistics, a EuroStats geocoding standard) to determine R. In Germany, NUTS2 has 39 regions, corresponding to government regions.

To include the geographic knowledge, we retrofit the existing city embeddings C. The goal is to make the representations of cities that are in the same region more similar to each other than to cities in other regions, resulting in a retrofit embeddings matrix $\hat{C}$. For a retrofit city vector $\hat{c}_i$, the update equation is

$$\hat{c}_i = \alpha c_i + \beta \frac{\sum_{j:(i,j)\in\Omega} \hat{c}_j}{N}$$

where $\hat{c}_i$ is the original city vector, and α and β are tradeoff parameters to control the influence of the geographic vs. the linguistic information. See Faruqui et al. (2015) and Hovy and Fornaciari (2018) for more details.

4 Evaluation

In order to evaluate our methodology, we measure both its ability to match German dialect distinctions, and the performance of the learned embeddings in a downstream geolocation task.

Figure 3 provides examples of different clustering solutions after retrofitting. Note that colors are assigned randomly and do *not* correspond to the linguistic similarity from Figure 2. Switzerland immediately forms a separate cluster (the 2-cluster solution separates Switzerland vs. everything else), and further clusters first separate out more southern German varieties before distinguishing the northern varieties. This is in line with sociolinguistic findings (Plewnia and Rothe, 2012) about ubiquity of dialect use (more common in the south, therefore more varied regions, reflected in our clustering). Due to space constraints, we have to omit further clustering stages, but find linguistically plausible solutions beyond the ones shown here. For an in-depth qualitative analysis of the different clustering solutions and the socio-demographic and linguistic factors, see Purschke and Hovy (In Preparation).

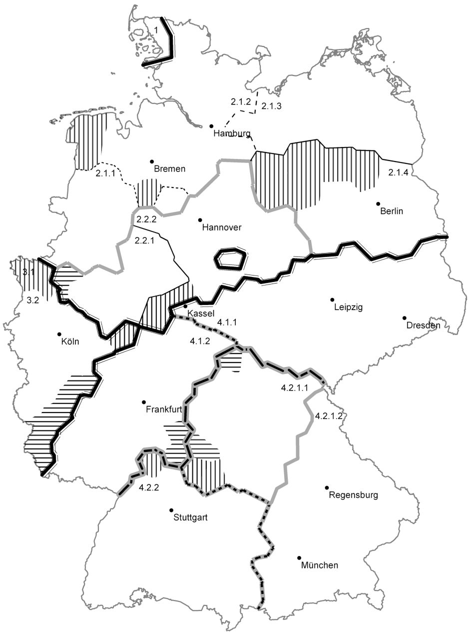

Figure 4: German dialect Regions after Lameli (2013). Shaded areas denote dialect overlap.

Dialect match We use the map of German dialects and their regions by Lameli (2013) (see Figure 4) and its 14 large-scale areas[9] as gold standard to measure how well the various clustering-solutions correspond to the dialect boundaries. This map is based on empirical quantitative analysis of German dialects, albeit based on data from the 19th century, and therefore naturally on different domains and media than our study.

Note that we can only assess the cities within modern-day Germany (clusters formed in Austria or Switzerland are not covered). We therefore rerun the clusterings on the subset of German cities, so results differ slightly from the clusters induced

---

[9] Some areas partially overlap with each other.

Table 1: Evaluation of the fit of various cluster solutions against the reference dialect map Lameli (2013). k-means results averaged over 5 runs. Agglomerative clustering with structure. Retrofitting on NUTS2 regions. Baseline: 0.74 V-score, 0.93 homogeneity, 0.62 completeness.

on the entire GSA.

We report *homogeneity* (whether a cluster contains only data points from a single region) and *completeness* (how many data points of a NUTS region are in the same cluster), as well as their harmonic mean, the *V-score*. This corresponds to precision/recall/F1 scores used in classification. Note that we will not be able to faithfully reconstruct Lameli's distinctions, since Lameli's map contains overlapping regions, whose data points therefore already violate perfect homogeneity.

The outline of dialect regions in Lameli's map is based on the NUTS2 regions, so we compare all clustering solutions to an informed baseline that assigns each city the NUTS2 region it is located in. Except for regions in dialect overlaps, each NUTS region is completely contained in one dialect region, so the baseline can achieve almost perfect homogeneity.

Downstream task geolocation For the geolocation task, we randomly select 100 cities with at least 200 threads from each country (7 in Austria, 82 in Germany, 11 in Switzerland). We then collect threads with at least 100 words from these cities for each country (11,240 threads from Austria, 137,081 from Germany, and 18,590 from Switzerland). Each thread is a training instance, i.e., we have 166,911 instances. We use the Doc2Vec model from before to induce a document representation for each instance and use the vector as input to a logistic regression model that predicts the city name.

For testing, we sample 5,000 threads from the same cities (maintaining the same proportional distribution and word count constraint), but from a *separate* data set, collected two months after the original sample. We again use the Doc2Vec model to induce representations, and evaluate the classifier on this data.

We measure accuracy, accuracy at 161km (100 miles), and the median distance between prediction and target. We compare the model with Doc2Vec representations to a bag-of-words (BOW) model with the same parameters. Since the representation here is based on words, we can not apply retrofitting. As baseline, we report the most-frequent city prediction.

5 Results

Dialect match Table 1 shows the results of clustering solutions up to 20 clusters for both retrofit and original embeddings. Irrespective of the clustering approach, retrofit representations perform markedly better.

Homogeneity increases substantially the more clusters we induce (in the limit, each data point becomes a single cluster, resulting in perfect homogeneity), whereas completeness decreases slightly with more clusters (they increase the likelihood that a region is split up into several clusters). We achieve the best V-score, 0.77, with 16 clusters.

Averaged k-means (over 5 runs) is much less consistent, due to random initialization, but presumably also because it cannot incorporate the geographic information. For few clusters, its performance is better than agglomerative clustering, but as the number of clusters increases (and the geographic distribution of the cities becomes more intricate), k-means stops improving.

The baseline achieves almost perfect homogeneity, as expected (the only outliers are NUTS regions in overlap areas). Completeness is lower than almost all clustering solutions, though. The V-score, 0.74, is therefore lower than the best clustering solution.

Both the cluster evaluation metrics and the visual correspondence suggest that our method captures regional variation at a lexical level well.

MODEL	↑ACC	↑ACC@161	↓MED. DIST.
baseline	0.03	0.31	269.33
BOW	0.21	0.50	156.17
D2V	**0.26**	**0.52**	**145.16**

Table 2: Geolocation performance for city embeddings and bag-of-word vectors on held-out data set. Baseline predicts most frequent city from training data.

Downstream Evaluation: Geolocation Table 2 shows the results of the geolocation downstream task. Despite the fact that the representation learning setup was *not* designed for this task and excluded all the most informative words for it (Salehi et al., 2017), the induced embeddings capture enough pertinent regional differences to achieve reasonable performance (albeit slightly below state of the art, which typically has a median distance around 100km, and an accuracy@161 of 0.54, see cf. Rahimi et al. (2017b)) and decidedly outperform the BOW model and most-frequent-city baseline on all measures.

6 Analysis

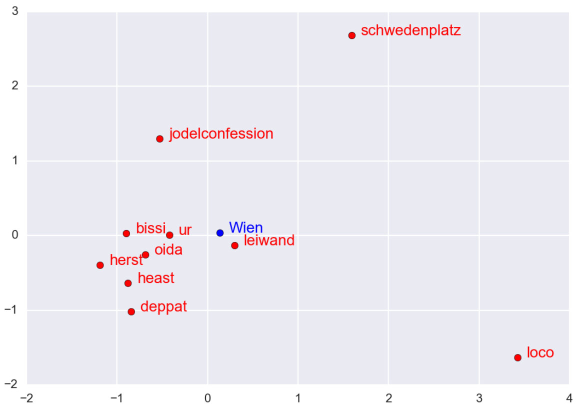

Figure 5: Visualization of city representation for Wien (Vienna) and its 10 nearest word neighbors in two dimensions. The closest seven words are all Austrian dialect words

Because both words and cities are represented in the same embeddings space (at least before retrofitting), we can compare the vectors of cities to each other (asking: which cities are linguistically most similar to each other, which is what we have done above) and words to cities (asking: which words are most similar to/indicative of a city). The latter allows us to get a qualitative sense of how descriptive the words are for each city.

Figure 5 shows an example of word and city similarity for the city representation of Vienna.

We can also use the cluster centroid of several city vectors to represent entire regions. The new vector no longer represents a real location, but is akin to the theoretic linguistic center of a dialect region. We can then find the most similar words to this centroid. For the solution with 3 clusters (cf. Figure 3), we get the solutions in Table 3. As expected, the regional prototypes do not overlap, but feature dialectal expressions in the south, and general standard German expressions in the north.

Again, for an in-depth qualitative analysis and discussion of the socio-linguistic correlations, see Purschke and Hovy (In Preparation).

7 Related Work

Dialectometric studies, exploring quantitative statistical models for regional variation, range from

CLUSTER	PROTOTYPES	TRANSLATION

work on dialect data in Dutch (Nerbonne and Heeringa, 1997; Prokić and Nerbonne, 2008; Wieling et al., 2011, inter alia) and British English (Szmrecsanyi, 2008), to Twitter-based approaches for American dialect distinctions (Grieve et al., 2011; Huang et al., 2016) and the regional differentiation of African American Vernacular English (Jones, 2015). While these papers rely on existing dialect maps for comparison, they rarely quantitatively evaluate against them, as we do.

Recently, NLP has seen increased interest in *computational sociolinguistics* (Nguyen et al., 2016). These works examine the correlation of socio-economic attributes with linguistic features, including regional distribution of lexical and phonological differences (Eisenstein et al., 2010; Doyle, 2014; Bamman et al., 2014), syntactic variation (Johannsen et al., 2015), diachronic variation (Danescu-Niculescu-Mizil et al., 2013; Kulkarni et al., 2015; Hamilton et al., 2016), and correlation with socio-demographic attributes (Eisenstein et al., 2011; Eisenstein, 2015). Other have further explored regional variation on social media, and showed the prevalence of regional lexical variants (Hovy et al., 2015; Hovy and Johannsen, 2016; Donoso and Sánchez, 2017). Several works include quantitative comparisons to measure the empirical fit of their findings (Peirsman et al., 2010; Han et al., 2014; Huang et al., 2016; Grieve, 2016; Kulkarni et al., 2016), albeit not on entire existing dialect maps.

The use of representation learning is new and relatively limited, especially given its prevalence in other areas of NLP. Bamman et al. (2014) have shown how regional meaning differences can be learned from Twitter via distributed word representations between US states, but not for individual cities. More recently, Kulkarni et al. (2016); Rahimi et al. (2017a) and Rahimi et al. (2017b) have shown how neural models can exploit regional lexical variation for geolocation, while also enabling dialectological insights, whereas our goals are exactly reversed. Östling and Tiedemann (2017) have shown how distributed representations of entire national languages capture typological similarities that improve translation quality. Most of these papers focus on downstream performance that accounts for regional variation, rather than on explicitly modeling variation. We include a downstream performance, but also evaluate the cluster composition quantitatively.

8 Conclusion

We use representation learning, structured clustering, and geographic retrofitting on city embeddings to study regional linguistic variation in German. Our approach captures gradual linguistic differences, and matches an existing German dialect map, achieving a V-score of 0.77. The learned city embeddings also capture enough regional distinction serve as input to a downstream geolocation task, outperforming a BOW baseline and producing competitive results. Our findings indicate that city embeddings capture regional linguistic variation, which can be further enriched with geographic information via retrofitting. They also suggest that traditional ideas of regionality persist online. Our methodology is general enough to be applied to other languages that lack dialect maps (e.g., Switzerland), and to other tasks studying regional variation. We publicly release our data and code.

Characterizing Interactions and Relationships between People

Farzana Rashid and **Eduardo Blanco**
Human Intelligence and Language Technologies Lab
University of North Texas
Denton, TX, 76203
farzanarashid@my.unt.edu, eduardo.blanco@unt.edu

Abstract

This paper presents a set of dimensions to characterize the association between two people. We distinguish between interactions (when somebody refers to somebody in a conversation) and relationships (a sequence of interactions). We work with dialogue scripts from the TV show Friends, and do not impose any restrictions on the interactions and relationships. We introduce and analyze a new corpus, and present experimental results showing that the task can be automated.

1 Introduction

People interact with each other and as a result form relationships. These relationships range from weak (e.g., John talking to a waiter to order a drink) to strong (e.g., John and his best friend discussing career options). Traditionally, information extraction systems target, among others, relationships between people, e.g., PARENT, SIBLING, OTHER-PERSONAL, OTHER-PROFESSIONAL (Doddington et al., 2004).

Extracting a label describing the general relationship between two entities—often called *relation type*—is useful for tasks such as summarization (Jijkoun et al., 2004) and question answering (White et al., 2001). Only assigning a relation type, however, does not account for nuances in the relationship between two individuals. First, a relationship can be characterized beyond a relation type. For example, people having a PROFESSIONAL relationship may be *spatially near* or *distant* (working at the same or different offices), and have an *equal* or *hierarchical* relationship (two software developers or a developer and the CEO). Second, relationships are defined by multiple interactions, and the fine-grained characteristics of interactions do not necessarily mirror the characteristics of the corresponding relationship. For example, software developers having a *cooperative* PROFESSIONAL relationship may have a *heated* interaction in a meeting that does not affect the long-term PROFESSIONAL relationship. Similarly, the same software developers having a *task-oriented* PROFESSIONAL relationship may have occasionally *pleasure oriented* interactions (e.g., when they go out for drinks on Fridays).

This kind of fine-grained characteristics of interactions and relationships are called *dimensions* in social science (Wish et al., 1976). Social scientists have also studied language usage and how people interact with each other depending on their relationship. For example, Gibbs (2000) studies irony (sarcasm, hyperbole, understatement, etc.) in communications among friends, and Snyder and Stukas Jr (1999) analyze the expectations in social interactions (e.g., interactions between strangers tend to be more formal) as well as the consequences of breaking expectations. In the social sciences, however, researchers mostly focus on how people act (e.g., how they talk to each other and about each other) and how people perceive interactions and relationships. In general, they do not attempt to automatically characterize interactions or relationships from language usage.

In this paper, we characterize the interactions between people and the resulting relationships. The main contributions of this paper are: (a) a set of dimensions to characterize interactions and relationships, including dimensions previously defined in the social sciences and two novel dimensions; (b) annotations of these dimensions for all interactions and relationships in 24 episodes of the TV show Friends (Season 1); (c) corpus analysis including agreements, label distributions and correlations; and (d) experimental results showing that classifiers grounded on language usage (and discarding the names of people being considered) are successful at automating the task.

Brussels, Belgium, October 31 - November 4, 2018.

2 Previous Work

Within natural language processing, there have been several recent efforts working with relationships between people. Voskarides et al. (2015) extract human-readable descriptions of relations in a knowledge graph. Unlike the work presented here, they experiment with a proprietary knowledge graph and rely heavily on features extracted from the graph. Iyyer et al. (2016) propose an unsupervised algorithm to extract relationship trajectories of fictional characters. Bracewell et al. (2012) introduce social acts (e.g., agreement, undermining) designed to characterize relationships exhibiting adversarial and collegial behavior (similar to our cooperative vs. competitive dimension). None of these works distinguish between interactions and relationships, characterize interactions and relationships with dimensions, or consider all interactions between two people.

In our previous work, we characterize interpersonal relationships with dimensions (Rashid and Blanco, 2017). In this paper, we improve upon our previous effort as follows. First, we distinguish between interpersonal interactions and relations. Second, we work with dialogues thus the same people interact with each other many times.

There have been a few studies on analyzing language usage when people communicate. For example, Danescu-Niculescu-Mizil et al. (2012) study how power differences affect language style in online communities, and Prabhakaran and Rambow (2014) present a classifier to detect power relationships in email threads. Similarly, Gilbert (2012) explores how people in hierarchical relationships communicate through email, and Bramsen et al. (2011) focus on identifying power relationships in social networks. Politeness in online forums has also been studied (Danescu-Niculescu-Mizil et al., 2013). While power (similar to our equal vs. hierarchical dimension, Section 3) and politeness could be considered dimensions, these works exploit structural and linguistic features derived from communications between two individuals. Unlike all of them, we distinguish between and characterize interactions and relationships, and automate the task using only information derived from language usage.

Information extraction systems target, among others, relationships between people. There have been many evaluations (Grishman and Sundheim, 1996; Doddington et al., 2004; Kulick et al., 2014; Surdeanu and Heng, 2014), and there are two main approaches. Traditionally, relationships are defined before training takes place (e.g., PARENT, FRIENDS), and systems are trained using supervised machine learning (Yu and Lam, 2010; Nguyen et al., 2016; West et al., 2014). On the other hand, open information extraction (Wu and Weld, 2010; Angeli et al., 2015) has emerged as an unsupervised domain-independent approach to extract relations. Regardless of details, these previous works extract explicit relationships and do not attempt to characterize instances of relationships with dimensions. Additionally, they do not distinguish between interactions and relationships.

3 Interpersonal Interactions and Relationships

In this paper, we work with transcripts of conversations and define interaction and relationship as follows. An *interaction* between two people x and y exists for each conversation turn by either x or y referring to the other person. A *relationship* between two people x and y exists if there is at least one interaction between them. One could understand a relationship between x and y as the association defined by a sequence of interactions between x and y. Beyond these definitions, we do not impose any restriction on what constitutes an interaction or relationship: interactions occur each time two people refer to each other in their speech (even if they are not talking to each other), and one or more interactions constitute a relationship.

Interactions and relationships between people have been extensively studied in psychology and social sciences in general. The *right* set of dimensions is not agreed upon (Wish et al., 1976; Deutsch, 2011; Adamopoulos, 2012), and we argue that it depends on the domain of interest (e.g., personal diaries vs. news articles covering politics). We note that dimensions apply to interactions and relationships between specific people (i.e., instances of interactions and relationships), not relation types. For example, a KINSHIP relationship between x and y could be *intense* or *superficial* (depending on x and y) and a particular interaction of that relationship may be *spatially near* or *distant* (even for the same x and y).

The dimensions we work with are briefly summarized in Table 1 and described below. All but two dimensions are defined in previous work in the social sciences (see references in Table 1).

		Other descriptors	Ref.
Interaction	Cooperative vs. Competitive	friendly vs. hostile, promotive vs. contrient	[1]
	Active vs. Passive	direct vs. indirect, unequivocal vs. equivocal	[2]
	Concurrent vs. Nonconcurrent	convergent vs. divergent, synchronous vs. asynchronous	New
	Spatially Near vs. Distant	nearby vs. faraway, attached vs. detached	New
Relationship	Equal vs. Hierarchical	autonomy vs. control, submission, dominance	[1]
	Intense vs. Superficial	important vs. insignificant, influential vs. trivial	[1]
	Pleasure vs. Task Oriented	emotionally involved vs. detached	[1]
	Intimate vs. Unintimate	close vs. distant, indifference, randomness	[3]
	Temporary vs. Enduring	momentary vs. lasting, provisional vs. permanent	[4]

Table 1: Dimensions of interpersonal interactions and relationships. [1] stands for (Wish et al., 1976), [2] for (Kelley, 2013), [3] for (Adamopoulos, 2012), and [4] for (Deutsch, 2011). *New* indicates a dimension defined after analyzing several examples and doing pilot annotations.

Dimensions of Interactions. We consider four dimension of interactions between people, i.e., when a speaker refers to a person in a conversation:

- *Cooperative vs. Competitive*. A interaction is *cooperative* if both people (a) have a common interest or goal, (b) like each other, (c) benefit from the interaction, or (d) think alike or share similar views. Otherwise, the interaction is *competitive*.
- *Active vs. Passive*. An interaction is *active* if both people communicate directly. Otherwise, the interaction is *passive*. For example, when John talks to Bill about Mary, John and Bill have an active interaction, and John and *Mary* have a passive interaction.
- *Concurrent vs. Nonconcurrent*. An interaction is *concurrent* if both people are involved in an event or action at the same time (the event does not need to be a communicating event). Otherwise, the interaction is *nonconcurrent*. For example, when John talks to Bill about a trip with Mary, John and Mary have a *concurrent* interaction, but when John talks to Bill about Paul's house, John and Paul have a nonconcurrent interaction.
- *Spatially Near vs. Distant*. An interaction is *spatially near* (or *near* for short) if the interaction is concurrent and both people are at the same location during the event in which they are involved. Otherwise, the interaction is *spatially distant* (or *distant* for short).

Dimensions of Relationships. We consider five dimensions of relationships between people:

- *Equal vs. Hierarchical*. A relationship is *equal* if both people (a) have the same social status, (b) are at the same level in the power structure, (c) share similar responsibilities, or (d) have the same role. Otherwise, the relationship is *hierarchical*.
- *Intense vs. Superficial*. A relationship is *intense* if both people interact with each other frequently, i.e., they are involved repeatedly. Otherwise, the relationship is *superficial*.
- *Pleasure vs. Task Oriented*. A relationship is *pleasure oriented* if both people interact socially and their relationship is not bound by professional rules or regulations. Otherwise, the relationship is *task oriented*.
- *Intimate vs. Unintimate*. A relationship is *intimate* if both people are emotionally close and warm to each other. Otherwise, the relationship in *unintimate*.
- *Temporary vs. Enduring*. A relationship is *temporary* if it lasts less than a day. A relationship is *enduring* if it last over a month. Otherwise (if it lasts more than a day and less than a month), this dimension is undefined.

4 Annotating Dimensions of Interactions and Relationships

Annotating dimensions of interactions and relationships requires a corpus in which the same people interact several times. We augment an existing corpus of scripts from the TV show Friends (Chen and Choi, 2016). More specifically, we work with the 24 episodes from Season 1 because they:

- contain a large number of conversation turns (9,168, see counts per episode in Table 2);
- involve many characters (42 characters speak at least 100 conservation turns, see the characters that interact the most in Table 2, and the full list in the supplementary materials);

- include speaker information (i.e., we have access to who says what); and
- include annotations linking each mention of people in each conversation turn to the actual person (the name of the person).

Beyond size, the main motivation to use this corpus is the last item above: starting from scratch with another corpus of dialogues would require a substantially larger annotation effort. We refer the reader to the afore-cited paper for details, but the original corpus clusters mentions to people such as *guy*, *my brother* and *he* together with other mentions of the same person. The original corpus is publicly available,[1] and we release our annotations as stand-alone annotations.[2]

4.1 Selecting Pairs of People

The corpus we start with makes it straightforward to select pairs of people whose interactions and corresponding relationships will be annotated. We consider as interactions all instances of somebody mentioning (or referring to) somebody else in a conversation turn. We consider as relationships individuals who interact at least once. Note that we do not (a) distinguish between x mentioning y and y mentioning x, and (b) consider as an interaction x talking to y unless the conversation turn contains a mention to y (the mention need not be the actual name, it could be a pronoun or any nominal mention). Our rationale is as follows. First, all dimensions of interactions are symmetric; and all dimensions of relationships are symmetric except *equal* vs. *hierarchical*. Second, the characters of Friends refer to each other explicitly at least once in most conversations and scenes, either using first names or the pronoun *you*. Thus we are considering as an interaction most verbal exchanges.

Table 2 shows basic counts per episode. We show the number of interactions, unique relationships (i.e., interactions between unique pairs of people), and the pair of people who interact the most. The supplementary materials include an extended table listing the number of times each pair of people interact per episode.

Episode	#Turns	#Inters	#Rels	People with most inters.
1	544	143	21	Monica-Rachel (23)
2	358	105	19	Rachel-Barry (14)
3	475	98	20	Joey-Chandler (12)
4	359	64	17	Monica-Rachel (15)
5	290	76	18	Chandler-Janice (14)
6	353	82	16	Chandler-Aurora (32)
7	291	76	15	Ross-Rachel (13)
8	371	64	19	Monica- Mrs. Geller (14)
9	375	75	18	Monica-Rachel (13)
10	273	69	19	Phoebe-David (22)
11	447	159	24	Chandler-Ross (22)
12	351	109	23	Phoebe-Paolo (14)
13	328	120	24	Joey-Mr.Tribbianni (21)
14	294	239	21	Chandler-Janice (28)

17	526	109	17	Monica-Rachel(28)
18	306	42	14	Ross-Rachel (9)
19	183	29	10	Ross-Rachel (9)
20	467	111	20	Rachel-Mindy (30)
21	403	85	24	Monica-Fake Monica (23)
22	468	92	22	Phoebe-Chandler (32)
23	457	104	26	Ross-Susan (19)
24	325	107	18	Ross-Rachel (30)

Table 2: Basic corpus counts. We show the number of conversation turns, interactions (i.e., one person referring to another one), unique relationships (i.e., unique pairs of people who interact with each other), and the pairs of people with most interactions.

4.2 Annotation Process

The annotations were done one episode at a time. Annotators were presented with the full transcript of the episode including speaker information (who speaks what?) and the names of the individuals mentioned in each conversation turn (who do speakers talk about?). Annotators read each episode from the beginning, and annotate dimensions of interactions and relationships after each interaction. Regarding interactions, they were instructed to annotate dimensions taking into account the language of the current conversation turn. Regarding relationships, they were instructed to annotate dimensions taking into account all previous conversation turns within the same episode. For example, if previous turns state that *Rachel* and *Monica* are best friends, the relationship will continue to be annotated *intense* even if an interaction does not indicate so (until a turn indicates that they are not friends, if applicable).

---

[1] `https://github.com/emorynlp/character-mining`

[2] `http://www.cse.unt.edu/~blanco/`

	Speaker	2nd party	Cooperative (I)
1: Wait, does he eat chalk?	Phoebe	Paul	-1
2: Hey, hey, hey, that's not the rule and you know it.	Ross	Woman	-1
3: She is so peaceful.	Monica	Phoebe	1
	Speaker	2nd party	Concurrent (I)
4: Well, then can we meet him?	Rachel	Alan	-1
5: Hey, buddy, what's up!	Chandler	Alan	1
6: Ma, I'm sorry.	Joey	Mrs. Tribbiani	1
	Speaker	2nd party	Equal (R)
7: Oh, ah-the kid has it.	Joey	the kid	-1
8: Happy birthday, pal!	Chandler	Ross	1
9: Hey dad, what's up?	Monica	Mr. Geller	-1
	Speaker	2nd party	Intense (R)
10: Um, has uh Dr. Franzblau been by?	Rachel	Dr. Franzblau	-1
11: There's a beautiful woman at eight, nine, ten o'clock!	Chandler	Aurora	-1
12: Uh, Rach, it's the Visa card people.	Monica	Rachel	1

Table 3: Annotation examples. We show examples of contrasting values for selected dimensions. The first party is always the speaker, and the second party is underlined. I stands for interactions, and R for relationship.

		raw	κ
Interaction	Cooperative	93.4%	0.82
	Active	95.4%	0.89
	Concurrent	93.7%	0.84
	Spat. Near	95.7%	0.87
Relationship	Equal	94.6%	0.85
	Intense	88.8%	0.80
	Pleasure Or.	97.4%	0.77
	Intimate	92.3%	0.85
	Temporary	94.8%	0.78

Table 4: Inter-annotator agreement (raw agreement and Cohen's κ). κ values between 0.6 and 0.8 indicate *substantial* agreement, κ values over 0.8 indicate *perfect* agreement (Artstein and Poesio, 2008).

We discovered during pilot annotations that the value for a dimension sometimes cannot be determined. For example, if the first interaction between *Rachel* and *Monica* is *Rachel: How are [you]$_{\text{Monica}}$ doing?*, we cannot tell if the relationship is *temporary* or *enduring*. We note, however, that all interaction after we find out that they are best friends (as long as they remain best friends) will be annotated *enduring*. Hereafter, we refer to dimensions by the first descriptor in Table 1, and use `1` if the first descriptor of a dimension is true, `-1` if the second descriptor is true, and `0` if neither the first nor the second descriptor can be chosen.

Annotation Quality. The annotations were done by two graduate students in computational linguistics. First, they did pilot annotations to better define the dimensions (Section 3). After several iterations, both of them annotated 3 episodes (15% of all interactions). Table 4 presents the inter-annotator agreements. Cohen's κ range between 0.77 and 0.89, and most (7 out of 9) are above 0.80, which is considered perfect agreement. Values between 0.60 and 0.80 are considered substantial (Artstein and Poesio, 2008). The remaining episodes were annotated once.

4.3 Annotation Examples

We present annotation examples in Table 3. The interactions in conversation turns 1 and 2 are *competitive*: Phoebe is ridiculing Paul by asking Monica if he eats chalk, and Ross is confronting an unnamed woman. In turn (3), Monica refers to Phoebe with affection (as the latter sleeps), thus the interaction is *cooperative*. Turns (4–6) exemplify *concurrent* vs. *nonconcurrent*. In (4), Rachel is inquiring whether she can meet Alan (Monica's boyfriend), and Rachel and Alan are not involved in the same event (at this point, the meeting may or may not happen). In (5–6), however the speaker and second party are involved directly in a communication event. In examples (4–6), the values for *active* are the same as for *concurrent*.

Turns 7–12 present examples for dimensions of relationships. Examples 7 and 9 are fairly straightforward: previous interactions reveal that *Joey* is

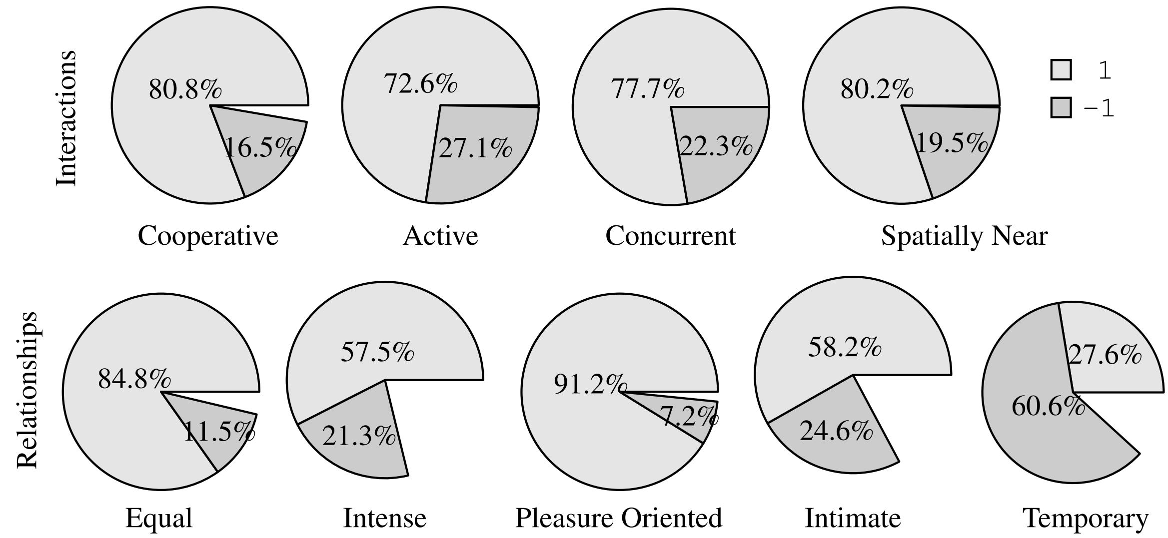

Figure 1: Label percentages per dimension. The missing portion of pie charts correspond to label `0` (unknown).

an adult and Monica's father is indeed *Mr. Geller*. Example 8 is annotated *equal*, as Chandler and Ross are friends based on previous interactions (the use of *pal* also helps). Examples 10–12 require more explanation, as additional information beyond the current conversation turn is required (recall that dimensions of relationships are annotated taking into account the previous turns within the same episode, Section 4.2). Dr. Franzblau is the doctor of a friend's ex-wife, so Monica and him have a *superficial* relationship (Turn 10). At the point Turn (11) is spoken by Chandler, she and *Aurora* are strangers, so they have a *superficial* relationship. In (12), previous conversations reveal that Monica and Rachel are close friends, and they interact often (*intense*).

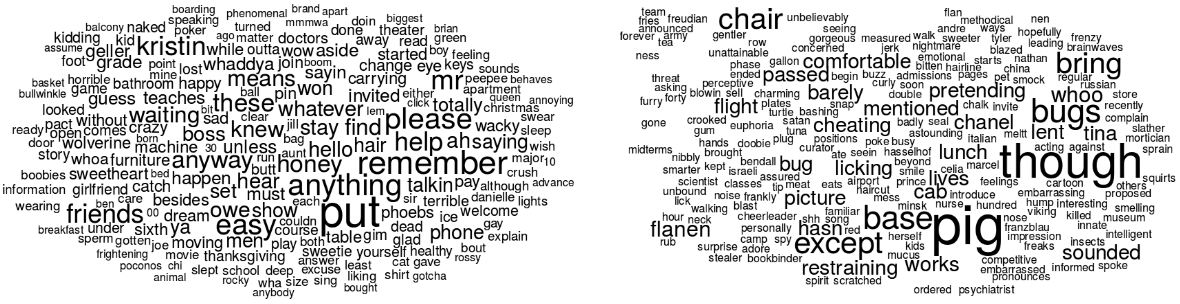
5 Corpus Analysis

The pie charts in Figure 1 present the label distributions per dimension. Regarding interactions, we note that (a) values for all dimensions can be determined almost always (the percentages of `0` (unknown) are almost zero), and (b) the first descriptor is much more common in all dimensions. These percentages do not represent the distribution of interactions between people in general: the scripts of the TV show Friends mostly contain conversation between friends. Regarding relationships, we observe a larger percentage of `0` (unknown) although values of all dimension can be determined most of the time (labels `1` and `-1`, indicating that the first or second descriptor apply). Most dimensions are biased towards `1` (the only exception is *temporary*, as most relationships are *enduring*), especially *pleasure oriented* and *equal* (91.2% and 84.8%). Again, these distributions would be different if we worked with other sources of dialogue than the TV show Friends.

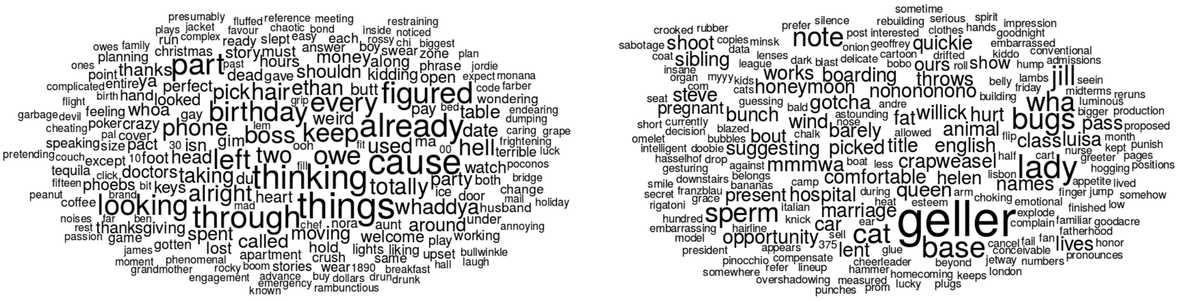
	Cooperative (I)	Active (I)	Concurrent (I)	Spat. Near (I)	Equal (R)	Intense (R)	Pleasure Or. (R)	Intimate (R)
Active	.06	–						
Conc.	.02	.81	–					
Near	.01	.71	.89	–				
Equal	-.01	.08	.06	.05	–			
Intense	.08	.28	.24	.22	.28	–		
Pleasure	-.05	.01	.08	.08	.50	.13	–	
Intimate	.12	.28	.26	.22	.32	.75	.28	–
Temp.	-.02	-.33	-.31	-.28	-.24	-.52	-.27	-.54

Table 5: Pearson correlations between pairs of dimensions of interactions and dimensions.

Many of the dimensions we consider in this work are intuitively correlated. For example, *concurrent* interactions must be *active*, and *pleasure oriented* interactions are probably also *equal*. We note, however, that interactions can be *passive* and *concurrent*, e.g., in *(Monica talking to Joey) [He]*$_{\text{Paul}}$ *is just [a guy]*$_{\text{Paul}}$ *I am dating!*, Monica and Paul have a *passive* and *concurrent* interaction (they are dating, but they are not talking to each other). Table 5 shows Pearson correlations between all dimensions of interactions and relationships. Most correlations are under 0.3 (29 out



Spatially Near vs. Spatially Distant (Interaction)



Intense vs. Superficial (Relationship)

Figure 2: Most salient words (calculated with tf-idf) for dimensions *spatially near* and *intense*.

of 36), although some pairs do have high correlations. In particular, *active* interactions tend to be both *concurrent* (0.81) and *spatially near* (0.71), and *spatially near* interactions tend to be concurrent (0.89). Regarding relationships, *intimate* correlates with *intense* (0.75), *pleasure oriented* with *equal* (0.50), and *temporary* with both *superficial* (0.52) and *intimate* (0.54).

Finally, Figure 2 shows the most salient words of dimensions *spatially near* and *intense*. We calculated salience using tf-idf (Schütze et al., 2008). Interactions containing derogatory words (e.g., *pig*, *bugs*, *pretending*, *cheating*) tend to be *distant*, and *near* interactions contain mostly neutral and nicer words such as *friends*, *sweatheart* and *please*. We also note that cognitive verbs and nouns (e.g., *thinking*, *figured (out)*, *looking (into)*, *cause*), as well as important events (*birthday*, *thanksgiving*) and slang usage (e.g., *whaddya*) signal *intense* relationships.

6 Experiments and Results

We experimented with SVM classifiers with RBF kernel to predict dimensions of interactions and relationships. We divided the 24 episodes into train (episodes 1–20) and test (21–24), and trained one classifier per dimension using scikit-learn (Pedregosa et al., 2011). Each classifier is trained with three labels: `1` (1st descriptor), `-1` (2nd descriptor) and `0` (unknown). The SVM parameters (C and γ) were tuned using 10-fold cross-validation with the train split, and results are reported using the test split.

		P	R	F
Majority Baseline		0.54	0.73	0.62
SVM	first word	0.62	0.71	0.65
	BOW current	0.66	0.73	0.67
	+ sentiment	0.65	0.72	0.66
	+ other	0.71	0.75	0.70
	+ BOW previous	0.73	0.76	0.72

Table 6: Results obtained with the test set with several systems (average of all dimensions). *Previous* refers to the previous conversation in which the same pair of people interacted not the immediately previous turn).

Note that different pairs of people interact more or less in each episode (Table 2). Thus, the classifiers are grounded on general language usage and not modeling who talks and who is talked about. We also experimented with LSTMs taking as input the current conversation turn and previous turns, but do not report results because SVM classifiers yielded better results.

		`1` (1st descriptor)			`0` (unknown)			`-1` (2nd descriptor)			All		
		P	R	F	P	R	F	P	R	F	P	R	F

	Spat. Near	0.89	0.94	0.91	n/a	n/a	n/a	0.69	0.53	0.60	0.85	0.86	0.85
Relationship	Equal	0.86	0.95	0.90	0.00	0.00	0.00	0.15	0.07	0.10	0.76	0.83	0.79
	Intense	0.70	0.81	0.75	0.28	0.11	0.16	0.38	0.46	0.41	0.56	0.60	0.57
	Pleasure Or.	0.82	1.00	0.90	0.00	0.00	0.00	1.00	0.02	0.04	0.82	0.83	0.75
	Intimate	0.61	0.85	0.71	0.26	0.05	0.09	0.42	0.36	0.39	0.48	0.56	0.49
	Temporary	0.53	0.42	0.47	0.67	0.17	0.27	0.62	0.85	0.72	0.60	0.60	0.57

Table 7: Results obtained per dimension with the best system (all features, Table 6). The results under *All* the weighted averages for all labels, recall that the label distribution is biased (Figure 1).

Feature Set. We use a combination of features extracted directly from the conversation turn, sentiment lexica and context. Specifically, we extract (a) the first word in the conversation turn, (b) bag-of-words features (binary flags and tf-idf scores), and (c) the root verb, and flags indicating the presence of exclamation, question marks and negation cues from (Morante and Daelemans, 2012) (other). Regarding sentiment, we extract flags indicating whether the turn has a positive, negative or neutral word in the list by Hamilton et al. (2016), the sentiment score of the turn (summation of sentiment scores per token over number of tokens in the turn), and a flag indicating whether the turn contains a negative word from the list by Hu and Liu (2004). Regarding context, we extract bag-of-words features from the previous conversation turn in which the same people interact (not necessarily the preceding turn).

6.1 Results

Table 6 shows the overall results (average of all dimensions) obtained with the majority baseline and several feature combinations. All feature combinations outperform the baseline. Sentiment features are not beneficial, leading to the conclusion that sentiment does not correlate with dimensions of interactions and relationships between people. This may look surprising at first sight, but recall that our dimensions capture much more than if two people get along (Table 1). Finally the bag-of-words features from the previous turn in which the same people interacted bring a small improvement (F: 0.70 vs. 0.72).

We show results per dimension for the best feature combination (all) in Table 7. Despite the label distributions are biased (Figure 1), the system predicts most labels for most dimensions except the very biased ones (*cooperative*, *equal* and *pleasure oriented*). Note that `0` (unknown) does not allow us to determine the value of a dimension, and the low results with this label are not a concern.

7 Conclusions

This paper presents the task of characterizing interactions and relationships between people. We work with dialogue transcripts, and define an *interaction* as a speaker referring to somebody else, and a *relationship* as a sequence of one or more interactions. Unlike previous work (Section 2), we target all interactions and relationships, and use dimensions that are applicable to any interaction or relationship regardless of the underlying type (e.g., SIBLINGS, FRIENDS, DOCTOR-PATIENT).

We have presented an annotation effort on 24 episodes of the popular TV show Friends (Season 1). The total number of conversation turns is 9,168, and the total number of interactions is 2,331. The label distribution per dimension shows that the labels are unbalanced, but a relatively straightforward SVM is able to outperform the majority baseline (F: 0.62 vs. 0.72, Table 6). Features extracted using well-known sentiment lexica yield no improvements, leading to the conclusion that the dimensions we work with capture information beyond whether two people get along.

Crucially, values for the dimensions we work with can be determined most of the time (Figure 1, labels `1` and `-1`). Since we do not impose any restriction on the interactions or relationships we work with, we conclude that these dimensions may be universally applicable.

Why Swear? Analyzing and Inferring the Intentions of Vulgar Expressions

Abstract

Vulgar words are employed in language use for several different functions, ranging from expressing aggression to signaling group identity or the informality of the communication. This versatility of usage of a restricted set of words is challenging for downstream applications and has yet to be studied quantitatively or using natural language processing techniques. We introduce a novel data set of 7,800 tweets from users with known demographic traits where all instances of vulgar words are annotated with one of the six categories of vulgar word use. Using this data set, we present the first analysis of the pragmatic aspects of vulgarity and how they relate to social factors. We build a model able to predict the category of a vulgar word based on the immediate context it appears in with 67.4 macro F1 across six classes. Finally, we demonstrate the utility of modeling the type of vulgar word use in context by using this information to achieve state-of-the-art performance in hate speech detection on a benchmark data set.

1 Introduction

Vulgarity is a common element of conversation (Jay, 2009; Mehl et al., 2007) and is used even more frequently in social networks such as Twitter (Wang et al., 2014). Understanding the motivation behind the choice to be vulgar and the way in which vulgarity is manifested in naturally occurring environments is of interdisciplinary interest. Pragmatic functions that dictate patterns of vulgarity usages may interact with speaker cultural background and demographics. This makes them appealing—and challenging—to model in NLP applications

Yet, to date, there has been no empirical study on the type of vulgar word usage. Research in linguistics and psychology has identified several types of usage for vulgar words (Andersson and Trudgill, 1990; Pinker, 2007; Wang, 2013). These range from use as an intensifier for an opinion or emotion, to offend others, or simply as a way of speaking or to signal the level of (in)formality in a conversation (Pinker, 2007). Table 1 shows example tweets with the six general functions of vulgar word usage.

Function	**Tweet**
Express aggression	<USER> You are an **ass** Your industry is full of assholes and you do nothing to improve (...)
Express emotion	There are so many things I want to do, But investing in equipment is a pain in the **ass**
Emphasise	today is a good **ass** day <URL>
Auxiliary	Wish <USER> could save my **ass** on these exams like he used to
Signal Group Identity	Now this is a group of **ass** kickers!
Non-vulgar	Kick **Ass** 2 - Red Band Trailer <URL>

Table 1: Examples of tweets containing the vulgar word **ass** with six different functions.

We notice that in one of the examples, the vulgar word *ass* is used to verbally abuse another user, while the same word can also be employed to emphasize a feeling ('good *ass* day') or to express an emotion ('pain in the *ass*'). Hence, explicitly modeling vulgar words use is expected to positively impact the performance of practical tasks such as hate speech detection or the way in which profanity filtering is performed.

The goal of our study is to present a comprehensive and multi-faceted analysis of the types of vulgar word usage. To this end, this paper presents:

1. The first data set of written utterances that contain vulgar words, where each vulgar word is labeled for one of six functions of use[1]
2. A quantitative analysis of vulgar word usage across different user demographic traits
3. A machine learning approach to predicting one of six types of vulgar word usage from context
4. Experiments demonstrating that modeling the type of vulgar word usage in context can im-

prove predictive performance of the hate speech prediction task on a benchmark data set

Our novel data set contains 7,800 tweets with 8,524 vulgar word labels annotated for one of six functions by seven annotators. We find that the way in which vulgarity is used interacts with user demographic variables such as age or political ideology. We then build a model for predicting the usage type of each vulgar word in the tweet using the tweet context. Finally, we explicitly model the vulgar word usage type in the task of hate speech detection to discriminate between hate speech and tweets including profanity, demonstrating an improvement in predictive accuracy of 3.7 F1. This demonstrates that using insights into vulgar word usage developed in linguistics and psychology, we can achieve quantitative improvements on downstream NLP applications and inform the way models are built and tailored to the task.

2 Related Work

Vulgar language and its uses and pragmatic functions have been studied in several linguistic and psychological studies and the phenomenon has many names. In this paper, we will use *vulgarity*, *profanity*, and *swear/curse words* interchangeably.

Vulgar words were found to be very versatile, with a vulgar word being able to perform different interpersonal functions according to different contexts. Four types of usage are identified in Andersson and Trudgill (1990), including abusive (intended to harm the hearer), expletive (used to express emotions; not directed towards others), humorous (looks like abusive swearing, but has the opposite function) and auxiliary (swearing as a way of speaking, often or always non-emphatic). The five functions of swear words suggested in Pinker (2007) are: dysphemistic (conveying negative sentiment), idiomatic (signaling informality or simply used as a manner of speaking), abusive (intending to offend or harm), emphatic (intending to stress a claim or intensify emotive content) and cathartic (communicating pain). Finally, Wang (2013) identifies four pragmatic roles for profanity with a considerable degree of overlap with Pinker: emoting, emphasizing, aggressing, and group identity signaling.

For the scope of this study, we aim to cover all the functions identified by past research that can be identified from text with restricted content and context such as tweets. Thus, we dropped the cathartic function from Pinker (2007), which is an instantaneous reaction more specific to speech to relieve the effect of physical pain (Stephens et al., 2009). This would thus be very rarely – if ever – expressed through social media and would be very hard to annotate with textual content alone while lacking the broader context of its utterance. We also considered the abuse and aggression functions as equivalent across categorizations, as they imply a face-threatening act (Brown and Levinson, 1987). We considered the auxiliary and idiomatic categories as equivalent across classes, but maintained signaling group identity as in Wang (2013). We also created a non-vulgar classification in case the vulgar word is used in a non-vulgar context (e.g., a name that doubles as a vulgar term).

Due to their affective impact, vulgar words are often used as *strange* synonyms by substituting each other in context or idioms, even when they have no affinity in syntax or meaning (Quang, 1971; Pinker, 2007) (e.g., for God's sake – for fuck's sake; 'I don't give a damn/fuck/shit). This heavily contributes to vulgar word volatility across different functions and higher ambiguity in context. However, this type of usage can allow computational approaches that model the immediate context around a word to generalize across words to functions. To date, there has been no research on quantitatively modeling the **function** of vulgar words in context.

The overall frequency of usage of vulgar words has been quantitatively studied in social media and online communities. For example, Wang et al. (2014) estimates that vulgar posts constitute upwards of 1.15% of tweets and examines vulgar token frequency and how it varies with time, geolocation, and gender. An analysis of profanity across gender and age also appears in Gauthier et al. (2015).

In fact, gender is the most studied sociodemographic factor in relation to the use of profanity. Many studies have shown that male-identifying users employ vulgar terms more frequently than female-identifying users (e.g. Selnow, 1985; Wang et al., 2014).

Jay and Janschewitz (2008) demonstrate that profanity is moderated by pragmatic or contextual factors that go beyond gender, including occupation, social status, and even the nature of the relationship between interlocutors – though this last point, proves difficult to explore via Twitter where the identity of the audience is at least partially obfuscated. Other social factors such as age, religiosity or social status have also been shown to vary with vulgar frequency (McEnery, 2004), as has political ideology (Sylwester and Purver, 2015; Preoţiuc-Pietro et al., 2017). It is thus likely that sociodemographic factors also influence the functions with which vulgar words are used.

This study expands the scope of this type of research, by going beyond simple frequency of usage to pragmatic functions of vulgar words and how they are used differently by different sociodemographic groups.

3 Data

We use social media as our data source as this contains a high level of expression of thoughts, opinions and emotions (Java et al., 2007; Kouloumpis et al., 2011) and represents a platform for observing written interactions and conversations between users (Ritter et al., 2010).

Social media and Twitter in particular provide vast volumes of text which are more informal and less curated compared to other domains such as newswire. An additional advantage of Twitter data is that it allows us to study the sociodemographic context.

3.1 Identifying Vulgar Tweets

We use the corpus of tweets utilized to construct the Vulgar Twitter corpus introduced in prior work (Cachola et al., 2018). Every tweet in this corpus contains at least one vulgar term. We then annotate each instance of a vulgar token for type of use. Note that we use the full dataset of 7,800 tweets which contains 1K more tweets[2] than the released version of the Vulgar Twitter corpus.

The Vulgar Twitter corpus was constructed by identifying tweets containing vulgarity through use of the vulgarity lexicon available at `www.noswearing.com`. A total of 82 tokens were removed from this list as they were deemed not to be unambiguously vulgar after manual inspection.[3] Regular expressions were utilized to identify common intentional spelling variations (e.g., vowel reduplication such as *fuuuuuck* or self-censorship such as *a$$*).

For the complete description of the composition and construction of the Vulgar Twitter corpus, we refer the interested reader to the original paper (Cachola et al., 2018).

3.2 Data Sampling

The Vulgar Twitter corpus overlaps with Preoţiuc-Pietro et al. (2017) which allows us to consider the relationship between sociodemographic features and vulgar functionality. The tweets are compiled from up to 3,200 most recent tweets (per Twitter Developer API) of 4,132 twitter users who provided sociodemographic information via self-report in an online survey (Preoţiuc-Pietro et al., 2017). This sociodemographic data has been utilized in our previous research Cachola et al. (2018); for a full description of its collection, we refer the reader to Preoţiuc-Pietro et al. (2017).

3.3 Demographic Variables and Coding

Demographic information (including gender, age, level of education, level of annual income, faith, an political ideology) was was self-reported via online survey. To control for cultural variation, data was only solicited from residents of the United States. All demographic variables are ordinal with the exception of gender, which is binary.

- **Gender:** a binary[4] variable (Female as 1; Male as 0).
- **Age:** an ordinal, integer-valued variable [13-90].
- **Income:** An ordinal variable [1-8]; the lowest level (1) stands for '< $20,000' and the highest (8) stands for '> $200,000'.
- **Education:** An ordinal variable [1-6]; the lowest level (1) stands for 'no high school degree' and the highest (6) stands for 'Advanced Degree (e.g., Ph.D.)'.
- **Political ideology:** an ordinal variable on the liberal-conservative spectrum (a common form of representation of US political ideology (Ellis and Stimson, 2012)). Reporting options ranged from 'Very Conservative'

---

[2] These tweets are excluded due to low sentiment agreement in Cachola et al. (2018).

[3] These terms were largely anatomical words or general verbs like *penis*, *vagina*, and *blow*, but some identity descriptors like *gay*, *queer*, and *lesbian* were also excluded after manual review of a large sampling of uses revealed they were not overwhelmingly employed as slurs.

[4] Users were asked to identify their gender as Male, Female, or via an open field. Users who did not respond as either Female or Male were excluded from data collection as there was not a sufficient population to be confident that data would be representative.

Function	**Definition**	**Freq.**
Express aggression (**Agr**)	The word is used in order to harm the person or group the tweet is about.	15.2%
Express emotion (**Emo**)	The word is used to express emotions (positive or negative) related to the users internal states, exclamations, feelings or attitudes towards an object. If removing the vulgar term, the expressed emotion is lacking.	24.8%
Emphasise (**Emp**)	The word is used to emphasize a statement or feeling.	29.8%
Auxiliary (**Aux**)	The use of this word is simply a manner of speaking and does not fit any of the above descriptions. Descriptions of external emotions (those of someone else) fall into this category.	17.0%
Signal Group Identity (**Sig**)	This word is used as a marker of identity in a specific social group.	4.7%
Non-vulgar Use (**Non**)	The use of this word is not vulgar (e.g., named entities that involve vulgar words).	8.2%

Table 2: Functions of vulgar words, their definition presented to the annotators and their frequency in the final data set.

	Agr	**Emo**	**Emp**	**Aux**	**Sig**	**Non**
Agr	0.63	0.11	0.09	0.07	0.10	0.01
Emo	0.07	0.59	0.20	0.13	0.01	0.01
Emp	0.04	0.18	0.68	0.07	0.01	0.02
Aux	0.07	0.16	0.15	0.56	0.03	0.03
Sig	0.17	0.06	0.07	0.11	0.57	0.02
Non	0.02	0.04	0.04	0.10	0.02	0.77

Table 3: Confusion matrix between aggregated function (row) and individual annotations (column), normalized by row.

(1) to ‘Moderate’ (4) to ’Very Liberal’ (7). Two additional responses, ‘Other’ (8) and ‘Apathetic’(9) were included to cover the full breadth of the ideological spectrum, but users selecting these options were excluded from our dataset (1,290 in total) in order to maintain an ordinal scale.

- **Faith:** an ordinal variable [1-6]; users were asked to report the average number of religious services attended. Available responses ranged from ‘Never’ (1) to ‘Multiple times per week’ (6).

3.4 Data Processing

We follow the same preprocessing procedure as in Cachola et al. (2018). URL’s and usernames are replaced by <URL> and <USER> tokens respectively to protect user privacy. Punctuation is then removed and all words are lowercased.

3.5 Annotation

We have collected annotations via Amazon Mechanical Turk (MTurk) for vulgar word usage type for 8,524 instances of vulgar words across the 7,800 tweets present in the Vulgar Twitter corpus (Cachola et al., 2018).

The task guidelines follow previous research from linguistics and psychology described in Section 2. For generality, we use a union of the different classes proposed and grouped classes where it was possible. The final guidelines include six different functions of vulgar words described in Table 2.

For quality control, we asserted the following qualifications on MTurk: locale=US, approval rate >90%, number of HITs approved >100. Further, we removed all ratings from users that have a Cohen’s Kappa of lower than 0.2 when compared to the majority rating of the other six annotations resulting in the removal of 8,430 ratings (14% of the total number) from 150 out of 663 users. These users were banned and annotations were recollected until 7 ratings were obtained for all instances.

We measured inter-annotator agreement using Krippendorf’s Alpha as this can handle cases where each item was labeled by different groups of users. The overall Krippendorfs Alpha is 0.506 despite there being a large number of classes (6). This alpha value (0.506) is regarded as a moderate level of agreement (Artstein and Poesio, 2008). To reduce uncertainty, we aggregate our labels across seven different annotators. In cases where no majority class emerged from the seven annotations (10.6% of the instances), the tie was broken by one of the authors of the paper, who have significant training and experience in linguistic annotation.

The distribution of the final vulgar word type is presented in the last column from Table 2. Table 3 shows the confusion matrix between aggregated function (row) and individual annotations (column); each cell is normalized by the row sum. Some patterns in disagreements include: (1) Vulgar words used to signal group identity are sometimes confused with aggression as annotating these may require additional social context about the user (e.g. if they are female, African-American, etc.) or about social relationships (e.g. *“lmao yeah cause a bitch can’t sing”*). (2) Emotion confused with auxiliary usage in idioms or where there is a lack on context about what is

Word	Rank	Entropy	Agr	Emo	Emp	Aux	Sig	Non
bitchy	35	1.547	3	5	2	3	2	0
dicks	33	1.442	7	2	0	6	2	2
bastard	26	1.307	18	3	1	7	1	3
fuck	4	1.272	246	345	190	75	0	0
pussy	21	1.256	17	3	2	33	1	7
ass	5	1.250	116	45	222	352	7	5
hell	2	1.220	16	242	602	71	0	238
dick	9	1.208	36	4	5	87	0	67
bitch	7	1.194	296	23	20	60	110	3
shit	1	1.170	59	555	200	488	1	1

Table 4: Top vulgar words sorted by entropy. Higher entropy indicates a more evenly distributed usage is across functions (maximum entropy over six values = 1.791, minimum entropy over all functions = 0). Rank represents the rank of the word by frequency in the data set.

the author's intent or target (e.g. *"Stop cryin.. Damn you got the foul"*). (3) Auxiliary use of vulgar words in an emotional tweet (e.g, *"ok knicks. we're winning. dont fuck it up."*). (4) Short tweets lacking context drive confusion about the target of vulgarity or if an emotion is expressed (e.g. *"Fuck yeah"*).

4 Analysis

We start with a quantitative analysis of our data. First, we examine the extent to which the same vulgar word is used for different functions. Then, we identify if sociodemographic factors impact the functions with which vulgar words are used.

4.1 Vulgar Word Analysis

To quantitatively measure which vulgar words are most used with different functions, we first compute its distribution over the six functions in our entire data set. Then, we compute the entropy as a measure of how evenly distributed the distribution over functions of each word is. To avoid uncertainly associated computing statistics over distributions with low counts, we keep only words that appear more than 10 times in our data set (43 words) after collapsing variants of the same word (e.g. fuck – f*ck – fuuuck).

The average entropy of all vulgar words is $\mu = 0.835$ ($\sigma = 0.36$), with 0 being the minimum entropy (i.e., all words are used with one function) and 1.791 being the maximum entropy (i.e., all words are used with the same frequency with all six functions). The words with the highest entropy are presented in Table 4.

The table shows that four of the most frequent five words are in the top ten words by entropy, with all of them having significant numbers of occurrences in at least three vulgar functions. Actually, the average entropy of words used at least 100 times in our data set (15 words) is 0.930 compared to 0.835 for words used at least 10 times.

We see that all words in the table are used significantly with three or more functions. On average, in the entire data set, each word is used at least once with $\mu = 4.00$ functions ($\sigma = 1.34$).

This highlights both the challenges in modeling vulgar word functions and the opportunity of using the function to improve practical applications.

In contrast, Table 5 shows the vulgar words which are most likely to be used with each of the six functions.

4.2 Demographic Analysis

Sociodemographic factors may impact the distribution with which each function of vulgar words is used. To measure this, we compute for each user a normalized distribution over the functions of vulgar words used in our data set. Then, we compute Pearson correlation where the dependent variable is the fraction of each vulgar word function and the independent variables are the user sociodemographic trait values. Following previous work (Schwartz and et al., 2013; Preoţiuc-Pietro et al., 2017), for all analyses we consider gender and age basic traits and control for potential data skew by introducing both variables as controls in partial correlation. When studying age and gender, we use the other trait as the control. Since we are running 36 tests at once without pre-stated hypotheses, we correct the correlations for multiple comparisons using Bonferroni correction. Results of these analyses are presented in Table 6.

The results show several vulgar word functions are specific of age. Younger users of Twitter are more likely to use vulgar words to signal group identity and to express emotion. Older age is more likely to be related to use of words that are vulgar with non-vulgar functions. These correlations show that there are differences in how younger generations are using vulgar words, even if tweets were posted in the same time interval, signaling a diachronic change in usage.

The analysis shows that the only significant correlation with the other five demographic variables is between both political ideology and faith and using vulgar words for emphasis and in non-vulgar functions. Liberals are more likely to use vulgar words for emphasis and less likely to use them with non-vulgar functions. Previous research

Aggression		Express Emotion		Emphasis		Auxiliary		Signal Group Identity		Non-Vulgar	
Word	**Freq**	**Word**	**Freq**	**Word**	**Freq**	**Word**	**Freq**	**Word**	**Freq**	**Word**	**Freq**
cunt	86.9%	pissed	84.4%	fucking	84.7%	asses	73.9%	bitches	88.9%	mick	100%
asshole	86.3%	bullshit	64.2%	fuckin	84.0%	shitting	69.2%	nigga	85.7%	cracker	97.5%
asshit	83.0%	fucked	61.3%	goddamn	70.0%	arse	69.2%	slut	26.0%	dyke	92.8%
faggot	81.8%	shitty	52.6%	damn	62.3%	cock	62.9%	whore	25.0%	coon	92.8%
fag	73.3%	shit	42.5%	hell	51.4%	pussy	52.3%	hoe	23.8%	ho	88.3%

Table 5: Vulgar words most used with each of the six functions.

Trait	Agr	Emo	Emp	Aux	Sig	Non
Gender	.011	-.005	.004	-.044	.051	.011
Age	-.013	-.085*	-.046	-.036	-.100**	.227**
Education	-.030	.009	-.006	-.007	-.032	.027
Income	.037	.002	.027	-.035	-.045	.032
Faith	-.031	-.047	-.112**	-.066	.014	.224**
Political Ideology	.009	.050	.092**	-.022	.003	-.124**

Table 6: Pearson correlation between user demographic traits and usage of the different functions of vulgar words. All correlations are significant at (*) $p < .05$, (**) $p < .01$, two-tailed t-test, **Bonferroni corrected** for multiple comparisons. Results for education, income and religiosity are controlled for age and gender.

showed that liberals are more likely to use more vulgarity overall in social media (Sylwester and Purver, 2015; Preoţiuc-Pietro et al., 2017) and are perceived by others to use more frequently than they do vulgar words (Carpenter et al., 2016), but this analysis shows this is especially due to vulgar word use to emphasise. The results are reversed for faith, which is known to be strongly correlated to conservative political ideology. Controlling for faith and political ideology with partial correlation does not alter the significance of this result.

Intriguingly, all other traits (gender, education and income) are not significantly correlated with an increased usage in any of the functions.

The vulgar word functions of aggression and auxiliary usage, which are more standard and traditional usages of vulgar words, do not show any significant differences with any sociodemographic trait.

5 Modeling Vulgar Word Use

The previous section showed that the same vulgar words can be used with several different functions. In this section, we use machine learning approaches to explicitly predict the function of a vulgar word given the tweet it appears in as context.

5.1 Method

We use logistic regression[5] to build six one vs. all binary classifiers for each of the six functions using information from the immediate lexical and syntactic context surrounding the word and general usage of the word in training data.

5.2 Features

We use the following feature types in our experiments:

Intention Distribution –We include six features encoding the distribution over intentional classes of the target word in training data, as some words use only several functions and some more predominantly than others.

Tweet Content –We derive a tweet-level representation of the entire content of the tweet by averaging vector representations of its constituent words. We utilize 200-dimensional GloVe embeddings pre-trained on 2B tweets (Pennington et al., 2014).

Sentiment Content –We include two features which represent the number of positive and negative valence words in the tweet, normalized by tweet length. For this feature group, we utilize the opinion lexicon introduced in Hu and Liu (2004).

Part of Speech Context –We encode the part of speech of the target word, the previous word and the next word as one-hot vectors as we expect syntactic information to be an indicator of different functions in context. We extract parts of speech using the Twitter version of the Stanford POS tagger which demonstrated good results on tagging tweets and uses the finer grained Penn Treebank tagset (Derczynski et al., 2013).

Brown Clusters –Finally, we include two one-hot feature groups which indicate the Brown Cluster (Brown et al., 1992) membership of word immediately before and immediately after the vulgar term.

---

[5] In preliminary experiments, we attempted to utilize a BiLSTM to encode tweet context, but it did significantly worse than the logistic regression model, possibly due to many parameters and classes compared to the size of the training data.

Method	Precision	Recall	F1
Most Frequent Class	5.05	16.6	7.76
All Features	**68.8**	**66.4**	**67.4**
– Intention Distribution	58.3	53.8	55.3
– Tweet Content	67.9	64.0	65.6
– Sentiment Content	68.6	66.3	67.3
– Part of Speech Context	67.8	64.6	65.9
– Brown Clusters	68.6	64.9	66.3

Table 7: Performance statistics for our baseline, predictive model with all features and with ablating each feature group. Precision, Recall and F1 score are macro-averaged across the six classes.

Brown Clusters are obtained by hierarchical clustering tokens based on contexts in which they immediately co-occur. We use the precomputed cluster representations as seen in Turian et al. (2010). We also experimented with Twitter-specific clusters (Owoputi et al., 2012), but found they did not perform as well on our development set.

Additionally, we experimented with a personal pronoun indicator feature in a three word window around the target, a one-hot lexical feature encoding the target vulgar item, and NRC emotion scores (Mohammad and Turney, 2013), but found there to be no improvement in performance as a result. We did not experiment with using the demographic variables as features as these are generally unavailable for use in predictive systems.

5.3 Experimental Results

We split our data into a training set of 6,883 tweets and a testing set of 1,087 tweets, and held out a set of 554 tweets as a validation set on which to test different hyperparameter settings.

Performance statistics for our predictive model are presented in Table 7, as well as ablation experiments for each feature group.

Our predictive model vastly outperforms the most frequent baseline, which uniformly selects the most frequent class overall (emphasis) and scores very low due to the very even distribution over functions. Our best model achieves a macro-averaged F1 score of 67.4 across the six classes.

In the ablation experiments, we see by removing one feature group at a time, which feature type adds most predictive value over others. Withholding the intention distribution feature group from the model shows the greatest loss in performance (12.1 macro F1). This is somewhat expected, as this feature gives a prior distribution over functions for the target word based on training data and, as most words are rarely used with some functions, allows the model to downweigh them. However, even with no word function prior, the predictive performance is still relatively high (55.3 macro F1 across six classes), showing that only the content and context is substantially predictive for the function of a vulgar word

Removing tweet content features or part-of-speech context introduce a similar drop in predictive performance, showing that the overall tweet content and the local syntactic context of the mention play complimentary roles in inference. The sentiment feature groups are the least informative, yielding an negligible increase in performance of only 0.1 macro F1.

The predictive model's F1 scores by class is as follows: *Aggression* – 65.6, *Emotion* – 62.4, *Emphasis* – 76.4, *Signal Group Identity* – 56.5, *Auxiliary* – 62.2, *Not Vulgar* – 81.4.

The highest predictive performance is obtained for vulgar words used in a non vulgar context, which is due to the different tweet content of these tweets and the restricted sets of words which are usually used as non-vulgar. The emphasis functions is the second most accurately predictable using our model, due to the very distinctive syntactic patterns of usage of this function (usually as an adjective). The least predictable function is signaling group identity. We observed that this function is usually used as part of larger conversational context and often relies on a shared social context.

6 Hate Speech Prediction

Finally, we aim to show that modeling the function of vulgar words explicitly has practical implications by using this in a downstream application.

6.1 Task

Automatic hate-speech detection on social media is the task defined as generally identifying abusive speech targeting specific group characteristics, such as ethnic origin, religion, gender, or sexual orientation (Warner and Hirschberg, 2012) with a clear intention to incite harm, or to promote hatred (Zhang and Luo, 2018). Several data sets and approaches to automatic hate speech detection have been recently proposed (Djuric et al., 2015; Burnap and Williams, 2015; Waseem and Hovy, 2016; Nobata et al., 2016; Davidson et al., 2017).

The task of predicting hate-speech is challenging for natural language processing using lexical information as it aims to predict the intention of the message and several words used in conveying hate speech can have other common uses (Davidson et al., 2017; Malmasi and Zampieri, 2018).

Hate speech is very often confused with offensive language, as highlighted in the error analyses of past hate speech detection papers (Davidson et al., 2017). Quantitative analysis of the machine learning models suggest that obscene words are very informative for both the hate speech and offensive classes of tweets (Malmasi and Zampieri, 2018), hinting that the functions of vulgar words usage are a major source of ambiguity.

Our hypothesis is that explicitly modeling the function a vulgar word has in context will benefit the hate speech prediction task, by differentiating between aggression and other usages.

6.2 Experiments

Data. We use the dataset introduced in Davidson et al. (2017) as this is publicly available, contains tweets collected using vulgar words and explicitly differentiates between offensive tweets and tweets containing hate speech. The three classes in this data set are hate speech, offensive, and neither.

Another public dataset on tweets, introduced in Waseem and Hovy (2016), focuses on specific forms of hate speech (sexist and racist), but is collected with a restricted set of keywords, has low coverage of vulgar words and does not explicitly distinguish between hate speech and other offensive language. Other datasets for this task are not publicly available e.g., Nobata et al. (2016).

Setup. In order to directly measure the impact on predicting performance introduced by explicitly modeling the function of the vulgar word in the tweet, we follow the same methodology to identify hate speech as described in Davidson et al. (2017), as implemented through the openly available code provided by the authors.[6] We thus train three one-vs-all logistic regression classifiers with L2 regularization as implemented in scikit-learn (Pedregosa et al., 2011). Features used in the model include unigram to trigram TF-IDF weighted word features, Part-of-Speech unigram to trigrams, reading level, sentiment words, Twitter specific features (e.g., hashtags, mentions, retweets, and URLs) as well as generic tweet-level features (e.g., number of characters, words, and syllables in each tweet).

	Method	
Class	Davidson et al.	+ vulgar features
Hate Speech	33.6	**39.7**
Offensive	92.1	**93.5**
Neither	82.2	**85.7**
Average	69.3	**73.0**

Table 8: F1 score per class and the macro average.

Vulgar Function Features. We directly and explicitly include the function of the vulgar word present in the tweet by introducing six new features to the hate speech detection model which represent the scores with which the vulgar word is associated with the six functions. If multiple vulgar words exist in a tweet, we use the average predictions over the six functions.

Metrics. We run the model from Davidson et al. (2017) using the provided code on 10-fold cross validation and report the average F1 score for each class as well as the macro-averaged F1 score across all ten folds. Using the available code, we could not reproduce exactly results presented in the Davidson et al. (2017) paper. For predicting the function of the vulgar words from context, we use our best predictive model described in Section 5. We also re-scale our six function features by multiplying them with a large exponent in order to make them significant in model training.

Results. As presented in Table 8, the addition of the six vulgar function features improves the F1 score for each of three classes to up to 6.1 F1 for the hate speech class, which had the lowest performance. This results in an improvement of the macro-F1 score for the entire classification task of 3.7 in F1. This demonstrates the importance of the proposed vulgar function modeling task in detecting hate speech.

7 Conclusion

This paper presents the first empirical study on the pragmatic functions of vulgar words. We created a novel, freely available data set of 7,800 vulgar tweets having 8,524 instances of vulgar words labeled for one of six functions by seven annotators and expert adjudication. We quantitatively showed, leveraging research in linguistics and psychology, that vulgar words are frequently used with different functions and, in the first quantitative analysis on this topic, uncovered that vulgar words are used with different functions by younger users to signal group identity and for expressing emotions.

We have built the first machine learning model

---

[6] `https://github.com/t-davidson/hate-speech-and-offensive-language`

for predicting vulgar word function from context, achieving a performance of 67.4 macro F1, demonstrating the practical feasibility of this task. We showed the usefulness of this task, by integrating predicted vulgar word function in the downstream task of hate speech detection, achieving an improvement of 3.7 in F1 on a benchmark data set.

This study showed that modeling pragmatic function is of practical importance. Future work will use this linguistic information to inform more complex machine learning models, e.g., deep neural networks, in an attempt to increase predictive gains. As two of the most used functions of vulgar words relate to expressing sentiment or emotions, we will also explore collecting sentiment annotations for joint sentiment and vulgar word function inference and use this to improve the task of sentiment analysis using multi-task methods.

Is it Time to Swish?
Comparing Deep Learning Activation Functions Across NLP tasks

Steffen Eger, Paul Youssef, Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)

Abstract

Activation functions play a crucial role in neural networks because they are the nonlinearities which have been attributed to the success story of deep learning. One of the currently most popular activation functions is ReLU, but several competitors have recently been proposed or 'discovered', including LReLU functions and swish. While most works compare newly proposed activation functions on few tasks (usually from image classification) and against few competitors (usually ReLU), we perform the first large-scale comparison of 21 activation functions across eight different NLP tasks. We find that a largely unknown activation function performs most stably across all tasks, the so-called penalized tanh function. We also show that it can successfully replace the sigmoid and tanh gates in LSTM cells, leading to a 2 percentage point (pp) improvement over the standard choices on a challenging NLP task.

1 Introduction

Activation functions are a crucial component of neural networks because they turn an otherwise linear classifier into a non-linear one, which has proven key to the high performances witnessed across a wide range of tasks in recent years. While different activation functions such as sigmoid or tanh are often equivalent on a theoretical level, in the sense that they can all approximate arbitrary continuous functions (Hornik, 1991), different activation functions often show very diverse behavior in practice.

For example, sigmoid, one of the activation functions dominating in neural network practice for several decades eventually turned out less suitable for learning because (according to accepted wisdom) of its small derivative which may lead to vanishing gradients. In this respect, the so-called ReLU function (Glorot et al., 2011) has proven much more suitable. It has an identity derivative in the positive region and is thus claimed to be less susceptible to vanishing gradients. It has therefore (arguably) become the most popular activation function. The recognition of ReLU's success has led to various extensions proposed (Maas et al., 2013; He et al., 2015; Klambauer et al., 2017), but none has reached the same popularity, most likely because of ReLU's simplicity and because the gains reported tended to be inconsistent or marginal across datasets and models (Ramachandran et al., 2017).

Activation functions have been characterized by a variety of properties deemed important for successful learning, such as ones relating to their derivatives, monotonicity, and whether their range is finite or not. However, in recent work, Ramachandran et al. (2017) employed automatic search to find high-performing novel activation functions, where their search space contained compositions of elementary unary and binary functions such as $\max$, $\min$, $\sin$, $\tanh$, or $\exp$. They found many functions violating properties deemed as useful, such as non-monotonic activation functions or functions violating the gradient-preserving property of ReLU. Indeed, their most successful function, which they call swish, violates both of these conditions. However, as with previous works, they also only evaluated their newly discovered as well as their (rectifier) baseline activation functions on few different datasets, usually taken from the image classification community such as CIFAR (Krizhevsky, 2009) and ImageNet (Russakovsky et al., 2015), and using few types of different networks, such as the deep convolutional networks abounding in the image classification community (Szegedy et al., 2016).

To our best knowledge, there exists no large-scale empirical comparison of different activations

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4415–4424
Brussels, Belgium, October 31 - November 4, 2018.

across a variety of tasks and network architectures, and even less so within natural language processing (NLP).[1] Thus, the question which activation function really performs best and most stably across different NLP tasks and popular NLP models remains unanswered to this date.

In this work, we fill this gap. We compare (i) 21 different activation functions, including the 6 top performers found from automatic search in Ramachandran et al. (2017), across (ii) three popular NLP task types (sentence classification, document classification, sequence tagging) comprising 8 individual tasks, (iii) using three different popular NLP architectures, namely, MLPs, CNNs, and RNNs. We also (iv) compare all functions across two different dimensions, namely: top vs. average performance.

We find that a largely unknown activation function, penalized tanh (Xu et al., 2016), performs most stably across our different tasks. We also find that it can successfully replace tanh and sigmoid activations in LSTM cells. We further find that the majority of top performing functions found in Ramachandran et al. (2017) do not perform well for our tasks. An exception is swish, which performed well across several tasks, but less stably than penalized tanh and other functions.[2]

2 Theory

Activation functions We consider 21 activation functions, 6 of which are "novel" and proposed in Ramachandran et al. (2017). The functional form of these 6 is given in Table 1, together with the sigmoid function.

The remaining 14 are: tanh, sin, relu, lrelu-0.01, lrelu-0.30, maxout-2, maxout-3, maxout-4, prelu, linear, elu, cube, penalized tanh, selu. We briefly describe them: lrelu-0.01 and lrelu-0.30 are the so-called leaky relu (LReLU) functions (Maas et al., 2013); the idea behind them is to avoid zero activations/derivatives in the negative region of relu. Their functional form is given in Table 1. prelu (He et al., 2015) generalizes the LReLU functions by allowing the slope in the negative region to be a learnable parameter. The maxout functions (Goodfellow et al., 2013) are different in that they introduce additional parameters and do not operate on a single scalar input. For example, maxout-2 is the operation that takes the maximum of two inputs: $\max\{\mathbf{xW}+\mathbf{b},\mathbf{xV}+\mathbf{c}\}$, so the number of learnable parameters is doubled. maxout-3 is the analogous function that takes the maximum of three inputs. As shown in Goodfellow et al. (2013), maxout can approximate any convex function. sin is the standard sine function, proposed in neural network learning, e.g., in Parascandolo et al. (2016), where it was shown to enable faster learning on certain tasks than more established functions. penalized tanh (Xu et al., 2016) has been defined in analogy to the LReLU functions, which can be thought of as "penalizing" the identity function in the negative region. The reported good performance of penalized tanh on CIFAR-100 (Krizhevsky, 2009) lets the authors speculate that the slope of activation functions near the origin may be crucial for learning. linear is the identity function, $f(x) = x$. cube is the function $f(x) = x^3$, proposed in Chen and Manning (2014) for an MLP used in dependency parsing. elu (Clevert et al., 2015) has been proposed as (yet another) variant of relu that assumes negative values, making the mean activations more zero-centered. selu is a scaled variant of elu used in Klambauer et al. (2017) in the context of so-called self-normalizing neural nets.

sigmoid	$f(x) = \sigma(x) = 1/(1+\exp(-x))$
swish	$f(x) = x \cdot \sigma(x)$
maxsig	$f(x) = \max\{x, \sigma(x)\}$
cosid	$f(x) = \cos(x) - x$
minsin	$f(x) = \min\{x, \sin(x)\}$
arctid	$f(x) = \arctan(x)^2 - x$
maxtanh	$f(x) = \max\{x, \tanh(x)\}$
lrelu-0.01	$f(x) = \max\{x, 0.01x\}$
lrelu-0.30	$f(x) = \max\{x, 0.3x\}$
penalized tanh	$f(x) = \begin{cases} \tanh(x) & x > 0, \\ 0.25\tanh(x) & x \leq 0 \end{cases}$

Table 1: Top: sigmoid activation function as well as 6 top performing activation functions from Ramachandran et al. (2017). Bottom: the LReLU functions with different parametrizations as well as penalized tanh.

Properties of activation functions Many properties of activation functions have been speculated to be crucial for successful learning. Some of these are listed in Table 2, together with brief de-

---

[1] An exception may be considered Xu et al. (2015), who, however, only contrast the rectifier functions on image classification datasets.

[2] Accompanying code to reproduce our experiments is available from `https://github.com/UKPLab/emnlp2018-activation-functions`.

Property	Description	Problems	Examples
derivative	f'	>1 exploding gradient (e) <1 vanishing (v)	sigmoid (v), tanh (v), cube (e)
zero-centered	range centered around zero?	if not, slower learning	tanh (+), relu (−)
saturating	finite limits	vanishing gradient in the limit	tanh, penalized tanh, sigmoid
monotonicity	$x > y \implies f(x) \geq f(y)$	unclear	exceptions: sin, swish, minsin

3 Experiments

We conduct experiments using three neural network types and three types of NLP tasks, described in §3.1, §3.2, and §3.3 below.

3.1 MLP & Sentence Classification

Model We experiment with a multi-layer perceptron (MLP) applied to sentence-level classification tasks. That is, input to the MLP is a sentence or short text, represented as a fixed-size vector embedding. The output of the MLP is a label which classifies the sentence or short text. We use two sentence representation techniques, namely, Sent2Vec (Pagliardini et al., 2018), of dimensionality 600, and InferSent (Conneau et al., 2017), of dimensionality 4096. Our MLP has the form:

$$\mathbf{x}_i = f(\mathbf{x}_{i-1} \cdot \mathbf{W}_i + \mathbf{b}_i)$$
$$\mathbf{y} = \text{softmax}(\mathbf{x}_N \mathbf{W}_{N+1} + \mathbf{b}_{N+1})$$

where $\mathbf{x}_0$ is the input representation, $\mathbf{x}_1, \ldots, \mathbf{x}_N$ are hidden layer representations, and $\mathbf{y}$ is the output, a probability distribution over the classes in the classification task. Vectors $\mathbf{b}$ and matrices $\mathbf{W}$ are the learnable parameters of our network. The activation function is given by f and ranges over the choices described in §2.

Data We use four sentence classification tasks, namely: movie review classification (MR), subjectivitiy classification (SUBJ), question type classification (TREC), and classifying whether a sentence contains an argumentation structure of a certain type (claim, premise, major claim) or else is non-argumentative (AM). The first three datasets are standard sentence classification datasets and contained in the SentEval framework.[3] We choose the AM dataset for task diversity, and derive it by projecting token-level annotations in the dataset from Stab and Gurevych (2017) to the sentence level. In the rare case (<5% of the cases) when a sentence contains multiple argument types, we choose one based on the ordering Major Claim (MC) > Claim (C) > Premise (P). Datasets and examples are listed in Table 3.

Approach We consider 7 "mini-experiments":

- (1): MR dataset with Sent2Vec-unigram embeddings as input and 1% of the full data as training data; (2): the same mini-experiment with 50% of the full data as training data. In both cases, the dev set comprises 10% of the full data and the rest is for testing.
- (3,4): SUBJ with InferSent embeddings and likewise 1% and 50% of the full data as train data, respectively.
- (5): The TREC dataset with original split in train and test; 50% of the train split is used as dev data.
- (6): The AM dataset with original split in train, dev, and test (Eger et al., 2017), and with InferSent input embeddings. (7): the same mini-experiment with Sent2Vec-unigram embeddings.

We report accuracy for mini-experiments (1-5) and macro-F1 for (6-7). We report macro-F1 for (6-7) because the AM dataset is imbalanced.

The motivation behind choosing different input embeddings for different tasks was to investigate a wider variety of conditions. Choosing subsets of the full data had the same intention.

For all 7 mini-experiments, we draw the same 200 randomly chosen hyperparameters from the ranges indicated in Table 4. All experiments are conducted in keras.[4]

For each of the 21 different activation functions detailed in §2, we conduct each mini-experiment with the 200 randomly chosen hyperparameters.

---

Table 3: Evaluation tasks used in our experiments, grouped by task type (sentence classification, document classification, sequence tagging), with statistics and examples. C is the number of classes to predict.

All activation functions use the same hyperparameters and the same train, dev, and test splits.

We store two results for each mini-experiment, namely: (i) the test result corresponding to the **best** (`best`) dev performance; (ii) the **average** (`mean`) test result across all hyperparameters. The `best` result scenario mirrors standard optimization in machine learning: it indicates the score one can obtain with an activation function when the MLP is well-optimized. The `mean` result scenario is an indicator for what one can expect when hyperparameter optimization is 'shallow' (e.g., because computing times are prohibitive): it gives the average performance for randomly chosen hyperparameters. We note that we run each hyperparameter combination with 5 different random weight initializations and all the reported scores (best dev score, best `best`, best `mean`) are averages over these 5 random initializations.

Finally, we set the following hyperparameters for all MLP experiments: patience of 10 for early stopping, batch size 16, 100 epochs for training.

Results Figure 1 shows `best` and `mean` results, averaged over all 7 mini-experiments, for each activation function. To make individual scores comparable across mini-experiments, we perform max normalization and divide each score by the maximum score achieved in any given mini-experiment (for `best` and `mean`, respectively) before averaging.[5]

For `best`, the top performers are the rectifier functions (relu, lrelu-0.01, prelu) as well as maxout and penalized tanh. The newly discovered activation functions lag behind, with the best of them being minsin and swish. linear is worst, together with elu and cube. Overall, the difference between the best activation function, relu, and the worst, linear, is only roughly 2pp, however. This means that if hyperparameter search is done carefully, the choice of activation function is less important for these sentence classification tasks. Particularly the (binary) tasks MR and SUBJ appear robust against the choice of activation function, with the difference between the best and worst function being always less than 1pp, in all settings. For TREC and AM, the situation is slightly different: for TREC, the difference is 2pp (swish vs. maxsig) and for AM, it is 3pp using InferSent embeddings (swish vs. cube) and 12pp using Sent2Vec embeddings (relu vs. linear). It is noteworthy that swish wins 2 out of 3 cases in which the choice of activation function really matters.

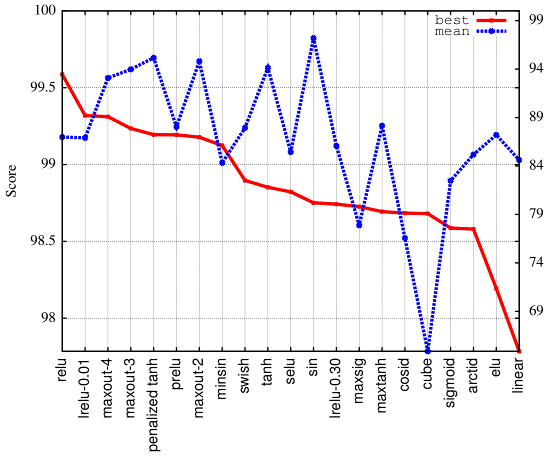

Figure 1: Sentence Classification. Left y-axis: `best`. Right y-axis: `mean`. Score on y-axes is the average over all mini-experiments.

`mean` results are very different from `best` results. Here, somewhat surprisingly, the oscillating

---

[5] We chose max normalization so that certain tasks/mini-experiments would not unduly dominate our averaged scores. Overall, our averaged scores are not (much) affected by this decision, however: the Spearman correlation of rankings of activation functions under max normalization and under no max normalization are above 0.98 in all our three classification scenarios considered in §3.1,§3.2,§3.3.

Model	Hyperparameter	Range
(a) MLP	(1) optimizer	$\{$Adam,RMSprop,Adagrad,Adadelta,Adamax,Nadam,sgd$\}$
	(2) #hidden layers N	$\{1, 2, 3, 4\}$
	(3) dropout value	$[0.1, 0.75]$
	(4) hidden units	$[30, 500]$
	(5) learning rate	$\mathcal{N}(m, m/5)$
	(6) weight initializer	$\{$random-n, random-u, varscaling, orthogonal, lecun-u, glorot-n, glorot-u, he-n, he-u$\}$
(b) CNN	(a) (1,3,5,6)	same as MLP
	embedding dimension	$[40, 200]$
	number of filters n_k	$[30, 500]$
	#hidden layers N	$\{1, 2, 3\}$
	filter size h	$\{1, 2, 2, 3, 3, 3, 4\}$
(c) RNN/LSTM	(a) (1-5)	same as MLP
	recurrent initializer	same as (a) (6) plus identity matrix

Table 4: Hyperparameter ranges for each network type. Hyperparameters are drawn using a discrete or continuous uniform distribution from the indicated ranges. Repeated values indicate multi-sets. $\mathcal{N}(\mu, s)$ is the normal distribution with mean μ and std s; $\mu = m$ is the default value from keras for the specific optimizer (if drawn learning rate is < 0, we choose it to be m).

sin function wins, followed by penalized tanh, maxout and swish. The difference between the best `mean` function, sin, and the worst, cube, is more than 30pp. This means that using cube is much riskier and requires more careful hyperparameter search compared to sin and the other top performers.

3.2 CNN & Document Classification

Model Our second paradigm is document classification using a CNN. This approach has been popularized in NLP by the ground-breaking work of Kim (2014). Even though shallow CNNs do not reach state-of-the-art results on large datasets anymore (Johnson and Zhang, 2017), simple approaches like (shallow) CNNs are still very competitive for smaller datasets (Joulin et al., 2016).

Our model operates on token-level and first embeds a sequence of tokens $x_1, \dots, x_n$, represented as 1-hot vectors, into learnable embeddings $\mathbf{x}_1, \dots, \mathbf{x}_n$. The model then applies 1D-convolution on top of these embeddings. That is, a filter $\mathbf{w}$ of size h takes h successive embeddings $\mathbf{x}_{i:i+h-1}$, performs a scalar product and obtains a feature c_i:

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b).$$

Here, f is the activation function and b is a bias term. We take the number n_k of different filters as a hyperparameter. When our network has multiple layers, we stack another convolutional layer on top of the first (in total we have n_k outputs at each time step), and so on. Our penultimate layer is a global max pooling layers that selects the maximum from each feature map. A final softmax layer terminates the network.

Data We use two document classification tasks, namely: 20 Newsgroup (NG) and Reuters-21578 R8 (R8). Both datasets are standard document classification datasets. In NG, the goal is to classify each document into one of 20 newsgroup classes (alt.atheism, sci.med, sci.space, etc.). In R8, the goal is to classify Reuters news text into one of eight classes (crude, earn, grain, interest, etc.). We used the preprocessed files from `https://www.cs.umb.edu/~smimarog/textmining/datasets/` (in particular, stopwords are removed and the text is stemmed).

Approach We consider 4 mini-experiments:

- (1,2) NG dataset with 5% and 50%, respectively of the full data as train data. In both cases, 10% of the full data is used as dev data, and the rest as test data.
- (3,4) Same as (1,2) for R8.

We report accuracy for all experiments. We use a batch size of 64, 50 epochs for training, and a patience of 10. For all mini-experiments, we again draw 200 randomly chosen hyperparameters from the ranges indicated in Table 4. The hyperparameters and train/dev/test splits are the same for all activation functions.

Results Figure 2 shows `best` and `mean` results, averaged over all mini-experiments. This time, the winners for `best` are elu, selu (again two members from the rectifier family), and maxout-3, but the difference between maxout-3 and several lower ranked functions is minimal. The cube function is again worst and sigmoid and cosid have similarly bad performance. Except for minsin, the newly proposed activation functions from Ramachandran et al. (2017) again considerably lag behind. The most stable activation functions are the maxout functions as well as penalized tanh, tanh and sin.

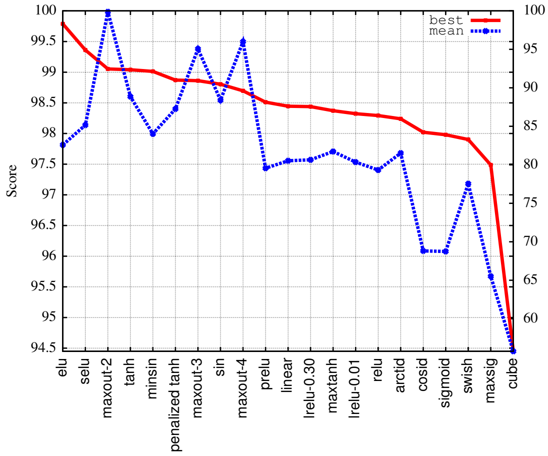

Figure 2: Doc classification.

3.3 RNN & Sequence Tagging

Model Our third paradigm is sequence tagging, a ubiquitous model type in NLP. In sequence tagging, a sequence of input tokens $w_1, \dots, w_K$ is mapped to a sequence of labels $y_1, \dots, y_K$. Classical sequence tagging tasks include POS tagging, chunking, NER, discourse parsing (Braud et al., 2017), and argumentation mining (Eger et al., 2017; Schulz et al., 2018). We use a standard recurrent net for sequence tagging, whose form is:

$$\mathbf{h}_i = f(\mathbf{h}_{i-1}\mathbf{W} + \mathbf{w}_i \cdot \mathbf{U} + \mathbf{b})$$
$$\mathbf{y}_i = \text{softmax}(\mathbf{h}_i\mathbf{V} + \mathbf{c})$$

Here, $\mathbf{w}_i$ are (pre-trained) word embeddings of words w_i. Vectors $\mathbf{b}, \mathbf{c}$ and matrices $\mathbf{U}, \mathbf{V}, \mathbf{W}$ are parameters to be learned during training. The above describes an RNN with only one hidden layer, $\mathbf{h}_i$, at each time step, but we consider the generalized form with $N \geq 1$ hidden layers; we also choose a bidirectional RNN in which the hidden outputs of a forward RNN and a backward RNN are combined. RNNs are particularly deep networks—indeed, the depth of the network corresponds to the length of the input sequence—which makes them particularly susceptible to the vanishing gradient problem (Pascanu et al., 2012).

Initially, we do not consider the more popular LSTMs here for reasons indicated below. However, we include a comparison after discussing the RNN performance.

Data We use two sequence tagging tasks, namely: English POS tagging (POS), and token-level argumentation mining (TL-AM) using the same dataset (consisting of student essays) as for the sentence level experiments. In token-level AM, we tag each token with a BIO-label plus the component type, i.e., the label space is $\mathcal{Y} = \{\mathrm{B}, \mathrm{I}\} \times \{\mathrm{MC}, \mathrm{C}, \mathrm{P}\} \cup \{\mathrm{O}\}$, where 'O" is a label for non-argumentative tokens. The motivation for using TL-AM is that, putatively, AM has more long-range dependencies than POS or similar sequence tagging tasks such as NER, because argument components are much longer than named entities and component labels also depend less on the current token.

Approach We consider 6 mini-experiments:

- (1): TL-AM with Glove-100d word embeddings and 5% of the original training data as train data; (2) the same with 30% of the original training data as train data. In both cases, dev and test follow the original train splits (Eger et al., 2017).
- (3,4) Same as (1) and (2) but with 300d Levy word embeddings (Levy and Goldberg, 2014).
- (5,6): POS with Glove-100d word embeddings and 5% and 30%, respectively, of the train data of a pre-determined train/dev/test split (13k/13k/178k tokens). Dev and test are fixed in both cases.

We report macro-F1 for mini-experiments (1-4) and accuracy for (5-6). For our RNN implementations, we use the accompanying code of (the state-of-the-art model of) Reimers and Gurevych (2017), which is implemented in keras. The network uses a CRF layer as an output layer. We use a batch size of 32, train for 50 epochs and use a patience of 5 for early stopping.

Results Figure 3 shows `best` and `mean` results, averaged over all 6 mini-experiments, for each activation function. We exclude prelu and the maxout functions because the keras implementation does not natively support these activation functions for RNNs. We also exclude the cube function because it performed very badly.

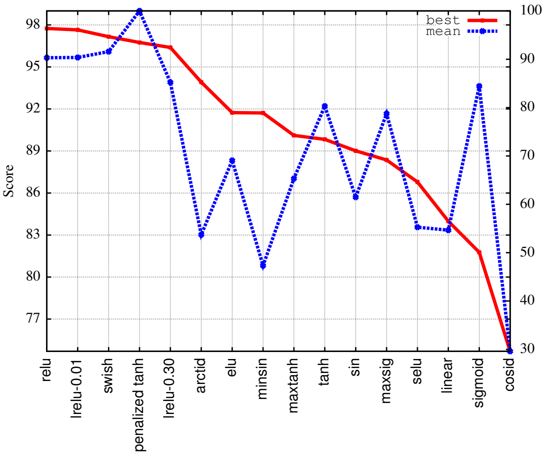

Figure 3: Sequence tagging.

Unlike for sentence classification, there are much larger differences between the activation functions. For example, there is almost 20pp difference between the best `best` activation functions: relu, lrelu-0.01, swish, penalized tanh, and the worst ones: linear, cosid, and sigmoid (the differences were larger had we included cube). Interestingly, this difference is mostly due to the TL-AM task: for POS, there is only 3pp difference between the best function (sigmoid (sic!), though with almost zero margin to the next best ones) and the worst one (linear), while this difference is almost 40pp for TL-AM. This appears to confirm our concerns regarding the POS tagging task as not being challenging enough due to lack of, e.g., long-range dependencies.

The four best `best` activation functions in Figure 3 are also the functions with the best `mean` results, i.e., they are most stable over different hyperparameters. The clear winner in this category is penalized tanh with 100% `mean` score, followed by swish with 91%. Worst is cosid with 30%. It is remarkable how large the difference between tanh and penalized tanh is both for `best` and `mean`—7pp and 20pp, respectively, which is much larger than the differences between the analogous pair of LReLU and relu. This appears to make a strong case for the importance of the slope around the origin, as suggested in Xu et al. (2016).

LSTM vs. RNN Besides an RNN, we also implemented a more popular RNN model with (bidirectional) LSTM blocks in place of standard hidden layers. Standard LSTM units follow the equations (simplified):

$$\begin{aligned}
\mathbf{f}_t &= \sigma([\mathbf{h}_{t-1};\mathbf{x}_t]\cdot\mathbf{W}_f),\\
\mathbf{i}_t &= \sigma([\mathbf{h}_{t-1};\mathbf{x}_t]\cdot\mathbf{W}_i),\\
\mathbf{o}_t &= \sigma([\mathbf{h}_{t-1};\mathbf{x}_t]\cdot\mathbf{W}_o)\\
\mathbf{c}_t &= \mathbf{f}_t\odot\mathbf{c}_{t-1}+\mathbf{i}_t\odot\tau([\mathbf{h}_{t-1};\mathbf{x}_t]\cdot\mathbf{W}_c)\\
\mathbf{h}_t &= \mathbf{o}_t\odot\tau(\mathbf{c}_t),
\end{aligned}$$

where $\mathbf{f}_t$ and $\mathbf{i}_t$ are perceived of as *gates* that control information flow, $\mathbf{x}_t$ is the input at time t and $\mathbf{h}_t$ is the hidden layer activation. In keras (and most standard references), σ is the (hard) sigmoid function, and τ is the tanh function.

We ran an LSTM on the TL-AM dataset with Levy word embeddings and 5% and 30% data size setup. We varied σ and τ independently, keeping the respective other function at its default.

We find that the top two choices for τ are penalized tanh and tanh (margin of 10pp), given that σ is sigmoid. For $\tau =$ tanh, the best choices are $\sigma =$ penalized tanh, sigmoid, and tanh. All other functions perform considerably worse. Thus, the top-performers are all saturating functions, indicating the different roles activation functions play in LSTMs—those of gates—compared to standard layers. It is worth mentioning that choosing σ or τ as penalized tanh is on average better than the standard choices for σ and τ. Indeed, choosing $\tau = \sigma =$ penalized tanh is on average 2pp better than the default choices of τ, σ.

It is further worth mentioning that the best `best` results for the LSTM are roughly 5pp better (absolute) than the best corresponding choices for the simple RNN.

4 Analysis & Discussion

Winner statistics Each of the three meta-tasks sentence classification, document classification, and sequence tagging was won, on average, by a member from the rectifier family, namely, relu (2) and elu, for `best`. Also, in each case, cube and cosid were among the worst performing activation functions. The majority of newly proposed functions from Ramachandran et al. (2017) ranked somewhere in the mid-field, with swish and minsin performing best in the `best` category. For the `mean` category, we particulary had the maxout functions as well as penalized tanh and sin regularly as top performers.

To get further insights, we computed a winner statistic across all 17 mini-experiments, counting how often each activation function was among the top 3. Table 5 shows the results, excluding prelu and the maxout functions because they were not considered in all mini-experiments.

`best`	penalized tanh (6), swish (6), elu (4), relu (4), lrelu-0.01 (4)
`mean`	penalized tanh (16), tanh (13) sin (10)

Table 5: Top-3 winner statistics. In brackets: number of times within top-3, keeping only functions with four or more top-3 rankings.

We see that penalized tanh and swish win here for `best`, followed by further rectifier functions. The `mean` category is clearly won by saturating activation functions with finite range. If this comparison were restricted to sentence and document classification, where we also included the maxout functions, then penalized tanh would have been outperformed by maxout for `mean`.

This appears to yield the conclusion that functions with limited range behave more stably across hyperparameter settings while non-saturating functions tend to yield better top-performances. The noteworthy exception to this rule is penalized tanh which excels in both categories (the more expensive maxout functions would be further exceptions). If the slope around the origin of penalized tanh is responsible for its good performance, then this could also explain why cube is so bad, since it is very flat close to the origin.

Influence of hyperparameters To get some intuition about how hyperparameters affect our different activation functions, we regressed the score of the functions on the test set on all the employed hyperparameters. For example, we estimated:

$$y = \alpha_l \cdot \log(n_l) + \alpha_d \cdot d + \cdots \qquad (1)$$

where y is the score on the test set, n_l is the number of layers in the network, d is the dropout value, etc. The coefficients α_k for each regressor k is what we want to estimate (in particular, their size and their sign). We logarithmized certain variables whose scale was substantially larger than those of others (e.g., number of units, number of filters). For discrete regressors such as the optimizer we used binary dummy variables. We estimated Eq. (1) independently for each activation function and for each mini-experiment. Overall, there was a very diverse pattern of outcomes, preventing us from making too strong conclusions. Still, we observed that while all models performed on average better with fewer hidden layers, particularly swish was robust to more hidden layers (small negative coefficient α_l), but also, to a lesser degree, penalized tanh. In the sentence classification tasks, sin and the maxout functions were particulary robust to an increase of hidden layers. Since penalized tanh is a saturating function and sin even an oscillating one, we therefore conclude that preserving the gradient (derivative close to one) is not a necessary prerequisite to successful learning in deeper neural networks.

5 Concluding remarks

We have conducted the first large scale comparison of activation functions across several different NLP tasks (and task types) and using different popular neural network types. Our main focus was on so-called scalar activation functions, but we also partly included the more costly 'many-to-one' maxout functions.

Our findings suggest that the rectifier functions (and the similarly shaped swish) can be top performers for each task, but their performance is unstable and cannot be predicted a priori. One of our major findings is that, in contrast, the saturating penalized tanh function performs much more stably in this respect and can with high probability be expected to perform well across tasks as well as different choices of hyperparameters. This appears to make it the method of choice particularly when hyperparameter optimization is costly. When hyperparameter optimization is cheap, we recommend to consider the activation function as another hyperparameter and choose it, e.g., from the range of functions listed in Table 5 along with maxout.

Another major advantage of the penalized tanh function is that it may also take the role of a gate (because of its finite range) and thus be employed in more sophisticated neural network units such as LSTMs, where the rectifiers fail completely. In this context, we noticed that replacing sigmoid and tanh in an LSTM cell with penalized tanh leads to a 2pp increase on a challenging NLP sequence tagging task. Exploring whether this holds across more NLP tasks should be scope for future work. Additionally, our research suggests it is worthwhile to further explore penalized tanh, an arguably marginally known activation function. For instance, other scaling factors than 0.25 (default value from Xu et al. (2016)) should be explored. Similarly as for prelu, the scaling factor can also be made part of the optimization problem.

Finally, we found that except for swish none of the newly discovered activation functions found in Ramachandran et al. (2017) made it in our top categories, suggesting that automatic search of activation functions should be made across multiple tasks in the future.

Abstract

Character-level string-to-string transduction is an important component of various NLP tasks. The goal is to map an input string to an output string, where the strings may be of different lengths and have characters taken from different alphabets. Recent approaches have used sequence-to-sequence models with an attention mechanism to learn which parts of the input string the model should focus on during the generation of the output string. Both soft attention and hard monotonic attention have been used, but hard non-monotonic attention has only been used in other sequence modeling tasks such as image captioning (Xu et al., 2015) and has required a stochastic approximation to compute the gradient. In this work, we introduce an exact, polynomial-time algorithm for marginalizing over the exponential number of non-monotonic alignments between two strings, showing that hard attention models can be viewed as neural reparameterizations of the classical IBM Model 1. We compare soft and hard non-monotonic attention experimentally and find that the exact algorithm significantly improves performance over the stochastic approximation and outperforms soft attention.

1 Introduction

Many natural language tasks are expressible as string-to-string transductions operating at the character level. Probability models with recurrent neural parameterizations currently hold the state of the art on many such tasks. On those string-to-string transduction tasks that involve a mapping between two strings of different lengths, it is often necessary to resolve which input symbols are related to which output symbols. As an example, consider the task of transliterating a Russian word into the Latin alphabet. In many cases, there exists a one-to-two mapping between Cyrillic and Latin letters: in Хурщёв (*Khrushchev*), the Russian Х can be considered to generate the Latin letters *Kh*. Supervision is rarely, if ever, provided at the level of character-to-character alignments—this is the problem that attention seeks to solve in neural models.

With the rise of recurrent neural networks, this problem has been handled with "soft" **attention** rather than traditional hard **alignment**. Attention (Bahdanau et al., 2015) is often described as "soft," as it does not clearly associate a single input symbol with each output symbol, but rather offers a fuzzy notion of what input symbols may be responsible for which symbols in the output. In contrast, an alignment directly associates a given input symbol with a given output symbol. To express uncertainty, practitioners often place a distribution over the exponential number of hard non-monotonic alignments, just as a probabilistic parser places a distribution over an exponential number of trees. The goal, then, is to learn the parameters of this distribution over all non-monotonic alignments through backpropagation. Incorporating hard alignment into probabilistic transduction models dates back much farther in the NLP literature; arguably, originating with the seminal paper by Brown et al. (1993). Some neural approaches have moved back towards this approach of a more rigid alignment, referring to it as "hard attention." We will refer to this as "hard attention" and to more classical approaches as "alignment."

This paper offers two insights into the usage of hard alignment. First, we derive a dynamic program for the exact computation of the likelihood in a neural model with latent hard alignment: Previous work has used a stochastic algorithm to approximately sum over the exponential number of alignments between strings. In so doing, we go on to relate neural hard alignment models to the classical IBM Model 1 for alignment in machine translation. Second, we provide an experimental comparison that indicates hard attention models outperform soft attention models on three character-level string-to-string transduction tasks: grapheme-to-phoneme conversion, named-entity transliteration and morphological inflection.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4425–4438
Brussels, Belgium, October 31 - November 4, 2018.

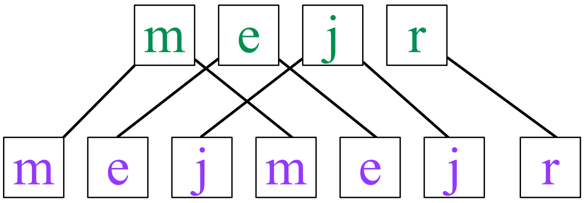

Figure 1: Example of a non-monotonic character-level transduction from the Micronesian language of Pingelapese. The infinitive *mejr* is mapped through a reduplicative process to its gerund *mejmejr* (Rehg and Sohl, 1981). Each input character is drawn in green and each output character is drawn in purple, connected with a line to the corresponding input character.

2 Non-Monotonic Transduction

This paper presents a novel, neural, probabilistic latent-variable model for **non-monotonic** transduction. As a concrete example of a non-monotonic transduction, consider the mapping of a Pingelapese infinitive to its gerund, as shown in Fig. 1. The mapping requires us to generate the output string left-to-right, bouncing around the input string out-of-order to determine the characters to transduce from. As the non-monotonic alignment is the latent variable, we will face a combinatorial problem: summing over all non-monotonic alignments. The algorithmic contribution of this paper is the derivation of a simple dynamic program for computing this sum in polynomial time that still allows for very rich recurrent neural featurization of the model. With respect to the literature, our paper represents the first instance of exact marginalization for a neural transducer with hard non-monotonic alignment; previous methods, such as Rastogi et al. (2016) and Aharoni and Goldberg (2017), are exclusively monotonic.

Non-monotonic methods dominate character-level transduction. Indeed, the state of art in classic character-level NLP tasks such as grapheme-to-phoneme conversion (Yao and Zweig, 2015), transliteration (Rosca and Breuel, 2016) and morphological inflection generation (Kann and Schütze, 2016) is held by the soft non-monotonic method of Bahdanau et al. (2015). Even though non-monotonicity is more common in word-level tasks, it also exists in character-level transduction tasks, as evidenced by our example in Fig. 1 and the superior performance of non-monotonic methods. Our error analysis in §8.4 sheds some light on why non-monotonic methods are the state of the art in a seemingly monotonic task.

A Note on the Character-level Focus. A natural question at this point is why we are not experimenting with word-level transduction tasks, such as machine translation. As we show in the §3.2 our method is often an order of magnitude slower, since it will involve a mixture of softmaxes. Thus, the exact marginalization scheme is practically unworkable for machine translation; we discuss future extensions for machine translation in §6. However, the slow-down is no problem for character-level tasks and we show empirical gains in §8.

3 Hard Non-Monotonic Alignment

3.1 The Latent-Variable Model

An alphabet is a finite, non-empty set. Given two alphabets $\Sigma_{\mathrm{x}} = \{x_1, \ldots, x_{|\Sigma_{\mathrm{x}}|}\}$ and $\Sigma_{\mathrm{y}} = \{y_1, \ldots, y_{|\Sigma_{\mathrm{y}}|}\}$, probabilistic approaches to the problem attempt to estimate a probability distribution $p(\mathbf{y} \mid \mathbf{x})$ where $\mathbf{y} \in \Sigma_{\mathrm{y}}^*$ and $\mathbf{x} \in \Sigma_{\mathrm{x}}^*$. Foreshadowing, we will define the parameters of p to be, in part, the parameters of a recurrent neural network, in line with the state-of-the-art models. We define the set $A = \{1, \ldots, |\mathbf{x}|\}^{|\mathbf{y}|}$, which has an interpretation as the set of all (potentially non-monotonic) alignments from $\mathbf{x}$ to $\mathbf{y}$ with the restriction that each output symbol y_i aligns to exactly one symbol in $\mathbf{x} \in \Sigma_{\mathrm{x}}^*$. In other words, A is the set of all many-to-one alignments between $\mathbf{x}$ and $\mathbf{y}$ where many may be as few as zero. We remark that $|A| = |\mathbf{x}|^{|\mathbf{y}|}$, which is exponentially large in the length of the target string $\mathbf{y}$. For an $\mathbf{a} \in A$, $a_i = j$ refers to the event that y_i, the i^{th} component of $\mathbf{y}$, is aligned to x_j, the j^{th} component of $\mathbf{x}$.

We define a probability distribution over output strings $\mathbf{y}$ conditioned on an input string $\mathbf{x}$ where we marginalize out *unobserved* alignments $\mathbf{a}$:

$$p(\mathbf{y} \mid \mathbf{x}) = \sum_{\mathbf{a} \in A(\mathbf{x},\mathbf{y})} p(\mathbf{y}, \mathbf{a} \mid \mathbf{x}) \tag{1}$$

$$= \underbrace{\sum_{\mathbf{a} \in A} \prod_{i=1}^{|\mathbf{y}|} p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x})\, p(a_i \mid \mathbf{y}_{<i}, \mathbf{x})}_{\textit{exponential number of terms}} \tag{2}$$

$$= \underbrace{\prod_{i=1}^{|\mathbf{y}|} \sum_{a_i=1}^{|\mathbf{x}|} p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x})\, p(a_i \mid \mathbf{y}_{<i}, \mathbf{x})}_{\textit{polynomial number of terms}} \tag{3}$$

$$= \prod_{i=1}^{|\mathbf{y}|} \sum_{j=1}^{|\mathbf{x}|} \mathbb{1}_{a_{i,j}}\, \alpha_j(i)\, p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x}) \tag{4}$$

where we define $\alpha_j(i) = p(a_i \mid \mathbf{y}_{<i}, \mathbf{x})$ in order to better notationally compare our model to that

of Bahdanau et al. (2015) in §5. Each distribution $p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x})$ in the definition of the model has a clean interpretation as a distribution over the output vocabulary Σ_y, given an input string $\mathbf{x} \in \Sigma_\mathrm{x}^*$, where y_i is aligned to x_j. Thus, one way of thinking about this hard alignment model is as a product of mixture models, one mixture at each step, with mixing coefficients $\alpha_j(i)$.

Why Does Dynamic Programming Work? Our dynamic program to compute the likelihood, fully specified in eq. (3), is quite simple: The non-monotonic alignments are independent of each other, i.e., $\alpha_j(i)$ is independent of $\alpha_j(i-1)$, conditioned on the observed sequence $\mathbf{y}$. This means that we can cleverly rearrange the terms in eq. (2) using the distributive property. Were this not the case, we could not do better than having an exponential number of summands. This is immediately clear when we view our model as a graphical model, as in Fig. 2: There is no active trail from a_i to a_k where $k > i$, ignoring the dashed lines. Note that this is no different than the tricks used to achieve exact inference in n^{th}-order Markov models—one makes an independence assumption between the current bit of structure and the previous bits of structure to allow an efficient algorithm. For a proof of eq. (2)–eq. (3), one may look in Brown et al. (1993). Foreshadowing, we note that certain parameterizations make use of input feeding, which breaks this independence; see §5.1.

Relation to IBM Model 1. The derivation above is similar to that of the IBM alignment model 1. We remark, however, two key generalizations that will serve our recurrent neural parameterization well in §4. First, traditionally, derivations of IBM Model 1 omit a prior over alignments $p(a_i \mid \mathbf{x})$, taking it to be uniform. Due to this omission, an additional multiplicative constant $\varepsilon/|\mathbf{x}|^{|\mathbf{y}|}$ is introduced to ensure the distribution remains normalized (Koehn, 2009). Second, IBM Model 1 does not condition on previously generated words on the output side. In other words, in their original model, Brown et al. (1993) assume that $p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x}) = p(y_i \mid a_i, \mathbf{x})$, forsaking dependence on $\mathbf{y}_{<i}$. We note that there is no reason why we need to make this independence assumption—we will likely want a target-side language model in transduction. Indeed, subsequent statistical machine translation systems, e.g., MOSES (Koehn et al., 2007), integrate a language model into the decoder. It is of note that many models in NLP have made similar independence assumptions, e.g., the emission distribution hidden Markov models (HMMs) are typically taken to be independent of all previous emissions (Rabiner, 1989). These assumptions are generally not necessary.

3.2 Algorithmic Analysis: Time Complexity

Let us assume that the requisite probability distributions are computable in $\mathcal{O}(1)$ time and the softmax takes $\mathcal{O}(\Sigma_\mathrm{y})$. Then, by inspection, the computation of the distribution in eq. (4) is $\mathcal{O}\left(|\mathbf{x}| \cdot |\mathbf{y}| \cdot |\Sigma_\mathrm{y}|\right)$, as the sum in eq. (3) contains this many terms thanks to the dynamic program that allowed us to rearrange the sum and the product. While this "trick" is well known in the NLP literature—it dates from the seminal work in statistical machine translation by Brown et al. (1993)—it has been forgotten in recent formulations of hard alignment (Xu et al., 2015), which use stochastic approximation to handle the exponential summands. As we will see in §5, we can compute the soft-attention model of Bahdanau et al. (2015) in $\mathcal{O}\left(|\mathbf{x}| \cdot |\mathbf{y}| + |\mathbf{y}| \cdot |\Sigma_\mathrm{y}|\right)$ time. When Σ_y is large, for example in case of machine translation with tens of thousands of Σ_y at least, we can ignore $|\mathbf{x}| \cdot |\mathbf{y}|$ in soft-attention model, and the exact marginalization has an extra $|\mathbf{x}|$-factor compared to soft-attention model. In practice, Shi and Knight (2017) show the bottleneck of a NMT system is the softmax layer, making the extra $|\mathbf{x}|$-factor practically cumbersome.

4 Recurrent Neural Parameterization

How do we parameterize $p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x})$ and $\alpha_j(i)$ in our hard, non-monotonic transduction model? We will use a neural network identical to the one proposed in the attention-based sequence-to-sequence model of Luong et al. (2015) *without input feeding* (a variant of Bahdanau et al. (2015)).

4.1 Encoding the Input

All models discussed in this exposition will make use of the same mechanism for mapping a source string $\mathbf{x} \in \Sigma_\mathrm{x}^*$ into a fixed-length representation in $\mathbb{R}^{d_h}$. This mapping will take the form of a bidirectional recurrent neural network encoder, which works as follows: each element of Σ_x is mapped to an embedding vector of length d_e through a mapping: $\mathbf{e} : \Sigma_\mathrm{x} \to \mathbb{R}^{d_e}$. Now, the RNN folds the

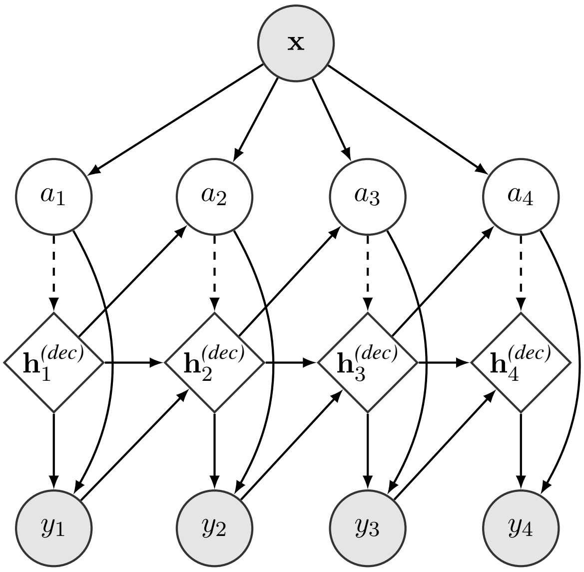

Figure 2: Our hard-attention model *without input feeding* viewed as a graphical model. Note that the circular nodes are random variables and the diamond nodes deterministic variables ($\mathbf{h}^{(dec)}_i$ is first discussed in §4.3). The independence assumption between the alignments a_i when the y_i are *observed* becomes clear. Note that we have omitted arcs from $\mathbf{x}$ to y_1, y_2, y_3 and y_4 for clarity (to avoid crossing arcs). We alert the reader that the dashed edges show the additional dependencies added in the *input feeding version*, as discussed in §5.1. Once we add these in, the a_i are no longer independent and break exact marginalization. Note the hard-attention model does not enforce an exactly one-to-one constraint. Each source-side word is free to align to many of the target-side words, independent of context. In the latent variable model, the x variable is a vector of source words, and the alignment may be over more than one element of x.

following recursion over the string $\mathbf{x}$ left-to-right:

$$\overrightarrow{\mathbf{h}}^{(enc)}_j = \tanh\Big(\overrightarrow{\mathbf{U}}^{(enc)}\,\mathbf{e}^{(enc)}(x_j) + \overrightarrow{\mathbf{V}}^{(enc)}\,\overrightarrow{\mathbf{h}}^{(enc)}_{j-1} + \overrightarrow{\mathbf{b}}^{(enc)}\Big) \tag{5}$$

where we fix the 0^{th} hidden state $\mathbf{h}^{(enc)}_0$ to the zero vector and the matrices $\overrightarrow{\mathbf{U}}^{(enc)} \in \mathbb{R}^{d_h \times d_e}$, $\overrightarrow{\mathbf{V}}^{(enc)} \in \mathbb{R}^{d_h \times d_h}$ and the bias term $\overrightarrow{\mathbf{b}}^{(enc)} \in \mathbb{R}^{d_h}$ are parameters to be learned. Performing the same procedure on the reversed string and using an RNN with different parameters, we arrive at hidden state vectors $\overleftarrow{\mathbf{h}}^{(enc)}_j$. The final hidden states from the encoder are the concatenation of the two, i.e., $\mathbf{h}^{(enc)}_j = \overrightarrow{\mathbf{h}}^{(enc)}_j \oplus \overleftarrow{\mathbf{h}}^{(enc)}_j$, where $\oplus$ is vector concatenation.

As has become standard, we will use an extension to this recursion: we apply the long short-term memory (LSTM; (Hochreiter and Schmidhuber, 1997)) recursions, rather than those of a vanilla RNN (Elman network; Elman (1990)).

4.2 Parameterization.

Now we define the alignment distribution $\alpha_j(i)$.

$$\alpha_j(i) = \frac{\exp(e_{ij})}{\sum_{j'=1}^{|\mathbf{x}|} \exp(e_{ij'})} \tag{6}$$

$$e_{ij} = \mathbf{h}^{(dec)\top}_i\, \mathbf{T}\, \mathbf{h}^{(enc)}_j \tag{7}$$

where $\mathbf{T} \in \mathbb{R}^{d_h \times 2d_h}$ and $\mathbf{h}^{(dec)}_i$, the decoder RNN's hidden state, is defined in §4.3. Importantly, the alignment distribution $\alpha_j(i)$ at time step i will *only* depend on the prefix of the output string $\mathbf{y}_{<i}$ generated so far. This is clear since the output-side decoder is a unidirectional RNN.

We also define $p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x})$.

$$p(y_i \mid a_i, \mathbf{y}_{<i}, \mathbf{x}) = \text{softmax}\Big(\mathbf{W}\,\mathbf{f}(\mathbf{h}^{(dec)}_i, \mathbf{h}^{(enc)}_{a_i})\Big) \tag{8}$$

The function $\mathbf{f}$ is a non-linear and vector-valued; one popular choice of $\mathbf{f}$ is a multilayer perceptron with parameters to be learned. We define:

$$\mathbf{f}(\mathbf{h}^{(dec)}_i, \mathbf{h}^{(enc)}_{a_i}) = \tanh\Big(\mathbf{S}\,(\mathbf{h}^{(dec)}_i \oplus \mathbf{h}^{(enc)}_{a_i})\Big) \tag{9}$$

where $\mathbf{S} \in \mathbb{R}^{d_s \times 3d_h}$.

4.3 Updating the hidden state $\mathbf{h}^{(dec)}_i$

The hidden state $\mathbf{h}^{(dec)}_i$ is also updated through the LSTM recurrences (Hochreiter and Schmidhuber, 1997). The RNN version of the recurrence mirrors that of the encoder,

$$\mathbf{h}^{(dec)}_i = \tanh\Big(\mathbf{U}^{(dec)}\,\mathbf{e}^{(dec)}(y_{i-1}) + \mathbf{V}^{(dec)}\,\mathbf{h}^{(dec)}_{i-1} + \mathbf{b}^{(dec)}\Big) \tag{10}$$

where $\mathbf{e}^{(dec)} : \Sigma_{\mathrm{y}} \to \mathbb{R}^{d_e}$ produces an embedding of each of the symbols in the output alphabet. What is crucial about this RNN, like the $\alpha_j(i)$, is that it only summarizes the characters decoded so far *independently of the previous attention weights*. In other words, the attention weights at time step i will have no influence from the attention weights at previous time steps, shown in Fig. 2. This is what allows for dynamic programming.

5 Transduction with Soft Attention

In order to contrast it with the hard alignment mechanism we develop, we here introduce Luong attention (Luong et al., 2015) for recurrent neural sequence to sequence models (Sutskever et al., 2014). Note that this model will also serve as an experimental baseline in §8.

The soft-attention transduction model defines a distribution over the output Σ_{y}^*, much like the hard-attention model, with the following expression:

$$p(\mathbf{y} \mid \mathbf{x}) = \prod_{i=1}^{|\mathbf{y}|} p(y_i \mid \mathbf{y}_{<i}, \mathbf{x}) \tag{11}$$

where we define each conditional distribution as

$$\begin{aligned} & p(y_i \mid \mathbf{y}_{<i}, \mathbf{x}) && (12) \\ & \quad = \text{softmax}\left(\mathbf{W}\, \mathbf{f}(\mathbf{h}_i^{(dec)}, \mathbf{c}_i)\right) \end{aligned}$$

We reuse the function $\mathbf{f}$ in eq. (9). The hidden state $\mathbf{h}_i^{(dec)}$, as before, is the i^{th} state of a target-side language model that summarizes the prefix of the string decoded so far; this is explained in §4.3. And, finally, we define the **context vector**

$$\mathbf{c}_i = \sum_{j=1}^{|\mathbf{x}|} \alpha_j(i)\, \mathbf{h}_j^{(enc)} \tag{13}$$

using the same alignment distribution as in §4.2. In the context of the soft-attention model, this distribution is referred to as the **attention weights**.

Inspection shows that there is only a small difference between the soft-attention model presented here and and our hard non-monotonic attention model. The difference is where we place the probabilities $\alpha_j(i)$. In the soft-attention version, we place them inside the softmax (and the function $\mathbf{f}$), as in eq. (12), and we have a mixture of the encoder's hidden states, the context vector, that we feed into the model. On the other hand, if we place them outside the softmax, we have a mixture of softmaxes, as shown in eq. (3). Both models have *identical* set of parameters.

5.1 Input Feeding: What's That?

The equations in eq. (10), however, are not the only approach. **Input-feeding** is another popular approach that is, perhaps, standard at this point (Luong et al., 2015). Input feeding refers to the setting where the architecture designer additionally feeds the attention weights into the update for the decoder's hidden state. This yields the recursion

$$\begin{aligned} \mathbf{h}_i^{(dec)} = \tanh\Big(&\mathbf{U}^{(dec)}\,(\mathbf{e}^{(dec)}(y_{i-1}) \oplus \bar{\mathbf{c}}_{i-1}) + \\ &\mathbf{V}^{(dec)}\,\mathbf{h}_{i-1}^{(dec)} + \mathbf{b}^{(dec)}\Big) \end{aligned} \tag{14}$$

where $\bar{\mathbf{c}}_{i-1} = \mathbf{f}(\mathbf{h}_{i-1}^{(dec)}, \mathbf{c}_{i-1})$. Note that this requires that $\mathbf{U}^{(dec)} \in \mathbb{R}^{d_h \times (d_e + d_s)}$. This is the architecture discussed in Bahdanau et al. (2015, §3.1). In contrast to the architecture above, this architecture has attention weights that do depend on previous attention weights due to the feeding in of the context vector $\mathbf{c}_i$. See Cohn et al. (2016) for an attempt to incorporate structural biases into the manner in which the attention distribution is influenced by previous attention distributions.

5.2 Combining Hard Non-Monotonic Attention with Input Feeding

To combine hard attention with input feeding, Xu et al. (2015) derive a variational lower bound on the log-likelihood though Jensen's inequality:

$$\begin{aligned} \log p(\mathbf{y} \mid \mathbf{x}) &= \log \sum_{\mathbf{a} \in A(\mathbf{x},\mathbf{y})} p(\mathbf{y}, \mathbf{a} \mid \mathbf{x}) \\ &= \log \sum_{\mathbf{a} \in A(\mathbf{x},\mathbf{y})} p(\mathbf{a} \mid \mathbf{x}) \cdot p(\mathbf{y} \mid \mathbf{x},) \\ &\geq \sum_{\mathbf{a} \in A(\mathbf{x},\mathbf{y})} p(\mathbf{a} \mid \mathbf{x}) \log p(\mathbf{y} \mid \mathbf{x}, \mathbf{a}) \end{aligned}$$

Note that we have omitted the dependence of $p(\mathbf{a} \mid \mathbf{x})$ on the appropriate prefix of $\mathbf{y}$; this was done for notational simplicity. Using this bound, Xu et al. (2015) derive an efficient approximation to the gradient using the REINFORCE trick of Williams (1992). This sampling-based gradient estimator is then used for learning, but suffers from high variance. We compare to this model in §8.

6 Future Work

Just as Brown et al. (1993) started with IBM Model 1 and build up to richer models, we can do the same. Extensions, resembling those of IBM Model 2 and the HMM aligner (Vogel et al., 1996)

	source	**target**

Table 1: Example of source and target string for each task as processed by the model

that generalize IBM Model 1, are easily bolted on to our proposed model as well. If we are willing to perform approximate inference, we may also consider fertility as found in IBM Model 4.

In order to extend our method to machine translation (MT) in any practical manner, we require an approximation to the softmax. Given that the softmax is already the bottleneck of neural MT models (Shi and Knight, 2017), we can not afford ourselves a $\mathcal{O}(|\mathbf{x}|)$ slowdown during training. Many methods have been proposed for approximating the softmax (Goodman, 2001; Bengio et al., 2003; Gutmann and Hyvärinen, 2010). More recently, Chen et al. (2016) compared methods on neural language modeling and Grave et al. (2017) proposed a GPU-friendly method.

7 The Tasks

The empirical portion of the paper focuses on character-level string-to-string transduction problems. We consider three tasks: G: grapheme-to-phoneme conversion, T: named-entity transliteration, and I: morphological inflection. We describe each briefly in turn and we give an example of a source and target string for each task in Tab. 1.

Grapheme-to-Phoneme Conversion. We use the standard grapheme-to-phoneme conversion (G2P) dataset: the Sphinx-compatible version of CMUDict (Weide, 1998) and NetTalk (Sejnowski and Rosenberg, 1987). G2P transduces a word, a string of graphemes, to its pronunciation, a string of phonemes. We evaluate with word error rate (WER) and phoneme error rate (PER) (Yao and Zweig, 2015). PER is equal to the edit distance divided by the length of the string of phonemes.

	no	③ Luong et al. (2015) *without input feeding*	④ *This work*

Table 2: The 4 architectures considered in the paper.

Named-Entity Transliteration. We use the NEWS 2015 shared task on machine transliteration (Zhang et al., 2015) as our named-entity transliteration dataset. It contains 14 language pairs. Transliteration transduces a named entity from its source language to a target language—in other words, from a string in the source orthography to a string in the target orthography. We evaluate with word accuracy in percentage (ACC) and mean F-score (MFS) (Zhang et al., 2015). For completeness, we include the definition of MFS in App. A.

Morphological Inflection. We consider the high-resource setting of task 1 in the CoNLL–SIGMORPHON 2017 shared task (Cotterell et al., 2017) as our morphological inflection dataset. It contains 51 languages in the high resource setting. Morphological inflection transduces a lemma (a string of characters) and a morphological tag (a sequence of subtags) to an inflected form of the word (a string of characters). We evaluate with word accuracy (ACC) and average edit distance (MLD) (Cotterell et al., 2017).

8 Experiments

The goal of the empirical portion of our paper is to perform a controlled study of the different architectures and approximations discussed up to this point in the paper. §8.1 exhibits the neural architectures we compare and the main experimental results[1] are in Tab. 3. In §8.2, we present the experimental minutiae, e.g. hyperparameters. In §8.3, we analyze our experimental findings. Finally, in §8.4, we perform error analysis and visualize the soft attention weight and hard alignment distribution.

8.1 The Architectures

The four architectures we consider in controlled comparison are: ①: soft attention *with* input feeding, ②: hard attention *with* input feeding, ③: soft attention *without* input feeding and ④: **hard attention *without* input feeding** (our system). They are also shown in Tab. 2. As a fifth system, we compare to the monotonic system Ⓜ: Aharoni and Goldberg (2017). Additionally, we present Ⓤ, a variant of ① where the number of parameters is not

8.2 Experimental Details

We implement the experiments with PyTorch (Paszke et al., 2017) and we port the code of Aharoni and Goldberg (2017) to admit batched training. Because we did not observe any improvements in preliminary experiments when decoding with beam search [2], all models are decoded greedily.

Data Preparation. For G, we sample 5% and 10% of the data as development set and test set, respectively. For T, we only run experiments with 11 out of 14 language pairs[3] because we do not have access to all the data.

Model Hyperparameters. The hyperparameters of all models are in Tab. 4. The hyperparameters of the large model are tuned using the baseline ③ on selected languages in I, and the search range is shown in Tab. 4. All three tasks have the same two sets of hyperparameters. To ensure that ① has the same number of parameters as the other models, we decrease d_s in eq. (9) while for the rest of the models $d_s = 3d_h$. Additionally, we use a linear mapping to merge $\mathbf{e}^{(dec)}(y_{i-1})$ and $\bar{\mathbf{c}}_{i-1}$ in eq. (14) instead of concatenation. The output of the linear mapping has the same dimension as $\mathbf{e}^{(dec)}(y_{i-1})$, ensuring that the RNN has the same size.

Ⓜ has quite a different architecture: The input of the decoder RNN is the concatenation of the previously predicted word embedding, the encoder's hidden state at a specific step, and in the case of I, the encoding of the morphological tag. Differing from Aharoni and Goldberg (2017), we concatenate all attributes' embeddings (0 for attributes that are not applicable) and merge them with a linear mapping. The dimension of the merged vector and attributes vector are d_e. To ensure that it has the same number of parameters as the rest of the model, we increase the hidden size of the decoder RNN.

Optimization. We train the model with Adam (Kingma and Ba, 2014) with an initial learning rate of 0.001. We halve the learning rate whenever the development log-likelihood doesn't improve. We stop after the learning rate dips to 1×10^{-5}. We save all models after each epoch and select the model with best development performance. We train the model for at most 50 epochs, though all the experiments stop early. We train on G, T, and I with batch sizes of 20, 50 and 20, respectively. We notice in the experiments that the training of ① and Ⓤ is quite unstable with the large model, probably because of the longer chain of gradient information flow. We apply gradient clipping to the large model with maximum gradient norm 5.

REINFORCE. In the REINFORCE training of Ⓡ and ②, we sample 2 and 4 positions at each time step for the small and large model, respectively. The latter is tuned on selected languages in I with search range {2,3,4,5}. To stabilize the training, we apply a baseline with a moving average reward and

---

[2] Compared to greedy decoding with an average error rate of 20.1% and an average edit distance of 0.385, beam search with beam size 5 gets a slightly better edit distance of 0.381 while hurting the error rate with 20.2%.

discount factor of 0.9, similar to Xu et al. (2015).

8.3 Experimental Findings

Finding #1: Effect of Input Feeding. By comparing ③ and ④ against ① and ② in Tab. 3, we find input feeding hurts performance in all settings and all tasks. This runs in contrast to the reported results of Luong et al. (2015), but they experiment on machine translation, rather than character-level transduction. This validates our independence assumption about the alignment distribution.

Finding #2: Soft Attention vs. Hard Attention. Training with REINFORCE hurts the performance of the hard attention model; compare ① and ② (trained with REINFORCE), in Tab. 3. On the other hand, training with exact marginalization causes the hard attention model to outperform soft attention model in nearly all settings; compare ③ and ④ in Tab. 3. This comparison shows that hard attention outperforms soft attention in character-level string transduction when trained with exact marginalization.

Finding #3: Non-monotonicity vs. Monotonicity. The monotonic model Ⓜ underperforms compared to non-monotonic models ③ in Tab. 3 except for one setting. It performs slightly worse on T and G due to the many-to-one alignments in the data and the fact that Aharoni and Goldberg (2017) can only use the hidden vector of the final element of the span in a many-to-one alignment to directly predict the one target element. The current state-of-the-art systems for character-level string transduction are non-monotonic models, despite the tasks' seeming monotonicity; see §8.4.

Finding #4: Approximate Hard Attention. Given our development of an exact marginalization method for neural models with hard attention, a natural question to ask is how much exact marginalization helps during learning. By comparing ④ and Ⓡ in Tab. 3, we observe that training with exact marginalization clearly outperforms training under stochastic approximation in every setting and on every dataset. We also observe that exact marginalization allows faster convergence, since training with REINFORCE is quite unstable where some runs seemingly to get stuck.

	NETtalk				CMUDict			
	③		④		③		④	
	✓	✗	✓	✗	✓	✗	✓	✗
Monotonic	18742	1230	18823	1172	95824	17294	96176	17159
Non-monotonic	31	5	12	1	158	162	37	66

Table 5: Breakdown of correct and incorrect predictions of monotonic and non-monotonic alignments of ③ and ④ in G, derived from the soft attention weights and the hard alignment distribution

Finding #5: Controlling for Parameters. Input feeding yields a more expressive model, but also leads to an increase in the number of parameters. Here, we explore what effect this has on the performance of the models. In their ablation, Luong et al. (2015) did not control the number of parameters when adding input feeding. The total number of parameters of Ⓤ is 1.679M for the small setting and 10.541M for the large setting, which has 40% and 22.3% more parameters than the controlled setting. By comparing ① and Ⓤ in Tab. 3, we find that the increase in parameters, rather than the increase in expressivity explains the success of input feeding.

8.4 Visualization and Error Analysis

We hypothesize that even though the model is non-monotonic, it can learn monotonic alignment with flexibility if necessary, giving state-of-the-art results on many seemingly monotonic character-level string transduction task. To show more insights, we compare the best soft attention model (③) against the best hard alignment model (④) on G by showing the confusion matrix of each model in Tab. 5. An alignment is non-monotonic when alignment edges predicted by the model cross. There is an edge connecting x_j and y_i if the attention weight or hard alignment distribution $\alpha_j(i)$ is larger than 0.1. We find that the better-performing transducers are more monotonic, and most learned alignments are monotonic. The results indicate that there are a few transductions that are indeed non-monotonic in the dataset. However, the number is so few that this does not entirely explain why non-monotonic models outperform the monotonic models. We speculate this lies in the architecture of Aharoni and Goldberg (2017), which does not permit many-to-one alignments, while monotonic alignment learned by the non-monotonic model is more flexible. Future work will investigate this.

In Fig. 3, we visualize the soft attention weights (③) and the hard alignment distribution (④) side by side. We observe that the hard alignment distribution is more interpretable, with a clear boundary when predicting the prefixes.

9 Conclusion

We exhibit an efficient dynamic program for the exact marginalization of all non-monotonic alignments in a neural sequence-to-sequence model. We show empirically that exact marginalization helps over approximate inference by REINFORCE and that models with hard, non-monotonic alignment outperform those with soft attention.

Min Zhang, Haizhou Li, Rafael E. Banchs, and A. Kumaran. 2015. Whitepaper of news 2015 shared task on machine transliteration. In *NEWS@ACL*.

A MFS

$$
\begin{aligned}
LCS(c, r) &= \frac{1}{2}(|c| + |r| - ED(c, r)) \\
R_i &= \frac{LCS(c_i, r_i)}{|r_i|} \\
P_i &= \frac{LCS(c_i, r_i)}{|c_i|} \\
FS_i &= 2\frac{R_i \times P_i}{R_i + P_i}
\end{aligned}
$$

where r_i and c_i is the i-th reference and prediction,

B Full breakdown of experiments

A full breakdown of G and T can be found in Tab. 6 and Tab. 7, respectively. A full breakdown of I can be found in Tab. 8 and Tab. 9.

Abstract

We present LSTM-Shuttle, which applies human speed reading techniques to natural language processing tasks for accurate and efficient comprehension. In contrast to previous work, LSTM-Shuttle not only reads shuttling forward but also goes back. Shuttling forward enables high efficiency, and going backward gives the model a chance to recover lost information, ensuring better prediction. We evaluate LSTM-Shuttle on sentiment analysis, news classification, and cloze on IMDB, Rotten Tomatoes, AG, and Children's Book Test datasets. We show that LSTM-Shuttle predicts both better and more quickly. To demonstrate how LSTM-Shuttle actually behaves, we also analyze the shuttling operation and present a case study.

1 Introduction

Recently, recurrent neural networks (RNNs) and long short-term memory (LSTM) cells and gate recurrent unit (GRU) cells have achieved great success and are increasingly being applied in nature language processing tasks, e.g., part-of-speech (POS) tagging (Wang et al., 2015), named-entity recognition (Chiu and Nichols, 2015), sentiment analysis (Zhang et al., 2018), document classification (Kim, 2014; Le and Mikolov, 2014a), cloze (Srinivasan et al., 2018), machine translation (Bahdanau et al., 2015), dialogue modeling (Mei et al., 2017), document summarization (Allahyari et al., 2017), automatic knowledge extraction (Durme and Schubert, 2008), and question answering (Chen et al., 2017).

Those tasks all call for text comprehension techniques. To solve these tasks, the proposed models read all the text available. That is, models read every token or word of the text from beginning to end. However, for some classification tasks, it is not necessary to treat each individual word equally. Take, for example, sentiment analysis: sentences such as "this movie is amazing" or "too boring" are sufficient to judge a sentiment without reading the entire comment. In addition, the fact that texts are often written redundantly also motivates reading selectively, especially for certain NLP tasks.

In terms of human reading habits, although people tend to skim text when reading a newspaper or a novel, this does not significantly impair comprehension. Speed reading, a reading technique, is used to improve one's ability to read quickly. Work has been done on modeling skimming behavior along with the original sequence modeling RNN. LSTM-Jump (Yu et al., 2017) predicts how many words to skim based on the RNN hidden state. They show that neglecting some words in a document does not greatly harm prediction accuracy but does significantly accelerate the process. They also show that for certain tasks such as cloze, skimming even outperforms traditional methods. In addition, (Yu et al., 2018) use RNN hidden states to decide when to stop. If the RNN judges it has achieved sufficient comprehension of the context, it stops early and produce the answer directly.

However, strictly speakly, simply skimming and stopping early is not speed reading. For example, imagine that during a reading test, we first read the question and then the long article. We read quickly and skip some information. What do we do if we encounter text that we don't understand? We go back, read the previous text, and try to fill in the gaps in our understanding. For speed reading, going back – or "reading backward" – is likewise important as it helps us to recover lost information or correct misunderstandings, leading to better comprehension of long documents. In fact, reading backward increases rather than decreases reading speed: given the opportunity to go back to correct

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4439–4448
Brussels, Belgium, October 31 - November 4, 2018.

misunderstandings, we skim more words and thus read faster without reducing our comprehension.

In this paper, we propose LSTM-Shuttle, which teaches the RNN model to speed read by modeling both forward and backward reading behavior. We evaluate the proposed method on sentiment analysis, document classification, and cloze tasks. We use IMDB (L. et al., 2011) and Rotten Tomatoes (Pang and Lee, 2005) as sentiment analysis datasets, AG New (Shang et al., 2015) as a document classification dataset, and Facebook Children's Book Test (Hill et al., 2015) as a cloze dataset. The experiments show that the proposed method achieves better prediction performance and reads faster at the same time, in comparison with the LSTM baseline (Hochreiter and Schmidhuber, 1997) and LSTM-Jump. We also analyze the shuttling behavior under different settings, proving that reading forward and backward does help in reading.

2 Related Work

The proposed method is inspired mainly by LSTM-Jump (Yu et al., 2017), which predicts how many words should be neglected, accelerating the reading process using RNN. Both their work and ours is related to the idea of learning visual attention per (Mnih et al., 2015), where a recurrent model is used to decide which image part to watch seriatim. They train the model end-to-end using the REINFORCE algorithm (Williams, 1992) and sample from a continuous Gaussian distribution. The difference between their and our methods is that we sample from a discrete distribution to reflect the properties of text and image.

Many recent natural language processing applications have explored the idea of filtering irrelevant content. As in our work, instead of skimming some words, (Seo et al., 2018) consider all words but use a small RNN for irrelevant words and the original large RNN for relevant ones. (Campos et al., 2018) also attempt to dynamically control the RNN's computational costs, but they instead control the number of units to update at each time step. In our method, in contrast, we skim words, directly setting the amount of computation to be zero, which streamlines the reading process.

From another perspective, (Yu et al., 2018) attempt to model early stopping behavior, deciding whether the model can answer confidently based on the hidden states. This is very effective for tasks such as question answering. To ensure accuracy, (Shen et al., 2016) focuses on early stopping after multiple passes, and (Shen et al., 2016) also using reinforcement learning to attempt to learn to reason. Both early stopping and our method adequately take into account research on sufficient comprehension. While, early stopping is not fast enough for classification, we can do better with text shuttling.

3 Main Idea

In this section, we describe the proposed LSTM-Shuttle, first presenting its architecture. Then, we show that due to the nondifferentiability of the shuttle mechanism, we apply a policy gradient (Sutton et al., 1999) to train it end-to-end. Finally, we present the implementation details and the inference approach.

3.1 Overview

As Fig. 1 illustrates, LSTM-Shuttle is based on an LSTM recurrent neural network to which is added an additional fully connected layer to predict forward or backward steps after a softmax distribution.

Given a text which denoted as $x_1, x_2, \ldots, x_L$ or $x_{1:L}$, LSTM-Shuttle first reads a fixed number of words sequentially and outputs the hidden state. Then, based on the hidden state, LSTM-Shuttle computes the shuttle softmax distribution over the forward or backward steps on $[-K, K]$. Given a negative step value, LSTM-Shuttle goes back to correct misunderstandings, and with a positive step value, LSTM-Shuttle speed reads, skimming unimportant words. After shuttling, LSTM-Shuttle reads words sequentially and then proceeds to shuttle again, iteratively. This process continues until one of the following occurs:

- The shuttle softmax samples a 0
- The number of shuttles exceeds the predefined upper limit
- The model has arrived at the last word

After stopping, the last hidden state is used to predict the desired task. The post-processing depends on the task. For instance, for classification, the hidden state generates a softmax distribution over the target class, and for cloze, it is used to find the correlation between the question article and each candidate answer. The detailed settings of each task are described in Section 4.

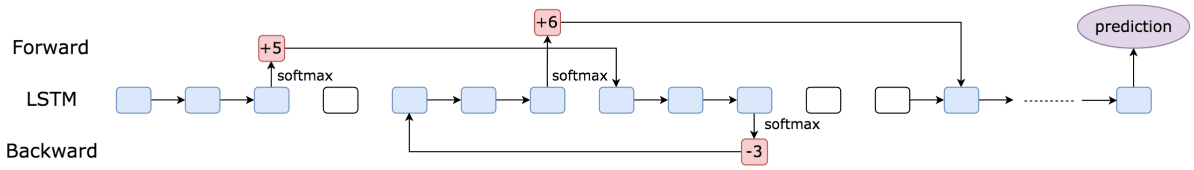

Figure 1: An overview of LSTM-Shuttle. In this example, we set the number of words read sequentially before shuttling $R = 2$, and the maximum shuttle size $K = 10$. The shuttle action is sampled from $[-K, K]$. After reading the entire text, the last hidden state is used to answer prediction. Note that when going backward, the shuttle step is counted before reading sequentially.

As with LSTM-Jump (Yu et al., 2017), we use the following notation:

- N: total number of allowed shuttles
- R: number of words to read before shuttling
- K: maximum shuttle size

Whereas K is a fixed hyperparameter during training, N and R can vary between training and testing. Note that as LSTM-Shuttle proceeds not only forwards but also backwards, the output shuttle size is $2K + 1$: K forward, K backward, and 1 for stopping. In contrast to LSTM-Jump (Yu et al., 2017), when going back, our shuttle step is counted before reading sequentially. In the example in Fig. 1, we set $R = 2$ and $K = 10$.

3.2 Training via Policy Gradient

In LSTM-Shuttle, there are two main parameter sets to compute: θ_R and θ_U. θ_R includes the RNN along with the output prediction parameters, and θ_U represents the parameters of the shuttle mechanism.

We compute θ_R via backpropagation directly by minimizing $J_1(\theta_R)$, the cross entropy loss, which is differentiable over θ_R and is the target objective function of the classification task.

However, this does not work for θ_U. Since cross entropy isn't differentiable over θ_U, we cannot use backpropagation to compute θ_U. Therefore, we recast it as a reinforcement learning problem and apply a policy gradient to train it: we seek to maximize the reward function over θ_U via the following formulation.

We first denote $s_{1:T}$ as the shuttle action sequence when training with text $x_{1:L}$. Assuming that h_i is the hidden state of LSTM before the i-th shuttle s_i, it is a function of $s_{i:i-1}$ and thus can be denoted as $h_i(s_{1:i-1})$. Also, the shuttle action can be sampled from the distribution of $p(s_t|h_i(s_{1:t-1}); \theta_U)$, which is determined by the shuttle softmax. We have the final prediction after LSTM-Shuttle processes text $x_{1:L}$ under the current θ_U shuttle strategy. As with (Yu et al., 2017), we set the reward to 1 if the prediction is correct, and -1 otherwise.

$$R = \begin{cases} 1 & \text{if predicted correctly} \\ -1 & \text{otherwise} \end{cases}$$

The objective function of θ_U we seek to maximize is the expected reward under the distribution over θ_U shuttle strategy, i.e.,

$$J_2(\theta_U) = \mathbb{E}_{p(s_{1:T};\theta_U)}[R], \tag{1}$$

where $p(s_{1:T;\theta_U}) = \prod_i p(s_{1:i}|h_i(s_{1:i-1}; \theta_U)$.

To maximize the objective function, we must compute the gradient of Eq. (1). We compute an approximate gradient by running M examples with the REINFORCE algorithm (Williams, 1992):

$$\nabla_{\theta_U} J_2(\theta_U) = \sum_{i=1}^{T} \mathbb{E}_{p(s_{1:T;\theta_U})}[\nabla_{\theta_U} \log p(s_{1:i}|h_i; \theta_U) R]$$
$$\approx \frac{1}{M} \sum_{m=1}^{M} \sum_{i=1}^{T} [\nabla_{\theta_U} \log p(s^m_{1:i}|h^m_i; \theta_U) R^m],$$

where the superscript m denotes that it belongs to the m-th example. Eventually, the term $\nabla_{\theta_U} \log p(s_{1:i}|h_i; \theta_U)$ is computed by backpropagation as usual.

Though the approximation of $\nabla_{\theta_U} J_2(\theta_U)$ is unbiased, it may have very high variance (Williams, 1992). One common way to reduce this variance is to subtract a baseline value b from the reward function R, transforming the approximated gradient into

$$\nabla_{\theta_U} J_2(\theta_U) \approx$$
$$\frac{1}{M} \sum_{m=1}^{M} \sum_{i=1}^{T} [\nabla_{\theta_U} \log p(s^m_{1:i}|h^m_i; \theta_U) R^m - b^m_i].$$

Here we apply same bias strategy as (Lewis et al., 2017), treating the bias value b as the average reward from then until now.

The final objective function for LSTM-Shuttle to minimize is

$$J(\theta_R, \theta_U) = J_1(\theta_R) - J_2(\theta_U),$$

which is entirely differentiable and can be computed by standard backpropagation.

3.3 Implementation detail and Inference

To simulate negative step selection, which corresponds to reading backward in the shuttle action, we set the shuttle output dimension to $[0, 2K]$, where 0 maps to $-K$, 1 maps to $-(K-1)$, $\ldots$, K maps to $0, \ldots, 2K-1$ maps to $+(K-1)$, and $2K$ maps to $+K$.

We used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 10^{-3} for all experiments. For a fair comparison with (Yu et al., 2017), the dropout rate between LSTM layers was set to 0.2 and the embedding dropout rate to 0.1. We implemented LSTM-Shuttle in PyTorch (Adam et al., 2017) on a GTX 1080Ti gpu.

During inference, we apply greedy sampling: we select the most probable shuttle step from the shuttle softmax distribution.

4 Experiments

In this section, we evaluate the proposed LSTM-Shuttle on three different tasks: sentiment analysis, news classification, and cloze on four different datasets. We use IMDB (L. et al., 2011) and Rotten Tomatoes (Pang and Lee, 2005) for sentiment analysis, AG (Shang et al., 2015) for news article classification, and Children's Book Test (Hill et al., 2015) for cloze. Table 1 contains statistics for the tasks and datasets in our experiments.

To show the improvement in not only accuracy but also efficiency, we compared LSTM-Shuttle with three baselines: vanilla LSTM (Hochreiter and Schmidhuber, 1997), LSTM-Jump (Yu et al., 2017), and bi-directional LSTM-Jump, as shown in Fig. 2. For a fair comparison, we trained LSTM-Shuttle with the same LSTM settings as LSTM-Jump. For example, for sentiment analysis on IMDB, LSTM-Jump was trained with R=20, K=40, and N=80; we trained LSTM-Shuttle with the same parameters. Vanilla LSTM is the traditional recurrent neural network using LSTM cells which reads the entire text and then outputs the prediction. LSTM-Jump has a skim mechanism which neglects some text. Bi-directional LSTM-Jump applies LSTM-Jump twice but starting from different directions, and concatenates the last hidden state for answer prediction. To shorten the presentation, for LSTM-Jump we selected only two results from the original paper directly on each dataset: one with the best accuracy and the other with the highest efficiency. This is to show the difference between reading in two directions and shuttling. The quantitative result of each dataset is shown in the following sections.

In addition to the quantitative results, we sought to investigate how the shuttle mechanism progresses in reality. We present the shuttle statistics for different K settings, and show that because of the backward mechanism which affords a chance to recover lost information, LSTM-Shuffle shuttles with larger steps, increasing the shuttle step size as it grows more and more confident in its prediction.

4.1 Sentiment Analysis on IMDB and Rotten Tomatoes

Sentiment analysis is a classic natural language processing task, in which we read an article and predict its latent sentiment as positive or negative. It is widely implied in many forms or questionnaires such as satisfaction surveys. Here we use IMDB (L. et al., 2011) and Rotten Tomatoes (Pang and Lee, 2005) as our sentiment analysis datasets.

4.1.1 IMDB Results

IMDB (L. et al., 2011), a well-known movie information website, also includes audience comments and their sentiments. It contains 25,000 training data and 25,000 testing data, where the average length is 241 words. Both baselines and LSTM-Shuttle used a single layer and 128 hidden units as LSTM cells. We used pre-trained word2vec embeddings (Le and Mikolov, 2014b) as initial word embeddings and trained it along with LSTM. For a comparison with the baselines, all models were trained under $R = 20$, $K = 40$, and $N = 5$. We also show the result of a larger shuttle step ($K = 75$) version of LSTM-Shuttle.

Table 2 shows the experimental results for IMDB, where the speedup ratio is compared with vanilla LSTM, conducted on a machine with a single GTX 1080Ti GPU. For bi-directional LSTM-Jump we used our own implementation, and the

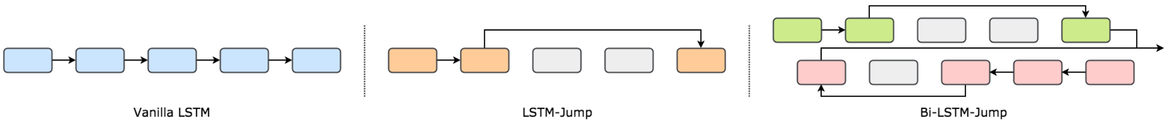

Figure 2: Baseline architectures. **Left:** Vanilla LSTM: reads entire text sequentially. **Middle:** LSTM-Jump: skims to neglect some words. **Right:** Bi-direction LSTM-Jump: skims in two directions, concatenates two latest hidden states.

LSTM-Shuttle	(50, **75**, 4)	89.7%*	2.27x	0.29
LSTM-Shuttle	(50, **75**, 2)	89.1%	2.45x*	0.21

Table 2: Sentiment analysis results on IMDB. * means the best accuracy or highest speedup for each method given the same setting of K.

"Backward" column in the table shows the frequency ratio of backward shuttles.

Under the same (R, K, N) setting, LSTM-Shuttle is a little slower than LSTM-Jump since the softmax size of K is larger, but the former yields better prediction. For bi-directional LSTM-Jump, since it applies LSTM-Jump twice, it predicts better than the original. However, we doubt whether it is worth sacrificing so much efficiency for such a small increase in prediction accuracy $(+0.2\%)$. Under the same (R, K, N), LSTM-Shuttle is more accurate and faster than bi-directional LSTM-Jump, even though $(80, 40, 8)$ is not in fact the best setting for LSTM-Shuttle. LSTM-Shuttle achieves the highest accuracy (89.9%) with 2.08× acceleration under $(60, 40, 6)$. Due to the shuttle mechanism that can go back, LSTM-Shuttle does not need to read many words before each shuttle, thus accelerating the overall reading process.

In general, the combination of (R, N) represents a trade-off between accuracy and efficiency. If we use a larger (R, N), the model reads more words and predicts better but more slowly. Otherwise, for a smaller (R, N), the model reads faster but yields predictions that are not as accurate. A similar tendency is found when it comes to the backward ratio. A smaller N means LSTM-Shuttle shuttles less often, so the model tends to read through as much as possible, making for a lower backward ratio. On the other hand, LSTM-Shuttle can shuttle many times so it is willing to go back to correct misunderstandings.

We also show the result for $K = 75$. With the larger shuttle step, fewer words are read before shuttling, which accelerates reading but has little impact on accuracy. LSTM-Shuttle achieves 89.7% with $2.27\times$ speedup under $(50, 75, 4)$ and 89.1% with $2.45\times$ times speedup under $(50, 75, 2)$: both settings yield both high accuracy and efficiency.

4.1.2 Rotten Tomatoes Results

The Rotten Tomatoes dataset (Pang and Lee, 2005) is to IMDB. We chose to use a two-layer LSTM and 256 hidden units, and again used the pre-trained word2vec embeddings (Le and Mikolov, 2014b). We trained all models under $R = 8$, $K = 10$, and $N = 3$.

The experimental results are shown in Table 3. LSTM-Shuttle achieves an accuracy of 79.5% with $1.55\times$ speedup; a higher efficiency version accelerates to $1.89\times$. These results demonstrate a similar trade-off tendency with different (R, N) combinations as those for IMDB. Since the average comment length in Rotten Tomatoes is short, we used lower shuttle times ($N = 2$) for better speed but also maintained high accuracy. Because

Method	(R, K, N)	Accuracy	Speedup	Backward
LSTM	-	79.1%	1x	-
LSTM-Jump	(7, 10, 4)	79.3%*	1.56x	-
LSTM-Jump	(9, 10, 2)	78.3%	1.94x*	-

LSTM-Shuttle	(40, 40, 6)	88.4%	0.82x	0.34
LSTM-Shuttle	(20, **80**, 4)	89.8%	**1.63x***	0.26
LSTM-Shuttle	(30, **80**, 4)	**90.1%***	1.29x	0.28

Table 4: News classification result on AG. * means the best accuracy or highest speedup for each method given the same setting of K.

of the shorter comments and lower shuttle times, LSTM-Shuttle prefers to shuttle over almost the entire text from the beginning, trying to see the last part of a comment, and then goes back to the middle part; thus the backward ratio is much higher.

We also show the results under a larger K ($K =$ 20). On Rotten Tomatoes, a larger shuttle step seems more suitable. LSTM-Shuttle achieves the best accuracy (79.8%) with 1.74× high efficiency. A setting with fewer shuttles further accelerates up to 1.97× while maintaining a high accuracy of 79.2%.

4.2 News Article Classification on AG dataset

News classification is a common application of document comprehension. Given a news article, the model must recognize which field it belongs to. Modern topic classification is applied on different target sources such as blog posts. We used AG (Shang et al., 2015) as news article classification dataset in our experiments.

4.2.1 Result on AG dataset

We used the subset constructed by (Shang et al., 2015) for classification at the character level. AG contains news covering four topics (World, Sports, Business, Sci/Tech), each of which includes 30,000 training and 1,900 testing documents. We used a single-layer LSTM with 64 hidden units. We trained the character embedding with 16 dimensions for 70 characters in total, per LSTM-Jump (Yu et al., 2017). We trained all models using $R =$ 30, $K =$ 40, and $N =$ 5.

As shown in Table 4, LSTM-Shuttle still yields improvement at the character level. For both LSTM-Jump and bidirectional LSTM-Jump, the speedup effect is not obvious because of the computational overhead of skim being larger than when processing the entire text directly. On the other hand, LSTM-Shuttle yields accurate predictions even when reading fewer characters before shuttling, and it clearly yields accelerated performance. We reach an accuracy of 90.1% with 1.34× speedup, both far from LSTM-Jump. Interestingly, $(20, 40, 5)$ reads fewer words than $(30, 40, 5)$, but the former predicts better. This may be due to the character-level nature of the task and because many characters actually mislead the model. This can be seen with LSTM-Jump as well. The backward ratio on the AG dataset is nearly to that of IMDB: almost three times forward with once backward.

We also show that a larger setting of K ($K =$ 80) yields further acceleration, even at the character level, achieving the highest (1.63×) speedup.

4.3 Cloze on Children's Book Test Name Entity dataset

For the cloze task, we must supply the missing words in an article. In the Children's Book Test (CBT) (Hill et al., 2015), the question includes a complete article and a query from which a specific word is deleted. The model must determine which of the ten candidate words is most suitable. In contrast to previous tasks, which have a fixed class type, CBT provides different candidate words for each question. Thus we cannot train it as with a normal classification problem. Inspired by (Chen et al., 2016), we formulate the task as

$$\text{softmax}(CWh_o) \in \mathbb{R}^{10}, \qquad (2)$$

where $C \in \mathbb{R}^{10\times d}$ is the word embedding matrix, h_o is the latest LSTM hidden state, and W is a trainable weight variable. The output of the above equation is taken as the index of the answer word. We train LSTM-Shuttle to maximize the distribution over a one-hot answer index. Therefore for

Method	(R, K, N)	Accuracy	Speedup	Backward
LSTM	-	45.3%	1x	-
LSTM-Jump	(1, 5, 5)	46.8%*	3.05x	-
LSTM-Jump	(1, 5, 1)	45.2%	**6.28x***	-
Bi-LSTM-Jump	(1, 5, 5)	47.0%*	2.64x	-
Bi-LSTM-Jump	(1, 5, 1)	45.3%	6.19x*	-
LSTM-Shuttle	(1, 5, 5)	**47.2%***	2.98x	0.31
LSTM-Shuttle	(1, 5, 1)	46.0%	6.16x*	0.18
LSTM-Shuttle	(1, **10**, 5)	47.1%*	2.91x	0.36
LSTM-Shuttle	(1, **10**, 1)	46.6%	6.13x*	0.27

Table 5: Cloze result on CBT-NE. * means the best accuracy or highest speedup for each method given the same setting of K.

different candidate words, we concatenate them as an embedding matrix, feed this into the above equation, and generate the prediction distribution. We used the named-entity (NE) part of CBT as the cloze dataset when evaluating LSTM-Shuttle.

4.3.1 Result on CBT-NE

CBT-NE includes 120,769 questions for training and 2,500 for testing. We trained all models using Eq. (2) with a two-layer LSTM and 256 hidden units. Pre-trained word2vec embeddings were again applied directly. We trained them under $R = 1$, $K = 5$, and $N = 5$ at the sentence level, which means that LSTM-Shuttle read one sentence and shuttled several sentences five times. Vanilla LSTM, LSTM-Jump, Bi-LSTM-Jump, and LSTM-Shuttle all read the query, but only vanilla LSTM read the entire question article. Others decided how to skim or shuttle.

The result is reported in Table 5. LSTM-Shuttle's best accuracy is 47.2% with 2.98× speedup, and the highest efficiency version achieved 46.0% accuracy with 6.16× speedup. Despite the modest acceleration effect, LSTM-Shuttle yields consistently better prediction accuracy with minimal drops in efficiency. Acceleration is only modest because the average number of article sentences was only 20, and it thus did not need to read many sentences ($R = 1$) before shuttling or shuttling so many times ($N = 5$). That is also why the backward ratio here is low in CBT-NE.

LSTM-Shuttle maintains accurate prediction and high efficiency under a larger K: 46.6% accuracy with 6.13× speedup. To demonstrate the proposed method, we offer a case study in Section 4.5.

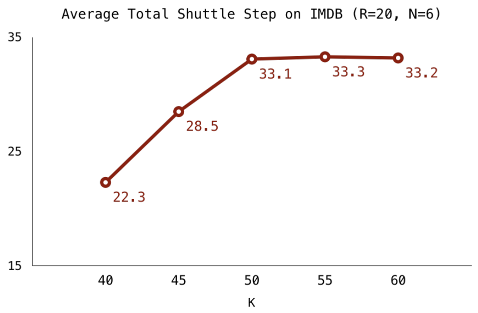

Figure 3: Average total shuttle steps

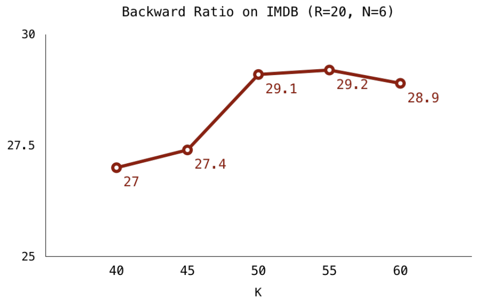

Figure 4: Backward ratio

4.4 Analysis of Shuttle Mechanism

Here we analyze how LSTM-Shuttle actually operates. We compute the total average shuttle steps and the average shuttle steps for each shuttle action under same $R = 20$ and $N = 6$ but different K on the IMDB datasets.

Fig. 3 shows the average total shuttle steps for different K, taking into consideration both forward and backward steps. For backward shuttling, we use the absolute value as its shuttle steps. For instance, shuttling -5 means it goes back 5 words, and the shuttle step is 5 indeed. We can see that a larger K, and thus a larger shuttle space, tends to shuttle larger steps, but also converges for large enough values of K. We see the same thing in the backward ratio. Fig. 4 shows the backward ratio

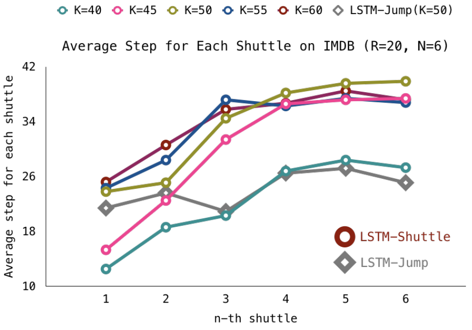

Figure 5: Average steps per shuttle

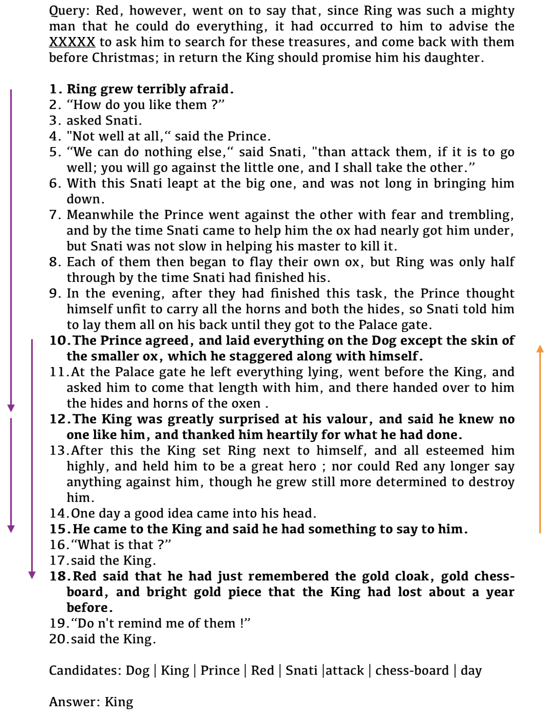


Query: Red, however, went on to say that, since Ring was such a mighty man that he could do everything, it had occurred to him to advise the XXXXX to ask him to search for these treasures, and come back with them before Christmas; in return the King should promise him his daughter.

1. **Ring grew terribly afraid.**
2. “How do you like them ?”
3. asked Snati.
4. "Not well at all,“ said the Prince.
5. “We can do nothing else,“ said Snati, "than attack them, if it is to go well; you will go against the little one, and I shall take the other.”
6. With this Snati leapt at the big one, and was not long in bringing him down.
7. Meanwhile the Prince went against the other with fear and trembling, and by the time Snati came to help him the ox had nearly got him under, but Snati was not slow in helping his master to kill it.
8. Each of them then began to flay their own ox, but Ring was only half through by the time Snati had finished his.
9. In the evening, after they had finished this task, the Prince thought himself unfit to carry all the horns and both the hides, so Snati told him to lay them all on his back until they got to the Palace gate.
10. **The Prince agreed, and laid everything on the Dog except the skin of the smaller ox, which he staggered along with himself.**
11. At the Palace gate he left everything lying, went before the King, and asked him to come that length with him, and there handed over to him the hides and horns of the oxen .
12. **The King was greatly surprised at his valour, and said he knew no one like him, and thanked him heartily for what he had done.**
13. After this the King set Ring next to himself, and all esteemed him highly, and held him to be a great hero ; nor could Red any longer say anything against him, though he grew still more determined to destroy him.
14. One day a good idea came into his head.
15. **He came to the King and said he had something to say to him.**
16. “What is that ?”
17. said the King.
18. **Red said that he had just remembered the gold cloak, gold chess-board, and bright gold piece that the King had lost about a year before.**
19. “Do n't remind me of them !”
20. said the King.

Candidates: Dog | King | Prince | Red | Snati |attack | chess-board | day

Answer: King

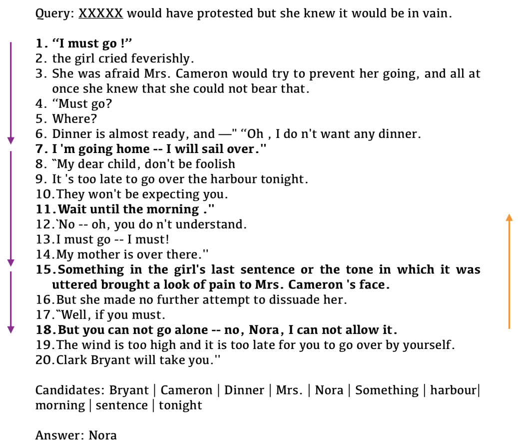
Figure 6: Example 1 for $R = 1$, $K = 15$, and $N = 4$, where read sentences are shown in bold

under different K. Since a larger K shuttles more both forward and backward, it has more chances to go back. Also, it converges when K is large enough.

In addition to the total average, we seek to understand how LSTM-Shuttle shuttles for each. As above, both forward and backward are taken into consideration and the absolute value is used for the backward steps. We show each shuttle record for a total of 6 shuttles under K between $[40, 50]$. As shown in Fig. 5, all settings of LSTM-Shuttle shuttle more steps after shuttling more times, but LSTM-Jump skims at an almost fixed frequency. Thus the model reads more words after more shuttles since it tends to read sequential words before each shuttle, in turn yielding better comprehension for the model. For LSTM-Shuttle, with its backward mechanism to recover lost information, it shuttles with larger and larger steps. However, for LSTM-Jump, as it cannot go back, it reads more carefully and maintains a constant skim step.

4.5 Case Study

Below, we show two examples of LSTM-Shuttle shuttling on the CBT-NE dataset. Example 1 in Fig. 6 illustrates a simple case. Based only on the query, “King should promise him his daughter”, the deleted word clearly should be “King”. LSTM-Shuttle shows more confidence providing the answer given only this query, so it shuttles with large steps to read the last part of the article, from sentence 1 to 12. Also, it goes back to confirm its prediction: from sentence 15 to 10. Example 2 in Fig. 7 is a more difficult task because the answer word “Nora” appears only once in the entire article. Thus LSTM-Shuttle must read more carefully. The shuttle steps are all smaller than 8 before discovering the answer in sentence 18, after which it goes back to see if it missed something. From these examples, we see that the shuttle mechanism is used in diverse manners for queries with different difficulties. For simple queries, LSTM-Shuttle shuttles in large steps, while for difficult queries, it shuttles more conservatively. In both cases we witness the ability to go back if necessary to make sure it understands correctly.



Query: XXXXX would have protested but she knew it would be in vain.

1. **“I must go !”**
2. the girl cried feverishly.
3. She was afraid Mrs. Cameron would try to prevent her going, and all at once she knew that she could not bear that.
4. “Must go?
5. Where?
6. Dinner is almost ready, and —" “Oh , I do n't want any dinner.
7. **I 'm going home -- I will sail over."**
8. ˝My dear child, don't be foolish
9. It 's too late to go over the harbour tonight.
10. They won't be expecting you.
11. **Wait until the morning ."**
12. `No -- oh, you do n't understand.
13. I must go -- I must!
14. My mother is over there.''
15. **Something in the girl's last sentence or the tone in which it was uttered brought a look of pain to Mrs. Cameron 's face.**
16. But she made no further attempt to dissuade her.
17. ˝Well, if you must.
18. **But you can not go alone -- no, Nora, I can not allow it.**
19. The wind is too high and it is too late for you to go over by yourself.
20. Clark Bryant will take you.''

Candidates: Bryant | Cameron | Dinner | Mrs. | Nora | Something | harbour| morning | sentence | tonight

Answer: Nora

Figure 7: Example 2 for $R = 1$, $K = 15$, and $N = 4$, where read sentences are shown in bold

5 Conclusion

We present LSTM-Shuttle to use human speed reading techniques for text comprehension. In addition to reading forward and skimming over text to accelerate, LSTM-Shuttle goes back to recover lost information or double-check its grasp of the text's meaning. We evaluate LSTM-Shuttle on sentiment analysis, news classification, and cloze on IMDB, Rotten Tomatoes, AG, and Children's Book Test datasets. We show that LSTM-Shuttle predicts better on all datasets with higher efficiency. We also analyze LSTM-Shuttle's behavior under different shuttle step restrictions, and provide case studies that reveal the specific shuttle operations; these show how the model comprehends the context to achieve specific goals.

Abstract

Self-attention networks have proven to be of profound value for its strength of capturing global dependencies. In this work, we propose to model localness for self-attention networks, which enhances the ability of capturing useful local context. We cast localness modeling as a learnable Gaussian bias, which indicates the central and scope of the local region to be paid more attention. The bias is then incorporated into the original attention distribution to form a revised distribution. To maintain the strength of capturing long distance dependencies and enhance the ability of capturing short-range dependencies, we only apply localness modeling to lower layers of self-attention networks. Quantitative and qualitative analyses on Chinese⇒English and English⇒German translation tasks demonstrate the effectiveness and universality of the proposed approach.

1 Introduction

Recently, a new simple architecture, the TRANSFORMER (Vaswani et al., 2017), that based solely on attention mechanisms has attracted increasing attention in machine translation community. Instead of using complex recurrent or convolutional neural networks, TRANSFORMER implements encoder and decoder as self-attention networks to draw global dependencies between input and output. By further parallel performing (multi-head) and stacking (multi-layer) attentive functions, TRANSFORMER has achieved state-of-the-art performance on various translation tasks (Shaw et al., 2018; Hassan et al., 2018).

One strong point of self-attention networks is the strength of capturing long-range dependencies by explicitly attending to all the signals. In this way, a representation is allowed to build a direct relation with another long-distance representation. Accordingly, it can serve as the role of RNN and CNN to capture both the short- and long-range relations among the representations.

Self-attention networks fully take into account all the signals with a weighted averaging operation. We argue that such operation disperses the distribution of attention, which results in overlooking the relation of neighboring signals. Recent works have shown that self-attention networks benefit from locality modeling. For example, Shaw et al. (2018) introduced relative position encoding to consider the relative distances between sequence elements, which produces substantial improvements on the translation task. Sperber et al. (2018) modeled the local information by restricting self-attention model to neighboring representations, which boosts performance on long-sequence acoustic modeling. Although not for self-attention, Luong et al. (2015) proposed a local attention model for translation task, which looks at only a subset of source words at a time. Inspired by these studies, we propose more flexible strategies for modeling localness for self-attention networks in this work.

Specifically, we cast the localness modeling as a learnable Gaussian bias, in which a central position (i.e. mean of the position) and a dynamic window (i.e. deviation of the distribution) are predicted with the intermediate representations in the self-attention network. Intuitively, the central position and the window respectively denote the center and the scope of the locality to be paid more attention. The learned Gaussian bias is then incorporated into the original attention distribution to form a revised distribution, which considers the expected local context.

Some researchers may doubt that self-attention networks augmented localness modeling focuses

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4449–4458
Brussels, Belgium, October 31 - November 4, 2018.

leanings toward local context, which weakens its strength of capturing long-range dependencies. Our extensive analyses can dispel such doubt by showing that the potential problem is compensated by multi-layer multi-head self-attention networks. First, multi-head attention attends to local regions centered at different positions, which can constitute the complete information of an input sequence. Second, we found that self-attention models tend to capture short-range dependencies among neighboring words in lower layers, while capture long-range dependencies beyond phrase boundaries in higher layers. Accordingly, we only apply localness modeling to lower layers.

We conducted experiments on two widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation tasks. The proposed approach consistently improves translation performance over the strong TRANSFORMER baseline, demonstrating its effectiveness and universality. In addition, our approach is complementary to the relative position encoding (Shaw et al., 2018), and combining them can further improve translation performance.

2 Background

Attention model has recently been a basic module of most deep learning models. The mechanism allows to dynamically select related representations as needed. In particular, it is very useful for generation models such as machine translation (Bahdanau et al., 2015; Luong et al., 2015; Yang et al., 2017) and image captioning (Xu et al., 2015).

2.1 Self-Attention Model

Recently, self-attention networks (Vaswani et al., 2017; Shaw et al., 2018; Shen et al., 2018a) have attracted increasing attention due to their flexibility in parallel computation and dependency modeling. Self-attention networks calculate attention weights between each pair of tokens in a single sequence, thus can capture long-range dependency more directly than their RNN counterpart.

Formally, given an input sequence $\mathbf{x} = \{x_1, \ldots, x_I\}$, each hidden state in the l-th layer is constructed by attending to the states in the $(l-1)$-th layer.[1] Specifically, the $(l-1)$-th layer $H^{l-1} \in \mathbb{R}^{I\times d}$ is first transformed into the queries $Q \in \mathbb{R}^{I\times d}$, the keys $K \in \mathbb{R}^{I\times d}$, and the values $V \in \mathbb{R}^{I\times d}$ with three separate weight matrices. The l-th layer is calculated as:

$$H^l = \textsc{Att}(Q,K)\,V, \tag{1}$$

where $\textsc{Att}(\cdot)$ is a dot-product attention model, defined as:

$$\textsc{Att}(Q,K) = softmax(energy) \tag{2}$$

$$energy = \frac{QK^T}{\sqrt{d}}, \tag{3}$$

where $\sqrt{d}$ is the scaling factor with d being the dimensionality of layer states.

2.2 Motivation

The self-attention network models the global dependencies without regard to their distances, by directly attending to all the positions in an input sequence (i.e. Equation 3). We argue that self-attention can be further improved by taking into account the local context. However, since the conventional self-attention models consider all of the words in a sequence, the weighted averaging inhibits the relation among the neighboring words.

From a linguistic intuition, when a word x_i is aligned to another word x_j, we also expect x_i to align mainly to the neighboring words of x_j, so as to capture the phrasal patterns that contain useful local context information. Take Figure 1 as an example, if "*Bush*" is aligned to "*held*" with high probability, we expect the self-attention model to pay more attention to the neighboring words "*a talk*". Consequently, the model is guided to capture the phrase "*held a talk*".

3 Localness Modeling

Figure 1 shows an example. We first learn a Gaussian bias, which is centered around the word "*talk*" (it is not necessary to be consistent with the original attention distribution), with a window size being 2 (in practice, it is a float number in our model). The distribution of attention is then regularized with the learned Gaussian bias to produce the final distribution, which pays more attention to the local context around the word "*talk*".

3.1 Localness Modeling as a Gaussian Bias

Specifically, a Gaussian bias G is placed to mask the logit similarity $energy$ in Equation 2, namely:

$$\textsc{Att}(Q,K) = softmax(energy + G). \tag{4}$$

The first term is the original dot product self-attention model. $G \in \mathbb{R}^{I\times I}$ is a favor alignment

---

[1] The first layer is the word embedding layer.

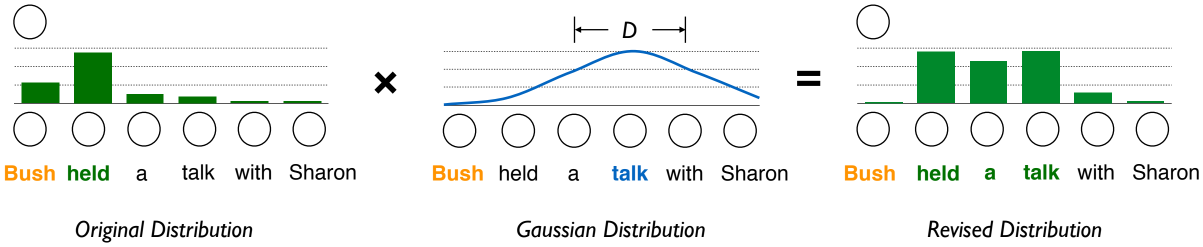

Figure 1: Illustration of the proposed approach. In this example, window size of 2 is used ($D = 2$).

position matrix (I denotes the sequence length). The element $G_{i,j} \in [0, -\infty)$ measures the tightness between the word x_j and the predicted central position P_i:

$$G_{i,j} = -\frac{(j - P_i)^2}{2{\sigma_i}^2}, \tag{5}$$

where σ_i denotes the standard deviation which is empirically set as $\sigma_i = \frac{D_i}{2}$, and D_i is a window size. Note that, due to the exponential operation in $softmax$ function, adding the logit similarity $energy$ with a bias $\in [0, -\infty)$ approximates to multiplying the attention distribution by a weight $\in [1, 0)$. The position and window size can be calculated as:

$$\begin{bmatrix} P_i \\ D_i \end{bmatrix} = I \cdot \text{sigmoid}(\begin{bmatrix} p_i \\ z_i \end{bmatrix}). \tag{6}$$

The scalar factor I is used to regulate P_i and D_i to real value numbers between 0 and the length of input sequence. The predictions are conditioned on two scalar p_i and z_i respectively.

3.2 Central Position Prediction

Since the prediction of each central position depends on its corresponding query vector,[2] we simply apply a feed-forward network to transform Q_i into a positional hidden state, which is then mapped into the scalar p_i by a linear projection $U_p \in \mathbb{R}^d$, namely:

$$p_i = {U_p}^T \tanh(W_p Q_i), \tag{7}$$

where $W_p \in \mathbb{R}^{d \times d}$ is the model parameter.

3.3 Window Size Prediction

Several alternative strategies are proposed to select the window size. Except a non-parametric approach, the other two define parametric windows. Among the parametric methods, the first strategy assigns a unified window size to all the hidden states in a layer, so as to consider the context of the sequence, while the second one calculates a distinct window size for each hidden state.

Fixed-Window A simple choice is to use a predefined window size D, which is a constant number throughout the whole training and testing process. In this study, following the common practice (Luong et al., 2015), D is set to 10.

Layer-Specific Window Furthermore, an interpretable way to select the window size is to account for the context of the sequence by summarizing the information from all the representations in a layer. In this study, we assign the mean of keys $\overline{\mathbf{K}}$ to represent the semantic context. Thus, the unified scalar z of a layer is defined as:

$$z = U_d^T \tanh(W_d \overline{\mathbf{K}}), \tag{8}$$

where $W_d \in \mathbb{R}^{d \times d}$ and $U_d \in \mathbb{R}^d$ are learnable parameters.

Query-Specific Window The last strategy provides a more flexible manner to differentiate the scope by conditioning on each query. Similar to the prediction of the central position (Equation 7), the query-specific window can be formally expressed as:

$$z_i = {U_d}^T \tanh(W_p Q_i). \tag{9}$$

Here, $U_d \in \mathbb{R}^d$ is a trainable linear projection. Note that, Equations 7 and 9 share same parameter W_p but use different U_p and U_d. The intuition behind this design is that the central position and window size interdependently locate the local scope, hence condition on the same hidden state. The distinct linear projections U_p and U_d are sufficient in distinguishing the two scalars, resulting in a smaller parameter size and faster computational speed than that of the layer-specific model.

---

[2] For the input of feed-forward network, we also tried an additive term to consider the weighted context O_i (Equation 1), namely: $\tanh(W_p Q_i + W_o O_i)$. Our experimental results showed that there is no progressive improvement.

3.4 Incorporating into TRANSFORMER

We evaluate our model on the advanced TRANSFORMER model (Vaswani et al., 2017), which builds an encoder-decoder framework merely using attention networks. Both the encoder and decoder are composed of a stack of $L = 6$ layers, each of which has two sub-layers. The first is a multi-head self-attention layer, and the second is a position-wise fully connected feed-forward layer. In this section, we describe how to apply our approach to TRANSFORMER by adapting to *multi-head* and *multi-layer* self-attention networks.

Adapting to Multi-Head Self-Attention Instead of performing a single attention function, the multi-head mechanism employs M separate attention models with distinct parameters to jointly attend to the information from different representation subspaces at different positions. Accordingly, we assign a distinct Gaussian bias to each attention head, and rewrite Equation 6 as:

$$\begin{bmatrix} P_i^m \\ D_i^m \end{bmatrix} = I \cdot \text{sigmoid}(\begin{bmatrix} p_i^m \\ z_i^m \end{bmatrix}), \qquad (10)$$

where p_i^m and z_i^m are trained with distinct parameters to predict the central position and window size for the m-th attention head.

We argue that multi-head self-attention may benefit more from localness modeling. Multi-head attention captures different features by attending to different positions, which complements the localness modeling that may potentially ignore the global information. Experimental results in Table 5 confirm our hypothesis by showing that localness modeling achieves more significant improvement when working with multi-head attention than its single-head counterpart.

Adapting to Multi-Layer Self-Attention Recent work shows that different layers capture different types of features. Anastasopoulos and Chiang (2018) indicated that higher-level layers are more representative than lower-level layers, while Peters et al. (2018) showed that higher-level layers capture context-dependent aspects of word meaning while lower-level layers model aspects of syntax. One question naturally arises: *is it necessary to model localness for all layers?*

In this work, we investigate which levels of layers benefit most from the localness modeling. In addition, we visualize the Gaussian biases across layers, to better understand the behaviors of different attentive layers.

4 Experiments

4.1 Setup

To compare with the results reported by previous work (Gehring et al., 2017; Vaswani et al., 2017; Hassan et al., 2018), we conducted experiments on both Chinese⇒English (Zh⇒En) and English⇒German (En⇒De) translation tasks. For the Zh⇒En task, the models were trained using all of the available parallel corpus from WMT17 dataset with maximum length limited to 50, consisting of about 20.62 million sentence pairs. We used newsdev2017 as the development set and newstest2017 as the test set. For the En⇒De task, we trained on the widely-used WMT14 dataset consisting of about 4.56 million sentence pairs. The models were validated on newstest2013 and examined on newstest2014. The Chinese sentences were segmented by the word segmentation toolkit *Jieba,*[3] and the English and German sentences were tokenized using the scripts provided in Moses. Then, all tokenized sentences were processed by byte-pair encoding (BPE) to alleviate the Out-of-Vocabulary problem (Sennrich et al., 2016) with 32K merge operations for both language pairs. The 4-gram NIST BLEU score (Papineni et al., 2002) is used as the evaluation metric.

We evaluated the proposed approaches on advanced TRANSFORMER model (Vaswani et al., 2017), and implemented on top of an open-source toolkit – THUMT[4] (Zhang et al., 2017). We followed Vaswani et al. (2017) to set the configurations and reproduced their reported results on the En⇒De task. We tested both the *Base* and *Big* models, which differ at the layer size (512 vs. 1024) and the number of attention heads (8 vs. 16). All the models were trained on eight NVIDIA P40 GPUs, each of which is allocated a batch of 4096 tokens. In consideration of the computation cost, we studied the variations of the *Base* model on Zh⇒En task, and evaluated the overall performance with the *Big* model on both Zh⇒En and En⇒De translation tasks.

4.2 Ablation Study

In the first series of experiments, we evaluated the impact of different components on the Zh⇒En validation set using the TRANSFORMER-BASE. First, we investigated the effect of different strategies to predict the localness window. Then, we

Model	Speed	Dev	△
Baseline	1.20	22.59	-
Fixed	1.14	23.07	+ 0.48
Layer-Spec.	1.07	23.13	+ 0.54
Query-Spec.	1.11	23.13	+ 0.54

Table 1: Evaluation of various window prediction strategies for localness modeling, which is only applied to encoder-side self-attention network. "Speed" denotes training speed measured in steps per second.

examined whether it is necessary to apply localness modeling to all the layers. Finally, given that TRANSFORMER consists of encoder and decoder side self-attention as well as encoder-decoder attention networks, we checked which types of attention networks benefit most from the localness modeling. To eliminate the influence of control variables, we conducted the first two ablation studies on encoder-side self-attention networks only.

Window Prediction Strategies As shown in Table 1, all the proposed window prediction strategies consistently improve the model performance over the baseline, validating the importance of localness modeling in self-attention networks. Among them, layer-specific and query-specific window outperform[5] their fixed counterpart, showing the benefit that flexible mechanism is able to capture varying local context according to layer and query information. Moreover, the flexible strategy does not reply on the handcrafted parameters (e.g. the pre-defined window size), which makes model robustly applicable to other language pairs and NLP tasks. Considering the training speed, we use the query-specific prediction mechanism as the default setting in subsequent experiments.

Layers to be Applied In this experiment, we investigated the question of which layers should be applied with the localness modeling. Recent works show that different layers tend to capture different features, thus there may have different needs for the local context. We applied localness modeling to different combinations of layers, as shown in Table 2. Clearly, modeling the localness for part of the layers consistently outperforms all layers in terms of the training speed and translation quality, which again validates our claim.

#	Layers	Speed	Dev	△
1	[1-6]	1.11	23.13	-
2	[1-1]	1.18	23.20	+ 0.07
3	[1-2]	1.17	23.23	+ 0.10
4	[1-3]	1.15	23.29	+ 0.16
5	[1-4]	1.14	23.26	+ 0.13
6	[4-6]	1.15	23.22	+ 0.09

Table 2: Evaluation of different layers in the encoder, which are implemented as self-attention with query-specific localness modeling.

Enc	Dec	Enc-Dec	Speed	Dev
✓	×	×	1.15	23.29
✓	✓	×	1.10	23.27
✓	×	✓	1.08	23.33
✓	✓	✓	1.02	23.19

Table 3: Effect of localness modeling on different types of attention networks. "Enc" and "Dec" denote the encoder and decoder side self-attention networks respectively, while "Enc-Dec" represents the encoder-decoder attention network.

Interestingly, the performance generally goes up with the increase of layers from bottom to top (Rows 2-4), while the trend does not hold when reaching the 4th-layer (Row 5). In addition, the lower three layers benefit more from the localness modeling than that of the higher three layers (Rows 4 and 6). These results reveal that lower-level layers benefit more from the local context. Accordingly, we only model the localness in the lower three layers in the following experiments.

Attention Networks to be Applied Table 3 lists the results of localness modeling on different types of attention networks. As observed, modeling localness for decoder-side self-attention and encoder-decoder attention networks only marginally improves or even harms the translation quality. We attribute the marginal improvement of the encoder-decoder attention network to the fact that it exploits the top-layer of encoder representations, which already embeds useful local context. Concerning decoder-side self-attention network, Zhang et al. (2018) pointed out

---

[5] Although the differences are not always significant, the flexible strategy consistently outperforms its fixed counterpart across language pairs. For example, the query-specific strategy improves performance over the fixed-window model by +0.07 and +0.23 BLEU points on Zh-En and En-De validation sets, respectively.

Table 4: Comparing with the existing NMT systems on WMT17 Zh⇒En and WMT14 En⇒De test sets. "# Para." denotes the trainable parameter size of each model (M = million). "$\uparrow$ / $\Uparrow$": significant over the conventional self-attention counterpart ($p < 0.05/0.01$), tested by bootstrap resampling (Koehn, 2004).

that it tends to only focus on its nearby representation, which poses difficulties to modeling localness on the decoder side. In the main experiments, we only applied localness modeling to the lower three layers of the encoder, which employs a query-specific window prediction strategy.

4.3 Main Results

In this section, we evaluated the proposed approach on both WMT17 Zh⇒En and WMT14 En⇒De translation tasks, as listed in Table 4. Our baseline models, both Transformer-Base and Transformer-Big, outperform the reported results on the same data, which we believe make the evaluation convincing. As seen, modeling localness ("Localness") consistently achieves improvement across language pairs and model variations, demonstrating the efficiency and universality of the proposed approach.

We also re-implemented the relative position encoding ("Rel_Pos") that recently proposed by Shaw et al. (2018), which considers the relative distances between sequence elements. Both Shaw et al. (2018) and our work have shown that explicitly modeling locality for self-attention networks can improve the model performance. This indicates that it is necessary to enhance the locality modeling for Transformer. Besides, our approach is complementary to theirs, and combining them is able to further improve the translation performance. We attribute this to the fact that the two models modeling localness from two different aspects: First, the position embeddings are the same across different positions (if the absolute positions or relative positions are the same) and training examples, our model assigns a distinct localness bias to each position from layer to layer. Second, contrast to position encoding which learns the locality through the positional information in embeddings, our model directly revises the attention distribution to focus on a local space.

5 Analysis

We conducted extensive analyses to better understand our model in terms of its compatibility with multi-head and multi-layer attention networks, as well as building the ability of capturing phrasal patterns. All the results are reported on Zh⇒En development set with Transformer-Base, unless otherwise stated.

5.1 Compatibility with Multi-Head Attention

In this section, we investigated whether multi-head attention and localness modeling are compatible from two perspectives: (1) whether multi-head attention benefits more from the localness modeling than its single-head counterpart; and (2) how does multi-head attention work together with localness modeling?

Model	1-Head		8-Head	
	Dev	△	Dev	△
BASE	22.05	-	22.59	-
OURS	22.18	+ 0.13	23.29	+ 0.70

Table 5: Evaluation of localness modeling on top of single and multiple attention heads.

Multi-Head vs. Single-Head The single-head attention and multi-head attention differ at: the former uses a single 512-dimension attention head while the latter uses eight 64-dimension heads. The results in Table 5 confirm our claim by showing that multi-head attention indeed benefits more from our model than the single-head model (+0.70 vs. +0.13). It should be noted that our model marginally improves the performance under single-head setting. One possible reason is that our model focuses more on local context thus may ignore global information, which cannot be complemented by the single-head attention.

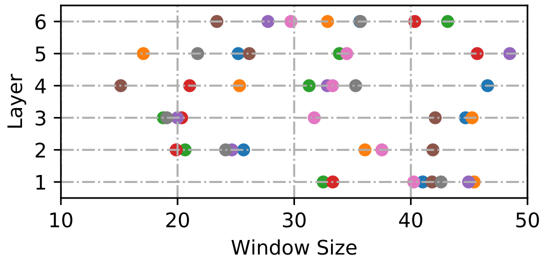

Figure 2: Instructions of the learned window size by head-specific parametric model, where colors distinguish the heads.

Can Multi-Head Separate Locality? To simplistically visualize how heads cooperate in modeling localness, we propose an additional parametric model which is assigned a learnable but unified window size for each head, namely **head-specific**. As a result, the window size D^m of the m-th head is calculated as:

$$D^m = N \cdot \text{sigmoid}(z^m), \qquad (11)$$

where the scalar z^m is a trainable parameter, $N = 50$ denotes a pre-defined constant number.

Figure 2 visualizes the distribution of the learned window size of each head, verifying that multi-head attention is able to capture diverse information by selecting suitable window sizes for different heads. For example, in the middle-level layers, heads are assigned to consider both the global and local information by regulating the different window sizes. One interesting finding is that the distributions of window size are not exactly same in different layers, which is explored in more details in the next section.

5.2 Analysis on Multi-Layer Attention

In this section, we try to answer how does each layer learn the localness. We first investigated how the window size varies across layers. Then we checked the specific behavior of the first word embedding layer, which is inconsistent with the trend of other layers.

The Higher Layer, The Larger Scope Shi et al. (2016) and Vaswani et al. (2017) have shown that different layers have the abilities to distinguish and capture diverse syntactic context (e.g. the dependents between words). Figure 3 shows the distribution of local scopes predicted by each layer. Except the first layer, the higher layers are more likely to pay attention to larger scopes, indicating that self-attention models tend to capture short-term dependencies among neighboring words in lower layers, while capture long-range dependencies beyond phrase boundaries in higher layers.

The Special First Layer Inconsistent with the intuition which the lower layers may focus on local information, in common, the first layer is assigned with large scopes of local context. The same phenomenon has also occurred for head-specific model (Figure 2). Since the first layer represents word embeddings that are deficient in context, we argue that the self-attention model at first layer has to encode the representations with global context. In addition, experimental results in Table 2 (Row 2) show that despite its large local size, modeling localness at the first layer is still valid.

5.3 Analysis on Phrasal Pattern

As aforementioned, one intuition of our approach is to capture useful phrase patterns. To evaluate the accuracy of phrase translations, we calculate the improvement of the proposed approaches over multiple N-grams, as shown in Figure 4. Although our models underperform the baseline on unigram translations, they consistently outperform the baseline on larger granularities, indicating that modeling locality can raise the ability of

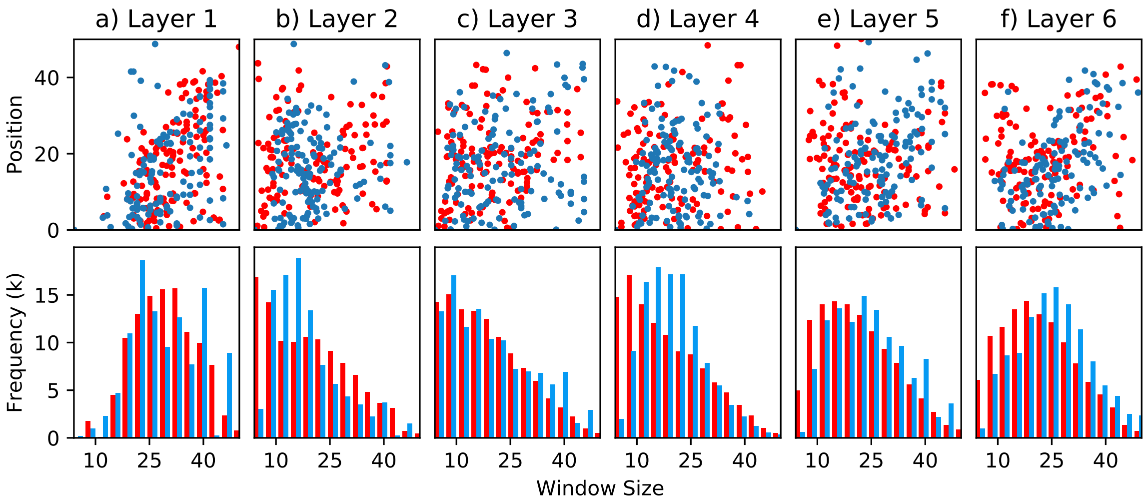

Figure 3: Distribution of the local scopes learned by each attentive layer. The upper figures illustrate the distribution of the predicted pairs of central position (Y-axis) and its correspond window size (X-axis) in each layer, the samples are randomly selected from the development set. The lower figures show the distribution of the window size in each layer. Blue color represents the layer-specific parametric approach, while the query-specific parametric method is indicated in red.

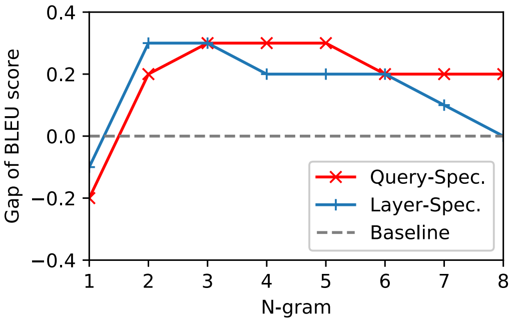

Figure 4: Performance improvement according to N-gram. Y-axis denotes the gap of BLEU score between our model and baseline.

self-attention model on capturing the phrasal information. Concerning the two variations, query-specific localness modeling surpasses its layer-specific counterpart on large phrases (i.e. 4-grams to 8-grams). We attribute this to the more modeling flexibility of query-specific strategy to differentiate the scope by conditioning on each query.

6 Related Work

A successful extension of neural language model is attention mechanism, which can directly capture long-distance dependencies by attending to previously generated words. Daniluk et al. (2017) proposed a *key-value-predict* attention to separate the key addressing, value reading, and word predicting functions explicitly. Im and Cho (2017) and Sperber et al. (2018) adopted self-attention networks for acoustic modeling and natural language inference tasks, respectively.

Vaswani et al. (2017) applied the idea of self-attention to neural machine translation. Shen et al. (2018a) and Shen et al. (2018b) proposed to improve the self-attention model with directional masks and multi-dimensional features. Although the standard self-attention model can give more bias toward localness,[6] several studies show that explicitly modeling localness for self-attention model can further improve performance. For example, Sperber et al. (2018) showed that restricting the self-attention model on the neighboring representations performs better for longer sequences in acoustic modeling and natural language inference tasks. Closely related to this work, Shaw et al. (2018) introduced relative position encoding to consider the relative distances between sequence elements. While they modeled localness from *static position embedding*, we improve locality modeling from *dynamically revising attention distribution*. Experimental results show

---

[6] As pointed out by one reviewer, in the original self-attention model, there are some considerations about given more bias toward the localness. For example, base on the definition of the positional embeddings, the adjacent words will have more similar positional embeddings compared with more further words. After summing word embeddings and corresponding positional embeddings together, the model would prefer the local words.

that the two models are complementary to each other, and combining them can further improve performance.

Several researches have shown that explicitly modeling phrases is useful for neural machine translation (Wang et al., 2017; Huang et al., 2018). Our results confirm these findings. Concerning attention models, Luong et al. (2015) proposed a modification to look at only a subset of input words at a time. This can be regarded as a "hard" variation of our fixed-window strategy. In this study, we propose more flexible strategies for placing and zooming the local scope, which yield better results than the fixed scope.

7 Conclusion

In this work, we enhanced the ability of capturing local context for self-attention networks with a learnable Gaussian bias. We proposed several strategies to learn the scope of the local context, and found that a query-specific mechanism yielded the best result due to its more modeling flexibility. Experimental results on widely-used English⇒German and Chinese⇒English translation tasks demonstrate the effectiveness and universality of the proposed approach. By visualizing the scopes of the learned Gaussian biases, we found that the higher the layer, the larger scope the bias, which is consistent with the findings in previous work (Shi et al., 2016; Peters et al., 2018).

As our approach is not limited to specific tasks, it is interesting to validate our model in other tasks, such as reading comprehension, language inference, and stance classification (Xu et al., 2018). Another promising direction is to design more powerful localness modeling techniques, such as incorporating linguistic knowledge (e.g. phrases and syntactic categories). It is also interesting to combine with other techniques (Shaw et al., 2018; Shen et al., 2018a; Dou et al., 2018; Li et al., 2018) to further improve the performance of Transformer.

Abstract

We introduce a novel type of text representation that preserves the 2D layout of a document. This is achieved by encoding each document page as a two-dimensional grid of characters. Based on this representation, we present a generic document understanding pipeline for structured documents. This pipeline makes use of a fully convolutional encoder-decoder network that predicts a segmentation mask and bounding boxes. We demonstrate its capabilities on an information extraction task from invoices and show that it significantly outperforms approaches based on sequential text or document images.

1 Introduction

Textual information is often represented through structured documents which have an inherent 2D structure. This is even more so the case with the advent of new types of media and communications such as presentations, websites, blogs and formatted notebooks. In such documents, the layout, positioning, and sizing might be crucial to understand its semantic content and provide a strong guidance to the human perception.

NLP addresses the task of processing and understanding natural language texts through subtasks like language modeling, classification, information extraction, summarization, translation, and question answering among others. NLP methods typically operate on serialized text, which is a 1D sequence of characters. Such methods have been proven very successful for various tasks on unformatted text (e.g. books, reviews, news articles, short text snippets). However, when processing structured and formatted documents in which the relation between words is impacted not only by the sequential order, but also by the document layout, NLP can result in significant shortcomings.

Computer vision algorithms, on the other hand, are designed to exploit 2D information in the visual domain. Images are commonly processed with convolutional neural networks (LeCun et al., 1998; Krizhevsky et al., 2012; Ren et al., 2015b; Pinheiro et al., 2016) (or likes) that preserve and exploit the 2D correlation between neighboring pixels. While it is feasible to convert structured documents into images and then apply computer vision algorithms, this approach is not optimal for understanding their semantics as it is driven mostly by the visual content and not by the textual content. As a result, a machine learning model would first need to extract the text from the image followed by learning the semantics. This purely visual approach requires a more complex model and significantly larger training data compared to text-based approaches.

We propose a novel paradigm for processing and understanding structured documents. Instead of serializing a document into a 1D text, the proposed method, named *chargrid*, preserves the spatial structure of the document by representing it as a sparse 2D grid of characters. We then formulate the document understanding task as instance-level semantic segmentation on *chargrid*. More precisely, the model predicts a segmentation mask with pixel-level labels and object bounding boxes to group multiple instances of the same class. We apply the chargrid paradigm on an information extraction task from invoices and demonstrate that this method is superior to both, state-of-the-art NLP algorithms as well as computer vision algorithms.

The rest of the document is organized in three parts: we first introduce the *chargrid* paradigm; we then describe a specific application of information extraction from documents; finally, we present experimental results and conclusion.

2 Related Work

NLP focuses on understanding natural language text through tasks like classification (Kim, 2014), translation (Bahdanau et al., 2014), summarization (Rush et al., 2015), and named entity recognition (Lample et al., 2016). Such methods expect unformatted text as input and, therefore, do not assume any intrinsic 2D structure.

Document Analysis, on the other hand, deals largely with problems such as recognizing printed/hand-written characters from a variety of documents (Graves and Schmidhuber, 2009), processing document images for document localization (Javed and Shafait, 2018), binarization (Tensmeyer and Martinez, 2017), and layout segmentation (Chen et al., 2015). As a result, it does not focus on understanding the character- and/or word-level semantics of the document the same way as NLP.

Within computer vision, problems such as scene text detection and recognition (Goodfellow et al., 2013), semantic segmentation (Badrinarayanan et al., 2017) as well as object detection (Gupta et al., 2014; Lin et al., 2017) can be considered as related problems to ours, but applied on a different domain, i.e., processing natural images instead of documents as input.

The closest to our work is Yang et al. (2017) that performs pixel-wise layout segmentation on a structured document, using sentence embeddings as additional input to an encoder-decoder network architecture. For each pixel inside the area of a sentence, the sentence embedding is appended to the visual feature embedding at the last layer of the decoder. The authors show that the layout segmentation accuracy can be significantly improved when using the textual features. Another related work is Palm et al. (2017) which extracts key-value information from structured documents (invoices) using a recurrent neural network (RNN). Their work addresses the problem of document understanding, however, the RNN operates on serialized 1D text.

Combining approaches from computer vision, NLP, and document analysis, our work is the first to systematically address the task of understanding 2D documents the same way as NLP while still retaining the 2D structure in structured documents.

3 Document Understanding with Chargrid

A human observer comprehends a document by understanding the semantic content of characters, words, paragraphs, and layout components. We encapsulate all such tasks under the common umbrella of *document understanding*. Therefore, we can formulate this problem as an instance segmentation task of characters on the page. In the following sections, we describe a new approach for solving that task.

3.1 Chargrid

Chargrid is a novel representation of a document that preserves its 2D layout. A chargrid can be constructed from *character boxes*, i.e., bounding boxes that each surround a single character somewhere on a given document page. This positional information can come from an optical character recognition (OCR) engine, or can be directly extracted from the layout information in the document as provided by, e.g., PDF or HTML. The coordinate space of a character box is defined by page height H and width W, and is usually measured in units of pixels.

The complete text of a document page can thus be represented as a set of tuples $\mathcal{D} = \{(c_k, \mathbf{b}_k) \mid k = 0, ..., n\}$, where c_k denotes the k-th character in the page and $\mathbf{b}_k$ the associated character box of the k-th character, which is formalized by the top-left pixel position, width and height, thus $\mathbf{b}_k = (x_k, y_k, w_k, h_k)$.

We can now construct the chargrid $g \in \mathbb{N}^{H \times W}$ of the original document page, and its *character-pixel* g_{ij} from the set $\mathcal{D}$ with

$$g_{ij} = \begin{cases} E(c_k) & \text{if} \quad (i,j) \prec \mathbf{b}_k \\ 0 \end{cases} \tag{1}$$

where $\prec$ means 'overlaps with', and where each point (i, j) corresponds to some pixel in the original document page pixel coordinate space defined by (H, W). $E(c_k)$ is some encoding of the character in the k-th character box, i.e. the value of character c_k may be mapped to a specific integer index. For instance, we may map the alphabet (or any character of interest) to non-zero indices $\{a, b, c, ...\} \rightarrow \{1, 2, 3, ...\}$. Note that we assume that character boxes cannot overlap, i.e. each character on a document page occupies a unique region on the page. In practice, it may happen that the

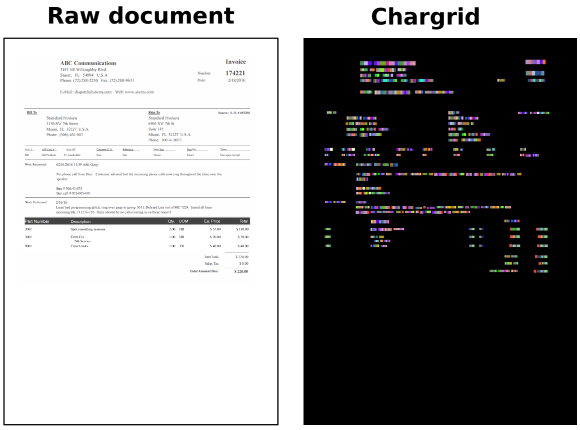

Figure 1: Example for a document page (left) and corresponding chargrid representation g (right).

corners and edges of a character box may overlap with other closeby characters. We solve such corner cases by assigning the character-pixel to the box that has the closest box center.

In other words, the chargrid representation is constructed as follows: for each character c_k at location $\mathbf{b}_k$, the area covered by that character is filled with some constant index value $E(c_k)$. All remaining character-pixels corresponding to empty regions on the original document page are initialized with 0. Figure 1 visualizes the chargrid representation of an example input document.

The advantage of the new chargrid representation is twofold: (i) we directly encode a character by a single scalar value rather than by a granular collection of grayscale pixels as is the case for images, thus making it easy for the subsequent document analysis algorithms to understand the document, and (ii), because the group of pixels that belonged to a given character are now all mapped to the same constant value, we can significantly downsample the chargrid representation without loss of any information. For instance, if the smallest character occupied a 10×10 pixel region in the original document, we can downsample the chargrid representation by a factor of 10×10. This significantly reduces the computational time of subsequent processing steps, such as training a machine learning model on this data representation.

We point out that a character can occupy a region spanning several character pixels. This is in contrast to traditional NLP where each character is represented by exactly one token. In our representation, therefore, the larger a given character, the more character-pixels represent that single character. We do not find this to be a problem, instead, it even helps since it implicitly encodes additional information, for example, the font size, that would otherwise not be available.

Before the chargrid representation is used as input to, e.g., a neural network (see Sec. 3.2), we apply 1-hot encoding to the chargrid g. Thus, the original chargrid representation $g \in \mathbb{N}^{H \times W}$ becomes a vector representation $\tilde{g} \in \mathbb{R}^{H \times W \times N_C}$, where N_C denotes the number of characters in the vocabulary including a padding/background character (in our case this is mapped to 0) and an unknown character (all characters that are not mapped by our encoding E will be mapped to this character).

We note that similar to using characters for constructing the chargrid, one can also use words to construct a *wordgrid* in the same way. In that case, rather than using 1-hot encoding, one may use a word embedding like word2vec or GloVe. While the construction of a wordgrid seems straightforward, we have not experimented with it in the present work as our dataset contains too many unusual words and spans multiple languages (see Sec. 4).

3.2 Network Architecture

We use the 1-hot encoded chargrid representation $\tilde{g}$ as input to a fully convolutional neural network to perform semantic segmentation on the chargrid and predict a class label for each character-pixel on the document. As there can be multiple and an unknown number of instances of the same class, we further perform instance segmentation. This means, in addition to predicting a segmentation mask, we may also predict bounding boxes using the techniques from object detection. This allows the model to assign characters from the same segmentation class to distinct instances.

Our model is described in Figure 2. It is comprised of two main parts: The encoder network and the decoder network. The decoder network is further made up of two branches: The segmentation branch and the bounding box regression branch. The encoder boils down to a VGG-type network (Simonyan and Zisserman, 2014) with dilated convolutions (Yu and Koltun, 2016), batch normalization (Ioffe and Szegedy, 2015), and spatial dropout (Tompson et al., 2015). Essentially, the encoder consists of five blocks where each block consists of three 3×3 convolutions (which

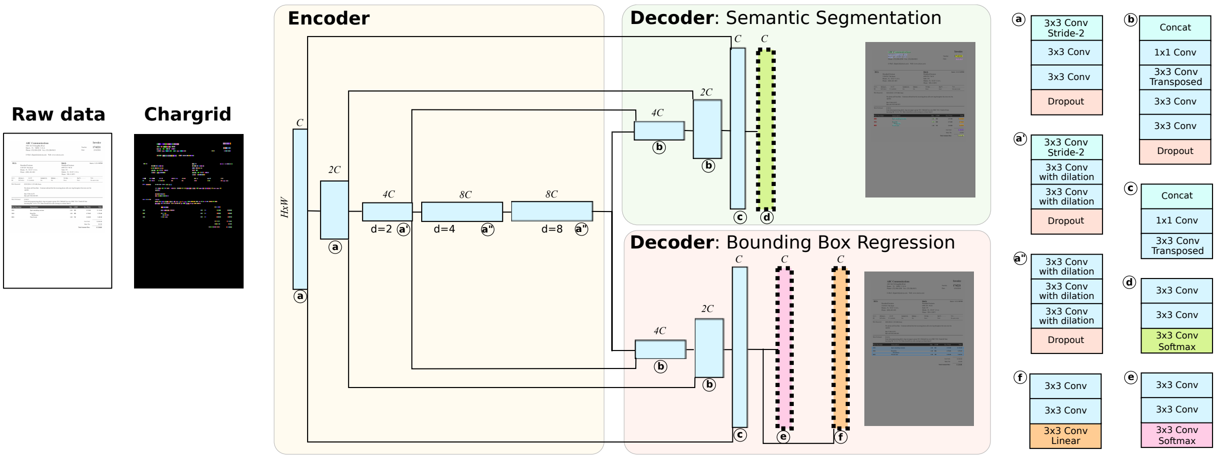

Figure 2: Network architecture for document understanding, the *chargrid-net*. Each convolutional block in the network is represented as a box. The height of a box is a proxy for feature map resolution while the width is a proxy for the number of output channels. C corresponds to the number of 'base' channels, which in turns corresponds to the number of output channels in the first encoder block. d denotes dilation rate.

themselves are made of convolution, batch normalization, ReLU activation) followed by spatial dropout at the end of a block. The first convolution in a block is a stride-2 convolution to downsample the input to that block. Whenever we downsample, we increase the number of output channels C of each convolution by a factor of two. We have found stride-2 convolutions to yield slightly better results compared to max pooling. In block four and five of the encoder, we do not apply any downsampling, and we leave the number of channels at 512 (the first block has $C = 64$ channels). We use dilated convolutions in block three, four, five with rates $d = 2, 4, 8$, respectively.

The decoder for semantic segmentation and for bounding box regression are both made of convolutional blocks which essentially reverse the downsampling of the encoder via stride-2 transposed convolutions. Each block first concatenates features from the encoder via lateral connections followed by 1×1 convolutions (Ronneberger et al., 2015; Pinheiro et al., 2016). Subsequently, we upsample via a 3×3 stride-2 transposed convolution. This is followed by two 3×3 convolutions. Note that whenever we upsample, we decrease the number of channels by a factor of two.

The two decoder branches are identical in architecture up to the last convolutional block. The decoder for semantic segmentation has an additional convolutional layer without batch normalization, but with bias and with softmax activation. The number of output channels of the last convolution corresponds to the number of classes. Together with the encoder, the decoder for the bounding box regression task forms a one-stage detector which makes use of focal loss (Lin et al., 2017). We also make use of the anchor box representation and corresponding bounding box regression targets as discussed in Ren et al. (2015a). The anchor-box representation allows us to handle bounding boxes that vary widely with respect to size and aspect ratios. Moreover, the anchor-box representation allows us to detect boxes of different classes. The number of output channels are $2N_a$ for the box mask (foreground versus background) and $4N_a$ for the four box coordinates, where N_a is the number of anchors per pixel. The weights of all layers are initialized following He et al. (2015), except for the last ones, which are initialized with a small constant value $1e-3$ for stabilization purposes.

In total, we have three equally contributing loss terms:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{seg}} + \mathcal{L}_{\text{boxmask}} + \mathcal{L}_{\text{boxcoord}}, \qquad (2)$$

where $\mathcal{L}_{\text{seg}}$ is the cross entropy loss for segmentation, e.g. (Ronneberger et al., 2015), $\mathcal{L}_{\text{boxmask}}$ is the binary cross entropy loss for box masks, and $\mathcal{L}_{\text{boxcoord}}$ is the Huber loss for box coordinate regression (Ren et al., 2015a). Both cross entropy loss terms are augmented following the focal loss idea (Lin et al., 2017). We also make use of aggressive static class weighting in both cross entropy loss terms mainly to counter the strong class imbalance between irrelevant and ”easy” pixels (the ”background” class) versus relevant and ”hard” pixels (all other classes; see Sec. 4.2 for further details).

We refer to the network depicted in Figure 2 as the *chargrid-net*.

4 Information Extraction from Invoices

As a concrete example for understanding structured 2D documents, we extract key-value information from invoices. We make no assumption on the format of the invoice, the country of origin (and consequently taxes, date formats, amount formats, currency etc.) or the language. In addition to that, real-world invoices often contain incomplete sentences, nouns, and abbreviations.

We want our model to parse an invoice and to extract 5 *header fields* (i.e., Invoice Number, Invoice Date, Invoice Amount, Vendor Name and Vendor Address) as well as the list of product items purchased, referred to as the *line-items*. Line-items include details for each item such as Line-item Description, Line-item Quantity and Line-item Amount. Together with the background class, this yields 9 classes and each character on the invoice is associated to exactly one class. We note that while header fields may only appear once on an invoice (are unique), line-items may occur in multiple instances.

To extract the values for each field, we collect all characters that are classified as belonging to the corresponding class. For line-items, we further group the characters by the predicted item bounding boxes.

4.1 Data

Our invoice dataset consists of 12k scanned sample invoices from a large variety of different vendors and languages. We assign 10k samples for training, 1k for validation and 1k for test on which we report our results (see Sec. 5). We ensure that vendors that appear in one set do not appear in any other set. This is more restrictive than necessary but gives a good estimate on how well the model generalizes to unseen invoice layouts. Figure 3 shows the distribution over vendors and languages. From the vendor distribution, it can be seen that most vendors contribute only one invoice to the dataset with at most 6 invoices coming from a single vendor. From the language distribution, it can be seen that while English is the predominant language, there are large representations from French, Spanish, Norwegian, and German.

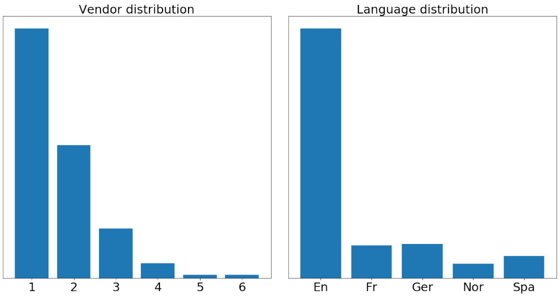

Figure 3: The left image shows a histogram of number of vendors over the number of contributing invoices in the dataset. Most vendors appear only once in the dataset. The right image shows a distribution over languages, illustrating the diversity of the invoice data.

For all invoices, we collected manual annotations with bounding boxes around the fields of interest. Considerable efforts were spent to ensure that the labels are correct. In particular, each invoice was analyzed by three annotators plus a reviewer. Over 35k invoices were investigated and finally only clean set of 12k invoices were selected. Furthermore, detailed instructions were given to the annotators for each field. Figure 4 visualizes the locations of annotated boxes on invoices for Invoice Amount and Line-item Quantity. It can be seen that while some regions are denser, the occurrences are spread widely over the whole invoice thereby illustrating the diversity in the invoice format.

4.2 Implementation Details

The invoices were processed with an open-source engine for OCR, Tesseract (v4), to extract the text from the documents.

We limit the number of distinct characters in our encoding E (in Eq. 1) to the most frequent ones, which in our present case means $N_C = 54$ different characters including the background/padding and unknown character. Thus, the 1-hot encoded chargrid $\tilde{g}$ has 54 channels. Each page of an invoice is processed independently.

Once we created the chargrid representation of a document page, we downsample to a fixed resolution using nearest neighbor interpolation to ensure that all chargrid representations have the same resolution for training (and inference). Note that this downsampling operation is still performed in the token space (i.e., before 1-hot encoding). To further ensure that no tokens in the chargrid representation are lost due to nearest neighbor interpolation, we downsample to twice the target resolution. This resolution is determined by the smallest characters in the training set. A second downsampling step, now in the 1-hot encoding to the final target resolution of 336x256 in our case, is performed using bilinear interpolation and fed into the network. Note that we could have also first performed 1-hot encoding on the document and applied bilinear interpolation directly to the target resolution. Computationally, however, this two-stage downsampling is more efficient.

We handle landscape documents by simply squeezing all input pages into our target resolution using interpolation (similar to image re-sizing). We have found that this approach is not harmful and for simplicity stick to it.

Line-items can occur in an unknown number of distinct instances. Therefore, we require instance segmentation of characters on the document. To accomplish this, the model is trained to predict bounding boxes that span across the entire row of one instance of a line-item, while the segmentation mask classifies those characters belonging to given column classes (such as, e.g., Line-item Quantity, or Line-item Description) of that line-item instance.

We implemented our model in TensorFlow 1.4. We use SGD with momentum $\beta = 0.9$ and learning rate $\alpha = 0.05$. We used weight decay of $\lambda = 10^{-4}$, and spatial dropout with probability $P = 0.1$. We perform random cropping of the chargrid for data augmentation (that is we pad by 16 character pixels in each direction after downsampling and then crop with a random offset in range $(16, 16)$).

We use aggressive class weighting in the cross-entropy loss for semantic segmentation and for the bounding box mask. We have found this to be more effective than the focal loss (which can bee seen as a form of dynamic class weighting). We implement class weighting following (Paszke et al., 2016) with a constant of $c = 1.04$. In early stages of our experiments not yet using class weights, we noted poor performance on the bounding box regression task as well as the segmentation task.

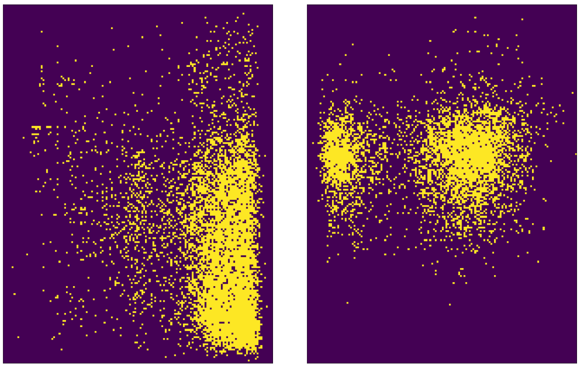

Figure 4: Spatial distribution of Invoice Amount (left) and Line-item Quantity (right) over the invoice. This depicts the variation in the invoice layouts contained in our dataset.

The distribution of line-items on invoices in our dataset reveals that around 50% of all invoices only contain less than three line-items. We found that repeating those invoices with more than three line-items during training more often than those with only few line-items significantly boosts bounding box regression accuracy. With a mini batch size of 7, each model took around $360k$ iterations and 3 days to fully converge on a single Nvidia Tesla V100.

4.3 Evaluation Measure

For evaluating our model, we would like to measure how much work would be saved by using the extraction system, compared to performing the field extraction manually. To capture this, we use a measure similar to the word error rate (Prabhavalkar et al., 2017) used in speech recognition or translation tasks.

For a given field, we count the number of insertions, deletions, and modifications of the predicted instances (pooled across the entire test set) to match the ground truth instances. Evaluations are made on the string level. We compute this measure as follows:

$$1 - \frac{\#[\text{insertions}] + \#[\text{deletions}] + \#[\text{modifications}]}{N}$$

where N is the total number of instances occurring in the ground truth of the entire test set. This measure can be negative, meaning that it would be less work to perform the extraction manually. In our present case, the error caused by the OCR engine does not affect this measure, because the same errors are present in the prediction and in the ground truth and are not considered a mismatch.

Figure 5: Sample invoices and their corresponding network predictions: the top row shows the chargrid input, the bottom row shows the predicted segmentation mask with overlaid bounding box predictions. Our model is able to handle a large diversity of layouts. The encoding of the characters on the chargrid has been scrambled to preserve privacy.

5 Experiments and Results

Figure 5 shows some sample predictions. It can be seen that the model can successfully extract key-value information on sample invoices despite significant diversity and complexity in the invoice layouts.

We show the quantitative results in Table 1. We compare the proposed model, chargrid-net (Sec. 3.2), against four other models. The first one is a *sequential* model based purely on text. It is a stack of bi-directional GRUs (Cho et al., 2014) taking a sequence of characters as input, and producing a sequence of labels as output. This model is our implementation of Palm et al. (2017) and serves as a baseline comparison against a more traditional NLP approach which is based on sequential input. We note that we have also experimented with a extension of this model that along with the characters also takes as input the position of each character on the document, however, with negligible returns. Therefore, we stick to this simpler model.

The second *image-only* model is identical to chargrid-net (Figure 2), except that we directly take the original image of the document page as network input rather than the chargrid $\tilde{g}$. This model serves as a baseline comparison to a purely image-based approach using directly the raw pixel information as input. We note that we downsample the image to the same input resolution as the chargrid representation, that is 336x256.

The third and fourth models are both a *hybrid* between the chargrid-net, and the image-only model. In both models, we replicate the encoder: one encoder for the chargrid input $\tilde{g}$, and one encoder for the image of the document page. Information from the two encoders is concatenated in the decoder: whenever a lateral connection from the encoder of the original chargrid-net is concatenated in a decoder block, we now concatenate lateral connections from the two encoders in a decoder block.

We distinguish two configurations of the hybrid model: model *chargrid-hybrid-C64* where chargrid and image encoders both have $C = 64$ base channels, and model *chargrid-hybrid-C32* where chargrid and image encoders have $C = 32$ base channels while the decoder still retains $C = 64$ base channels. The latter model is used to assess the influence on the number of encoder parameters since the hybrid model effectively has more parameters due to the two encoders.

It can be seen that compared to the purely text-based approach, the chargrid-net performs equivalently on single-instance single-word fields where the 2D structure is not as important. Examples of single-instance, single-word fields are 'Invoice Number', 'Invoice Amount', and 'Invoice Date'. The extraction of these fields could essentially also be easily tackled with named entity recognition approaches based on serialized text (Gillick et al., 2015; Lample et al., 2016).

The chargrid-net, however, significantly outper-

Model/Field	Invoice Number	Invoice Amount	Invoice Date	Vendor Name	Vendor Address	Line-item Description	Line-item Quantity	Line-item Amount
sequential	80.98%	79.13%	83.98%	28.97%	16.94%	-0.01%	-0.18%	0.22%
image-only	47.79%	68.91%	45.67%	19.68%	13.99%	49.50%	46.79%	63.49%
chargrid-net	80.48%	80.74%	83.78%	36.00%	39.13%	52.80%	65.20%	65.57%
chargrid-hybrid-C32	74.85%	77.93%	80.40%	32.00%	31.48%	46.27%	64.04%	63.25%
chargrid-hybrid-C64	82.49%	80.14%	84.28%	34.27%	36.83%	48.81%	64.59%	64.53%

Table 1: Accuracy measure (c.f. Sec. 4.3) for an 8-class information extraction problem on invoices. The proposed chargrid models perform consistently well on all extracted fields compared to sequential and image models.

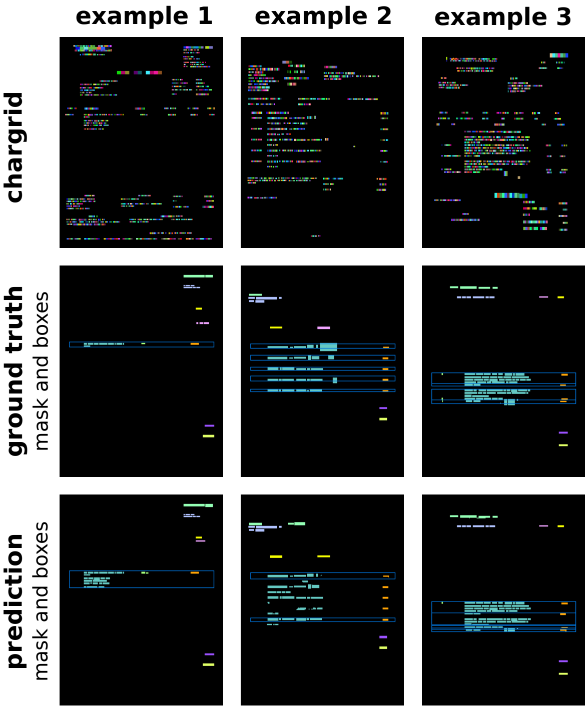

Figure 6: In example 1, chargrid-net attributes unrelated rows of text to the line-item's description. Moreover, some character-pixels are misclassified such that the predicted header field above the line-item is incorrect. Thus, we observe errors in both, the segmentation mask and the bounding box predictions. In example 2, the model predicts the segmentation mask mostly correct, but it fails to predict boxes for two of the four line-items. In example 3, the model fails to separate adjacent multi-row line-items from each other correctly. Please note that the ground truth is debatable in some cases; for example, it may be hard to decide which information belongs to a line-item's description and which does not.

forms the sequential model on multi-instance or multi-word fields where 2D relationships between text entities are important. Examples of such fields are Line-item Description, Line-item Quantity and Line-item Amount, which are all grouped as *sub-fields* to a specific line-item. Each of those fields may span a varying number of rows per line-item, see Figure 5. The sequential model fails to correctly identify those line-item fields which is manifested in a negative accuracy measure (Sec. 4.3). This implies that it is better to perform manual extraction over using automatic extraction. This is understandable since the line-item fields have a strong 2D structure that the sequential approach is not designed to capture.

In comparison with the image-only model, chargrid-net still performs much better. This is especially true for smaller fields which need to be *read* to be accurately localized. On the other hand, for larger fields like Line-item Description, which can be localized by only vision, the gap is much smaller.

The values for the hybrid models are a bit more interesting. One could expect that combining two complementary inputs such as the chargrid representation and image - one capturing the content and the other capturing, e.g. table delineations - would boost the accuracy. It turns out, however, that at least in the case of our invoice dataset, the additional image encoder does not bring additional benefits. Model chargrid-hybrid-C64, where the chargrid encoder branch has the same number of base channels $C = 64$ as the original chargrid-net, is essentially as accurate as chargrid-net. Model chargrid-hybrid-C32, where the image and chargrid encoder combined have the same number of channels (that is the chargrid encoder branch only has $C = 32$ base channels), the accuracy is significantly reduced.

We conclude that at least in our present extraction problem, most of the discriminative information comes from the chargrid encoder branch and thus from the chargrid representation.

Error examples of the chargrid-net model are depicted in Figure 6. One frequent error-type is that the model may fail to disentangle line-items, if they have a peculiar structure. While this is also challenging for human experts, other erroneous predictions are observed in samples for which the ground truth annotations are debatable.

6 Discussion

We introduce a new way of modeling documents by using a character grid as document representation. The chargrid allows models to capture 2D relationships between characters, words, and larger units of text. The idea of the chargrid paradigm is inspired by the human perception which is heavily guided by 2D shapes and structures for understanding this type of documents. Therefore, the chargrid allows to encode the positioning, size and alignment for textual components in a meaningful manner. While the chargrid paradigm could be applied to various kinds of NLP tasks, we demonstrate its potential on an information extraction task from invoices. We train a deep neural network with an encoder-decoder architecture and we show that the network computes accurate segmentation masks and bounding boxes, which pinpoint the relevant information on the invoice.

We evaluate the accuracy of the model and compare it to state-of-the-art NLP and computer vision approaches. While those baseline models achieve accurate predictions for individual fields, only the chargrid performs well on all information extraction tasks. Some fields such as Invoice Number are relatively easy to detect for a model that operates on serialized text, as discriminative keywords are commonly preceding the words to be extracted. However, more complex extraction tasks (e.g. Vendor Address or Line-item Quantity) cannot be performed accurately as they require to exploit both, textual components and 2D layout structures. The traditional image-only computer vision model yields accurate predictions only for large visual columns (such as Line-item Amount) and it fails to locate extractions that require to understand the text.

However, compared to traditional sequential neural NLP models, the benefits in accuracy come at a larger computational cost compared. Even though the proposed model is fully convolutional and parallelizes very well on a single (or even multiple) GPU(s), the added complexity introduced by using a 2D data representation can significantly increase the total data dimensionality. In our current use case, a chargrid-net training requires up to three days until full convergence, whereas our sequential model converges after only a few hours.

Comparing chargrid to semantic segmentation on natural images, one should note that character-pixels, unlike pixels of a gray-scale image, are categorical. This requires the character-pixels to be encoded as 1-hot. This yields a highly sparse data representation. While such representation is very common for NLP problems, it is new for segmentation networks that have previously only been applied to image segmentation.

7 Conclusion

Chargrid is a generic representation for 2D text. Using this as a base, one could solve any task on a 2D text such as document classification, named-entity recognition, information extraction, parts-of-speech tagging etc. Furthermore,chargrid is highly beneficial for scenarios where text and natural images are blended. One could imagine performing all the above NLP tasks also on such inputs. This work demonstrates the advantages of chargrid for an information extraction task but we believe that it is only the first step towards incorporating the 2D document structure into document understanding tasks. Some follow-up direction could be solving other NLP tasks on structured documents using chargrid or experimenting with other computer vision algorithms on chargrid. Furthermore, it may be interesting to use word embeddings rather than 1-hot encoded characters, i.e. a wordgrid, as 2D text input representation.

Abstract

Common recurrent neural architectures scale poorly due to the intrinsic difficulty in parallelizing their state computations. In this work, we propose the Simple Recurrent Unit (SRU), a light recurrent unit that balances model capacity and scalability. SRU is designed to provide expressive recurrence, enable highly parallelized implementation, and comes with careful initialization to facilitate training of deep models. We demonstrate the effectiveness of SRU on multiple NLP tasks. SRU achieves 5–9x speed-up over cuDNN-optimized LSTM on classification and question answering datasets, and delivers stronger results than LSTM and convolutional models. We also obtain an average of 0.7 BLEU improvement over the Transformer model (Vaswani et al., 2017) on translation by incorporating SRU into the architecture.[1]

1 Introduction

Recurrent neural networks (RNN) are at the core of state-of-the-art approaches for a large number of natural language tasks, including machine translation (Cho et al., 2014; Bahdanau et al., 2015; Jean et al., 2015; Luong et al., 2015), language modeling (Zaremba et al., 2014; Gal and Ghahramani, 2016; Zoph and Le, 2016), opinion mining (Irsoy and Cardie, 2014), and situated language understanding (Mei et al., 2016; Misra et al., 2017; Suhr et al., 2018; Suhr and Artzi, 2018). Key to many of these advancements are architectures of increased capacity and computation. For instance, the top-performing models for semantic role labeling and translation use eight recurrent layers, requiring days to train (He et al., 2017; Wu et al., 2016b). The scalability of these models has become an important problem that impedes NLP research.

The difficulty of scaling recurrent networks arises from the time dependence of state computation. In common architectures, such as Long Short-term Memory (LSTM; Hochreiter and Schmidhuber, 1997) and Gated Recurrent Units (GRU; Cho et al., 2014), the computation of each step is suspended until the complete execution of the previous step. This sequential dependency makes recurrent networks significantly slower than other operations, and limits their applicability. For example, recent translation models consist of non-recurrent components only, such as attention and convolution, to scale model training (Gehring et al., 2017; Vaswani et al., 2017).

In this work, we introduce the Simple Recurrent Unit (SRU), a unit with light recurrence that offers both high parallelization and sequence modeling capacity. The design of SRU is inspired by previous efforts, such as Quasi-RNN (QRNN; Bradbury et al., 2017) and Kernel NN (KNN; Lei et al., 2017), but enjoys additional benefits:

- SRU exhibits the same level of parallelism as convolution and feed-forward nets. This is achieved by balancing sequential dependence and independence: while the state computation of SRU is time-dependent, each state dimension is independent. This simplification enables CUDA-level optimizations that parallelize the computation across hidden dimensions and time steps, effectively using the full capacity of modern GPUs. Figure 1 compares our architecture's runtimes to common architectures.

- SRU replaces the use of convolutions (i.e., n-gram filters), as in QRNN and KNN, with more recurrent connections. This retains modeling capacity, while using less computation (and hyper-parameters).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4470–4481
Brussels, Belgium, October 31 - November 4, 2018.

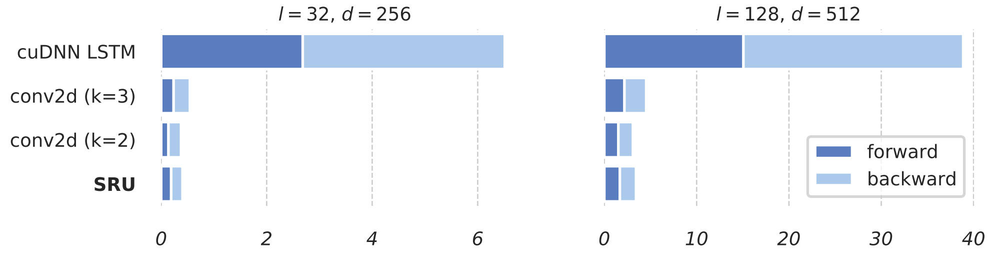

Figure 1: Average processing time in milliseconds of a batch of 32 samples using cuDNN LSTM, word-level convolution `conv2d` (with filter width $k = 2$ and $k = 3$), and the proposed SRU. We vary the number of tokens per sequence (l) and feature dimension (d).

- SRU improves the training of deep recurrent models by employing highway connections (Srivastava et al., 2015) and a parameter initialization scheme tailored for gradient propagation in deep architectures.

We evaluate SRU on a broad set of problems, including text classification, question answering, translation and character-level language modeling. Our experiments demonstrate that light recurrence is sufficient for various natural language tasks, offering a good trade-off between scalability and representational power. On classification and question answering datasets, SRU outperforms common recurrent and non-recurrent architectures, while achieving 5–9x speed-up compared to cuDNN LSTM. Stacking additional layers further improves performance, while incurring relatively small costs owing to the cheap computation of a single layer. We also obtain an average improvement of 0.7 BLEU score on the English to German translation task by incorporating SRU into Transformer (Vaswani et al., 2017).

2 Related Work

Improving on common architectures for sequence processing has recently received significant attention (Greff et al., 2017; Balduzzi and Ghifary, 2016; Miao et al., 2016; Zoph and Le, 2016; Lee et al., 2017). One area of research involves incorporating word-level convolutions (i.e. n-gram filters) into recurrent computation (Lei et al., 2015; Bradbury et al., 2017; Lei et al., 2017). For example, Quasi-RNN (Bradbury et al., 2017) proposes to alternate convolutions and a minimalist recurrent pooling function and achieves significant speed-up over LSTM. While Bradbury et al. (2017) focus on the speed advantages of the network, Lei et al. (2017) study the theoretical characteristics of such computation and possible extensions. Their results suggest that simplified recurrence retains strong modeling capacity through layer stacking. This finding motivates the design of SRU for both high parallelization and representational power. SRU also relates to IRNN (Le et al., 2015), which uses an identity diagonal matrix to initialize hidden-to-hidden connections. SRU uses point-wise multiplication for hidden connections, which is equivalent to using a diagonal weight matrix. This can be seen as a constrained version of diagonal initialization.

Various strategies have been proposed to scale network training (Goyal et al., 2017) and to speed up recurrent networks (Diamos et al., 2016; Shazeer et al., 2017; Kuchaiev and Ginsburg, 2017). For instance, Diamos et al. (2016) utilize hardware infrastructures by stashing RNN parameters on cache (or fast memory). Shazeer et al. (2017) and Kuchaiev and Ginsburg (2017) improve the computation via conditional computing and matrix factorization respectively. Our implementation for SRU is inspired by the cuDNN-optimized LSTM (Appleyard et al., 2016), but enables more parallelism – while cuDNN LSTM requires six optimization steps, SRU achieves more significant speed-up via two optimizations.

The design of recurrent networks, such as SRU and related architectures, raises questions about representational power and interpretability (Chen et al., 2018; Peng et al., 2018). Balduzzi and Ghifary (2016) applies type-preserving transformations to discuss the capacity of various simplified RNN architectures. Recent work (Anselmi et al., 2015; Daniely et al., 2016; Zhang et al., 2016; Lei et al., 2017) relates the capacity of neural networks to deep kernels. We empirically demonstrate SRU can achieve compelling results by stacking multiple layers.

3 Simple Recurrent Unit

We present and explain the design of Simple Recurrent Unit (SRU) in this section. A single layer of SRU involves the following computation:

$$\begin{aligned}
\mathbf{f}_t &= \sigma\left(\mathbf{W}_f\mathbf{x}_t + \mathbf{v}_f \odot \mathbf{c}_{t-1} + \mathbf{b}_f\right) && (1)\\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + (1-\mathbf{f}_t) \odot (\mathbf{W}\mathbf{x}_t) && (2)\\
\mathbf{r}_t &= \sigma\left(\mathbf{W}_r\mathbf{x}_t + \mathbf{v}_r \odot \mathbf{c}_{t-1} + \mathbf{b}_r\right) && (3)\\
\mathbf{h}_t &= \mathbf{r}_t \odot \mathbf{c}_t + (1-\mathbf{r}_t) \odot \mathbf{x}_t && (4)
\end{aligned}$$

where $\mathbf{W}$, $\mathbf{W}_f$ and $\mathbf{W}_r$ are parameter matrices and $\mathbf{v}_f$, $\mathbf{v}_r$, $\mathbf{b}_f$ and $\mathbf{b}_v$ are parameter vectors to be learnt during training. The complete architecture decomposes to two sub-components: a *light recurrence* (Equation 1 and 2) and a *highway network* (Equation 3 and 4).

The light recurrence component successively reads the input vectors $\mathbf{x}_t$ and computes the sequence of states $\mathbf{c}_t$ capturing sequential information. The computation resembles other recurrent networks such as LSTM, GRU and RAN (Lee et al., 2017). Specifically, a forget gate $\mathbf{f}_t$ controls the information flow (Equation 1) and the state vector $\mathbf{c}_t$ is determined by adaptively averaging the previous state $\mathbf{c}_{t-1}$ and the current observation $\mathbf{W}\mathbf{x}_t$ according to $\mathbf{f}_t$ (Equation 2).

One key design decision that differs from previous gated recurrent architectures is the way $\mathbf{c}_{t-1}$ is used in the sigmoid gate. Typically, $\mathbf{c}_{t-1}$ is multiplied with a parameter matrix to compute $\mathbf{f}_t$, e.g., $\mathbf{f}_t = \sigma(\mathbf{W}_f\mathbf{x}_t + \mathbf{V}_f\mathbf{c}_{t-1} + \mathbf{b}_f)$. However, the inclusion of $\mathbf{V}_f\mathbf{c}_{t-1}$ makes it difficult to parallelize the state computation: each dimension of $\mathbf{c}_t$ and $\mathbf{f}_t$ depends on all entries of $\mathbf{c}_{t-1}$, and the computation has to wait until $\mathbf{c}_{t-1}$ is fully computed. To facilitate parallelization, our light recurrence component uses a point-wise multiplication $\mathbf{v}_f \odot \mathbf{c}_{t-1}$ instead. With this simplification, each dimension of the state vectors becomes independent and hence parallelizable.

The highway network component (Srivastava et al., 2015) facilitates gradient-based training of deep networks. It uses the reset gate $\mathbf{r}_t$ (Equation 3) to adaptively combine the input $\mathbf{x}_t$ and the state $\mathbf{c}_t$ produced from the light recurrence (Equation 4), where $(1-\mathbf{r}_t) \odot \mathbf{x}_t$ is a skip connection that allows the gradient to directly propagate to the previous layer. Such connections have been shown to improve scalability (Wu et al., 2016a; Kim et al., 2016; He et al., 2016; Zilly et al., 2017).

The combination of the two components makes the overall architecture simple yet expressive, and easy to scale due to enhanced parallelization and gradient propagation.

3.1 Parallelized Implementation

Despite the parallelization friendly design of SRU, a naive implementation which computes equations (1)–(4) for each step t sequentially would not achieve SRU's full potential. We employ two optimizations to enhance parallelism. The optimizations are performed in the context of GPU / CUDA programming, but the general idea can be applied to other parallel programming models.

We re-organize the computation of equations (1)–(4) into two major steps. First, given the input sequence $\{\mathbf{x}_1 \cdots \mathbf{x}_L\}$, we batch the matrix multiplications across all time steps. This significantly improves the computation intensity (e.g. GPU utilization). The batched multiplication is:

$$\mathbf{U}^\top = \begin{pmatrix} \mathbf{W} \\ \mathbf{W}_f \\ \mathbf{W}_r \end{pmatrix} [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_L] \ ,$$

where L is the sequence length, $\mathbf{U} \in \mathbb{R}^{L \times 3d}$ is the computed matrix and d is the hidden state size. When the input is a mini-batch of B sequences, $\mathbf{U}$ would be a tensor of size $(L, B, 3d)$.

The second step computes the remaining point-wise operations. Specifically, we compile all point-wise operations into a single fused CUDA kernel and parallelize the computation across each dimension of the hidden state. Algorithm 1 shows the pseudo code of the forward function. The complexity of this step is $O(L \cdot B \cdot d)$ per layer, where L is the sequence length and B is the batch size. In contrast, the complexity of LSTM is $O(L \cdot B \cdot d^2)$ because of the hidden-to-hidden multiplications (e.g. $\mathbf{V}\mathbf{h}_{t-1}$), and each dimension can not be independently parallelized. The fused kernel also reduces overhead. Without it, operations such as sigmoid activation would each invoke a separate function call, adding kernel launching latency and more data moving costs.

The implementation of a bidirectional SRU is similar: the matrix multiplications of both directions are batched, and the fused kernel handles and parallelizes both directions at the same time.

3.2 Initialization

Proper parameter initialization can reduce gradient propagation difficulties and hence have a positive

Algorithm 1 Mini-batch version of the forward pass defined in Equations (1)–(4).

```
Indices: Sequence length $L$, mini-batch size $B$, hidden state dimension $d$.
Input: Input sequences batch $\mathbf{x}[l,i,j]$; grouped matrix multiplication $\mathbf{U}[l,i,j']$;
  initial state $\mathbf{c}_0[i,j]$; parameters $\mathbf{v}_f[j]$, $\mathbf{v}_r[j]$, $\mathbf{b}_f[j]$ and $\mathbf{b}_r[j]$.
Output: Output $\mathbf{h}[\cdot,\cdot,\cdot]$ and internal $\mathbf{c}[\cdot,\cdot,\cdot]$ states.
  Initialize $\mathbf{h}[\cdot,\cdot,\cdot]$ and $\mathbf{c}[\cdot,\cdot,\cdot]$ as two $L \times B \times d$ tensors.
  for $i = 1,\cdots,B; j = 1,\cdots,d$ do          // Parallelize each example $i$ and dimension $j$
    $c = \mathbf{c}_0[i,j]$
    for $l = 1,\cdots,L$ do
      $f = \sigma\,(\,\mathbf{U}[l,i,j+d] + \mathbf{v}_f[j] \times c + \mathbf{b}_f[j]\,)$
      $c = f \times c + (1-f) \times \mathbf{U}[l,i,j]$
      $r = \sigma\,(\,\mathbf{U}[l,i,j+d\times 2] + \mathbf{v}_r[j] \times c + \mathbf{b}_r[j]\,)$
      $h = r \times c + (1-r) \times \mathbf{x}[l,i,j]$
      $\mathbf{c}[l,i,j] = c$
      $\mathbf{h}[l,i,j] = h$
  return $\mathbf{h}[\cdot,\cdot,\cdot]$ and $\mathbf{c}[\cdot,\cdot,\cdot]$
```

impact on the final performance. We now describe an initialization strategy tailored for SRU.

We start by adopting common initializations derived for feed-forward networks (Glorot and Bengio, 2010; He et al., 2015). The weights of parameter matrices are drawn with zero mean and $1/d$ variance, for instance, via the uniform distribution $[-\sqrt{3/d}, +\sqrt{3/d}]$. This ensures the output variance remains approximately the same as the input variance after the matrix multiplication.

However, the light recurrence and highway computation would still reduce the variance of hidden representations by a factor of $1/3$ to $1/2$:

$$\frac{1}{3} \le \frac{\mathrm{Var}[\mathbf{h}_t]}{\mathrm{Var}[\mathbf{x}_t]} \le \frac{1}{2} \ ,$$

and the factor converges to $1/2$ in deeper layers (see Appendix A). This implies the output $\mathbf{h}_t$ and the gradient would vanish in deep models. To offset the problem, we introduce a *scaling correction* constant α in the highway connection

$$\mathbf{h}_t \ = \ \mathbf{r}_t \odot \mathbf{c}_t \ + \ (1-\mathbf{r}_t) \odot \mathbf{x}_t \cdot \alpha \ \ ,$$

where α is set to $\sqrt{3}$ such that $\mathrm{Var}[\mathbf{h}_t] \approx \mathrm{Var}[\mathbf{x}_t]$ at initialization. When the highway network is initialized with a non-zero bias $\mathbf{b}_r = b$, the scaling constant α can be accordingly set as:

$$\alpha \ = \ \sqrt{1 + \exp(b) \times 2} \ \ .$$

Figure 2 compares the training progress with and without the scaling correction. See Appendix A for the derivation and more discussion.

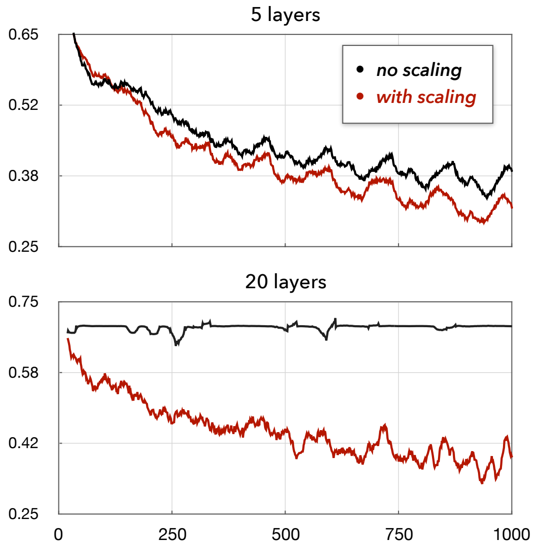

Figure 2: Training curves of SRU on classification. The x-axis is the number of training steps and the y-axis is the training loss. Scaling correction improves the training progress, especially for deeper models with many stacked layers.

4 Experiments

We evaluate SRU on several natural language processing tasks and perform additional analyses of the model. The set of tasks includes text classification, question answering, machine translation, and character-level language modeling. Training time on these benchmarks ranges from minutes (classification) to days (translation), providing a variety of computation challenges.

The main question we study is the performance-speed trade-off SRU provides in comparison to

Table 1: Test accuracies on classification benchmarks (Section 4.1). The first block presents best reported results of various methods. The second block compares SRU and other baselines given the same setup. For the SST dataset, we report average results of 5 runs. For other datasets, we perform 3 independent trials of 10-fold cross validation (3×10 runs). The last column compares the wall clock time (in seconds) to finish 100 epochs on the SST dataset.

other architectures. We stack multiple layers of SRU to directly substitute other recurrent, convolutional or feed-forward modules. We minimize hyper-parameter tuning and architecture engineering for a fair comparison. Such efforts have a non-trivial impact on the results, which are beyond the scope of our experiments. Unless noted otherwise, the hyperparameters are set identical to prior work.

4.1 Text Classification

Dataset We use six sentence classification benchmarks: movie review sentiment (MR; Pang and Lee, 2005), sentence subjectivity (SUBJ; Pang and Lee, 2004), customer reviews polarity (CR; Hu and Liu, 2004), question type (TREC; Li and Roth, 2002), opinion polarity (MPQA; Wiebe et al., 2005), and the Stanford sentiment treebank (SST; Socher et al., 2013).[2]

Following Kim (2014), we use word2vec embeddings trained on 100 billion Google News tokens. For simplicity, all word vectors are normalized to unit vectors and are fixed during training.

Setup We stack multiple SRU layers and use the last output state to predict the class label for a given sentence. We train for 100 epochs and use the validation (i.e., development) set to select the best training epoch. We perform 10-fold cross validation for datasets that do not have a standard train-evaluation split. The result on SST is averaged over five independent trials. We use Adam (Kingma and Ba, 2014) with the default learning rate 0.001, a weight decay 0 and a hidden dimension of 128.

We compare SRU with a wide range of methods on these datasets, including various convolutional models (Kalchbrenner et al., 2014; Kim, 2014; Zhang and Wallace, 2017) and a hierarchical sentence model (Zhao et al., 2015) reported as the state of the art on these datasets (Conneau et al., 2017). Their setups are not exactly the same as ours, and may involve more tuning on word embeddings and other regularizations. We use the setup of Kim (2014) but do not fine-tune word embeddings and the learning method for simplicity. In addition, we directly compare against three baselines trained using our code base: a re-implementation of the CNN model of Kim (2014), a two-layer LSTM model and Quasi-RNN (Bradbury et al., 2017). We use the official implementation of Quasi-RNN and also implement a version with highway connection for a fair comparison. These baselines are trained using the same hyper-parameter configuration as SRU.

Results Table 1 compares the test results on the six benchmarks. We select the best number re-

---

[2] We use the binary version of SST dataset.

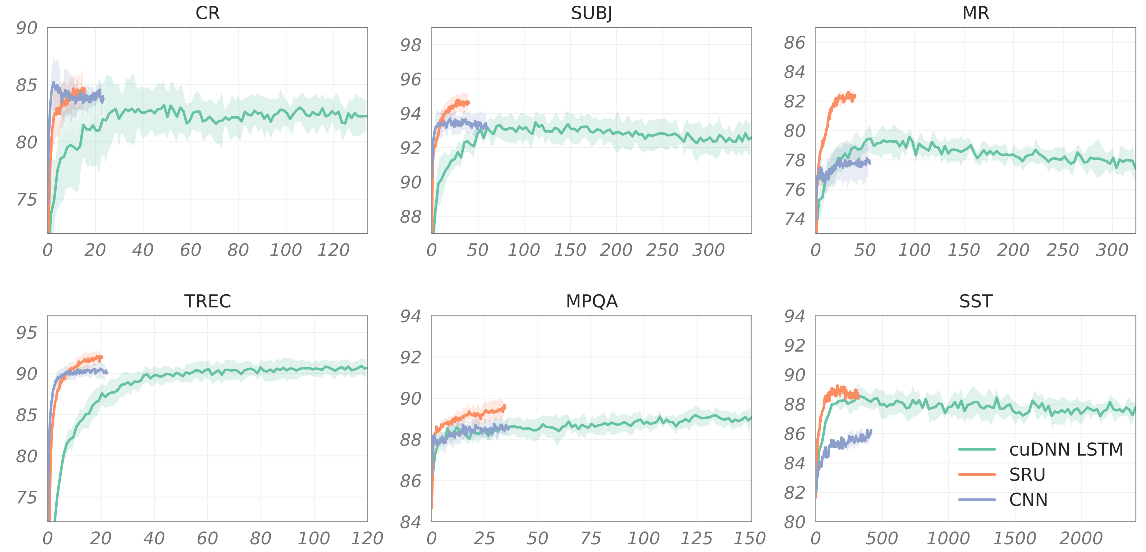

Figure 3: Mean validation accuracies (y-axis) and standard deviations of the CNN, 2-layer LSTM and 2-layer SRU models. We plot the curves of the first 100 epochs. X-axis is the training time used (in seconds). Timings are performed on NVIDIA GeForce GTX 1070 GPU, Intel Core i7-7700K Processor and cuDNN 7003.

ported in previous methods when multiple model variants were explored in their experiments. Despite our simple setup, SRU outperforms most previous methods and achieves comparable results compared to the state-of-the-art but more sophisticated model of Zhao et al. (2015). Figure 3 shows validation performance relative to training time for SRU, cuDNN LSTM and the CNN model. Our SRU implementation runs 5–9 times faster than cuDNN LSTM, and 6–40% faster than the CNN model of Kim (2014). On the movie review (MR) dataset for instance, SRU completes 100 training epochs within 40 seconds, while LSTM takes over 320 seconds.

4.2 Question Answering

Dataset We use the Stanford Question Answering Dataset (SQuAD; Rajpurkar et al., 2016). SQuAD is a large machine comprehension dataset that includes over 100K question-answer pairs extracted from Wikipedia articles. We use the standard train and development sets.

Setup We use the Document Reader model of Chen et al. (2017) as our base architecture for this task. The model is a combination of word-level bidirectional RNNs and attentions, providing a good testbed to compare our bidirectional SRU implementation with other RNN components.[3]

We use the open source implementation of Document Reader in our experiments.[4] We train models for up to 100 epochs, with a batch size of 32 and a hidden dimension of 128. Following the author suggestions, we use the Adamax optimizer (Kingma and Ba, 2014) and variational dropout (Gal and Ghahramani, 2016) during training. We compare with two alternative recurrent components: the bidirectional LSTM adopted in the original implementation of Chen et al. (2017) and Quasi-RNN with highway connections for improved performance.

Results Table 2 summarizes the results on SQuAD. SRU achieves 71.4% exact match and 80.2% F1 score, outperforming the bidirectional LSTM model by 1.9% (EM) and 1.4% (F1) respectively. SRU also exhibits over 5x speed-up over LSTM and 53–63% reduction in total training time. In comparison with QRNN, SRU obtains 0.8% improvement on exact match and 0.6% on F1 score, and runs 60% faster. This speed improvement highlights the impact of the fused ker-

---

[3] The current state-of-the-art models (Seo et al., 2016; Wang et al., 2017) make use of additional components such as character-level embeddings, which are not directly comparable to the setup of Chen et al. (2017). However, these models can potentially benefit from SRU since RNNs are incorporated in the model architecture.

[4] `https://github.com/hitvoice/DrQA`

Model	# layers	Size	Dev EM	Dev F1	Time per epoch RNN	Time per epoch Total
LSTM (Chen et al., 2017)	3	4.1m	69.5	78.8	316s	431s
QRNN (k=1) + highway	4	2.4m	70.1 ± 0.1	79.4 ± 0.1	113s	214s
	6	3.2m	70.6 ± 0.1	79.6 ± 0.2	161s	262s
SRU	3	2.0m	**70.2** ± 0.3	**79.3** ± 0.1	58s	159s
SRU	4	2.4m	**70.7** ± 0.1	**79.7** ± 0.1	72s	173s
SRU	6	3.2m	**71.4** ± 0.1	**80.2** ± 0.1	100s	201s

Table 2: Exact match (EM) and F1 scores of various models on SQuAD (Section 4.2). We also report the total processing time per epoch and the time spent in RNN computations. SRU outperforms other models, and is more than five times faster than cuDNN LSTM.

nel (Algorithm 1). While the QRNN baseline involves a similar amount of computation, assembling all element-wise operations of both directions in SRU achieves better GPU utilization.

4.3 Machine Translation

Dataset We train translation models on the WMT English→German dataset, a standard benchmark for translation systems (Peitz et al., 2014; Li et al., 2014; Jean et al., 2015). The dataset consists of 4.5 million sentence pairs. We obtain the pre-tokenized dataset from the OpenNMT project (Klein et al., 2017). The sentences were tokenized using the word-piece model (Wu et al., 2016b), which generates a shared vocabulary of about 32,000 tokens. Newstest-2014 and newstest-2017 are provided and used as the validation and test sets.[5]

Setup We use the state-of-the-art Transformer model of Vaswani et al. (2017) as our base architecture. In the base model, a single Transformer consists of a multi-head attention layer and a bottleneck feed-forward layer. We substitute the feed-forward network using our SRU implementation:

$$\begin{aligned} \text{base:} \quad & \mathbf{W} \cdot \text{ReLU\_layer}(\mathbf{x}) + \mathbf{b} \\ \text{ours:} \quad & \mathbf{W} \cdot \text{SRU\_layer}(\mathbf{x}) + \mathbf{b} \ . \end{aligned}$$

The intuition is that SRU can better capture sequential information as a recurrent network, and potentially achieve better performance while requiring fewer layers.

We keep the model configuration the same as Vaswani et al. (2017): the model dimension is $d_{\text{model}} = 512$, the feed-forward and SRU layer has inner dimensionality $d_{\text{ff}} = d_{\text{sru}} = 2048$, and positional encoding (Gehring et al., 2017) is applied on the input word embeddings. The base model without SRU has 6 layers, while we set the number of layers to 4 and 5 when SRU is added. Following the original setup, we use a dropout probability 0.1 for all components, except the SRU in the 5-layer model, for which we use a dropout of 0.2 as we observe stronger over-fitting in training.

We use a single NVIDIA Tesla V100 GPU for each model. The published results were obtained using 8 GPUs in parallel, which provide a large effective batch size during training. To approximate the setup, we update the model parameters every 5×5120 tokens and use 16,000 warm-up steps following OpenNMT suggestions. We train each model for 40 epochs (250,000 steps), and perform 3 independent trials for each model configuration. A single run takes about 3.5 days with a Tesla V100 GPU.

Results Table 3 shows the translation results. When SRU is incorporated into the architecture, both the 4-layer and 5-layer model outperform the Transformer base model. For instance, our 5-layer model obtains an average improvement of 0.7 test BLEU score and an improvement of 0.5 BLEU score by comparing the best results of each model achieved across three runs. SRU also exhibits more stable performance, with smaller variance over 3 runs. Figure 4 further compares the validation accuracy of different models. These results confirm that SRU is better at sequence modeling compared to the original feed-forward network (FFN), requiring fewer layers to achieve sim-

---

[5] `https://github.com/OpenNMT/OpenNMT-tf/tree/master/scripts/wmt`

Model	# layers	Size	BLEU score Valid	BLEU score Test	Speed (toks/sec)	Hours per epoch
Transformer (base)	6	76m	26.6±0.2 (26.9)	27.6±0.2 (27.9)	20k	2.0
Transformer (+SRU)	4	79m	26.7±0.1 (26.8)	27.8±0.1 (28.3)	**22k**	**1.8**
Transformer (+SRU)	5	90m	**27.1**±0.0 (**27.2**)	**28.3**±0.1 (**28.4**)	19k	2.1

Table 3: English→German translation results (Section 4.3). We perform 3 independent runs for each configuration. We select the best epoch based on the valid BLEU score for each run, and report the average results and the standard deviation over 3 runs. In addition, we experiment with averaging model checkpoints and use the averaged version for evaluation, following (Vaswani et al., 2017). We show the best BLEU results achieved in brackets.

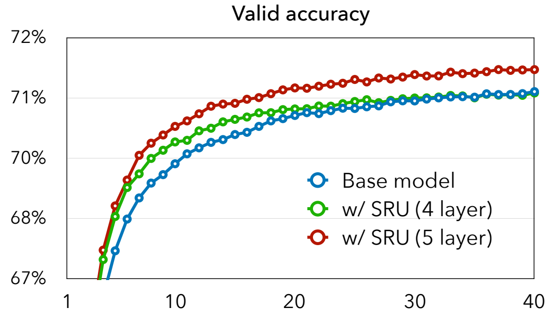

Figure 4: Mean validation accuracy (y-axis) of different translation models after each training epoch (x-axis).

ilar accuracy. Finally, adding SRU does not affect the parallelization or speed of Transformer – the 4-layer model exhibits 10% speed improvement, while the 5-layer model is only 5% slower compared to the base model. We present more results and discussion in Appendix B.3.

4.4 Character-level Language Modeling

Dataset We use Enwik8, a large dataset for character-level language modeling. Following standard practice, we use the first 90M characters for training and the remaining 10M split evenly for validation and test.

Setup Similar to previous work, we use a batch size of 128 and an unroll size of 100 for truncated backpropagation during training. We also experiment with an unroll size of 256 and a batch size of 64 such that each training instance has longer context. We use a non-zero highway bias $\mathbf{b}_r = -3$ that is shown useful for training language model (Zilly et al., 2017). Previous methods employ different optimizers and learning rate schedulers for training. For simplicity and consistency, we use the Adam optimizer and the same learning rate scheduling (i.e., Noam scheduling) as the translation experiments. We train a maximum of 100 epochs (about 700,000 steps).

We compare various recurrent models and use a parameter budget similar to previous methods. In addition, we experiment with the factorization trick (Kuchaiev and Ginsburg, 2017) to reduce the total number of parameters without decreasing the performance. See details in Appendix B.

Results Table 4 presents the results of SRU and other recurrent models. The 8-layer SRU model achieves validation and test bits per character (BPC) of 1.21, outperforming previous best reported results of LSTM, QRNN and recurrent highway networks (RHN). Increasing the layer of SRU to 12 and using a longer context of 256 characters in training further improves the BPC to 1.19

4.5 Ablation Analysis

We perform ablation analyses on SRU by successively disabling different components:

(1) Remove the point-wise multiplication term $\mathbf{v} \odot \mathbf{c}_{t-1}$ in the forget and reset gates. The resulting variant involves less recurrence and has less representational capacity.

(2) Disable the scaling correction by setting the constant $\alpha = 1$.

(3) Remove the skip connections.

We train model variants on the classification and question answering datasets. Table 5 and Figure 5 confirm the impact of our design decisions – removing these components result in worse classification accuracies and exact match scores.

Model	Size	# layers	Unroll size	Valid	Test	Time
MI-LSTM (Wu et al., 2016c)	17m	1	100	-	1.44	-
HM-LSTM (Chung et al., 2016)	35m	3	100	-	1.32	-
LSTM (Melis et al., 2017)	46m	4	50	1.28	1.30	-
RHN (Zilly et al., 2017)	46m	10	50	-	1.27	-
FS-LSTM (Mujika et al., 2017)	47m	4	100	-	1.25	-
QRNN (Merity et al., 2018)	26m	4	200	-	1.33	-
LSTM (Merity et al., 2018)	47m	3	200	-	1.23	-
SRU	37m	6	100	1.29	1.30	28min
SRU	37m	10	100	1.26	1.27	29min
SRU (with projection)	37m	6	100	1.25	1.26	29min
SRU (with projection)	47m	8	100	1.21	1.21	39min
SRU (with projection)	49m	12	256	1.19	1.19	41min

Table 4: Validation and test BPCs of different recurrent models on Enwik8 dataset. The last column presents the training time per epoch. For SRU with projection, we set the projection dimension to 512.

Model	4 layers	6 layers
SRU (full)	70.7	71.4
− remove $\mathbf{v} \odot \mathbf{c}_{t-1}$	70.6	71.1
− remove α-scaling	70.3	71.0
− remove highway	69.4	69.1

Table 5: Ablation analysis on SQuAD. Components are successively removed and the EM scores are averaged over 4 runs.

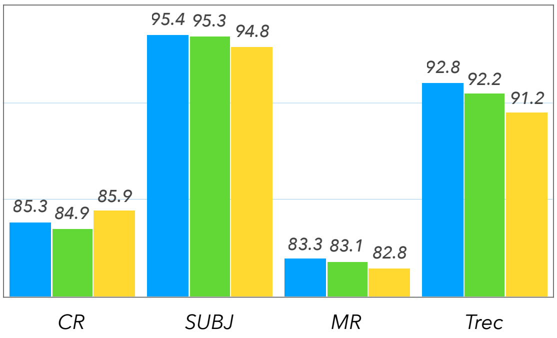

Figure 5: Ablation analysis on the classification datasets. Average validation results are presented. We compare the full SRU implementation (left blue), the variant without $\mathbf{v} \odot \mathbf{c}_{t-1}$ multiplication (middle green) and the variant without highway connection (right yellow).

5 Discussion

This work presents Simple Recurrent Unit (SRU), a scalable recurrent architecture that operates as fast as feed-forward and convolutional units. We confirm the effectiveness of SRU on multiple natural language tasks ranging from classification to translation. We open source our implementation to facilitate future NLP and deep learning research.

Trading capacity with layers SRU achieves high parallelization by simplifying the hidden-to-hidden dependency. This simplification is likely to reduce the representational power of a single layer and hence should be balanced to avoid performance loss. However, unlike previous work that suggests additional computation (e.g., n-gram filters) within the layer (Balduzzi and Ghifary, 2016; Bradbury et al., 2017), we argue that increasing the depth of the model suffices to retain modeling capacity. Our empirical results on various tasks confirm this hypothesis.

Acknowledgement

We thank Alexander Rush and Yoon Kim for help with machine translation experiments, and Danqi Chen for help with SQuAD experiments. We thank Adam Yala, Howard Chen, Jeremy Wohlwend, Lili Yu, Kyle Swanson and Kevin Yang for providing useful feedback on the paper and the SRU implementation. A special thanks to Hugh Perkins for his support on the experimental environment setup and Runqi Yang for answering questions about his code.

Abstract

Pseudo relevance feedback (PRF) is commonly used to boost the performance of traditional information retrieval (IR) models by using top-ranked documents to identify and weight new query terms, thereby reducing the effect of query-document vocabulary mismatches. While neural retrieval models have recently demonstrated strong results for ad-hoc retrieval, combining them with PRF is not straightforward due to incompatibilities between existing PRF approaches and neural architectures. To bridge this gap, we propose an end-to-end neural PRF framework that can be used with existing neural IR models by embedding different neural models as building blocks. Extensive experiments on two standard test collections confirm the effectiveness of the proposed NPRF framework in improving the performance of two state-of-the-art neural IR models.

1 Introduction

Recent progress in neural information retrieval models (NIRMs) has highlighted promising performance on the ad-hoc search task. State-of-the-art NIRMs, such as DRMM (Guo et al., 2016), HiNT (Fan et al., 2018), (Conv)-KNRM (Xiong et al., 2017; Dai et al., 2018), and (Co)-PACRR (Hui et al., 2017, 2018), have successfully implemented insights from traditional IR models using neural building blocks. Meanwhile, existing IR research has already demonstrated the effectiveness of incorporating relevance signals from top-ranked documents through pseudo relevance feedback (PRF) models (Buckley and Robertson, 2008; Diaz et al., 2016). PRF models expand the query with terms selected from top-ranked documents, thereby boosting ranking performance by reducing the problem of vocabulary mismatch between the original query and documents (Rocchio, 1971). Existing neural IR models do not have a mechanism for treating expansion terms differently from the original query terms, however, making it non-trivial to combine them with existing PRF approaches. In addition, neural IR models differ in their architectures, making the development of a widely-applicable PRF approach a challenging task.

To bridge this gap, we propose a generic neural pseudo relevance feedback framework, coined NPRF, that enables the use of PRF with existing neural IR models. Given a query and a target document, the top-ranked documents from the initial ranking are consumed by NPRF, which expands the query by interpreting it from different perspectives. Given a target document to evaluate, NPRF produces a final relevance score by considering the target document's relevance to these top-ranked documents and to the original query.

The proposed NPRF framework can directly incorporate different established neural IR models, which serve as the concrete scorers in evaluating the relevance of a document relative to the top-ranked documents and to the query, without changing their architectures. We instantiate the NPRF framework using two state-of-the-art neural IR models, and we evaluate their performance on two widely-used TREC benchmark datasets for ad-hoc retrieval. Our results confirm that the NPRF framework can substantially improve the performance of both models. Moreover, both neural models perform similarly inside the NPRF framework despite the fact that without NPRF one model performed substantially worse than the other model. The contributions of this work are threefold: 1) the novel NPRF framework; 2) two instantiations of the NPRF framework using two state-of-the-art neural IR models; and 3) the experiments that confirm the effectiveness of the NPRF framework.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4482–4491
Brussels, Belgium, October 31 - November 4, 2018.

The rest of this paper is organized as follows. Section 2 presents the proposed NPRF framework in details. Following that, Section 3 describes the setup of the evaluation, and reports the results. Finally, Section 4 recaps existing literature, before drawing conclusions in Section 5.

2 Method

In this section, we introduce the proposed neural framework for pseudo relevance feedback (NPRF). Recall that existing unsupervised PRF models (Rocchio, 1971; Lavrenko and Croft, 2001; Ye et al., 2009) issue a query to obtain an initial ranking, identify promising terms from the top-m documents returned, and expand the original query with these terms. Rather than selecting the expanded terms within the top-m documents, NPRF uses these documents directly as expansion queries by considering the interactions between them and a target document. Thus, each document's ultimate relevance score depends on both its interactions with the original query and its interactions with these feedback documents.

2.1 Overview

Given a query q, NPRF estimates the relevance of a target document d relative to q as described in the following steps. The architecture is summarized in Figure 1. Akin to the established neural IR models like DRMM (Guo et al., 2016), the description is based on a query-document pair, and a ranking can be produced by sorting the documents according to their scores.

- **Create initial ranking.** Given a document corpus, a ranking method $rel_q(q, d)$ is applied to individual documents to obtain the top-m documents, denoted as D_q for q.

- **Extract document interactions.** To evaluate the relevance of d, each d_q in D_q is used to expand q, where d is compared against each d_q, using a ranking method $rel_d(d_q, d)$.

- **Combine document interactions.** The relevance scores $rel_d(d_q, d)$ for individual $d_q \in D_q$ are further weighted by $rel_q(q, d_q)$, which serves as an estimator for the confidence of the contribution of d_q relative to q. The weighted combination of these relevance scores is used to produce a relevance score for d, denoted as $rel_D(q, D_q, d)$.

While the same ranking model can be used for both $rel_q(.,.)$ and $rel_d(.,.)$, we denote them separately in the architecture. In our experiments, the widely-used unsupervised ranking method BM25 (Robertson et al., 1995) serves as $rel_q(.,.)$; meanwhile two state-of-the-art neural IR relevance matching models, namely, DRMM (Guo et al., 2016) and K-NRM (Xiong et al., 2017), serve as the ranking method $rel_d(.,.)$. However, it is worth noting that in principle rel_q and rel_d can be replaced with any ranking method, and the above choices mainly aim to demonstrate the effectiveness of the NPRF framework.

2.2 Model Architecture

The NPRF framework begins with an initial ranking for the input query q determined by $rel_q(.,.)$, which forms D_q, the set of the top-m documents D_q. The ultimate query-document relevance score $rel_D(q, D_q, d)$ is computed as follows.

Extracting document interactions. Given the target document d and each feedback document $d_q \in D_q$, $rel_d(.,.)$ is used to evaluate the relevance between d and d_q, resulting in m real-valued relevance scores, where each score corresponds to the estimated relevance of d according to one feedback document d_q.

As mentioned, two NIRMs are separately used to compute $rel_d(d_q, d)$ in our experiments. Both models take as input the cosine similarities between each pair of terms in d_q and d, which are computed using pre-trained word embeddings as explained in Section 3.1. Given that both models consider only unigram matches and do not consider term dependencies, we first summarize d_q by retaining only the top-k terms according to their *tf-idf* scores, which speeds up training by reducing the document size and removing noisy terms. In our pilot experiments, the use of top-k *tf-idf* document summarization did not influence performance. For different $d_q \in D_q$, the same model is used as $rel_d(.,.)$ for different pairs of (d_q, d) by sharing model weights.

Combining document interactions. When determining the relevance of a target document d, there exist two sources of relevance signals to consider: the target document's relevance relative to the feedback documents D_q and its relevance relative to the query q itself. In this step, we combine $rel_d(d_q, d)$ for each $d_q \in D_q$ into an overall feedback document relevance score

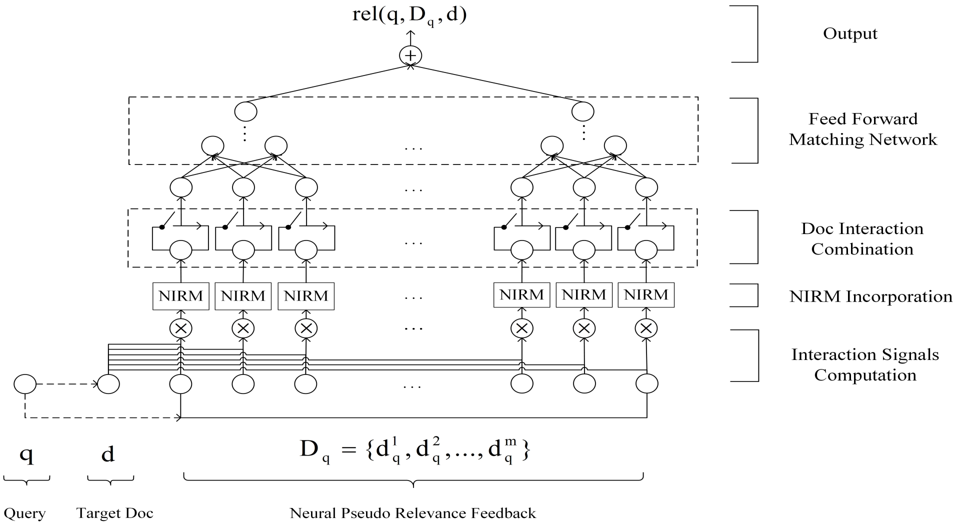

Figure 1: Architecture of the proposed neural pseudo relevance feedback (NPRF) framework.

$rel_D(q, D_q, d)$. When combining the relevance scores, the agreement between q and each d_q is also important, since d_q may differ from q in terms of information needs. The relevance of d_q from the initial ranking $rel_q(q, d_q)$ is employed to quantify this agreement and weight each $rel_d(d_q, d)$ accordingly.

When computing such agreements, it is necessary to remove the influence of the absolute ranges of the scores from the initial ranker. For example, ranking scores from a language model (Ponte and Croft, 1998) and from BM25 (Robertson et al., 1995) can differ substantially in their absolute ranges. To mitigate this, we use a smoothed min-max normalization to rescale $rel_q(q, d_q)$ into the range $[0.5, 1]$. The min-max normalization is applied by considering $min(rel_q(q, d_q)|d_q \in D_q)$ and $max(rel_q(q, d_q)|d_q \in D_q)$. Hereafter, $rel_q(q, d_q)$ is used to denote this relevance score after min-max normalization for brevity. The (normalized) relevance score is smoothed and then weighted by the relevance evaluation of d_q, producing a weighted document relevance score $rel_d{}'(d_q, d)$ for each $d_q \in D_q$ that reflects the relevance of d_q relative to q. This computation is described in the following equation.

$$rel_d{}'(d_q, d) = rel_d(d_q, d)(0.5 + 0.5 \times rel_q(q, d_q)) \quad (1)$$

As the last step, we propose two variants for combining the $rel_d{}'(d_q, d)$ for different d_q into a single score $rel_D(q, D_q, d)$: (i) performing a direct summation and (ii) using a feed forward network with a hyperbolic tangent ($tanh$) non-linear activation. Namely, the first variant simply sums up the scores, whereas the second takes the ranking positions of individual feedback documents into account.

2.3 Optimization and Training

Each training sample consists of a query q, a set of m feedback documents D_q, a relevant target document d^+ and a non-relevant target document d^- according to the ground truth. The Adam optimizer (Kingma and Ba, 2014) is used with a learning rate 0.001 and a batch size of 20. Training normally converges within 30 epochs, with weights uniformly initialized. A hinge loss is employed for training as shown below.

$$loss(q, D_q, d^+, d^-) =$$
$$max(0, 1 - rel(q, D_q, d^+) + rel(q, D_q, d^-))$$

3 Evaluation

3.1 Evaluation Setup

Dataset. We evaluate our proposed NPRF framework on two standard test collections, namely, TREC1-3 (Harman, 1993) and Robust04 (Voorhees, 2004). TREC1-3 consists of 741,856 documents with 150 queries used in the TREC 1-3 ad-hoc search tasks (Harman, 1993, 1994, 1995). Robust04 contains 528,155 documents and 249 queries used in the TREC 2004 Robust track (Voorhees, 2004). We use those two collections to balance between the number of queries and the TREC pooling depth, i.e., 100 on both collections, allowing for sufficient training data. Manual relevance judgments are available on both collections, where both the relevant and non-relevant documents are labeled for each query.

Two versions of queries are included in our experiments: a short keyword query (*title query*), and a longer description query that restates the corresponding keyword query's information need in terms of natural language (*description query*). We evaluate each type of query separately using the metrics Mean Average Precision at 1,000 (MAP), Precision at 20 (P@20) (Manning et al., 2008), and NDCG@20 (Järvelin and Kekäläinen, 2002).

Preprocessing. Stopword removal and Porter's stemmer are applied (Manning et al., 2008). The word embeddings are pre-trained based on a pool of the top 2,000 documents returned by BM25 for individual queries as suggested by (Diaz et al., 2016). The implementation of Word2Vec[1] from (Mikolov et al., 2013) is employed. In particular, we employ CBOW with the dimension set to 300, window size to 10, minimum count to 5, and a subsampling threshold of 10^{-3}. The CBOW model is trained for 10 iterations on the target corpus.

Unsupervised ranking models serve as baselines for comparisons. We use the open source Terrier platform's (Macdonald et al., 2012) implementation of these ranking models:

- **BM25** (Robertson et al., 1995), a classical probabilistic model, is employed as an unsupervised baseline. The hyper-parameters b and k_1 are tuned by grid search. As mentioned in Sec. 2.1, BM25 also generates the initial rankings D_q, serving as $rel_q(.,.)$ in the NPRF framework.

- On top of BM25, we use an adapted version of Rocchio's query expansion (Ye et al., 2009), denoted as **BM25+QE**. Note that, as demonstrated in the results, BM25+QE's performance is comparable with the base neural IR models, including DRMM, K-NRM and PACRR. This illustrates the difficulty in making improvements on the TREC benchmarks through the uses of deep learning methods. The hyper-parameters, including the number of feedback documents and the number of expansion terms, are optimized using grid search on training queries.

- In addition, **QL+RM3**, the query likelihood language model with the popular RM3 PRF (Lavrenko and Croft, 2001), is used as another unsupervised baseline.

Neural IR models are used for $rel_d(.,.)$. As mentioned in Section 2.1, two unigram neural IR models are employed in our experiments:

- **DRMM**. We employ the variant with the best effectiveness on Robust04 according to (Guo et al., 2016), namely, DRMM$_{LCH\times IDF}$ with the original configuration.

- **K-NRM**. Due to the lack of training data compared with the commercial data used by (Xiong et al., 2017), we employ a K-NRM variant with a frozen word embedding layer. To compensate for this substantial reduction in the number of learnable weights, we add an additional fully connected layer to the model. These changes lead to a small but competitive K-NRM variant, as demonstrated in (Hui et al., 2018).

- We additionally implement **PACRR** (Hui et al., 2017) for the purpose of performing comparisons, but do not use PACRR to compute $rel_d(.,.)$ due to the computational costs. In particular, PACRR-firstk is employed where the first $1,000$ terms are used to compute the similarity matrices, and the original configuration from (Hui et al., 2017) is used.

- **NIRM(QE)** uses the modified query generated by the query expansion of BM25+QE (Ye et al., 2009) as input to the neural IR model. Both DRMM and K-NRM are used to instantiate NIRM(QE).

- **Variants of the proposed NPRF approach.** As indicated in Section 2.2, NPRF includes two variants that differ in the combination of the relevance scores from different $d_q \in D_q$: the variant **NPRF$_{\mathbf{ff}}$** uses a feed forward network with a hidden layer with five neurons to compute $rel(d, D_q)$, and the other variant **NPRF$_{\mathbf{ds}}$** performs a direct summation of the different relevance scores. For the purposes of comparison, we additionally introduce another variant coined **NPRF$_{\mathbf{ff'}}$**, where the relevance of d_q to q is not considered in the combination by directly setting $rel'_d(d, d_q) = rel_d(d, d_q)$ in place of Equation 1, thereafter combining the scores with a fully connected layer as in NPRF$_{ff}$. We combine each of the three NPRF variants with

---

[1] https://code.google.com/p/word2vec/

the DRMM and K-NRM models, and report results for all six variants. Our implementation of the NPRF framework is available to enable future comparisons[2].

Akin to (Guo et al., 2016; Xiong et al., 2017; Hui et al., 2017), the NIRM baselines and the proposed NPRF are employed to re-rank the search results from BM25. In particular, the top-10 documents from the unsupervised baseline are used as the pseudo relevance feedback documents D_q as input for NPRF, where each $d_q \in D_q$ is represented by its top-20 terms with the highest tf-idf weights. As illustrated later in Section 3.3, NPRF's performance is stable over a wide range of settings for both parameters.

Cross-validation. Akin to (Hui et al., 2018), owing to the limited number of labeled data, five-fold cross-validation is used to report the results by randomly splitting all queries into five equal partitions. In each fold, three partitions are used for training, one for validation, and one for testing. The model with the best MAP on the validation set is selected. We report the average performance on all *test* partitions. A two-tailed paired t-test is used to report the statistical significance at 95% confidence interval.

3.2 Results

Comparison to BM25. We first compare the proposed NPRF models with the unsupervised BM25. The results are summarized in Tables 1 and 2, where the best result in each column is highlighted in bold. From Tables 1 and 2, it can be seen that the proposed NPRF variants obtain significant improvement relative to BM25 on both test collections with both kinds of test queries. Moreover, the results imply that the use of different query types does not affect the effectiveness of NPRF, which consistently outperforms BM25.

Comparison to neural IR models. NPRF is further compared with different neural IR models, as summarized in Tables 3 & 4. It can be seen that NPRF regularly improves on top of the NIRM baselines. For both types of queries, NPRF-DRMM outperforms DRMM and NPRF-KNRM outperforms K-NRM when re-ranking BM25. Remarkably, the proposed NPRF is able to improve the weaker NIRM baseline. For instance, on Robust04, when using the description queries, DRMM and K-NRM obtain highly different results, with MAPs of 0.2630 and 0.1687 after reranking the initial results from BM25, respectively. When NPRF is used in conjunction with the NIRM models, however, the gap between the two models is closed; that is, MAP=0.2801 for NRFF$_{ds}$-DRMM and MAP=0.2800 for NRFF$_{ds}$-KNRM (see Table 4). This finding highlights that our proposed NPRF is robust with respect to the use of the two embedded NIRM models. A possible explanation for the poor performance of K-NRM on two TREC collections is the lack of training data, as suggested in (Dai et al., 2018). While K-NRM could be improved by introducing weak supervision (Dai et al., 2018), we achieve the same goal by incorporating pseudo relevance feedback information without extra training data.

While the six NPRF variants exhibit similar results across both kinds of queries, NPRF$_{ds}$-DRMM in general achieves the best performance on Robust04, and NPRF$_{ds}$-KNRM appears to be the best variant on TREC1-3. In the meantime, NPRF$_{ds}$ outperforms NPRF$_{ff}$ variants. One difference between the two methods is that NPRF$_{ff}$ considers the position of each d_q in the D_q ranked documents, whereas NPRF$_{ds}$ simply sums up the scores regardless of the positions. The fact that NPRF$_{ds}$ performs better suggests that the ranking position within the D_q documents may not be a useful signal. In the remainder of this paper, we mainly report on the results obtained by NPRF$_{ds}$.

Comparison to query expansion baselines. In Table 5, the proposed NPRF model is compared with three kinds of query expansion baselines, namely, the unsupervised BM25+QE (Ye et al., 2009), QL+RM3 (Lavrenko and Croft, 2001), and DRMM/K-NRM(QE), the neural IR models using expanded queries as input. According to Table 5, the unsupervised BM25+QE baseline appears to achieve better performance in terms of MAP@1k, owing to its use of query expansion to match relevant documents containing the expansion terms from the whole collection. On the other hand, NPRF$_{ds}$, which reranks the top-1000 documents returned by BM25, outperforms the query expansion baselines in terms of early precision, as measured by either NDCG@20 or P@20. These measures on shallow rankings are particularly important for general IR applications where the quality of the top-ranked results is crucial to the user satisfaction. Moreover, our NPRF outperforms

NIRM(QE) in most cases, indicating the benefit brought by wrapping up the feedback information in a document-to-document matching framework as in NPRF, as opposed to directly adding unweighted expansion terms to the query. Recall that, it is not straightforward to incorporate these expanded terms within the existing NIRMs' architectures because the NIRMs do not distinguish between them and the original query terms.

3.3 Analysis

Parameter sensitivity. Moreover, we analyze factors that may influence NPRF's performance. We report results on NPRF$_{ds}$ using title queries on Robust04 for the sake of brevity, but similar observations also hold for the other NPRF variants, as well as on TREC1-3. Figure 2 illustrates the sensitivity of NPRF relative to two parameters: the number of feedback documents m within D_q and the number of terms k that are used to summarize each $d_q \in D_q$. Specifically, Figure 2 shows the performance of NPRF$_{ds}$ as the number of feedback documents m varies (top), and as the number of top terms k varies (bottom). The effectiveness of NPRF appears to be stable over a wide range of the parameter configurations, where the proposed model consistently outperforms the BM25 baseline.

Case study. A major advantage of the proposed NPRF over existing neural IR models is that it allows for soft-matching query-related terms that are missing from both the query and the target document. Table 6 presents an illustrative example of soft matching in NPRF. From Table 6, it can be seen that there exist query-related terms in the top-10 documents returned by BM25 in the initial ranking. However, since those query-related terms are missing in both the query and the target document, they are not considered in the document-to-query matching and, consequently, the target document is ranked 122^{nd} by BM25 despite the facts that it was judged relevant by a human assessor. In contrast, the NPRF framework allows for the soft-matching of terms that are missing in both the query and target document. As a result, the matching signals for the query terms and query-related terms in the target document are enhanced. This leads to enhanced effectiveness with the target document now ranked in the 5^{th} position.

In summary, the evaluation on two standard TREC test collections shows promising results obtained by our proposed NPRF approach, which outperforms state-of-the-art neural IR models in most cases. Overall, NPRF provides effective retrieval performance that is robust with respect to the two embedded neural models used for encoding the document-to-document interactions, the two kinds of queries with varied length, and wide range of parameter configurations.

4 Related Work

Recently, several neural IR models (NIRMs) have been proposed to apply deep learning techniques in ad-hoc information retrieval. One of the essential ideas from prior work is to model the document-to-query *interaction* via neural networks, based on a matrix of document-to-query embedding term similarities, incorporating both the "exact matching" of terms appearing in both the document and query and the "soft matching" of different query and document term pairs that are semantically related.

DSSM, one of the earliest NIRMs proposed in (Huang et al., 2013), employs a multi-layer neural network to project queries and document into a common semantic space. The cosine similarity between a query and a document (document title) is used to produce a final relevance score for the query-document pair. CDSSM is a convolutional version of DSSM, which uses the convolutional neural network (CNN) and max-pooling strategy to extract semantic matching features at the sentence level (Shen et al., 2014). (Pang et al., 2016) also employ a CNN to construct the MatchPyramid model, which learns hierarchical matching patterns between local interactions of document-query pair. (Guo et al., 2016) argue that both DSSM and CDSSM are representation-focused models, and thus are better suited to capturing semantic matching than relevance matching (i.e., lexical matching), and propose the interaction-focused relevance model named DRMM. DRMM maps the local interactions between a query-document pair into a fixed-length histogram, from which the exact matching signals are distinguished from the other matching signals. These signals are fed into a feed forward network and a term gating network to produce global relevance scores. Similar to DRMM, K-NRM (Xiong et al., 2017) builds its model on top of a matrix of local interaction signals, and utilizes multiple Gaussian kernels to obtain multi-level exact/soft matching features that are input into a ranking layer to produce the final ranking score. K-NRM is later improved by Conv-KNRM, which employs CNN filters to capture n-gram representations of queries and documents (Dai et al., 2018). DeepRank (Pang et al., 2017) models the relevance generation process by identifying query-centric contexts, processing them with a CNN or LSTM, and aggregating them to produce a final relevance score. Building upon DeepRank, (Fan et al., 2018) propose to model diverse relevance patterns by a data-driven method to allow rele-

Table 6: An illustrative example of soft matching in NPRF. The target document FBIS3-23332, judged relevant, is ranked 122^{nd} by BM25 for query 341 on Robust04, and is promoted to the 5^{th} by NPRF$_{ds}$-DRMM. The NPRF mechanism increases the chances of soft-matching query-related terms that appear in the top-ranked documents (terms in blue), but are missing in both the query and the target document. Subsequently, the matching signals with the query terms (in **bold**) and the query-related terms (in red) in the target document are enhanced.

vance signals at different granularities to compete with each other for the final relevance assessment.

Duet (Mitra et al., 2017) employs two separate deep neural networks to build a relevance ranking model, in which a local model estimates the relevance score according to exact matches between query and document terms, and a distributed model estimates relevance by learning dense lower-dimensional representations of query and document text. (Zamani et al., 2018) extends the Duet model by considering different fields within a document.

(Hui et al., 2017) propose the PACRR model based on the idea that an appropriate combination of convolutional kernels and pooling operations can be used to successfully identify both unigram and n-gram query matches. PACRR is later improved upon by Co-PACRR, a context-aware variant that takes the local and global context of matching signals into account through the use of three new components (Hui et al., 2018).

(Ran et al., 2017) propose a document-based neural relevance model that utilizes complemented medical records to address the mismatch problem in clinical decision support. (Nogueira and Cho, 2017) propose a reinforcement learning approach to reformulating a task-specific query. (Li et al., 2018) propose DAZER, a CNN-based neural model upon interactions between seed words and words in a document for zero-shot document filtering with adversarial learning. (Ai et al., 2018) propose to refine document ranking by learning a deep listwise context model.

In summary, most existing neural IR models are based on query-document interaction signals and do not provide a mechanism for incorporating relevance feedback information. This work proposes an approach for incorporating relevance feedback information by embedding neural IR models within a neural pseudo relevance feedback framework, where the models consume feedback information via document-to-document interactions.

5 Conclusions

In this work we proposed a neural pseudo relevance feedback framework (NPRF) for incorporating relevance feedback information into existing neural IR models (NIRM). The NPRF framework uses feedback documents to better estimate relevance scores by considering individual feedback documents as different interpretations of the user's information need. On two standard TREC datasets, NPRF significantly improves the performance of two state-of-the-art NIRMs. Furthermore, NPRF was able to improve their perfor-

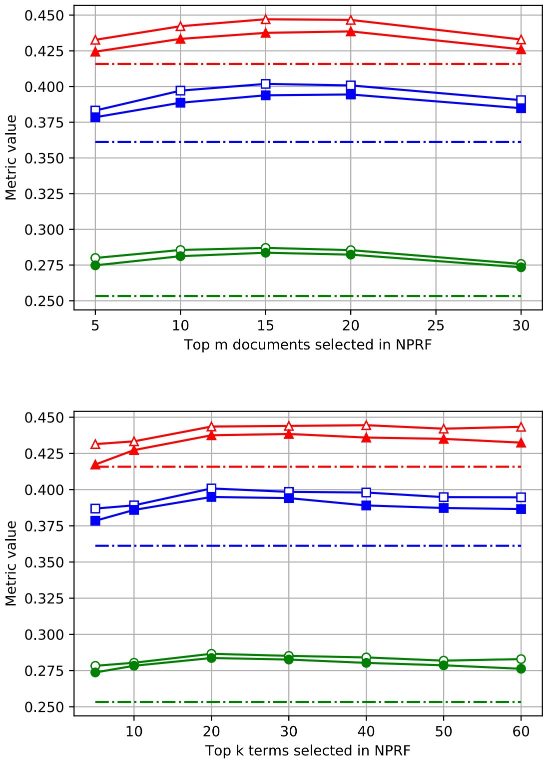

Figure 2: Performance of NPRF$_{ds}$ with different numbers of PRF documents (top) and different umber of terms which are used to summarize the feedback documents (bottom). The ○, □, △ correspond to results measured by MAP, P@20 and NDCG@20 respectively, and the empty or solid symbols correspond to those for NPRF$_{ds}$-DRMM and NPRF$_{ds}$-KNRM. Abstract

Learning a matching function between two text sequences is a long standing problem in NLP research. This task enables many potential applications such as question answering and paraphrase identification. This paper proposes Co-Stack Residual Affinity Networks (CSRAN), a new and universal neural architecture for this problem. CSRAN is a deep architecture, involving stacked (multi-layered) recurrent encoders. Stacked/Deep architectures are traditionally difficult to train, due to the inherent weaknesses such as difficulty with feature propagation and vanishing gradients. CSRAN incorporates two novel components to take advantage of the stacked architecture. Firstly, it introduces a new bidirectional alignment mechanism that learns affinity weights by fusing sequence pairs across stacked hierarchies. Secondly, it leverages a multi-level attention refinement component between stacked recurrent layers. The key intuition is that, by leveraging information across all network hierarchies, we can not only improve gradient flow but also improve overall performance. We conduct extensive experiments on six well-studied text sequence matching datasets, achieving state-of-the-art performance on all.

1 Introduction

Determining the semantic affinity between two text sequences is a long standing research problem in natural language processing research. This is understandable, given that technical innovations in this domain would naturally bring benefits to a diverse plethora of applications ranging from paraphrase detection to standard document retrieval. This work focuses on short textual sequences, focusing on a myriad of applications such as natural language inference, question answering, reply prediction and paraphrase detection. This paper presents a new deep matching model for universal text matching.

Neural networks are dominant state-of-the-art approaches for many of these matching problems (Gong et al., 2017; Shen et al., 2017; Wang et al., 2017; Chen et al., 2017). Fundamentally, neural networks operate via a concept of feature hierarchy, in which hierarchical representations are constructed as sequences propagate across the network. In the context of matching, representations are often (1) encoded, (2) matched, and then (3) aggregated for prediction. Each key step often comprises several layers, which consequently adds to the overall depth of the network.

Unfortunately, it is a well established fact that deep networks are difficult to train. This is attributed to not only vanishing/exploding gradients but also an instrinsic difficulty pertaining to feature propagation. To this end, commonly adopted solutions include Residual connections (He et al., 2016) and/or Highway layers (Srivastava et al., 2015). The key idea in these approaches is to introduce additional (skip/residual) connections, propagating shallower layers to deeper layers via shortcuts. To the best of our knowledge, these techniques are generally applied to single sequences and therefore the notion of pairwise residual connections have not been explored.

This paper presents Co-Stack Residual Affinity Networks (CSRAN), a stacked multi-layered recurrent architecture for general purpose text matching. Our model proposes a new co-stacking mechanism that computes bidirectional affinity scores by leveraging all feature hierarchies between text sequence pairs. More concretely, word-by-word affinity scores are not computed just from the final encoded representations but across all the entire feature hierarchy.

There are several benefits to our co-stacking

[*] Denotes equal contribution.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4492–4502
Brussels, Belgium, October 31 - November 4, 2018.

mechanism. Firstly, co-stacking acts as a form of residual connector, alleviating the instrinsic issues with network depth. Secondly, there are more extensive matching interfaces between text sequences as the affinity matrix is not computed by just one representation but multiple representations instead. Naturally, increasing the opportunities for interactions between sequences is an intuitive method for improving performance.

Additionally, our model incorporates a Multi-level Attention Refinement (MAR) architecture in order to fully leverage the stacked recurrent architecture. The MAR architecture is a multi-layered adaptation and extension of the CAFE model (Tay et al., 2017c), in which attention is computed, compressed and then re-fed into the input sequence. In our approach, we use CAFE blocks to repeatedly *refine* representations at each level of the stacked recurrent encoder.

The overall outcome of the above-mentioned architectural synergies is a highly competitive model that establishes state-of-the-art performance on six well-known text matching datasets such as SNLI and TrecQA. The overall contributions of this work are summarized as follows:

- We propose a new deep stacked recurrent architecture for matching text sequences. Our model is based on a new co-stacking mechanism which learns to align by exploiting matching across feature hierarchies. This can be interpreted as a new way to incorporate shortcut connections within neural models for sequence matching. Additionally, we also propose a multi-level attention refinement scheme to leverage our stacked recurrent model.
- While stacked architectures can potentially lead to considerable improvements in performance, our experiments show that in the absence of our proposed CSRA (Co-stack Residual Affinity) mechanism, stacking may conversely lead to performance degradation. As such, this demonstrates that our proposed techniques are essential for harnessing the potential of deep architectures.
- We conduct extensive experiments on four text matching tasks across six well-studied datasets, i.e., *Natural Language Inference* (SNLI (Bowman et al., 2015), SciTail (Khot et al., 2018)), *Paraphrase Identification* (Quora, TwitterURL (Lan et al., 2017)), *Answer Sentence Selection* (Wang et al., 2007) and *Utterance-Response Matching* (Ubuntu (Lowe et al., 2015)). Our model achieves state-of-the-art performance on all datasets.

2 Co-Stack Residual Affinity Networks

In this section, we introduce our proposed model architecture for general/universal text matching. The key idea of this architecture is to leverage deep stacked layers, while mitigating the inherent weaknesses of going deep. As such, our network is in similar spirit to highway networks, residual networks and DenseNets, albeit tailored specifically for pairwise architectures. Figure 1 illustrates a high-level overview of our proposed model architecture.

2.1 Input Encoder

The inputs to our model are standard sequences of words A and B which represent sequence a and sequence b respectively. In the context of different applications, a and b take different roles such as premise/hypothesis or question/answer. Both sequences are converted into word representations (via pretrained word embeddings) and character-based representations. Character embeddings are trainable parameters and a final character-based word representation of d dimensions is learned by passing all characters into a Bidirectional LSTM encoder. This is standard, following many works such as (Wang et al., 2017). Word embeddings and character-based word representations are then concatenated to form the final word representation. Next, the word representation is passed through a (optional and tuned as a hyperparameter) 2-layered highway network of d dimensions.

2.2 Stacked Recurrent Encoders

Next, word representations are passed into a stacked recurrent encoder layer. Specifically, we use Bidirectional LSTM encoders at this layer. Let k be the number of layers of the stacked recurrent encoder layer.

$$h^i_t = \text{BiLSTM}_i(h_{t-1}) \;\; \forall t \in [1, 2 \cdots \ell] \quad (1)$$

where BiLSTM_i represents the i-th BiLSTM layer and h^i_t represents the t-th hidden state of the i-th BiLSTM layer. ℓ is the sequence length. Note that the parameters are shared for both a and b.

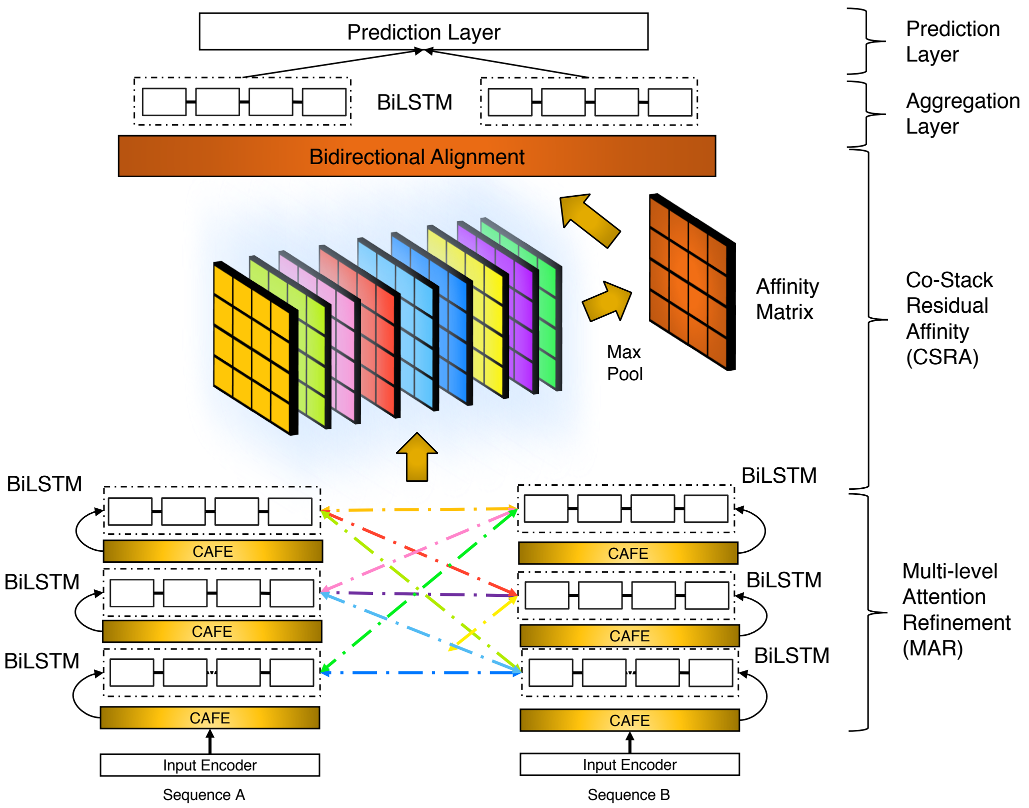

Figure 1: Illustration of the proposed Co-Stack Residual Affinity Network (CSRAN) architecture. Each color coded matrix represents the interactions between two layers of sequence A and sequence B. (Best viewed in color)

2.3 Multi-level Attention Refinement (MAR)

Inspired by CAFE (Tay et al., 2017c) (Compare-Align-Factorized Encoders), a top performing model on the SNLI benchmark, we utilize CAFE blocks between the BiLSTM layers. Each CAFE block returns *six* features, which are generated by a factorization operation using factorization machines (FM). While the authors in (Tay et al., 2017c) simply use this operation in a single layer, we utilize this in a multi-layered fashion which we found to have worked well. This constitutes our multi-level attention refinement mechanism. More concretely, we apply the CAFE operation to the outputs of each BiLSTM layer, allowing the next BiLSTM layer to process the 'augmented' representations. The next layer retains its dimensionality by projecting the augmented representation back to its original size using the BiLSTM encoder. This can be interpreted as repeatedly refining representations via attention. As such, adding CAFE blocks is a very natural fit to the stacked recurrent architecture.

CAFE Blocks This section describes the operation of each CAFE block. The key idea behind CAFE blocks is to align a and b, and compress alignment vectors such as $b' - a$ (subtraction), $b' \odot a$ (element-wise multiplication) and $[b'; a]$ (concatenation) into scalar features. These scalar features are concatenated to the original input embedding, which can be pased into another BiLSTM layer for refining representations. Firstly, a, b are modeled aligned via $E_{ij} = F(a)^\top F(b)$ and then aligned via:

$$A' = E^\top B \text{ and } B' = AE^\top \tag{2}$$

Given aligned pairs (A', B) and (B', A), we generate *three* matching vectors for the concatenation ($[a'_i; b_i]$), element-wise multiplication ($a'_i \odot b_i$) and subtraction vectors ($a'_i - b_i$) of each pair. After which, we apply a factorization machine (Rendle, 2010) $M(x)$ on each matching vector.

$$M(x) = w_0 + \sum_{i=1}^{n} w_i\, x_i + \sum_{i=1}^{n} \sum_{j=i+1}^{n} \langle v_i, v_j \rangle\, x_i\, x_j \tag{3}$$

where $v \in \mathbb{R}^{d \times k}$, $w_0 \in \mathbb{R}$ and $w_i \in \mathbb{R}^d$. The output $M(x)$ is a scalar. Intuitively, this layer tries to learn pairwise interactions between every x_i and x_j using factorized (vector) parameters v.

Factorization machines model low-rank structure within the matching vector, producing a scalar feature. This enables efficient propagation of these matching features to the next layer. The output of each CAFE block is the original input to the CAFE module, augmented with the output of the factorization machines. As such, if the input sequence is of d dimensions, then the output is $d + 3$ dimensions. Additionally, intra-attention is applied in similar fashion as above to generate *three* more features for each sequence. As a result, the output dimensions for each word becomes $d + 6$.

2.4 Co-Stack Residual Affinity (CSRA)

This layer is the cornerstone of our proposed approach and is represented as the middle segment of Figure 1 (the colorful matrices).

Co-Stacking Co-stacking refers to the fusion of a and b across multiple hierarchies. Recall that the affinity score between two words is typically computed by $s_{ij} = a^\top b$. We extend this to a residual formulation. More concretely, the affinity score between both words is now computed as the *maximum* influence it has over all layers.

$$s_{ij} = \max \sum_p \sum_q a_{pi}^\top \, b_{qj} \tag{4}$$

where a_{pi} is the i-th word for the p-th stacked layer for a and b_{qj} is the j-th word for the q-th stacked layer for b. The choice of the maximum operator is intuitive and is strongly motivated by the fact that we would like to give a high affinity for each word pair that shows a strong match at any of different hierarchical stages of learning representations. Note that this layer can be interpreted as constructing a matching tensor based on multi-hierarchical information and selecting the most informative match across all representation hierarchies.

Bidirectional Alignment In order to learn (bidirectionally) attentive representations, we first concatenate all stacked outputs to form a $\ell \times kd$ vector. Next, we apply the following operations to $A \in \mathbb{R}^{\ell_a \times kd}$ and $B \in \mathbb{R}^{\ell_b \times kd}$.

$$\bar{A} = S^\top B \text{ and } \bar{B} = AS^\top \tag{5}$$

where $\bar{A} \in \mathbb{R}^{\ell_b \times kd}, \bar{B} \in \mathbb{R}^{\ell_a \times kd}$ are the attentive (aligned) representations.

2.4.1 Matching and Aggregation Layer

Next, we match the attentive (aligned) representations using the subtraction, element-wise multiplication and concatenation of each aligned word. Subsequently, we pass this matching vector into a k layered BiLSTM layer.

$$a_i' = \text{BiLSTM}_k([\bar{b}_i - a_i, \bar{b}_i \odot a_i, \bar{b}_i, a_i]) \tag{6}$$

$$b_i' = \text{BiLSTM}_k([\bar{a}_i - b_i, \bar{a}_i \odot b_i, \bar{a}_i, b_i]) \tag{7}$$

The final feature representation is learned via the summation across the temporal dimension as follows:

$$z = [\sum_{i=1}^{\ell_a} a_i' \; ; \; \sum_{i=1}^{\ell_b} b_i'] \tag{8}$$

where $[.;.]$ is the concatenation operator.

2.5 Output and Prediction Layer

Our model predicts using the feature vector z for every given sequence pair. At this layer, we utilize standard fully connected layers. The number of output layers is typically 2-3 and is a tuned hyperparameter. Softmax is applied onto the final layer. The final layer is application specific, e.g., k classes for classification tasks and a two-class softmax for pointwise ranking. For all datasets, we optimize the cross entropy loss.

3 Experimental Evaluation

In this section, we introduce our experimental setup, baselines and results.

3.1 Datasets and Competitor Baselines

We use six public benchmark datasets for evaluating our proposed approach. This section briefly introduces each dataset, along with several state-of-the-art approaches that we compare against. Table 1 provides a summary of the datasets used in our experiments.

Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) is a well-known dataset for *entailment classification* (or natural language inference). The task is to determine if two sequences entail/contradict or are neutral to each other. This task is a three-way classification problem. On this dataset, we compare with several state-of-the-art models such as BiMPM (Wang et al., 2017), ESIM (Chen et al., 2017), DIIN (Gong et al., 2017), DR-BiLSTM (Ghaeini et al., 2018) and CAFE (Tay et al., 2017c).

Dataset	Task	$\|C\|$	Pairs
SNLI	Premise-Hypothesis	3	570K
Scitail	Premise-Hypothesis	2	27K
Quora	Question-Question	2	400K
Twitter	Tweet-Tweet	2	51K
TrecQA	Question-Answer	R	56K
Ubuntu	Utterance-Response	R	1M

Table 1: Statistics of datasets used in our experiment. $|C|$ denotes the number of classes and R denotes a ranking formulation. Twitter stands for the TwitterURL dataset.

Science Entailment (SciTail) (Khot et al., 2018) is a new entailment classification dataset that was constructed from science questions and answers. This dataset involves two-way classification (entail or non-entail). We compare with DecompAtt (Parikh et al., 2016), ESIM, DGEM (Khot et al., 2018) and CAFE.

Quora Duplicate Detection is a well-studied paraphrase identification dataset[1]. We use the splits provided by (Wang et al., 2017). The task is to determine if two questions are paraphrases of each other. This task is formulated as a binary classication problem. We compare with L.D.C (Wang et al., 2016b), BiMPM, the DecompAtt implementation by (Tomar et al., 2017) (word and char level) and DIIN.

TwitterURL (Lan et al., 2017) is another dataset for paraphrase identification. It was constructed using Tweets referring to news articles. This task is also a binary classification problem. We compare with (1) MultiP (Xu et al., 2014), a strong baseline, (2) the implementation of (He and Lin, 2016) by (Lan et al., 2017) and (3) the Subword + LM model from (Lan and Xu, 2018).

TrecQA (Wang et al., 2007) is a well-studied dataset for *answer sentence selection task* (or question-answer matching). The goal is to rank answers given a question. This task is formulated as a pointwise learning-to-rank problem. Baselines include HyperQA (Tay et al., 2017a), Ranking-based Multi-Perspective CNN (He et al., 2015) implementation by (Rao et al., 2016), BiMPM, the compare-aggregate (Wang and Jiang, 2016a) model extension by (Bian et al., 2017) (we denote this model as CA), IWAN (Shen et al., 2017) and the recent MCAN model, i.e., Multi-Cast Attention Networks (Tay et al., 2018c). A leaderboard is maintained at `https://aclweb.org/aclwiki/Question_Answering_(State_of_the_art)`.

Ubuntu (Lowe et al., 2015) is a dataset for *Utterance-Response Matching* and comprises 1-million utterance-response pairs. This dataset is based on the Ubuntu dialogue corpus. The goal is to predict the response to a message. We use the same setup as (Wu et al., 2016). Baselines include CNTN (Qiu and Huang, 2015), APLSTM (dos Santos et al., 2016), MV-LSTM (Wan et al., 2016a) and KEHNN (Wu et al., 2016). Results are reported from (Wu et al., 2016).

Metrics For all datasets, we follow the evaluation procedure from all the original papers. The metric for SNLI, SciTail and Quora is the accuracy metric. The metric for the TwitterURL dataset is the F1 score. The metric for TrecQA is the Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) metric. The metric for Ubuntu is the Recall@K for $k = 1, 2, 5$ (given 9 negative samples) and the binary classification accuracy score.

3.2 Experimental Setup

All baselines are reported from the respective papers. All models are trained with the Adam optimizer (Kingma and Ba, 2014) with learning rates tuned amongst $\{0.001, 0.0003, 0.0004\}$. Batch size is tuned amongst $\{32, 64, 128, 256\}$. The dimensions of the BiLSTM encoders are tuned amongst $\{64, 100, 200, 300\}$ and the number of hidden dimensions of the prediction layers are tuned amongst $\{100, 200, 300, 600\}$. The number of stacked recurrent layers is tuned from $[2, 5]$ and the number of aggregation BiLSTM layers is tuned amongst $\{1, 2\}$. The number of prediction layers is tuned from [1,3]. Parameters are initialized using glorot uniform (Glorot and Bengio, 2010). All unspecified activation functions are ReLU activations. Word embeddings are initialized with GloVe (Pennington et al., 2014) and fixed during training. We implement our model in Tensorflow (Abadi et al., 2015) and use the cuDNN implementation for all BiLSTM layers.

3.3 Experimental Results

Overall, our proposed CSRAN architecture achieves state-of-the-art performance on all six well-established datasets.

---

[1] `https://data.quora.com/First-Quora-Dataset-Release-Question-Pairs`

On SNLI (Table 2), CSRAN achieves the best[2] single model performance to date on the well-established dataset. This demonstrates the effectiveness of CSRAN, taking into consideration of the inherent competitiveness of this well-known benchmark. On SciTail (Table 3), CSRAN similarly achieves the best performance to date on this dataset, outperforming the existing CAFE model by +3.4% absolute accuracy.

On Quora (Table 4), CSRAN also achieves the best single model score, outperforming strong baselines such as BiMPM (+1.1%) and DIIN (+0.2%). Moreover, there is also considerable performance improvement on the TwitterURL dataset (Table 5) as CSRAN outperforms the existing state-of-the-art Subword + LM model (+8%) and Deep Pairwise Word (+9.1%).

On TrecQA (Table 6), CSRAN achieves the best performance on this dataset. CSRAN outperforms the existing state-of-the-art model, IWAN (+3.2%/ + 4.6%). CSRAN also outperforms strong competitive baselines such as BiMPM (+5.2%/+3.6%) and MPCNN (+5.3%/+5.8%). Finally, on Ubuntu (Table 7), CSRAN also outperforms many competitive models such as CNTN, APLSTM and KEHNN. Performance improvement over all metrics are $\approx 9\% - 10\%$ compared to the existing state-of-the-art.

Overall, CSRAN achieves state-of-the-art performance on six well-studied datasets. On several datasets, our achieved performance is not only the highest reported score but also outperforms the existing state-of-the-art models by a considerable margin.

Model	Acc
BiMPM (Wang et al., 2017)	87.5
ESIM (Chen et al., 2017)	88.0
DIIN (Gong et al., 2017)	88.0
DR-BiLSTM (Ghaeini et al., 2018)	88.5
CAFE (Tay et al., 2017c)	88.5
CSRAN	**88.7**

Table 2: Experimental results on single model SNLI dataset.

Model	Acc
DecompAtt (Parikh et al., 2016)	72.3
ESIM (Chen et al., 2017)	70.6
DGEM (Khot et al., 2018)	77.3
CAFE (Tay et al., 2017c)	83.3
CSRAN	**86.7**

Table 3: Experimental results on SciTail dataset.

Table 7: Experimental results on the Ubuntu dataset for utterance-response matching. Baseline results are reported from (Wu et al., 2016).

---

[2] For fair comparison, we do not compare with (1) models that use external contextualized word embeddings, e.g., CoVe (McCann et al., 2017) / ELMo (Peters et al., 2018) / generative pretraining (Radford et al.) and (2) ensemble systems. As either (1) and/or (2) would also intuitively boost the performance of the base CSRAN model.

3.3.1 Training Efficency

With many BiLSTM layers, it is natural to be skeptical about the training efficiency of our model. However, since we use the CUDNN implementation of the BiLSTM model, the runtime is actually very manageable. On SNLI, with a batch size of 128, our model with 3 stacked recurrent layers and 2 aggregation BiLSTM layers runs at ≈17 minutes per epoch and converges in less than 20 epochs. On SciTail, our model runs at ≈ 2 minutes per epoch with a batch size of 32. This is benchmarked on a TitanXP GPU. While our model is targetted at performance and not efficiency, this section serves as a reassurance that our model is not computationally prohibitive.

3.4 Ablation Study

In order to study the effectiveness of the key components in our proposed architecture, we conduct an extensive ablation study. Table 8 reports the results on several ablation baselines. There are three key ablation baselines as follows: (1) we removed MAR from the stacked recurrent network, (2) we removed CSRA from the network and finally (3) we removed both MAR and CSRA from the network. All ablation baselines reported are stacked with 3 layers. Firstly, we observe that both MAR and CSRA are critical components in our model, i.e., removing any of them would result in a drop in performance. Secondly, we observe that the relative utility of CSRA and MAR depends on the dataset. Removing MAR significantly reduces performance on SciTail and TrecQA. On the other hand, removing CSRA degrades the performance more than MAR on SNLI. Finally, it is good to note that, while performance degradation on SNLI development set may not seem significant, the *w/o MAR and CSRA* ablation performance baseline achieved only 87.7% accuracy on the test set, compared to 88.7% of the original model. This is equivalent to dropping from state-of-the-art to the 5th ranked model. Overall, we are able to conclude that the CSRA and MAR make meaningful improvements to our model architecture.

Ablation	SNLI	SciTail	TrecQA
Original	88.6	88.0	0.86/0.90
w/o MAR	88.4	82.5	0.79/0.85
w/o CSRA	88.1	86.2	0.84/0.89
w/o MAR/CSRA	88.0	83.0	0.79/0.84

Table 8: Ablation study (development score) of our key model components on three datasets.

3.5 Effect of Stack Depth

In this section, our goals are twofold - (1) studying the effect of stack depth on model performance and (2) determining if the proposed CSRAN model indeed helps with enabling deeper stack depths. In order to do so, we compute the development set performance of two models. The first is the full CSRAN architecture and the second is a baseline stacked model architecture. Note that the bidirectional alignment layer and remainder of the model architecture (highway layers, etc.) remain completely identical to CSRAN to make this study as fair as possible.

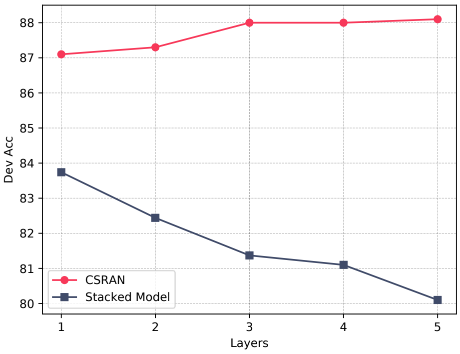

Figure 2: Relative effect of stack depth on CSRAN and the baseline Stacked Model on SciTail dataset.

Figure 2 illustrates the model performance with varying stack depth. As expected, the performance of the stacked model declines when increasing the stack depth. On the other hand, the performance of CSRAN improves by adding additional layers. The largest gain is when jumping from 2 layers to 3 layers. The subsequent performance improvement from 3-5 layers is marginal. From this study, the takeaway is that standard stacked architectures are insufficient. As such, our proposed CSRA mechanism can aid in enabling deeper models which can result in stronger model performance[3].

Next, we study the general effect of stack depth (number of layers) on model performance. Figure 3 reports the model performance (dev accuracy) of our CSRAN architecture on Quora and

---

[3] The best result on Scitail was obtained with 5 layers. Moreover, the difference in test performance between stacked and single-layered model was considerably high (+2.5%) even though dev performance increased by +1%.

SNLI datasets. We observe that a stacked architecture with 3 layers is significantly better than a single-layered architecture. The optimal development score is 3-4 layers for SNLI and 3 layers for Quora. However, we observe the performance of Quora declines after 3 layers (notably it is still higher than an unstacked model). However, the performance on SNLI remains relatively stable.

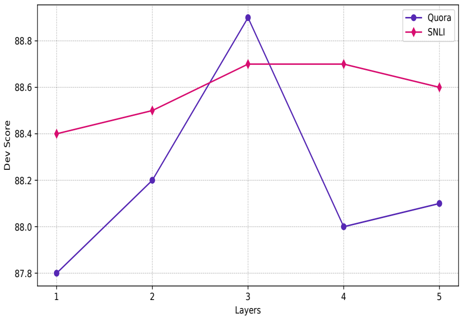

Figure 3: Effect of stack depth on CSRAN performance on Quora and SNLI datasets.

4 Related Work

Learning to matching text sequences is a core and fundamental research problem in NLP and Information Retrieval. A wide range of NLP applications fall under this paradigm such as natural language inference (Bowman et al., 2015; Khot et al., 2018), paraphrase identification (Lan and Xu, 2018), question answering (Severyn and Moschitti, 2015), document search (Shen et al., 2014; Hui et al., 2017), social media search (Rao et al., 2018) and entity linking (Phan et al., 2017). As such, universal text matching algorithms are generally very attractive, in lieu of the prospects of potentially benefitting an entire suite of NLP applications.

Neural networks have been the prominent choice for text matching. Earlier works are mainly concerned with learning a matching function between RNN/CNN encoded representations (Severyn and Moschitti, 2015; Yu et al., 2014; Qiu and Huang, 2015; Tay et al., 2017b, 2018b). Models such as Recursive Neural Networks have also been explored (Wan et al., 2016b). Subsequently, attention-based models were adopted (Rocktäschel et al., 2015; Wang et al., 2016a; Parikh et al., 2016), demonstrating superior performance relative to their non-attentive counterparts.

Today, the dominant state-of-the-art approaches for text matching are mostly based on neural models configured with bidirectional attention layers (Shen et al., 2017; Tay et al., 2017c). Bidirectional attention comes in various flavours which can be known as soft alignment (Shen et al., 2017; Chen et al., 2017), decomposable attention (Parikh et al., 2016), attentive pooling (dos Santos et al., 2016) and even complex-valued attention (Tay et al., 2018a). The key idea is to jointly soft align text sequences such that they can be compared at the index level. To this end, various comparison functions have been utilized, ranging from feed-forward neural networks (Parikh et al., 2016) to factorization machines (Tay et al., 2017c). Notably, these attention (and bi-attention) mechanisms are also widely adopted (or originated) from many related sub-fields of NLP such as machine translation (Bahdanau et al., 2014) and reading comprehension (Xiong et al., 2016; Seo et al., 2016; Wang and Jiang, 2016b).

Many text matching neural models are heavily grounded in the compare-aggregate architecture (Wang and Jiang, 2016a). In these models, matching and comparisons occur between text sequences, aggregating features for making the final prediction. Recent state-of-the-art models such as BiMPM (Wang et al., 2017) and DIIN (Gong et al., 2017) are representative of such architectural paradigm, utilizing an attention-based matching scheme and then a CNN or LSTM-based feature aggregator. Earlier works (Wan et al., 2016a; He et al., 2015; He and Lin, 2016) exploit a similar paradigm, albeit without the usage of attention.

Across many NLP and machine learning applications, utilizing stacked architectures is a common way to enhance representation capability of the encoder (Sutskever et al., 2014; Graves et al., 2013; Zhang et al., 2016; Nie and Bansal, 2017), leading to performance improvement. Deep networks suffer from inherent difficulty in feature propagation and/or vanishing/exploding gradients. As a result, residual strategies have often been employed (He et al., 2016; Srivastava et al., 2015; Huang et al., 2017). However, to the best of our knowledge, this work presents a new way of residual connections, leveraging on the fact that pairwise formulation of the text matching task.

5 Conclusion

We proposed a deep stacked recurrent architecture for general-purpose text sequence matching. We proposed a new co-stack residual affinity mechanism for matching sequence pairs, leveraging multi-hierarchical information for learning bidirectional alignments. Our proposed CSRAN model achieves state-of-the-art performance across six well-studied benchmark datasets and four different problem domains.

Spherical Latent Spaces for Stable Variational Autoencoders

Jiacheng Xu and **Greg Durrett**

Abstract

A hallmark of variational autoencoders (VAEs) for text processing is their combination of powerful encoder-decoder models, such as LSTMs, with simple latent distributions, typically multivariate Gaussians. These models pose a difficult optimization problem: there is an especially bad local optimum where the variational posterior always equals the prior and the model does not use the latent variable at all, a kind of "collapse" which is encouraged by the KL divergence term of the objective. In this work, we experiment with another choice of latent distribution, namely the von Mises-Fisher (vMF) distribution, which places mass on the surface of the unit hypersphere. With this choice of prior and posterior, the KL divergence term now only depends on the variance of the vMF distribution, giving us the ability to treat it as a fixed hyperparameter. We show that doing so not only averts the KL collapse, but consistently gives better likelihoods than Gaussians across a range of modeling conditions, including recurrent language modeling and bag-of-words document modeling. An analysis of the properties of our vMF representations shows that they learn richer and more nuanced structures in their latent representations than their Gaussian counterparts.[1]

1 Introduction

Recent work has established the effectiveness of deep generative models for a range of tasks in NLP, including text generation (Hu et al., 2017; Yu et al., 2017), machine translation (Zhang et al., 2016), and style transfer (Shen et al., 2017; Zhao et al., 2017a). Variational autoencoders, which have been explored in past work for text modeling (Miao et al., 2016; Bowman et al., 2016), posit a continuous latent variable which is used to capture latent structure in the data. Typical VAE implementations assume the prior of this latent space is a multivariate Gaussian; during training, a Kullback-Leibler (KL) divergence term in loss function encourages the variational posterior to approximate the prior. One major limitation of this approach observed by past work is that the KL term may encourage the posterior distribution of the latent variable to "collapse" to the prior, effectively rendering the latent structure unused (Bowman et al., 2016; Chen et al., 2016).

In this paper, we propose to use the von Mises-Fisher (vMF) distribution rather than Gaussian for our latent variable. vMF places a distribution over the unit hypersphere governed by a mean parameter μ and a concentration parameter κ. Our prior is a uniform distribution over the unit hypersphere ($\kappa = 0$) and our family of posterior distributions treats κ as a *fixed* model hyperparameter. Since the KL divergence only depends on κ, we can structurally prevent the KL collapse and make our model's optimization problem easier. We show that this approach is actually more robust than trying to flexibly learn κ, and a wide range of settings for fixed κ lead to good performance. Our model systematically achieves better log likelihoods than analogous Gaussian models while having higher KL divergence values, showing that it more successfully makes use of the latent variables at the end of training.

Past work has suggested several other techniques for dealing with the KL collapse in the Gaussian case. Annealing the weight of KL term (Bowman et al., 2016) still leaves us with brittleness in the optimization process, as we show in Section 2. Other prior work (Yang et al., 2017; Semeniuta et al., 2017) focuses on using CNNs rather than RNNs as the decoder in order to weaken the model and encourage the use of the

Brussels, Belgium, October 31 - November 4, 2018.

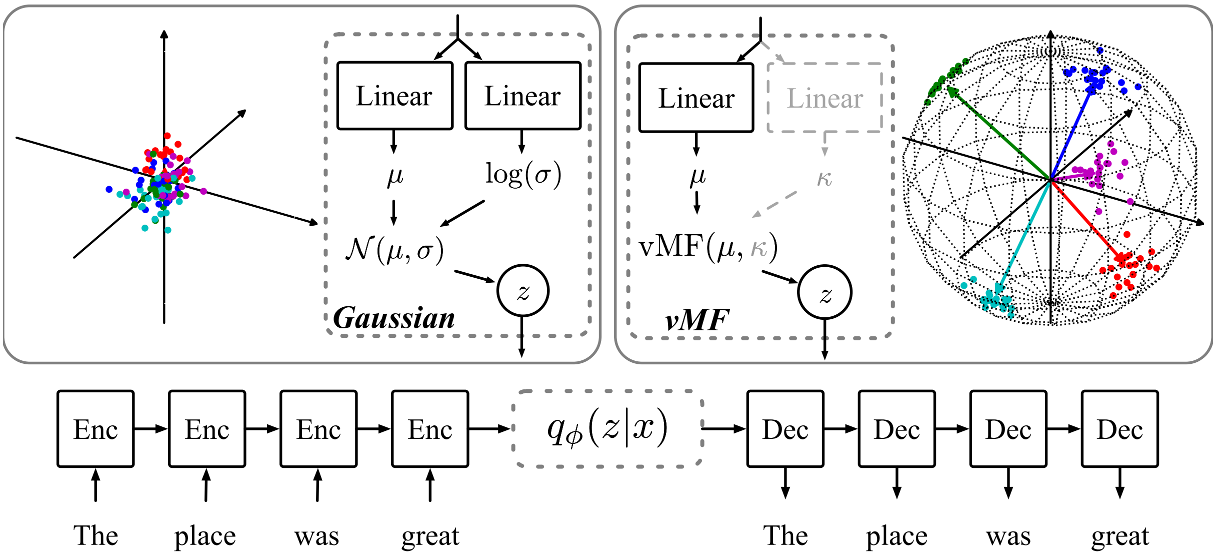

Figure 1: The Neural Variational RNN (NVRNN) language model based on a Gaussian prior (left) and a vMF prior (right). The encoder model first computes the parameters for the variational approximation $q_\phi(z|x)$ (see dotted box); we then sample z and generate the word sequence x given z. We show samples from $\mathcal{N}(0, I)$ and vMF($\cdot$,$\kappa = 100$); the latter samples lie on the surface of the unit sphere. While κ can be predicted from the encoder network, we find experimentally that fixing it leads to more stable optimization and better performance.

latent code, but the gains are limited and changing the decoder in this way requires ad hoc model engineering and careful tuning of various decoder capacity parameters. Our method is orthogonal to the choice of the decoder and can be combined with any of these approaches. Using vMF distributions in VAEs also leaves us the flexibility to modify the prior in other ways, such as using a product distribution with a uniform (Guu et al., 2018) or piecewise constant term (Serban et al., 2017a).

We evaluate our approach in two generative modeling paradigms. For both RNN language modeling and bag-of-words document modeling, we find that vMF is more robust than a Gaussian prior, and our model learns to rely more on the latent variable while achieving better held-out data likelihoods. To better understand the contrast between these models, we design and conduct a series of experiments to understand the properties of the Gaussian and vMF latent code spaces, which make different structural assumptions. Unsurprisingly, these latent code distributions capture much of the same information as in a bag of words, but we show that vMF can more readily go beyond this, capturing ordering information more effectively than a Gaussian code.

2 Variational Autoencoders for Text

Bowman et al. (2016) propose a variational autoencoder model for generative text modeling inspired by Kingma and Welling (2013). Instead of modeling $p(x)$ directly as in vanilla language models, VAEs introduce a continuous latent variable z and take the form $p(z)p(x|z)$. To train a VAE, we optimize the marginal likelihood $p(x) = \int p_\theta(z)p(x|z)dz$. The marginal log likelihood can be written as:

$$\log p_\theta(x) = \mathrm{KL}(q_\phi(z|x)||p_\theta(z|x)) + \mathcal{L}(\theta, \phi; x)$$

$$\begin{aligned}\mathcal{L}(\theta, \phi; x) = &-\mathrm{KL}(q_\phi(z|x)||p_\theta(z)) \\ &+ \mathbb{E}_{q_\phi(z|x)} \log p_\theta(x|z) \quad (1)\end{aligned}$$

$q_\phi(z|x)$, a variational approximation to the posterior $p(z|x)$, can be variously interpreted as a *recognition model* or encoder, parameterized by a neural network to encode the sentence x into a dense *code* z. $\mathcal{L}(\theta, \phi; x)$ is often called the evidence lower bound (ELBO). The first term of ELBO is the KL divergence of the approximate posterior from prior and the second term is an expected reconstruction error.

Since KL divergence is always non-negative, we can use $\mathcal{L}(\theta, \phi; x)$ as a lower bound of marginal likelihood $\log p_\theta(x)$. We optimize $\mathcal{L}(\theta, \phi; x)$, jointly learning the recognition model parameters ϕ and generative model parameters θ.

As the choice of prior $p(z)$, most previous work uses a centered multivariate Gaussian $p_\theta(z) =$

$\mathcal{N}(z; 0, I)$. Since Gaussians are a location-scale family of distributions, using them for both the prior and posterior allows us to apply the reparameterization trick and differentiate through the sampling stage $z \sim \mathbb{E}_{q_\phi(z|x)}$ when optimizing ELBO in practice (Kingma and Welling, 2013).

2.1 Case Study: NVRNN

A Neural Variational RNN (NVRNN) for language modeling is described in Bowman et al. (2016) and depicted in Figure 1. The goal of the NVRNN model is to extract a high level representation of a sentence into z and reconstruct the sentence with a neural language model.

We denote a sequence of words as $x = \{x_1, x_2, \cdots, x_n\}$. Unlike in vanilla language modeling, an NVRNN conditions on the latent variable z at each step of the generation $p_\theta(x|z) = p_\theta(x_1|z) \prod_{i=1}^{n} p(x_i|x_1, \ldots, x_{i-1}, z)$. This probability distribution is modeled using a recurrent model like an LSTM (Hochreiter and Schmidhuber, 1997) as illustrated in Figure 1. There is nothing unique about this choice; other recurrent sequence models like a CNN or a Transformer (Vaswani et al., 2017) could be used.

2.2 Posterior Collapse

When training a VAE, we update θ and ϕ simultaneously. Optimizing Eq. 1 gives two gradient terms: an update from the reconstruction loss (likelihood of the correct labels) and an update from the KL divergence. While the reconstruction loss term encourages the z to convey useful information to this model, the KL term consistently tries to regularize $q(z|x)$ towards the prior on every gradient update. This may trap the model in a bad local optimum where $q_\phi(z|x) = p_\theta(z)$ for all x: in this case, z is simply a noise source, which is useless to the model, so the model has learned to ignore it and will not make large enough gradient updates to break $q(z|x)$ out of this optimum.

Bowman et al. (2016) termed this issue *KL collapse* and proposed an annealing schedule to handle it, where the weight of the KL term is increased over the course of training.[2] In this way, the model initially learns to use the latent code but is then regularized towards the prior as training progresses. However, this trick is not sufficient to avert KL collapse in all scenarios, particularly when strong decoders are used and z has a minor impact on $p_\theta(x|z)$.

	No annealing		Sigmoid annealing	
	3-layer	1-layer	3-layer	1-layer
KL	0.00	3.37	1.05	**6.52**
NLL	135	129	132	**125**

Table 1: Development set KL and NLL values for two NVRNN models trained on the Penn Treebank with and without the annealing technique of Bowman et al. (2016). The higher-capacity 3-layer model collapses when no annealing is used, and while annealing works to improve performance, it still does not perform as well as the 1-layer variant. By contrast, a variant of the 1-layer model with vMF gives an NLL value of 117 and a KL of 18.6, a stronger result relying more heavily on the latent variable.

Table 1 shows experiments in a similar setup to that of Bowman et al. (2016). We train an NVRNN model on the Penn Treebank with four different hyperparameter settings. We either use a 3-layer LSTM encoder or a 1-layer LSTM and use or do not use a sigmoid annealing schedule (increase the KL weight from 0 to 1 over the first 20 epochs). We observe the best performance using the 1-layer model with annealing. One might conclude from this table that the annealing trick has worked since both models achieve better performance when annealing is used. But in fact, a vMF-based model can do better than either (NLL of 117), and moreover, we have no way of knowing that a better annealing scheme might not achieve even higher performance after training. Furthermore, the higher-capacity 3-layer model can theoretically do anything the 1-layer model can, so its lower performance indicates that our training is derailed either by overfitting or getting stuck in a local optimum where the latent variable is unused.[3]

Getting the best performance out of a VAE is, therefore, a challenging problem that requires careful tuning of the objective function and optimization procedure (Bowman et al., 2016; Zhao et al., 2017b; Higgins et al., 2017). Beyond the well-documented problem of KL collapse, an optimizer may simply get stuck in a local optimum during training and as a result, fail to find a model that most effectively exploits the latent variable.

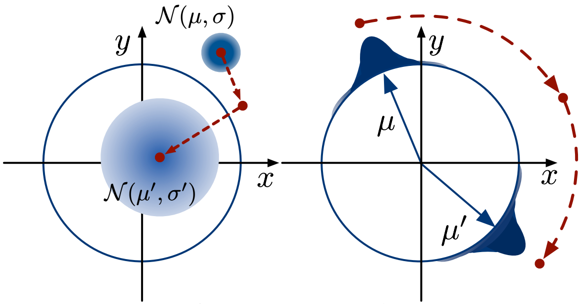
The solution we advocate for in this paper is

---

[2] Reweighting the KL term is also used in methods like β-VAE (Higgins et al., 2017) and InfoVAE (Zhao et al., 2017b).

[3] In our experiments, we found significant variance in collapse frequency due to other hyperparameters including whether the encoder is a unidirectional or bidirectional LSTM.

to change the distribution for the latent space and simplify the optimization problem. In the next section, we describe the von Mises-Fisher distribution and its use in VAE, where it forces the model to put the latent representations on the surface of the unit hypersphere rather than squeezing everything to the origin. Critically, this distribution lets us fix the value of the KL term by fixing the distribution's concentration parameter κ; this averts the KL collapse and leads to good model performance across two generative modeling paradigms.



(a) Gaussian (b) vMF

Figure 2: Visualization of optimization of how q varies over time for a single example during learning. In the Gaussian case, the KL term tends to pull the model towards the prior (moving from μ, σ to μ', σ'), whereas in the vMF case there is no such pressure towards a single distribution.

3 von Mises-Fisher VAE

The von Mises-Fisher distribution is a distribution on the $(d-1)$-dimensional sphere in $\mathbb{R}^d$. The vMF distribution is defined by a direction vector μ with $||\mu||= 1$ and a concentration parameter $\kappa \geq 0$. The PDF of the vMF distribution for the d-dimensional unit vector x is defined as:

$$f_d(x; \mu, \kappa) = C_d(\kappa) \exp(\kappa \mu^T x) \tag{2}$$

$$C_d(\kappa) = \frac{\kappa^{d/2-1}}{(2\pi)^{d/2} I_{d/2-1}(\kappa)} \tag{3}$$

where I_v stands for the modified Bessel function of the first kind at order v.

Figure 1 shows samples from vMF distributions with various μ vectors (arrows), $d = 3$, and $\kappa = 100$. This is a high κ value, leading to samples that are tightly clustered around μ, which is the mean and mode of the distribution. When $\kappa = 0$, the distribution degenerates to a uniform distribution over the hypersphere independent of μ.

Past work has used vMF as an emission distribution in unsupervised clustering models (Banerjee et al., 2005), VAE for other domains (Davidson et al., 2018; Hasnat et al., 2017), and a generative editing model for text (Guu et al., 2018). We focus specifically on the empirical properties of vMF for text modeling and conduct a systematic examination of how this prior affects VAE models compared to using a Gaussian.

VAE with vMF We will use vMF as both our prior and variational posterior in our VAE models. Otherwise, the setup for our VAE remains the same as in the Gaussian case established in Section 2. Our prior is the uniform distribution vMF$(\cdot, \kappa = 0)$. Since true posterior $p_\theta(z|x)$ is intractable, we will approximate it with a variational posterior $q_\phi(z|x) = \text{vMF}(z; \mu, \kappa)$ where the mean direction μ is the output of encoding neural networks (Figure 1, right side) and κ is treated as a constant.

Before we can implement a VAE, we need to derive an expression for KL divergence in order to optimize ELBO (Equation 1) and give a sampling algorithm that admits the reparameterization trick (Kingma and Welling, 2013).

KL divergence With vMF$(\cdot, 0)$ as our prior, the KL divergence is:[4]

$$\begin{aligned} \text{KL}(\text{vMF}(\mu, \kappa)||\text{vMF}(\cdot, 0)) &= \kappa \frac{I_{d/2}(\kappa)}{I_{d/2-1}(\kappa)} \\ + \left(\frac{d}{2} - 1\right) \log \kappa - \frac{d}{2} \log(2\pi) &- \log I_{d/2-1}(\kappa) \\ + \frac{d}{2} \log \pi + \log 2 &- \log \Gamma \left(\frac{d}{2}\right) \end{aligned}$$

Critically, this only depends on κ, not on μ. κ will be treated as a fixed hyperparameter, so this term will be constant for our model; KL collapse will therefore be rendered impossible.

Figure 2 shows a visualization of the learning trajectories of Gaussian and vMF VAE. For the Gaussian VAE, the KL divergence in the objective function tends to pull the posterior towards the prior centered at the origin and, therefore, make the optimization difficult as mentioned before. For the vMF VAE, given fixed κ, there is no such vacuous state and μ can vary freely.

---

[4] Our KL divergence agrees with that of Davidson et al. (2018) (see their appendix for a derivation), and we have verified it empirically. The equation in Guu et al. (2018) gives slightly different KL values, though differences are small (<5%) for most κ and dimension values we encounter.

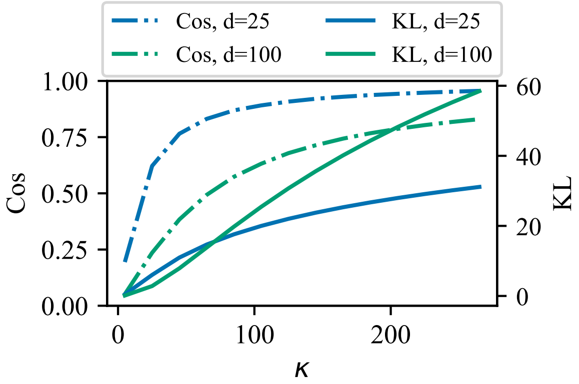


Figure 3: Visualization of the interaction between κ, KL, and dimensionality in vMF. Cos represents the cosine similarity between μ and samples from $\text{vMF}_d(\mu, \kappa)$ which reflects how disperse the distribution is. KL is defined as KL with a uniform vMF prior, $\text{KL}(\text{vMF}_d(\mu, \kappa) || \text{vMF}(\cdot, 0))$. Higher κ values yield higher cosine similarities, but also higher KL costs.

Figure 3 shows the KL value and concentration of $\text{vMF}(\mu, \kappa)$ for two different dimensionalities. KL increases monotonically with κ, as does concentration measured by cosine similarity. To get a fixed cosine dispersion as dimensionality increases, higher κ values are needed, resulting in higher KL values.

Sampling from vMF Following the implementation of Guu et al. (2018), we use the rejection sampling scheme of Wood (1994) to sample a "change magnitude" w. Our sample is then given by $z = w\mu + v\sqrt{1 - w^2}$, where v is a randomly sampled unit vector tangent to the hypersphere at μ. Neither v nor w depends on μ, so we can now take gradients of z with respect to μ as required.

4 Experiments on Language Modeling

We first evaluate our vMF approach in the NVRNN setting. We will return to this model and analyze its properties further in Sections 6 and 7 after showing experiments on document modeling.

Dataset For NVRNN, we use the Penn Treebank (Marcus et al., 1993), also used in Bowman et al. (2016), and Yelp 2013 (Xu et al., 2016). Examples in the Yelp dataset are much longer and more diverse than those from PTB, requiring more understanding of high-level semantics to generate a coherent sequence. Yelp has a long tail of very long reviews, so we truncate the examples to a maximum length of 50 words; this still gives an average length over twice as long as in the PTB setting.

Name	Train	Dev	Test	Len	Vocab
PTB	42068	3370	3761	21.1	10K
Yelp	62522	7773	8671	49.5	15K
20NG	11268	-	7505	96.1	2K
RC	794414	-	10000	116.8	10K

Table 2: Statistics of the datasets used in our experiments. Len stands for the average length of an example. Vocab is the vocabulary size; these follow prior work.

Statistics about all datasets used in this paper are shown in Table 2.

Settings We evaluate our NVRNN as in Bowman et al. (2016) and explore two different settings. In the **Standard** setting, the input to the RNN at each time step is the concatenation of the latent code z and the ground truth word from the last time step, while the **Inputless** setting does not use the prior word. The more powerful decoder of the Standard setting makes the latent representations inherently less useful. In the Inputless setting, the decoder needs to predict the whole sequence with only the help of given latent code. In this case, a high-quality representation of the sentence is badly needed and the model is driven to learn it.

Our implementation of VAE uses a one layer unidirectional LSTM as both encoder and decoder. We use an embedding size of 100 and hidden units of size 400 in the LSTM. The dimension of the latent code is chosen from $\{25, 50, 100\}$ by tuning on the development set. We use SGD to optimize all models with decayed learning rate and gradient clipping. For Yelp, the sentiment bit, which ranges from 1 to 5, is also embedded into a 50 dimension vector and input for every time step of the decoding phase.

Results Experimental results of the NVRNN are shown in Table 3. We report negative log likelihood (NLL)[5] and perplexity (PPL) on the test set. We follow the implementation reported in Bowman et al. (2016) where the KL term weight is annealed for the Gaussian VAE; vMF VAE works well without weight annealing. The vMF distribution gives a performance boost in all datasets in both the Standard and Inputless settings. Even in the Standard setting, our model is able to successfully use nonzero KL values to achieve better

---

[5] Reported values are actually a lower bound on the true NLL, computed from ELBO by sampling z.

Model	PTB				Yelp			
	Standard		Inputless		Standard		Inputless	
	NLL	PPL	NLL	PPL	NLL	PPL	NLL	PPL
RNNLM (2016)	100 (–)	116	135 (–)	>600	–	–	–	–
G-VAE (2016)	101 (2)	119	125 (15)	380	–	–	–	–
RNNLM (Ours)	100 (–)	114	134 (–)	596	199 (–)	55	300 (–)	432
G-VAE (Ours)	99 (4.4)	109	125 (6.3)	379	199 (0.5)	55	274 (13.4)	256
vMF-VAE (Ours)	**96 (5.7)**	**98**	**117 (18.6)**	**262**	**198 (6.4)**	**54**	**242 (48.5)**	**134**

Table 3: Experimental results of NVRNN on the test sets of PTB and Yelp. The upper RNNLM and G-VAE shows the result from Bowman et al. (2016). KL divergence is shown in the parenthesis, along with total NLL. Best results are in bold. vMF consistently uses higher KL term weights but achieves comparable or better NLL and perplexity values across all four settings.

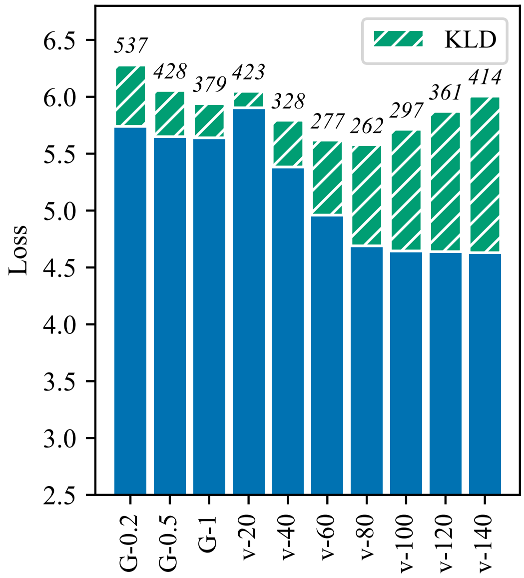

Figure 4: Comparison of Gaussian- and vMF-NVRNN with different hyper-parameters. All models are trained on PTB in the Inputless setting where the latent dimension is 50. G-α indicates Gaussian VAE with KL annealed by the given constant α, and V-κ indicates VAE with κ set to the given value. The green bar reflects the amount of KL loss while the total height reflects the whole objective. *Numbers* above bars are perplexity. vMF is more highly tunable and also achieves stronger results across a wide range of κ values.

perplexities, and even when KL collapse does not appear to be the case (e.g., G-VAE on the PTB-Standard setting), a Gaussian family of distributions results in lower KLs and worse log likelihoods, possibly due to optimization challenges. In the Inputless setting, we see large gains: vMF VAE reduces PPL from 379 to 262 in PTB, and from 256 to 134 in Yelp compared to Gaussian VAE.

Trade-off Comparison Besides the overall perplexity, we are also interested in the trade-off between reconstruction loss and KL, and the contribution of KL to the whole objective. Figure 4 shows the ability of our model to explicitly control the balance between the KL and the reconstruction term. First, we "permanently" anneal the Gaussian VAE by setting the weight of the KL term to a constant smaller than 1 (0.2 and 0.5 in our case). We find that this trick does mitigate the KL collapse, but the overall performance is worse. Therefore, this is not only a numerical game about the KL vs. NLL trade-off but a deeper challenge of how to structure models to learn effective latent representations.

For vMF VAE, when we gradually increase the value of κ, the concentration of the distribution around the mean direction μ is higher and samples from vMF are closer to μ. The model achieves the best perplexity when $\kappa = 80$. The reconstruction error is bounded around 4.5 due to the difficulty of the task and limited capacity of LSTM decoder. While κ is a hyperparameter that needs to be tuned, the model is overall not very sensitive to it, and we show in Section 7 that reasonable κ values transfer across similar tasks.

5 Experiments on Document Modeling

We also investigate how vMF VAE performs in a different setting, one less plagued by the KL collapse issue. Specifically, the Neural Variational Document Model (NVDM), proposed by Miao et al. (2016), is a VAE-based unsupervised document model. This model follows the VAE framework introduced in Section 2. Our document representation is an indicator vector x of word presence or absence in the document. Since this is a fixed-size representation, we use 2-layer MLPs with 400 hidden units for both the encoder $q(z|x)$ and decoder $p(x|z)$; the decoder places a simple

Model	Dim	20NG	RCV1
fDARN (2014)	50	917	724
	200	-	598
G-NVDM (2016)	50	836	563
	200	852	550
v-NVDM (Ours)	25	**793**	558
	50	830	**529**
	200	851	609

Table 4: Test set perplexities for the document modeling task. Feedforward Deep Auto Regressive Neural Network (fDARN) is implemented by Mnih and Gregor (2014). Gaussian-based NVDM (G-NVDM) is proposed in Miao et al. (2016). Dim indicates the dimension of the latent code. Our v-NVDM model outperforms past models by a substantial margin.

multinomial distribution over words in the vocabulary, and the probability of a document is the product of the probabilities of its words.

Dataset For NVDM, we use two standard news corpus, 20 News Groups (20NG) and the Reuters RCV1-v2, which were used in Miao et al. (2016).[6]

Results Experimental results[7] are shown in Table 4. In contrast with NVRNN, the NVDM fully relies on the power of latent code to predict the word distribution, so we never observe a KL collapse, yet vMF still achieves better performance than Gaussian. As shown in Figure 3, in order to keep the same amount of dispersion in samples from the variational posterior, larger latent dimensions need larger κ values and correspondingly larger KL term values. For 20NG, which is much smaller than RCV1, smaller dimensions therefore give better performance. For both datasets, the settings of $\kappa = 100, \text{dim} = 25$ and $\kappa = 150, \text{dim} \in \{50, 200\}$ work well.

6 What do our VAEs encode?

We design more probing tasks to demonstrate what is encoded in latent representations induced by vMF VAE. One additional model variant we explore here is the NVRNN-BoW model. This is a variant of NVRNN where the decoder additionally conditions on the vector $BoW = \frac{1}{n}\sum_{i=1}^{n} e(x_i)$, the average word embedding value of the sentence x. While an artificial setting, this lets us see how effectively the latent code can capture information other than simple word choice by making a form of this information independently available. Table 5 shows results in this setting, where once again we see the KL collapse problem for the Gaussian models and better performance from vMF on perplexity in both the Standard and Inputless settings.

$P(x\|z, \text{BoW})$	Standard NLL	Standard PPL	Inputless NLL	Inputless PPL
RNNLM	79 (–)	43	106 (–)	152
G-VAE	79 (0.0)	43	106 (0.4)	153
v-VAE	**73 (0.2)**	**33**	**93 (11.4)**	**82**

Table 5: Experimental results of NVRNN-BoW on PTB; i.e., the decoder also conditions on a bag of words representation of the sentence to generate. In this case, the Gaussian models exhibit KL collapse but vMF can still learn effectively.

Is the latent code more than a bag of words? For all of these models, one hypothesis is that the encoder may be learning to memorize the bag of words and then preferentially generate words in that bag from the decoder. To verify this, we investigate whether the BoW representation and the learned latent code can be reconstructed from each other. Specifically, given a sentence x we can compute BoW as defined above and $\mu = \text{enc}(x)$, the latent encoding of x as represented by the mean vector output by the encoder. We can use a simple multilayer perceptron to to try to map from the bag of words to the latent code: $\hat{\mu} = MLP(BoW)$, then learn the parameters of the MLP by minimizing $\|\hat{\mu} - \mu\|^2$ on a sample. The same process can be used to learn a mapping from μ back to the bag of words.

Table 6 shows averaged cosine similarities of our reconstructions under both Gaussian and vMF models. For vMF, μ can reconstruct the bag-of-words more accurately than the bag-of-words can reconstruct μ, indicating that the latent code in vMF captures more information beyond the bag of words.

We repeat this experiment in a separate NVRNN model where the decoder can explicitly condition on the BoW vector described above. The results are shown in the right column of Table 6. Our model, v-VAE, achieves a lower cosine

---

[6] The preprocessed version can be downloaded from `https://github.com/ysmiao/nvdm`

[7] We do not compare to results from Serban et al. (2017a). Compared to our current results, that work reports very strong performance on 20NG and very weak performance on RCV1; we believe they either used different preprocessing or made a mistake in reporting the results, but could not confirm this with the authors.

Model	NVRNN		NVRNN-BoW
Setting	$\mu \rightarrow$ BoW	BoW $\rightarrow \mu$	$\mu \rightarrow$ BoW
G-VAE	0.74	0.74	0.32
v-VAE	0.77	0.57	0.23

Table 6: Average cosine similarity when trying to reconstruct the latent code μ from the bag of words and vice versa. In vMF, the latent code contains more information beyond the bag of words, as shown by the lower cosine similarity when predicting BoW $\rightarrow$ μ (0.57). When the latent code is learned in a model conditioned on the bag of words (right column), it predicts the bag of words much less well, indicating that the model successfully learns orthogonal information.

similarity than G-VAE (0.23 vs. 0.32), indicating that it capturing less redundant information and using the latent space to more efficiently model other properties of the data.

Sensitivity to word order Table 6 shows that NVRNN with vMF encodes information beyond the bag of words; a natural hypothesis is that it is encoding word order. We can more directly investigate this in the context of both NVRNN and NVRNN-BoW settings. Inspired by Zhao et al. (2017a), we propose an experiment probing the sensitivity to randomly swapping adjacent pairs of words for the encoding in the Inputless setting on PTB. We vary the probability of swapping each word pair and see how the latent code changes as the number of swaps increases. Ideally, our models should capture ordering information and therefore be sensitive to this change.

Figure 5 shows the results. v-VAE's representations are more sensitive than those of the G-VAE: they change faster as swaps become more likely.[8] In the NVRNN-BoW setting, we see that the models are even more sensitive. vMF enables us to more easily learn this kind of desirable information in our sentence encodings.

7 Controlling Variance with κ

A core aspect of our approach so far has been treating κ as a fixed hyperparameter. Fixing κ is beneficial from an optimization standpoint: it makes it more difficult for the model to get stuck in local optima. But it also reduces the model's flexibility, since we can no longer predict per-example κ values, and it introduces another parameter that the system designer must tune.

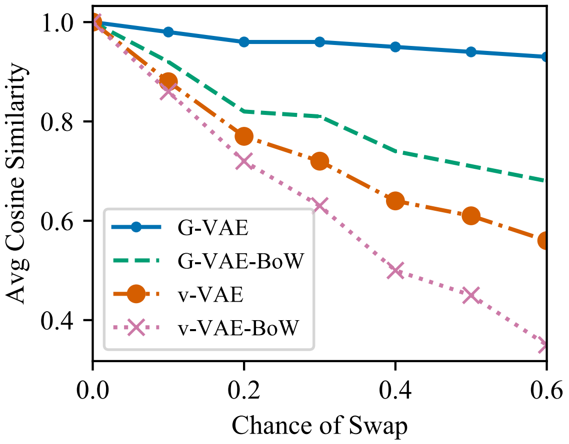

Figure 5: Sensitivity of latent codes to swapping adjacent words of encoding sequence. Cosine similarity is measured between the latent code (encoded mean vector) of the original sentence and the sentence after swaps are applied. We see that vMF is more highly sensitive to swaps in both the NVRNN and NVRNN-BoW settings, indicating that its latent space likely encodes more ordering information.

Fortunately, a wide range of κ values appear to work well for the tasks we consider. Figure 6 shows how the concentration parameter κ changes the results on PTB when the latent dimension and other hyperparameters are held fixed. We have ordered the tasks left-to-right from "hardest" to "easiest" in terms of necessity of latent representation: the Inputless setting needs heavy information from the latent code to reconstruct the sentence, whereas the Standard-BoW setting has an extremely strong decoder to predict the next word. We see that in each of these cases, a wide range of κ values works, and moreover reasonable κ values transfer between the two Standard and between the two Inputless settings, indicating that the overall approach is not highly sensitive to these hyperparameter values.

Brittleness of Learning κ Throughout this work, we have treated κ as a fixed parameter. However, we can treat κ in the same way as σ in the Gaussian case and learn it on a per-instance basis. The KL divergence of vMF is differentiable with respect to κ given gradients of the modified Bessel function of the first kind,[9] allowing us to change the concentration on a per-instance basis. However, this reintroduces the issue of KL collapse: the KL term will encourage κ to be as low

---

[8] The Gaussian VAE here makes very little use of the latent variable, hence why the representations change very little.

[9] $\nabla_\kappa I_d(\kappa) = \frac{1}{2}(I_{d-1}(\kappa) + I_{d+1}(\kappa))$

Figure 6: Perplexity of v-VAE in different settings with different κ values when the latent dimension is 50. Darker colors correspond to perplexity values closer to the best observed for that setting. For each task, we see that there is a range of κ values that work well, and these transfer between comparable tasks.

as possible, potentially making the latent variable vacuous.

In practice, we observe that it is necessary to clip κ values to a certain range for numerical reasons. Within this range, the model gravitates towards the smallest κ values and performs substantially worse than models trained with our fixed κ approach. This indicates that even with the vMF model, the optimization problem posed by ELBO is simply a hard one and the approach of fixing KL divergence is a surprisingly good optimization technique.

8 Related Work

Applications of VAE in NLP Deep generative models have achieved impressive successes in domains adjacent to NLP such as image generation (Gregor et al., 2015; Oord et al., 2016a) and speech generation (Chung et al., 2015; Oord et al., 2016b). VAEs specifically (Kingma and Welling, 2013; Rezende et al., 2014) have been a popular model variant in NLP. They have been applied to tasks including document modeling (Miao et al., 2016), language modeling (Bowman et al., 2016), and dialogue generation (Serban et al., 2017b). VAEs can be also be applied for semi-supervised classification (Xu et al., 2017). Recent twists on the standard VAE approach including combining VAE and holistic attribute discriminators for conditional generation (Hu et al., 2017) and using a more flexible latent space regularized by an adversarial method (Zhao et al., 2017a).

VAE Objective Several pieces of recent work have highlighted the issues with optimizing the VAE objective. Alemi et al. (2018) shed light on the problem from the perspective of information theory. Zhao et al. (2017b) and Higgins et al. (2017) both propose various reweightings of the objective along with theoretical and empirical justification.

Choices of Priors for VAE Some past work has explored various priors for VAE. Serban et al. (2017a) proposed a piecewise constant distribution which deals with multiple modes, but which sacrifices the property of continuous interpolation. Guu et al. (2018) also applied vMF in a VAE model, but used theirs specifically in the sentence-editing case. Davidson et al. (2018) explored vMF in a VAE model for MNIST and a link prediction task. Hasnat et al. (2017) applied the vMF distribution for facial recognition. Other past work has used different decoders, including CNNs (Yang et al., 2017) and CNN-RNN hybrids (Semeniuta et al., 2017). Changing the decoder is a change largely orthogonal to changing the prior: it can alleviate the KL vanishing issue, but it does not necessarily scale to new settings and does not give explicit control over utilization of the latent code.

9 Conclusion

In this paper, we propose the use of a von Mises-Fisher VAE to resolve optimization issues in variational autoencoders for text. This choice of distribution allows us to explicitly control the balance between the capacity of the decoder and the utilization of the latent representation in a principled way. Experimental results demonstrate that the proposed model has better performance than a Gaussian VAE across a range of settings. Further analysis shows that vMF VAE is more sensitive to word order information and makes more effective use of the latent code space.

Abstract

In order to learn universal sentence representations, previous methods focus on complex recurrent neural networks or supervised learning. In this paper, we propose a mean-max attention autoencoder (mean-max AAE) within the encoder-decoder framework. Our autoencoder rely entirely on the MultiHead self-attention mechanism to reconstruct the input sequence. In the encoding we propose a mean-max strategy that applies both mean and max pooling operations over the hidden vectors to capture diverse information of the input. To enable the information to steer the reconstruction process dynamically, the decoder performs attention over the mean-max representation. By training our model on a large collection of unlabelled data, we obtain high-quality representations of sentences. Experimental results on a broad range of 10 transfer tasks demonstrate that our model outperforms the state-of-the-art unsupervised single methods, including the classical skip-thoughts (Kiros et al., 2015) and the advanced skip-thoughts+LN model (Ba et al., 2016). Furthermore, compared with the traditional recurrent neural network, our mean-max AAE greatly reduce the training time. [1]

1 Introduction

To automatically get the distributed representations of texts (words, phrases and sentences) is a fundamental task for natural language processing (NLP). There have been efficient learning algorithms to acquire the representations of words (Mikolov et al., 2013a), which have shown to provide useful features for various tasks. Interestingly, the acquired word representations reflect some observed aspects of human conceptual organization (Hill et al., 2015). In recent years, learning sentence representations has attracted much attention, which is to encode sentences into fixed-length vectors that could capture the semantic and syntactic properties of sentences and can then be transferred to a variety of other NLP tasks.

The most widely used method is to employ an encoder-decoder architecture with recurrent neural networks (RNN) to predict the original input sentence or surrounding sentences given an input sentence (Kiros et al., 2015; Ba et al., 2016; Hill et al., 2016; Gan et al., 2017). However, the RNN becomes time consuming when the sequence is long. The problem becomes more serious when learning general sentence representations that needs training on a large amount of data. For example, it took two weeks to train the skip-thought (Kiros et al., 2015). Moreover, the traditional RNN autoencoder generates words in sequence conditioning on the previous ground-truth words, i.e., teacher forcing training (Williams and Zipser, 1989). This teacher forcing strategy has been proven important because it forces the output of the RNN to stay close to the ground-truth sequence. However, at each time step, allowing the decoder solely to access the previous ground-truth words weakens the encoder's ability to learn the global information of the input sequence.

Some other approaches (Conneau et al., 2017; Cer et al., 2018; Subramanian et al., 2018) attempt to use the labelled data to build a generic sentence encoder, such as the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015), but such large-scale high-quality labelled data appropriate for training sentence representations is generally not available in other languages.

In this paper, we are interested in learning universal sentence representations based on a large amount of naturally occurring corpus, without using any labelled data. We propose a mean-max

attention autoencoder (mean-max AAE) to model sentence representations. Specifically, an encoder performs the MultiHead self-attention on an input sentence, and then the combined mean-max pooling operation is employed to produce the latent representation of the sentence. The representation is then fed into a decoder to reconstruct the input sequence, which also depends entirely on the MultiHead self-attention. At each time step, the decoder performs attention operations over the mean-max encoding, which on the one hand, enables the decoder to utilize the global information of the input sequence rather than generating words solely conditioning on the previous ground-truth words, and on the other hand, allows the decoder to attend to different representation subspaces dynamically.

We train our autoencoder on a large collection of unlabelled data, and evaluate the sentence embeddings across a diverse set of 10 transfer tasks. The experimental results show that our model outperforms the state-of-the-art unsupervised single models, and obtains comparable results with the combined models. Our mean-max representations yield consistent performance gain over the individual mean and max representations. At the same time, our model can be efficiently parallelized and so achieves significant improvement in computational efficiency.

In summary, our contributions are as follows:

- We apply the MultiHead self-attention mechanism to train autoencoder for learning universal sentence representations, which allows our model to do processing parallelization and thus greatly reduce the training time in large unlabelled data.
- we adopt a mean-max representation strategy in the encoding and then the decoder conducts attention over the latent representations, which can well capture the global information of the input from different views.
- After training only on naturally occurring unordered sentences, we obtain a simple and fast sentence encoder, which is an unsupervised single model and achieves state-of-the-art performance on various transfer tasks.

2 Related Work

With the flourishing of deep learning in NLP research, a variety of approaches have been developed for mapping word embeddings to fixed-length sentence representations. The methods generally fall into the following categories.

Unsupervised training with unordered sentences. This kind of methods depends only on naturally occurring individual sentences. Le and Mikolov (2014) propose the paragraph vector model, which incorporates a global context vector into the log-linear neural language model (Mikolov et al., 2013b), but at test time, inference needs to be performed to compute a new vector. Arora et al. (2017) propose a simple but effective Smooth Inverse Frequency (SIF) method, which represents sentence by a weighted average of word embeddings. Hill et al. (2016) introduce sequential denoising autoencoders (SDAE), which employ the denoising objective to predict the original source sentence given a corrupted version. They also implement bag-of-words models such as word2vec-SkipGram, word2vec-CBOW. Our model belongs to this group, which has no restriction on the required training data and can be trained on sets of sentences in arbitrary order.

Unsupervised training with ordered sentences. This kind of method is trained to predict the surrounding sentences of an input sentence, based on the naturally occurring coherent texts. Kiros et al. (2015) propose the skip-thoughts model, which uses an encoder RNN to encode a sentence and two decoder RNN to predict the surrounding sentences. The skip-thought vectors perform well on several tasks, but training this model is very slow, requiring several days to produce meaningful results. Ba et al. (2016) further obtain better results by adding layer-norm regularization on the skip-thoughts model. Gan et al. (2017) explore a hierarchical model to predict multiple future sentences, using a convolutional neural network (CNN) encoder and a long-short term memory (LSTM) decoder. Logeswaran and Lee (2018) reformulate the problem of predicting the context in which a sentence appears as a classification task. Given a sentence and its context, a classifier distinguishes context sentences from other contrastive sentences based on their vector representations.

Supervised learning of sentence representations. Hill et al. (2016) implement models trained on supervised data, including dictionary definitions, image captions from the COCO dataset (Lin et al., 2014) and sentence-aligned translated texts. Conneau et al. (2017) attempt to exploit the SNLI dataset for building generic sentence encoders. Through examining 7 different model schemes, they show that a bi-directional LSTM network with the max pooling yields excellent performance. Cer et al. (2018) apply multi-task learning to train sentence encoders, including a skip-thought like task, a conversational input-response task and classification tasks from the SNLI dataset. They also explore combining the sentence and word level transfer models. Subramanian et al. (2018) also present a multi-task learning framework for sentence representations, and train their model on several data resources with multiple training objectives on over 100 million sentences.

3 Model Description

Our model follows the encoder-decoder architecture, as shown in Figure 1. The input sequence is compressed into a latent mean-max representation via an encoder network, which is then used to reconstruct the input via a decoder network.

3.1 Notation

In our model, we treat the input sentence as one sequence of tokens. Let S denote the input, which is comprised of a sequence of tokens $\{w_1, w_2, \ldots, w_N\}$, where N denotes the length of the sequence. An additional "$</S>$" token is appended to each sequence. Each word w_t in S is embedded into a k-dimensional vector $e_t = W_e[w_t]$, where $W_e \in \mathbb{R}^{d_w \times V}$ is a word embedding matrix, w_t indexes one element in a V-dimensional set (vocabulary), and $W_e[v]$ denotes the v-th column of matrix W_e.

In order for the model to take account of the sequence order, we also add "positional encodings" (Vaswani et al., 2017) to the input embeddings:

$$p_t[2i] = sin(\frac{t}{10000^{2i/d_w}}) \tag{1}$$

$$p_t[2i+1] = cos(\frac{t}{10000^{2i/d_w}}) \tag{2}$$

where t is the position and i is the dimension. Each dimension of the positional encoding corresponds to a sinusoid. Therefore, the input of our model can be represented as $x_t = e_t + p_t$.

In the following description, we use h_t^e and h_t^d to denote the hidden vectors of the encoder and decoder respectively, the subscripts of which indicate timestep t, and the superscripts indicate operations at the encoding or decoding stage.

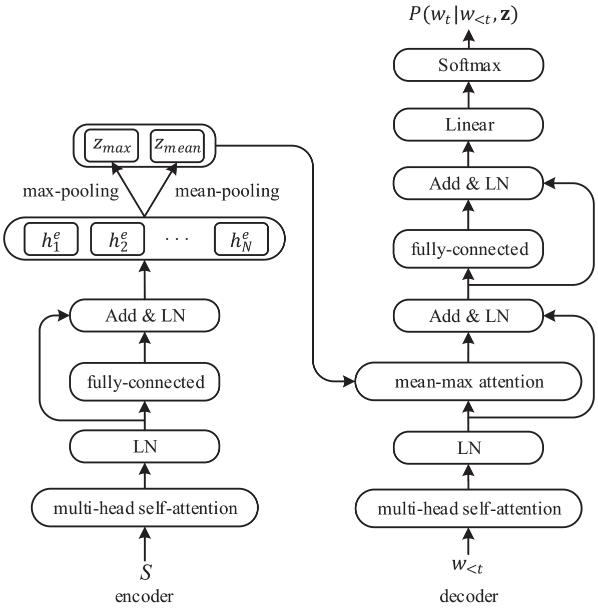

Figure 1: Illustration of the mean-max attention autoencoder.

3.2 MultiHead Self-Attention

In this subsection, we give a quick overview of MultiHead Self-Attention mechanism (Vaswani et al., 2017). The attention is to map a query q and a set of key-value pairs (K, V) to an output. The output is computed as a weighted sum of the values, where the weight assigned to each value is computed based on the query and the corresponding key. The MultiHead mechanism applies multiple attention operations in parallel. Given q and (K, V), we can obtain the attention vector a by:

$$\begin{aligned} a &= MultiHead(q, K, V) && (3)\\ &= concat(head_1, \ldots, head_l) && (4)\\ head_i &= attention(\overline{q}, \overline{K}, \overline{V}) && (5)\\ &= softmax(\frac{\overline{q}\overline{K}^T}{\sqrt{d_k}})\overline{V} && (6) \end{aligned}$$

where

$$\overline{q}, \overline{K}, \overline{V} = qW_i^q, KW_i^K, VW_i^V \tag{7}$$

W_i^q, W_i^K and W_i^V are parameter matrices; $\overline{q} \in \mathbb{R}^{d_k}$, $\overline{K} \in \mathbb{R}^{n_k \times d_k}$ and $\overline{V} \in \mathbb{R}^{n_k \times d_v}$; d_k and d_v are the dimensions of $\overline{K}$ and $\overline{V}$ respectively; n_k is the number of key-value pairs.

The MultiHead self-attention allows the model to jointly attend to information from different positions. Due to the reduced dimension of each head and parallel operations, the total computational cost is similar to that of a single-head attention.

3.3 Attention Encoder

The encoder has two sub-layers. The first is a MultiHead self-attention mechanism, and the second is a position-wise fully connected feed-forward network which consists of two linear transformations with a ReLU activation in between. Different from Vaswani et al. (2017), we remove the residual connections in the MultiHead self-attention layer and only employ a residual connection in the fully connected layer, allowing the model to expand the dimension of hidden vectors to incorporate more information.

Given the input $\mathbf{x} = (x_1, \ldots, x_N)$, the hidden vector h_t^e at time-step t is computed by:

$$a_t^e = MultiHead(x_t, \mathbf{x}, \mathbf{x}) \tag{8}$$
$$\overline{a}_t^e = LN(a_t^e) \tag{9}$$
$$\overline{h}_t^e = max(0, \overline{a}_t^e W_1^e + b_1^e) W_2^e + b_2^e \tag{10}$$
$$h_t^e = LN(\overline{h}_t^e + \overline{a}_t^e) \tag{11}$$

where $W_1^e \in \mathbb{R}^{d_m \times d_f}$ and $W_2^e \in \mathbb{R}^{d_f \times d_m}$ are parameter matrices; $b_1^e \in \mathbb{R}^{d_f}$ and $b_2^e \in \mathbb{R}^{d_m}$ are bias vectors; d_m and d_f are the dimensions of hidden vector and fully connected inner layer respectively; LN denotes layer normalization.

Our model can be efficiently parallelized over the whole input. We can obtain all hidden vectors $(h_1^e, \ldots, h_N^e)$ simultaneously for an input sequence, thus greatly reducing the computational complexity compared with the sequential processing of LSTM.

3.4 Mean-Max Representation

Given the varying number of hidden vectors $\{h_t^e\}_{t=[1,\ldots,N]}$, we need to transform these local hidden vectors into a global sentence representation. We would like to apply the pooling strategy, which makes the extracted representation independent of the length of the input sequence and obtains a fixed-length vector. Conneau et al. (2017) examine BiLSTM with mean and max pooling for fixed-size sentence representation, and they conclude that the max pooling operation performs better on transfer tasks.

In this work, we propose to apply mean and max pooling simultaneously. The max pooling takes the maximum value over the sequence, which tries to capture the most salient property while filtering out less informative local values. On the other hand, the mean pooling does not make sharp choices on which part of the sequence is more important than others, and so it captures general information while not focusing too much on specific features. Obviously, the two pooling strategies can complement each other. The mean-max representation is obtained by:

$$z_{max}[i] = \max_t h_{ti}^e \tag{12}$$
$$z_{mean} = \frac{1}{N} \sum_t h_t^e \tag{13}$$
$$\mathbf{z} = [z_{max}, z_{mean}] \tag{14}$$

Through combining two different pooling strategies, our model enjoys the following advantages. First, in the encoder, we can summarize the hidden vectors from different perspectives and so capture more diverse features of the input sequence, which will bring robustness on different transfer tasks. Second, in the decoder (as described in the next subsection), we can perform attention over the mean-max representation rather than over the local hidden vectors step by step, which would potentially make the autoencoder objective trivial.

3.5 Attention Decoder

As with the encoder, the decoder also applies the MultiHead self-attention to reconstruct the input sequence. As shown in Figure 1, the encoder and decoder are connected through a mean-max attention layer, which performs attention over the mean-max representation generated by the encoder.

To facilitate expansion of the hidden size, we employ residual connections in the mean-max attention layer and the fully connected layer, but not in the MultiHead self-attention layer. Given $\mathbf{y} = (x_1, \ldots, x_{t-1})$ and $\mathbf{z}$ as the decoder input, the hidden vector h_t^d at time step t is obtained by:

$$a_t^d = MultiHead(y_t, \mathbf{y}, \mathbf{y}) \tag{15}$$
$$\overline{a}_t^d = LN(a_t^d) \tag{16}$$
$$a_t^z = MultiHead(\overline{a}_t^d, \mathbf{z}, \mathbf{z}) \tag{17}$$
$$\overline{a}_t^z = LN(a_t^z + \overline{a}_t^d) \tag{18}$$
$$\overline{h}_t^d = max(0, \overline{a}_t^z W_1^d + b_1^d) W_2^d + b_2^d \tag{19}$$
$$h_t^d = LN(\overline{h}_t^d + \overline{a}_t^z) \tag{20}$$

where $W_1^d \in \mathbb{R}^{d_m \times d_f}$ and $W_2^d \in \mathbb{R}^{d_f \times d_m}$ are parameter matrices; $b_1^d \in \mathbb{R}^{d_f}$ and $b_2^d \in \mathbb{R}^{d_m}$ are bias vectors. $\mathbf{z}$ in Equation (17) is the mean-max representation generated by Equation (14).

Given the hidden vectors $(h_1^d, \ldots, h_N^d)$, the probability of generating a sequence S with length-N is defined as:

$$P(w_t|w_{<t}, \mathbf{z}) \propto exp(W_3^d h_t^d + b_3^d) \tag{21}$$

$$J(\theta) = \sum_t logP(w_t|w_{<t}, \mathbf{z}) \tag{22}$$

The model learns to reconstruct the input sequence by optimizing the objective in Equation (22).

4 Evaluating Sentence Representations

In the previous work, researchers evaluated the distributed representations of sentences by adding them as features in transfer tasks (Kiros et al., 2015; Gan et al., 2017; Conneau et al., 2017). We use the same benchmarks and follow the same procedure to evaluate the capability of sentence embeddings produced by our generic encoder.

4.1 Transfer Tasks

We conduct extensive experiments on 10 transfer tasks. We first study the classification task on 6 benchmarks: movie review sentiment (MR, SST) (Pang and Lee, 2005; Socher et al., 2013), customer product reviews (CR) (Hu and Liu, 2004), subjectivity/objectivity classification (SUBJ) (Pang and Lee, 2004), opinion polarity (MPQA) (Wiebe et al., 2005) and question type classification (TREC) (Li and Roth, 2002).

We also consider paraphrase detection on the Microsoft Research Paraphrase Corpus (MRPC) (Dolan et al., 2004), where the evaluation metrics are accuracy and F1 score.

We then evaluate on the SICK dataset (Marelli et al., 2014) for both textual entailment (SICK-E) and semantic relatedness (SICK-R). The evaluation metric is Pearson correlation for SICK-R. We also evaluate on the SemEval task of STS14 (Agirre et al., 2014), where the evaluation metrics are Pearson and Spearman correlations.

The processing on each task is as follows: 1) Employ the pre-trained attention autoencoder to encode all sentences into the latent mean-max representations. 2) Using the representations as features, apply the open SentEval with a logistic regression classifier (Conneau et al., 2017) to automatically evaluate on all the tasks. For a fair comparison of the plain sentence embeddings, we adopt all the default settings.

4.2 Experiment Setup

We train our model on the open Toronto Books Corpus (Zhu et al., 2015), which was also used to train the skip-thoughts (Kiros et al., 2015) and skip-thoughts+LN (Ba et al., 2016). The Toronto Book Corpus consists of 70 million sentences from over $7,000$ books, which is not biased towards any particular domain or application.

The dimensions of hidden vectors and fully connected inner layer are set to $2,048$ and $4,096$ respectively. Hence, our mean-max AAE represents sentences with $4,096$ dimensional vectors. We set $l = 8$ parallel attention heads according to the development data.

We use the Adam algorithm (Kingma and Ba, 2014) with learning rate 2×10^{-4} for optimization. Gradient clipping is adopted by scaling gradients when the norm of the parameter vector exceeds a threshold of 5. We perform dropout (Srivastava et al., 2014) and set the dropout rate to 0.5. Minibatches of size 64 are used. Our model learns until the reconstruction accuracy in the development data stops improving.

Our aim is to learn a generic sentence encoder that could encode a large number of words. There always are some words that haven't been seen during training, and so we use the publicly available GloVe vectors [2] to expand our encoder's vocabulary. We set the word vectors in our models as the corresponding word vectors in GloVe, and do not update the word embeddings during training. Thus, any word vectors from GloVe can be naturally used to encode sentences. Our models are trained with a vocabulary of $21,583$ top frequent words in the Toronto Book corpus. After vocabulary expansion, we can now successfully cover $2,196,017$ words.

All experiments are implemented in Tensorflow (Abadi et al., 2016), using a NVIDIA GeForce GTX 1080 GPU with 8GB memory.

4.3 Evaluation Results

A summary of our experimental results on 10 tasks is given in Table 1, in which the evaluation metric of the first 8 tasks is accuracy. To make a clear comparison of the overall performance, we compute the "macro" and "micro" average of accuracy

Table 2: The macro and micro average accuracy across different tasks. The bold is the highest score among all unsupervised models.

in Table 2, where the micro average is weighted by the number of test samples in each task. In the previous work, different approaches conduct experiments on different benchmarks. Therefore we report the average scores on 6 tasks, 7 tasks and 8 tasks, respectively.

We divide related models into three groups. The first group contains unsupervised single models, including the Paragraph Vector model (Le and Mikolov, 2014), the SDAE method (Hill et al., 2016), the SIF model (Arora et al., 2017), the FastSent (Hill et al., 2016), the skip-thoughts (uni-skip and bi-skip) (Kiros et al., 2015), the CNN encoder (hierarchical-CNN and composite-CNN) (Gan et al., 2017) and skip-thoughts+LN (Ba et al., 2016). Our mean-max attention autoencoder sits in this group. The second group consists of unsupervised combined models, including combine-skip (Kiros et al., 2015) and combine-CNN (Gan et al., 2017). In the third group, we list the results from the work of Conneau et al. (2017) only for reference, since it is trained on labelled data.

Comparison with skip-thoughts+LN. The skip-thoughts+LN is the best model among the existing single models. Compared with the skip-thoughts+LN, our method obtains better results on 4 datasets (SST, TREC, SICK-E, STS14) and comparable results on 3 datastes (SUBJ, MPQA, SICK-R). Looking at the STS14 results, we observe that the cosine metrics in our representation space is much more semantically informative than in skip-thoughts+LN representation space (pearson score of 0.58 compared to 0.44). Considering the overall performance shown in Table 2, our model obtains better results both in the macro and micro average accuracy across 7 considered tasks. In view of the required training data, the skip-thoughts+LN needs coherent texts while our model needs only individual sentences. Moreover, we train our model in less than 5 hours on a single GPU compared to the best skip-thoughts+LN network trained for a month.

Unsupervised combined models. The results of the individual models (Kiros et al., 2015; Gan et al., 2017) are not promising. To get better performance, they train two separate models on the same corpus and then combine the latent representations together. As shown in Table 2, our mean-max attention autoencoder outperforms the classical combine-skip model by 1.3 points in the average performance across 8 considered tasks. Specially, the pearson correlation of our model is 2 times over the combine-skip model on the STS14 task. Looking at the overall performance of 6 tasks, our model gets comparable results with the combine-CNN, which combines the hierarchical and composite approaches to exploit the intra-sentence and inter-sentence information. Obviously, our model is simple and fast to implement compared with the combined methods.

Supervised representation training. It is unfair to directly compare our totally unsupervised model with the supervised representation learning method. Conneau et al. (2017) train the BiLSTM-Max (on ALLNLI) on the high-quality natural language inference data. Our model even performs better than the BiLSTM-Max (on ALLNLI) on the SUBJ and TREC tasks. More importantly, our model can be easily adapted to other low-resource languages.

4.4 Model Analysis

Our model contains three main modules: the mean-max attention layer, the combined pooling strategy and the encoder-decoder network. We make a further study on these components. The experimental results are shown in Table 3.

In our model, the mean-max attention layer allows the decoder to pay attention to the encoding representation of the full sentence at each time step dynamically. To summarize the contribution of the mean-max attention layer, we compare with traditional baselines, including the sequential denoising autoencoder (SDAE) with LSTM networks (Hill et al., 2016) and the CNN-LSTM autoencoder (Gan et al., 2017), both of which only use the encoding representation to set the initial state of the decoder and follow the teacher forcing strategy.

We employ both the mean and max pooling operations over the local hidden vectors to obtain sentence embeddings. To validate the effectiveness of our mean-max representations, we train two additional models: (i) an attention autoencoder only with max pooling (max AAE) and (ii) an attention autoencoder only with mean pooling (mean AAE). The dimension of hidden vectors is also set to $2,048$.

Our encoder-decoder network depends on the MultiHead self-attention mechanism to reconstruct the input sequence. To test the effect of the MultiHead self-attention mechanism, we replace it with RNN and implement a mean-max RNN autoencoder (mean-max RAE) training on the same Toronto Books Corpus. A bidirectional LSTM computes a set of hidden vectors on an input sentence, and then the mean and max pooling operations are employed to generate the latent mean-max representation. The representation is then fed to a LSTM decoder to reconstruct the input sequence through attention operation over the latent representation. The parameter configurations are consistent with our other models. Moreover, we also train two additional models with different pooling strategies: mean RAE and max RAE.

Analysis on the mean-max attention layer. Our mean-max attention layer brings significant performance gain over the previous autoencoders. Compared the mean RAE with LSTM-SDAE, both of which use the RNN-RNN encoder-decoder network to reconstruct the input sequence, our mean RAE consistently obtains better performance than LSTM-SDAE across all considered tasks. In particular, it yields a performance gain of 10.4 on the TREC dataset and 29 on the STS14 dataset. Compared with another CNN-LSTM autoencoder, our mean RAE also gets better performance for all but one task. It demonstrates that the mean-max attention layer enables the decoder to attend to the global information of the input sequence, thus go beyond the “teacher forcing training”.

Analysis on the pooling strategy. Considering the overall performance, our mean-max representations outperform the individual mean and max representations both in the attention and RNN networks. In our attention autoencoder, the macro average score of the mean-max AAE is more than 0.6 over the individual pooling strategy. In the RNN autoencoder, the combined pooling strategy

Method	Macro	MR	CR	SUBJ	MPQA	SST	TREC	MRPC	SICK-E	SICK-R	STS14
mean AAE	84.1	78.6	81.6	93.3	88.6	83.5	90.2	74.8/82.3	82.2	0.851	.57/.55
max AAE	84.1	78.6	81.4	93.1	88.7	82.8	90.6	75.1/82.5	82.2	0.851	.57/.55
mean-max AAE	84.7	78.7	82.3	93.4	88.8	83.8	91.4	75.5/82.6	83.5	0.854	.58/.56
mean RAE	83.1	77.1	80.2	92.4	88.4	81.9	88.8	74.3/82.2	81.9	0.836	.66/.64
max RAE	83.0	77.2	80.1	92.0	88.4	81.0	88.6	74.3/82.0	82.0	0.851	.68/.66
mean-max RAE	83.6	77.4	80.1	92.2	88.5	82.3	90.6	74.6/82.0	83.2	0.853	.68/.65
LSTM SDAE	-	74.6	78.0	90.8	86.9	-	78.4	73.7/80.7	-	-	.37/.38
CNN-LSTM AE	-	75.5	79.0	92.0	88.0	-	89.8	73.6/82.1	-	-	-

Table 3: Performance of different pooling strategies and different encoder-decoder networks on 10 transfer tasks. Macro is the macro average over the first 8 tasks whose metric is accuracy.

yields a performance gain of 0.5 over the mean pooling and 0.6 over the max pooling. The results indicate that our mean-max pooling captures more diverse information of the input sequence, which is robust and effective in dealing with various transfer tasks.

Comparison with RNN-based autoencoder. As shown in Table 3, our MultiHead self-attention network obtains obvious improvement over the RNN network in different sets of pooling strategies, and it yields a performance gain of 1.1 when applying the best combined mean-max pooling operation. The results demonstrate that the MultiHead self-attention mechanism enables the sentence representations to capture more useful information about the input sequence.

Analysis on computational complexity. A self-attention layer connects all positions with a constant number of sequentially executed operations, whereas a recurrent layer requires $O(n)$ sequential operations. Therefore, our model greatly reduces the computational complexity. Excluding the number of parameters used in the word embeddings, the skip-thought model (Kiros et al., 2015) contains 40 million parameters, while our mean-max AAE has approximately 39 million parameters. It took nearly 50.4 and 25.4 minutes to train the skip-thought model (Kiros et al., 2015) and the skip-thoughts+LN (Ba et al., 2016) per 1000 mini-batches respectively. Both the skip-thought and skip-thought+LN are implemented in Theano. A recent implementation of the skip-thoughts model was released by Google [3], which took nearly 25.9 minutes to train 1000 mini-batches on a GTX 1080 GPU. In our experiment, it took 3.3 minutes to train the mean-max AAE model every 1000 mini-batches.

Figure 2: Two examples illustrate that our mean-max attention layer could attend to the two different representations dynamically.

4.5 Attention Visualization

The above experimental results have proven the effectiveness of the mean-max attention mechanism in the decoding. We further inspect the attention distributions captured by the mean-max attention layer, as shown in Figure 2. The side-by-side heat illustrates how much the decoder pay attention to the mean representation and max representation respectively at each decoding step. We can see that the attention layer learns to selectively retrieve the mean or max representations dynamically, which relieve the decoder from the burden of generating words solely conditioning on the previous ground-truth words. Also, the two different representations can complement each other, and the mean representation plays a greater role.

---

5 Conclusion

In this paper, we present a mean-max AAE to learn universal sentence representations from unlabelled data. Our model applies the MultiHead self-attention mechanism both in the encoder and decoder, and employs a mean-max pooling strategy to capture more diverse information of the input. To avoid the impact of "teacher forcing training", our decoder performs attention over the encoding representations dynamically. To evaluate the effectiveness of sentence representations, we conduct extensive experiments on 10 transfer tasks. The experimental results show that our model obtains state-of-the-art performance among the unsupervised single models. Furthermore, it is fast to train a high-quality generic encoder due to the paralleling operation. In the future, we will adapt our mean-max AAE to other low-resource languages for learning universal sentence representations.

Abstract

While the celebrated Word2Vec technique yields semantically rich representations for individual words, there has been relatively less success in extending to generate unsupervised sentences or documents embeddings. Recent work has demonstrated that a distance measure between documents called *Word Mover's Distance* (WMD) that aligns semantically similar words, yields unprecedented KNN classification accuracy. However, WMD is expensive to compute, and it is hard to extend its use beyond a KNN classifier. In this paper, we propose the *Word Mover's Embedding* (WME), a novel approach to building an unsupervised document (sentence) embedding from pre-trained word embeddings. In our experiments on 9 benchmark text classification datasets and 22 textual similarity tasks, the proposed technique consistently matches or outperforms state-of-the-art techniques, with significantly higher accuracy on problems of short length.

1 Introduction

Text representation plays an important role in many NLP-based tasks such as document classification and clustering (Zhang et al., 2018; Gui et al., 2016, 2014), sense disambiguation (Gong et al., 2017, 2018a), machine translation (Mikolov et al., 2013b), document matching (Pham et al., 2015), and sequential alignment (Peng et al., 2016, 2015). Since there are no explicit features in text, much work has aimed to develop effective text representations. Among them, the simplest bag of words (BOW) approach (Salton and Buckley, 1988) and its term frequency variants (e.g. TF-IDF) (Robertson and Walker, 1994) are most widely used due to simplicity, efficiency and often surprisingly high accuracy (Wang and Manning, 2012). However, simply treating words and phrases as discrete symbols fails to take into account word order and the semantics of the words, and suffers from frequent near-orthogonality due to its high dimensional sparse representation. To overcome these limitations, Latent Semantic Indexing (Deerwester et al., 1990) and Latent Dirichlet Allocation (Blei et al., 2003) were developed to extract more meaningful representations through singular value decomposition (Wu and Stathopoulos, 2015) and learning a probabilistic BOW representation.

A recent empirically successful body of research makes use of distributional or contextual information together with simple neural-network models to obtain vector-space representations of words and phrases (Bengio et al., 2003; Mikolov et al., 2013a,c; Pennington et al., 2014). A number of researchers have proposed extensions of these towards learning semantic vector-space representations of sentences or documents. A simple but often effective approach is to use a weighted average over some or all of the embeddings of words in the document. While this is simple, important information could easily be lost in such a document representation, in part since it does not consider word order. A more sophisticated approach (Le and Mikolov, 2014; Chen, 2017) has focused on jointly learning embeddings for both words and paragraphs using models similar to Word2Vec. However, these only use word order within a small context window; moreover, the quality of word embeddings learned

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4524–4534
Brussels, Belgium, October 31 - November 4, 2018.

in such a model may be limited by the size of the training corpus, which cannot scale to the large sizes used in the simpler word embedding models, and which may consequently weaken the quality of the document embeddings.

Recently, Kusner et al. (Kusner et al., 2015) presented a novel document distance metric, Word Mover's Distance (WMD), that measures the dissimilarity between two text documents in the Word2Vec embedding space. Despite its state-of-the-art KNN-based classification accuracy over other methods, combining KNN and WMD incurs very high computational cost. More importantly, WMD is simply a distance that can be only combined with KNN or K-means, whereas many machine learning algorithms require a fixed-length feature representation as input.

A recent work in building kernels from distance measures, D2KE (distances to kernels and embeddings) (Wu et al., 2018a) proposes a general methodology of the derivation of a positive-definite kernel from a given distance function, which enjoys better theoretical guarantees than other distance-based methods, such as k-nearest neighbor and distance substitution kernel (Haasdonk and Bahlmann, 2004), and has also been demonstrated to have strong empirical performance in the time-series domain (Wu et al., 2018b).

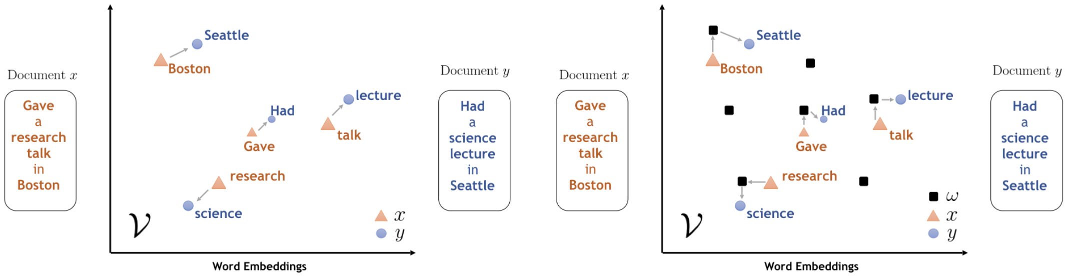
In this paper, we build on this recent innovation D2KE (Wu et al., 2018a), and present the *Word Mover's Embedding* (WME), an unsupervised generic framework that learns continuous vector representations for text of variable lengths such as a sentence, paragraph, or document. In particular, we propose a new approach to first construct a positive-definite *Word Mover's Kernel* via an infinite-dimensional feature map given by the Word Mover's distance (WMD) to random documents from a given distribution. Due to its use of the WMD, the feature map takes into account alignments of individual words between the documents in the semantic space given by the pre-trained word embeddings. Based on this kernel, we can then derive a document embedding via a Random Features approximation of the kernel, whose inner products approximate exact kernel computations. Our technique extends the theory of *Random Features* to show convergence of the inner product between WMEs to a positive-definite kernel that can be interpreted as a soft version of (inverse) WMD.

The proposed embedding is more efficient and flexible than WMD in many situations. As an example, WME with a simple linear classifier reduces the computational cost of WMD-based KNN *from cubic to linear* in document length and *from quadratic to linear* in number of samples, while simultaneously improving accuracy. WME is extremely easy to implement, fully parallelizable, and highly extensible, since its two building blocks, Word2Vec and WMD, can be replaced by other techniques such as GloVe (Pennington et al., 2014; Wieting et al., 2015b) or S-WMD (Huang et al., 2016). We evaluate WME on 9 real-world text classification tasks and 22 textual similarity tasks, and demonstrate that it consistently matches or outperforms other state-of-the-art techniques. Moreover, WME often achieves orders of magnitude speed-up compared to KNN-WMD while obtaining the same testing accuracy. Our code and data is available at `https://github.com/IBM/WordMoversEmbeddings`.

2 Word2Vec and Word Mover's Distance

We briefly introduce Word2Vec and WMD, which are the key building blocks of our proposed method. Here are some notations we will use throughout the paper. Given a total number of documents N with a vocabulary $\mathcal{W}$ of size $|\mathcal{W}| = n$, the Word2vec embedding gives us a d-dimensional vector space $\mathcal{V} \subseteq \mathbb{R}^d$ such that any word in the vocabulary set $w \in \mathcal{W}$ is associated with a semantically rich vector representation $\boldsymbol{v}_w \in \mathbb{R}^d$. Then in this work, we consider each document as a collection of word vectors $x := (\boldsymbol{v}_j)_{j=1}^{L}$ and denote $\mathcal{X} := \bigcup_{L=1}^{L_{\max}} \mathcal{V}^L$ as the space of documents.

Word2Vec. In the celebrated Word2Vec approach (Mikolov et al., 2013a,c), two shallow yet effective models are used to learn vector-space representations of words (and phrases), by mapping those that co-occur frequently, and consequently with plausibly similar meaning, to nearby vectors in the embedding vector space. Due to the model's simplicity and scalability, high-quality word embeddings can be generated to capture a large number of precise syntactic and semantic word relationships by training over hundreds of billions of words and millions of named entities. The advantage of document representations building on top of word-level embeddings is that one can make full use of high-quality pre-trained word embeddings. Throughout this paper we use Word2Vec as our first building block but other (unsupervised or supervised) word



(a) WMD

(b) WME

Figure 1: An illustration of the WMD and WME. All non-stop words are marked as bold face. WMD measures the distance between two documents. WME approximates a kernel derived from WMD with a set of random documents.

embeddings (Pennington et al., 2014; Wieting et al., 2015b) could also be utilized.

Word Mover's Distance. Word Mover's Distance was introduced by (Kusner et al., 2015) as a special case of the Earth Mover's Distance (Rubner et al., 2000), which can be computed as a solution of the well-known transportation problem (Hitchcock, 1941; Altschuler et al., 2017). WMD is a distance between two text documents x, $y \in \mathcal{X}$ that takes into account the alignments between words. Let $|x|$, $|y|$ be the number of distinct words in x and y. Let $\boldsymbol{f}_x \in \mathbb{R}^{|x|}$, $\boldsymbol{f}_y \in \mathbb{R}^{|y|}$ denote the normalized frequency vectors of each word in the documents x and y respectively (so that $\boldsymbol{f}_x^\intercal \mathbf{1} = \boldsymbol{f}_y^\intercal \mathbf{1} = 1$). Then the WMD distance between documents x and y is defined as:

$$\begin{aligned} \mathrm{WMD}(x,y) &:= \min_{F\in\mathbb{R}_+^{|x|\times|y|}} \langle C, F\rangle, \\ s.t., F\mathbf{1} &= \boldsymbol{f}_x, \quad F^\intercal\mathbf{1} = \boldsymbol{f}_y. \end{aligned} \tag{1}$$

where F is the transportation flow matrix with F_{ij} denoting the amount of flow traveling from i-th word x_i in x to j-th word y_j in y, and C is the transportation cost with $C_{ij} := \mathrm{dist}(\boldsymbol{v}_{x_i}, \boldsymbol{v}_{y_j})$ being the distance between two words measured in the Word2Vec embedding space. A popular choice is the Euclidean distance $\mathrm{dist}(\boldsymbol{v}_{x_i}, \boldsymbol{v}_{y_j}) = \|\boldsymbol{v}_{x_i} - \boldsymbol{v}_{y_j}\|_2$. When $\mathrm{dist}(\boldsymbol{v}_{x_i}, \boldsymbol{v}_{y_j})$ is a *metric*, the WMD distance in Eq. (1) also qualifies as a metric, and in particular, satisfies the triangle inequality (Rubner et al., 2000). Building on top of Word2Vec, WMD is a particularly useful and accurate for measure of the distance between documents with semantically close but syntactically different words as illustrated in Figure 1(a).

The WMD distance when coupled with KNN has been observed to have strong performance in classification tasks (Kusner et al., 2015). However, WMD is expensive to compute with computational complexity of $O(L^3 \log(L))$, especially for long documents where L is large. Additionally, since WMD is just a document distance, rather than a document representation, using it within KNN incurs even higher computational costs $O(N^2 L^3 \log(L))$.

3 Document Embedding via Word Mover's Kernel

In this section, we extend the framework in (Wu et al., 2018a), to derive a positive-definite kernel from an alignment-aware document distance metric, which then gives us an unsupervised semantic embeddings of texts of variable length as a by-product through the theory of *Random Feature Approximation* (Rahimi and Recht, 2007).

3.1 Word Mover's Kernel

We start by defining the *Word Mover's Kernel*:

$$\begin{aligned} k(x,y) &:= \int p(\omega)\phi_\omega(x)\phi_\omega(y)d\omega, \\ \text{where} \ \ \phi_\omega(x) &:= \exp(-\gamma \mathrm{WMD}(x,\omega)). \end{aligned} \tag{2}$$

where ω can be interpreted as a random document $\{\boldsymbol{v}_j\}_{j=1}^D$ that contains a collection of random word vectors in $\mathcal{V}$, and $p(\omega)$ is a distribution over the space of all possible random documents $\Omega := \bigcup_{D=1}^{D_{max}} \mathcal{V}^D$. $\phi_\omega(x)$ is an possibly infinite-dimensional feature map derived from the WMD between x and all possible documents $\omega \in \Omega$.

An insightful interpretation of this kernel (2):

$$k(x,y) := \exp(-\gamma \, \mathit{softmin}_{p(\omega)} f(\omega))$$

where

$$softmin_{p(\omega)}\ f(\omega) := -\frac{1}{\gamma}\log\int p(\omega)e^{-\gamma f(\omega)}d\omega,$$

and $f(\omega) = \{\text{WMD}(x,\omega) + \text{WMD}(\omega,y)\}$, is a version of soft minimum function parameterized by $p(\omega)$ and γ. Comparing this with the usual definition of soft minimum $softmin_i f_i := -softmax(-f_i) = -\log\sum_i e^{-f_i}$, it can be seen that the soft-min-variant in the above Equations uses a weighting of the objects ω via the probability density $p(\omega)$, and moreover has the additional parameter γ to control the degree of smoothness. When γ is large and $f(\omega)$ is Lipschitz-continuous, the value of the soft-min-variant is mostly determined by the minimum of $f(\omega)$.

Note that since WMD is a metric, by the triangular inequality we have

$$\text{WMD}(x,y) \ \leq \ \min_{\omega\in\Omega}\ (\text{WMD}(x,\omega) + \text{WMD}(\omega,y))$$

and the equality holds if we allow the length of random document $D_{\max}$ to be not smaller than L. Therefore, the kernel (2) serves as a good approximation to the WMD between any pair of documents x, y as illustrated in Figure 1(b), while it is *positive-definite* by the definition.

3.2 Word Mover's Embedding

Given the Word-Mover's Kernel in Eq. (2), we can then use the Monte-Carlo approximation:

$$k(x,y) \approx \langle Z(x), Z(y)\rangle = \frac{1}{R}\sum_{i=1}^{R}\phi_{\omega_i}(x)\phi_{\omega_i}(y) \tag{3}$$

where $\{\omega_i\}_{i=1}^{R}$ are i.i.d. random documents drawn from $p(\omega)$ and $Z(x) := (\frac{1}{\sqrt{R}}\phi_{\omega_i}(x))_{i=1}^{R}$ gives a vector representation of document x. We call this random approximation *Word Mover's Embedding*. Later, we show that this Random Features approximation in Eq. (3) converges to the exact kernel (2) uniformly over all pairs of documents (x, y) .

Distribution $p(\omega)$**.** A key ingredient in the Word Mover's Kernel and Embedding is the distribution $p(\omega)$ over random documents. Note that $\omega \in \mathcal{X}$ consists of sets of words, each of which lies in the Word2Vec embedding space; the characteristics of which need to be captured by $p(\omega)$ in order to generate (sets of) "meaningful" random words. Several studies have found that the word vectors $\boldsymbol{v}$ are roughly uniformly dispersed in the word embedding space (Arora et al., 2016, 2017). This is also consistent with our empirical findings, that the uniform distribution centered by the mean of all word vectors in the documents is generally applicable for various text corpora. Thus, if d is the dimensionality of the pre-trained word embedding space, we can draw a random word $u \in \mathbb{R}^d$ as $u_j \sim \text{Uniform}[v_{\min}, v_{\max}]$, for $j = 1, \ldots, d$, and where $v_{\min}$ and $v_{\max}$ are some constants.

Given a distribution over random words, the remaining ingredient is the length D of random documents. It is desirable to set these to a small number, in part because this length is indicative of the number of hidden global topics, and we expect the number of such global topics to be small. In particular, these global topics will allow short random documents to align with the documents to obtain "topic-based" discriminatory features. Since there is no prior information for global topics, we choose to uniformly sample the length of random documents as $D \sim \text{Uniform}[1, D_{\max}]$, for some constant $D_{\max}$. Stitching the distributions over words, and over the number of words, we then get a distribution over random documents. We note that our WME embedding allows potentially other random distributions, and other types of word embeddings, making it a flexible and powerful feature learning framework to utilize state-of-the-art techniques.

Algorithm 1 Word Mover's Embedding: An Unsupervised Feature Representation for Documents

```
Input: Texts $\{x_i\}_{i=1}^N$, $D_{\max}$, $R$.
Output: Matrix $Z_{N\times R}$, with rows corresponding to text embeddings.
Compute $v_{\max}$ and $v_{\min}$ as the maximum and minimum values, over all coordinates of the word vectors $\boldsymbol{v}$ of $\{x_i\}_{i=1}^N$, from any pre-trained word embeddings (e.g. Word2Vec, GloVe or PSL999).
for $j = 1, \ldots, R$ do
    Draw $D_j \sim \text{Uniform}[1, D_{\max}]$.
    Generate a random document $\omega_j$ consisting of $D_j$ number of random words drawn as $\omega_{j\ell} \sim \text{Uniform}[v_{\min}, v_{\max}]^d$, $\ell = 1, \ldots, D_j$.
    Compute $\boldsymbol{f}_{x_i}$ and $\boldsymbol{f}_{\omega_j}$ using a popular weighting scheme (e.g. NBOW or TF-IDF).
    Compute the WME feature vector $Z_j = \phi_{\omega_j}(\{x_i\}_{i=1}^N)$ using WMD in Equation (2).
end for
Return $Z(\{x_i\}_{i=1}^N) = \frac{1}{\sqrt{R}}[Z_1\ Z_2\ \ldots\ Z_R]$
```

Algorithm 1 summarizes the overall procedure to generate feature vectors for text of any length such as sentences, paragraphs, and documents.

KNN-WMD, which uses the WMD distance together with KNN based classification, requires $O(N^2)$ evaluations of the WMD distance, which in turn has $O(L^3 \log(L))$ complexity, assuming that documents have lengths bounded by L, leading to an overall complexity of $O(N^2 \, L^3 \, \log(L)$. In contrast, our WME approximation only requires super-linear complexity of $O(NRLlog(L))$ when D is constant. This is because in our case each evaluation of WMD only requires $O(D^2 \, L \log(L))$ (Bourgeois and Lassalle, 1971), due to the short length D of our random documents. This dramatic reduction in computation significantly accelerates training and testing when combined with empirical risk minimization classifiers such as SVMs. A simple yet useful trick is to pre-compute the word distances to avoid redundant computations since a pair of words may appear multiple times in different pairs of documents. Note that the computation of the ground distance between each pair of word vectors in documents has a $O(L^2 \, d)$ complexity, which could be close to one WMD evaluation if document length L is short and word vector dimension d is large. This simple scheme leads to additional improvement in runtime performance of our WME method that we show in our experiments.

3.3 Convergence of WME

In this section, we study the convergence of our embedding (3) to the exact kernel (2) under the framework of Random Features (RF) approximation (Rahimi and Recht, 2007). Note that the standard RF convergence theory applies only to the shift-invariant kernel operated on two vectors, while our kernel (2) operates on two documents $x, y \in \mathcal{X}$ that are sets of word vectors. In (Wu et al., 2018a), a general RF convergence theory is provided for any *distance-based kernel* as long as a finite covering number is given w.r.t. the given distance. In the following lemma, we provide the covering number for all documents of bounded length under the *Word Mover's Distance*. Without loss of generality, we will assume that the word embeddings $\{\boldsymbol{v}\}$ are normalized s.t. $\|\boldsymbol{v}\| \leq 1$.

Lemma 1. *There exists an ϵ-covering $\mathcal{E}$ of $\mathcal{X}$ under the WMD metric with Euclidean ground distance, so that:*

$$\forall x \in \mathcal{X}, \exists x_i \in \mathcal{E}, \; \mathit{WMD}(x, x_i) \leq \epsilon,$$

that has size bounded as $|\mathcal{E}| \leq (\frac{2}{\epsilon})^{d\,L}$, where L is a bound on the length of document $x \in \mathcal{X}$.

Equipped with Lemma 1, we can derive the following convergence result as a simple corollary of the theoretical results in (Wu et al., 2018a). We defer the proof to the appendix A.

Theorem 1. *Let $\Delta_R(x, y)$ be the difference between the exact kernel (2) and the random approximation (3) with R samples, we have uniform convergence*

$$P\left\{\max_{x,y \in \mathcal{X}} |\Delta_R(x,y)| > 2t\right\} \leq 2\left(\frac{12\gamma}{t}\right)^{2dL} e^{-Rt^2/2}.$$

where d is the dimension of word embedding and L is a bound on the document length. In other words, to guarantee $|\Delta_R(x, y)| \leq \epsilon$ with probability at least $1 - \delta$, it suffices to have

$$R = \Omega\left(\frac{dL}{\epsilon^2}\log(\frac{\gamma}{\epsilon}) + \frac{1}{\epsilon^2}\log(\frac{1}{\delta})\right).$$

4 Experiments

We conduct an extensive set of experiments to demonstrate the effectiveness and efficiency of the proposed method. We first compare its performance against 7 unsupervised document embedding approaches over a wide range of text classification tasks, including sentiment analysis, news categorization, amazon review, and recipe identification. We use 9 different document corpora, with 8 of these drawn from (Kusner et al., 2015; Huang et al., 2016); Table 1 provides statistics of the different datasets. We further compare our method against 10 unsupervised, semi-supervised, and supervised document embedding approaches on the 22 datasets from SemEval semantic textual similarity tasks. Our code is implemented in Matlab, and we use C Mex for the computationally intensive components of WMD (Rubner et al., 2000).

4.1 Effects of R and D on WME

Setup. We first perform experiments to investigate the behavior of the WME method by varying the number of Random Features R and the length D of random documents. The hyper-parameter γ is set via cross validation on training set over the range $[0.01, \; 10]$. We simply fix the $D_{min} = 1$, and vary D_{max} over the range $[3, \; 21]$. Due to limited space, we only show selected subsets of our results, with the rest listed in the Appendix B.2.

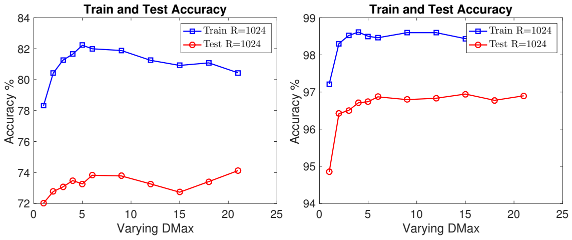
Figure 2: Train (Blue) and Test (Red) accuracy when varying R with fixed D.



(a) TWITTER (b) CLASSIC

Figure 3: Train (Blue) and Test (Red) accuracy when varying D with fixed R.

Effects of R. We investigate how the performance changes when varying the number of Random Features R from 4 to 4096 with fixed D. Fig. 2 shows that both training and testing accuracies generally converge very fast when increasing R from a small number ($R = 4$) to a relatively large number ($R = 1024$), and then gradually reach to the optimal performance. This confirms our analysis in Theory 1 that the proposed WME can guarantee the fast convergence to the exact kernel.

Effects of D. We further evaluate the training and testing accuracies when varying the length of random document D with fixed R. As shown in Fig. 3, we can see that near-peak performance can usually be achieved when D is small (typically $D \leq 6$). This behavior illustrates two important aspects: (1) using very few random words (e.g. $D = 1$) is not enough to generate useful Random Features when R becomes large; (2) using too many random words (e.g. $D \geq 10$) tends to generate similar and redundant Random Features when increasing R. Conceptually, the number of random words in a random document can be thought of as the number of the global topics in documents, which is generally small. This is an important desired feature that confers both a performance boost as well as computational efficiency to the WME method.

4.2 Comparison with KNN-WMD

Baselines. We now compare two WMD-based methods in terms of testing accuracy and total training and testing runtime. We consider two variants of WME with different sizes of R. WME(LR) stands for WME with large rank that achieves the best accuracy (using R up to 4096) with more computational time, while WME(SR) stands for WME with small rank that obtains comparable accuracy in less time. We also consider two variants of both methods where +P denotes that we precompute the ground distance between each pair of words to avoid redundant computations.

Setup. Following (Kusner et al., 2015; Huang et al., 2016), for datasets that do not have a predefined train/test split, we report average and standard deviation of the testing accuracy and average run-time of the methods over five 70/30 train/test splits. For WMD, we provide the results (with respect to accuracy) from (Kusner et al., 2015); we also reran the experiments of KNN-WMD and found them to be consistent with the reported results. For all methods, we perform 10-fold cross validation to search for the best parameters on the training documents. We employ a linear SVM implemented using LIBLINEAR (Fan et al., 2008) on WME since it can isolate the effectiveness of the feature representation from the power of the nonlinear learning solvers. For additional results on all KNN-based methods, please refer to Appendix B.3.

Results. Table 2 corroborates the significant advan-

Table 2: Test accuracy, and total training and testing time (in seconds) of WME against KNN-WMD. Speedups are computed between the best numbers of KNN-WMD+P and these of WME(SR)+P when achieving similar testing accuracy. Bold face highlights the best number for each dataset.

tages of WME compared to KNN-WMD in terms of both accuracy and runtime. First, WME(SR) can consistently achieve better or similar accuracy compared to KNN-WMD while requiring order-of-magnitude less computational time on all datasets. Second, both methods can benefit from precomputation of the ground distance between a pair of words but WME gains much more from prefetch (typically 3-5x speedup). This is because the typical length D of random documents is very short where computing ground distance between word vectors may be even more expensive than the corresponding WMD distance. Finally, WME(LR) can achieve much higher accuracy compared to KNN-WMD while still often requiring less computational time, especially on large datasets like 20NEWS and relatively long documents like OHSUMED.

4.3 Comparisons with Word2Vec & Doc2Vec

Baselines. We compare against 6 document representations methods: 1) *Smooth Inverse Frequency* (SIF) (Arora et al., 2017): a recently proposed simple but tough to beat baseline for sentence embeddings, combining a new weighted scheme of word embeddings with dominant component removal; 2) *Word2Vec+nbow*: a weighted average of word vectors using NBOW weights; 3) *Word2Vec+tf-idf*: a weighted average of word vectors using TF-IDF weights; 4) *PV-DBOW* (Le and Mikolov, 2014): distributed bag of words model of Paragraph Vectors; 5) *PV-DM* (Le and Mikolov, 2014): distributed memory model of Paragraph Vectors; 6) *Doc2VecC* (Chen, 2017): a recently proposed document-embedding via corruptions, achieving state-of-the-art performance in text classification.

Setup. *Word2Vec+nbow*, *Word2Vec+tf-idf* and WME use pre-trained Word2Vec embeddings while SIF uses its default pre-trained GloVe embeddings. Following (Chen, 2017), to enhance the performance of *PV-DBOW*, *PV-DM*, and *Doc2VecC* these methods are trained transductively on both train and test, which is indeed beneficial for generating a better document representation (see Appendix B.4). In contrast, the hyperparameters of WME are obtained through a 10-fold cross validation only on training set. For a fair comparison, we run a linear SVM using LIBLINEAR on all methods.

Results. Table 3 shows that WME consistently outperforms or matches existing state-of-the-art document representation methods in terms of testing accuracy on all datasets except one (OHSUMED). The first highlight is that simple average of word embeddings often achieves better performance than *SIF(Glove)*, indicating that removing the first principle component could hurt the expressive power of the resulting representation for some of classification tasks. Surprisingly, these two methods often achieve similar or better performance than *PV-DBOW* and *PV-DM*, which may be because of the high-quality pre-trained word embeddings. On

Table 4: Pearson's scores of WME against other unsupervised, semi-supervised, and supervised methods on 22 textual similarity tasks. Results are collected from (Arora et al., 2017) except our approach.

Approaches	Supervised						Unsupervised					Semi-supervised	
WordEmbeddings	PSL						GloVe					PSL	
Tasks	PP	Dan	RNN	iRNN	LSTM(no)	LSTM(o.g.)	ST	nbow	tf-idf	SIF	WME	SIF	WME
STS'12	58.7	56.0	48.1	58.4	51.0	46.4	30.8	52.5	58.7	56.2	60.6	59.5	**62.8**
STS'13	55.8	54.2	44.7	56.7	45.2	41.5	24.8	42.3	52.1	56.6	54.5	**61.8**	56.3
STS'14	70.9	69.5	57.7	70.9	59.8	51.5	31.4	54.2	63.8	68.5	65.5	**73.5**	68.0
STS'15	75.8	72.7	57.2	75.6	63.9	56.0	31.0	52.7	60.6	71.7	61.8	**76.3**	64.2
SICK'14	71.6	70.7	61.2	71.2	63.9	59.0	49.8	65.9	69.4	72.2	68.0	**72.9**	68.1
Twitter'15	52.9	**53.7**	45.1	52.9	47.6	36.1	24.7	30.3	33.8	48.0	41.6	49.0	47.4

the other hand, *Doc2VecC* achieves much better testing accuracy than these previous methods on two datasets (20NEWS, and RECIPE_L). This is mainly because that it benefits significantly from transductive training (See Appendix B.4). Finally, the better performance of WME over these strong baselines stems from fact that WME is empowered by two important building blocks, WMD and Word2Vec, to yield a more informative representation of the documents by considering both the word alignments and the semantics of words.

We refer the readers to additional results on the Imdb dataset in Appendix B.4, which also demonstrate the clear advantage of WME even compared to the supervised RNN method as well as the aforementioned baselines.

4.4 Comparisons on textual similarity tasks

Baselines. We compare WME against 10 supervised, simi-sepervised, and unsupervised methods for performing textual similarity tasks. Six supervised methods are initialized with Paragram-SL999(PSL) word vectors (Wieting et al., 2015b) and then trained on the PPDB dataset, including: 1) *PARAGRAM-PHRASE* (PP) (Wieting et al., 2015a): simple average of refined PSL word vectors; 2) *Deep Averaging Network* (DAN) (Iyyer et al., 2015); 3) *RNN*: classical recurrent neural network; 4) *iRNN*: a variant of RNN with the activation being the identify; 5) *LSTM(no)* (Gers et al., 2002): LSTM with no output gates; 6) *LSTM(o.g.)* (Gers et al., 2002): LSTM with output gates. Four unsupervised methods are: 1) *Skip-Thought Vectors* (ST) (Kiros et al., 2015): an encoder-decoder RNN model for generalizing Skip-gram to the sentence level; 2) *nbow*: simple averaging of pre-trained GloVe word vectors; 3) *tf-idf*: a weighted average of GloVe word vecors using TF-IDF weights; 4) *SIF* (Arora et al., 2017): a simple yet strong method on textual similarity tasks using GloVe word vecors. Two semi-supervised methods use PSL word vectors, which are trained using labeled data (Wieting et al., 2015b).

Setup. There are total 22 textual similarity datasets from STS tasks (2012-2015) (Agirre et al., 2012, 2013, 2014, 2015), SemEval 2014 Semantic Relatedness task (Xu et al., 2015), and SemEval 2015 Twitter task (Marelli et al., 2014). The goal of these tasks is to predict the similarity between two input sentences. Each year STS usually has 4 to 6 different tasks and we only report the averaged Pearson's scores for clarity. Detailed results on each dataset are listed in Appendix B.5.

Results. Table 4 shows that WME consistently matches or outperforms other unsupervised and supervised methods except the *SIF* method. Indeed, compared with *ST* and *nbow*, WME improves Pearson's scores substantially by 10% to 33% as a result of the consideration of word alignments and the use of TF-IDF weighting scheme. *tf-idf* also improves over these two methods but is slightly worse than our method, indicating the importance of taking into account the alignments between the words. *SIF* method is a strong baseline for textual similarity tasks but WME still can beat it on STS'12 and achieve close performance in other cases. Interestingly, WME is on a par with three supervised methods *RNN*, *LSTM(no)*, and *LSTM(o.g.)* in most cases. The final remarks stem from the fact that, WME can gain significantly benefit from the supervised word embeddings similar to *SIF*, both showing strong performance on PSL.

5 Related Work

Two broad classes of *unsupervised* and *supervised* methods have been proposed to generate sentence and document representations. The former primarily generate general purpose and domain independent embeddings of word sequences (Socher et al., 2011; Kiros et al., 2015; Arora et al., 2017); many unsupervised training research efforts have focused on either training an auto-encoder to learn the latent structure of a sentence (Socher et al., 2013), a paragraph, or document (Li et al., 2015); or generalizing Word2Vec models to predict words in a paragraph (Le and Mikolov, 2014; Chen, 2017) or in neighboring sentences (Kiros et al., 2015). However, some important information could be lost in the resulting document representation without considering the word order. Our proposed WME overcomes this difficulty by considering the alignments between each pair of words.

The other line of work has focused on developing compositional supervised models to create a vector representation of sentences (Kim et al., 2016; Gong et al., 2018b). Most of this work proposed composition using recursive neural networks based on parse structure (Socher et al., 2012, 2013), deep averaging networks over bag-of-words models (Iyyer et al., 2015; Wieting et al., 2015a), convolutional neural networks (Kim, 2014; Kalchbrenner et al., 2014; Xu et al., 2018), and recurrent neural networks using long short-term memory (Tai et al., 2015; Liu et al., 2015). However, these methods are less well suited for domain adaptation settings.

6 Conclusion

In this paper, we have proposed an alignment-aware text kernel using WMD for texts of variable lengths, which takes into account both word alignments and pre-trained high quality word embeddings in learning an effective semantics-preserving feature representation. The proposed WME is simple, efficient, flexible, and unsupervised. Extensive experiments show that WME consistently matches or outperforms state-of-the-art models on various text classification and textual similarity tasks. WME embeddings can be easily used for a wide range of downstream supervised and unsupervised tasks.

Abstract

Clustering news across languages enables efficient media monitoring by aggregating articles from multilingual sources into coherent stories. Doing so in an online setting allows scalable processing of massive news streams. To this end, we describe a novel method for clustering an incoming stream of multilingual documents into monolingual and crosslingual story clusters. Unlike typical clustering approaches that consider a small and known number of labels, we tackle the problem of discovering an ever growing number of cluster labels in an online fashion, using real news datasets in multiple languages. Our method is simple to implement, computationally efficient and produces state-of-the-art results on datasets in German, English and Spanish.

1 Introduction

Following developing news stories is imperative to making real-time decisions on important political and public safety matters. Given the abundance of media providers and languages, this endeavor is an extremely difficult task. As such, there is a strong demand for automatic clustering of news streams, so that they can be organized into stories or themes for further processing. Performing this task in an online and efficient manner is a challenging problem, not only for newswire, but also for scientific articles, online reviews, forum posts, blogs, and microblogs.

A key challenge in handling document streams is that the story clusters must be generated on the fly in an online fashion: this requires handling documents one-by-one as they appear in the document stream. In this paper, we provide a treatment to the problem of *online document clustering*, i.e. the task of clustering a stream of documents into themes. For example, for news articles, we would want to cluster them into related news stories.

To this end, we introduce a system which aggregates news articles into fine-grained story clusters across different languages in a completely online and scalable fashion from a continuous stream. Our clustering approach is part of a larger *media monitoring* project to solve the problem of monitoring massive text and TV/Radio streams (speech-to-text). In particular, media monitors write intelligence reports about the most relevant events, and being able to search, visualize and explore news clusters assists in gathering more insight about a particular story. Since relevant events may be spawned from any part of the world (and from many multilingual sources), it becomes imperative to cluster news across different languages.

In terms of granularity, the type of story clusters we are interested in are the group of articles which, for example : (i) Narrate recent air-strikes in Eastern Ghouta (Syria); (ii) Describe the recent launch of Space X's Falcon Heavy rocket.

Main Contributions While most existing news clustering approaches assume a monolingual document stream – a non-realistic scenario given the diversity of languages on the Web – we assume a general, multilingual, document stream. This means that in our problem-formulation story documents appear in multiple languages and we need to cluster them to crosslingual clusters. Our main contributions are as follows:

- We develop a system that aggregates news articles into fine-grained story clusters across different languages in a completely online and scalable fashion from a continuous stream. As discussed in the introduction, this is a highly relevant task for the use-case of media monitoring.
- We formulate the problem of online multilingual document clustering and the representation that such clustering takes by interlacing the problem

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4535–4544
Brussels, Belgium, October 31 - November 4, 2018.

of monolingual clustering with crosslingual clustering. The representation of our clusters is interpretable, and similarly to topic models, consists of a set of keywords and weights associated with the relevant cluster. In our formulation, a monolingual cluster is a group of documents, and a crosslingual cluster is a group of monolingual clusters in different languages.

- We compare our approach to our own implementation of a state-of-the-art streaming method, and show much superior results for a dataset in English, Spanish and German.

2 Problem Formulation

We focus on clustering of a stream of documents, where the number of clusters is not fixed and learned automatically. We denote by D a (potentially infinite) space of multilingual documents. Each document d is associated with a language in which it is written through a function $L\colon D \to \mathcal{L}$ where $\mathcal{L}$ is a set of languages. For example, $L(d)$ could return English, Spanish or German. (In the rest of the paper, for an integer n, we denote by $[n]$ the set $\{1, \ldots, n\}$.)

We are interested in associating each document with a monolingual cluster via the function $C(d) \in \mathbb{N}$, which returns the cluster label given a document. This is done independently for each language, such that the space of indices we use for each language is separate. Furthermore, we interlace the problem of monolingual clustering with crosslingual clustering. This means that as part of our problem formulation we are also interested in a function $E\colon \mathbb{N} \times \mathcal{L} \to \mathbb{N}$ that associates each monolingual cluster with a crosslingual cluster, such that each crosslingual cluster only groups one monolingual cluster per different language, at a given time. The crosslingual cluster for a document d is $E(C(d), L(d))$. As such, a crosslingual cluster groups together monolingual clusters, at most one for each different language.

Intuitively, building both monolingual and crosslingual clusters allows the system to leverage high-precision monolingual features (e.g., words, named entities) to cluster documents of the same language, while simplifying the task of crosslingual clustering to the computation of similarity scores across monolingual clusters - which is a smaller problem space, since there are (by definition) less clusters than articles. We validate this choice in §5.

3 The Clustering Algorithm

Each document d is represented by two vectors in $\mathbb{R}^{k_1}$ and $\mathbb{R}^{k_2}$. The first vector exists in a "monolingual space" (of dimensionality k_1) and is based on a bag-of-words representation of the document. The second vector exists in a "crosslingual space" (of dimensionality k_2) which is common to all languages. More details about these representations are discussed in §4.

Online Clustering With our clustering algorithm, we maintain two types of centroid functions for each monolingual cluster. The first is a centroid function $H\colon \mathbb{N} \times \mathcal{L} \to \mathbb{R}^{k_1} \cup \{\perp\}$ that assists in associating each document with a monolingual cluster. The second is a centroid function $G\colon \mathbb{N} \to \mathbb{R}^{k_2} \cup \{\perp\}$ that assists in associating each monolingual cluster with a crosslingual cluster. The $\perp$ symbol is reserved to denote documents which are not associated with any cluster yet.

In our algorithm, we need to incrementally construct the functions H, G (the two centroid functions), C (the monolingual clustering function) and E (the crosslingual clustering function). Informally, we do so by first identifying a monolingual cluster for an incoming document by finding the closest centroid with the function H, and then associate that monolingual cluster with the crosslingual cluster that is closest based on the function G. The first update changes C and the second update changes E. Once we do that, we also update H and G to reflect the new information that exists in the new incoming document.

Example Figure 1 depicts the algorithm and the state it maintains. A document in some language (d_9) appears in the stream, and is clustered into one of the monolingual clusters (circles) that group together documents about the same story (for example, $\langle c_2, \mathrm{DE}\rangle$ could be a German cluster about a recent political event). Then, following this monolingual update, the online clustering algorithm updates the crosslingual clusters (round rectangles), each grouping together a set of monolingual clusters, one per language at the most. The centroids for the monolingual clusters are maintained by the function H. For example, $H(2, \mathrm{English})$ gives the centroid of the upper left English monolingual cluster. The function G maintains the crosslingual clusters. Considering the upper-left most crosslingual cluster, a_1, then $G(1)$ returns its centroid.

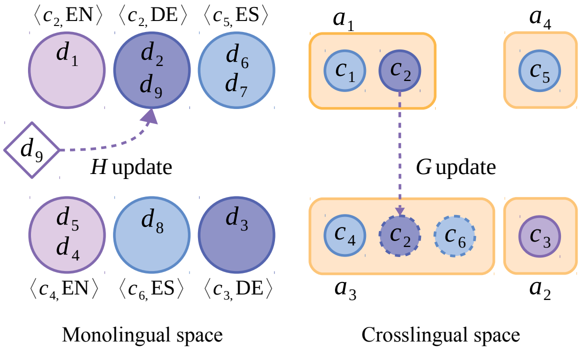

Figure 1: A pictorial description of the algorithm and the state it maintains. The algorithm maintains a monolingual cluster space, in which each cluster is a set of documents in a specific language. The algorithm also maintains a crosslingual cluster space, in which a cluster is a set of monolingual clusters in different languages. Documents are denoted by d_i, monolingual clusters by c_i (circles) and crosslingual clusters by a_i.

Algorithm To be more precise, the online clustering process works as follows. H and G start with just returning $\perp$ for any cluster number, both monolingual and crosslingual. With a new incoming document d, represented as a vector, we compute a similarity metric $\Gamma_0 \colon \mathbb{R}^{k_1} \times \mathbb{R}^{k_1} \rightarrow \mathbb{R}$ between the document vector and each of the existing centroids $\{i \mid H(i, L(d)) \neq \perp\}$. If the largest similarity exceeds a threshold τ for cluster index j, then we set $C(d) = j$. In that case, we also update the value of $H(i, L(d))$ to include new information from document d, as detailed below under "H update." If none of the similarity values exceed a threshold τ, we find the first i such that $H(i, L(d)) = \perp$ (the first cluster id which is still unassigned), and set $C(d) = i$, therefore creating a new cluster. We again follow an "H update" – this time for starting a new cluster.

In both cases, we also update the function G, by selecting the best crosslingual cluster for the recently updated (or created) monolingual cluster. To this end, we use another similarity metric $\Gamma_1 \colon \mathbb{R}^{k_2} \times \mathbb{R}^{k_2} \rightarrow \mathbb{R}$. Accordingly, we compute the similarity (using Γ_1) between the updated (or created) monolingual cluster and all monolingual clusters in each candidate crosslingual cluster, in the crosslingual feature space. The crosslingual cluster with highest sum of similarity scores is then selected. We also experimented computing this similarity by considering just the monolingual cluster of a particular "pivot language". The pivot language is a language that serves as the main indicator for a given crosslingual cluster. In our experiments, we mostly use English as the pivot language.

H Update To update H, we maintain a centroid for each cluster that is created as the average of all monolingual representations of documents that belong to that cluster. This is done for each language separately. This update can be done in $O(k_1)$ time in each step. Similarly, the update of G can be done in $O(k_2)$ time. In principle, we consider an "infinite" stream of documents, which means the number of documents in each cluster can be large. As such, for efficiency purposes, updates to H are immutable, which means that when a document is assigned to a monolingual cluster, that assignment is never changed.

G Update As described, updates to function G result in associating a monolingual cluster with a crosslingual cluster (and consequently, other monolingual clusters). Therefore, errors committed in updating G are of a higher magnitude than those committed in H, since they involve groups of documents. We also note that the best crosslingual cluster for a particular monolingual cluster might not be found right at the beginning of the process. We experiment with two types of updates to G. One which is immutable, in which changes to G are not reversed (and are described above), and one in which we introduce a novel technique to make a sequence of changes to G if necessary, as a mechanism to self-correct past clustering decisions. When a past decision is modified, it may result in a chaining of consequent modifications ("toppling of dominoes") which need to be evaluated. We coin this method "domino-toppling".

The motivation behind this technique is the change in news stories over time. The technique allows the method to modify past crosslingual clustering decisions and enables higher quality clustering results. When a past decision is modified, it may result in a chain of consequent modifications which need to be evaluated.

Our method of "domino-toppling" works by making (potentially sequences) of changes to previous clustering decisions for the crosslingual clusters, at each step placing a residual monolingual cluster in a crosslingual cluster that is most similar to it. Figure 2 gives the pseudocode for domino toppling.

This "domino-toppling" technique could have in principle a quadratic complexity in the number

```
Inputs: A monolingual cluster $c$ and a list of pairs $\langle a_j, \Gamma_1(c, a_j)\rangle$, $j \in [N]$.

Algorithm:
  • For all pairs $\langle a_j, \Gamma_1(c, a_j)\rangle$, $j \in [N]$, ordered by the second coordinate:
      • If $L(c)$ is not in $a_j$, add $c$ to $a_j$ and break.
      • Otherwise, let $y \leftarrow M(a_j, L(c))$. If $\Gamma_1(c, a_j) > \Gamma_1(y, a_j)$ then:
          • Add $c$ to $a_j$, remove $y$ from $a_j$ and call domino toppling with $y$ playing the role of $c$ and break.
  • If $c$ is left unassigned, create $a_{N+1}$ and add $c$ to it.
```

Figure 2: Crosslingual "domino-toppling". a_j is the jth crosslingual cluster (out of total N clusters) and Γ_1 is the similarity between them as in §4. $L(c)$ is the language for cluster c. $M(a, \ell)$ returns the monolingual cluster for language $\ell \in \mathcal{L}$ in crosslingual cluster a. See text for details.

of crosslingual clusters. However, we have verified that in practice it converges very fast, and in our evaluation dataset only 1% of the crosslingual updates result in topples. We apply this technique only to update G (and not H) because reversing cluster assignments in G can be done much more efficiently than in H – the total number of monolingual clusters (the clustered elements in G) is significantly smaller than the number of documents (the clustered elements in H). Crosslingual clustering is also a harder problem, which motivated the additional effort of developing this algorithm.

4 Document Representation

In this section, we give more details about the way we construct the document representations in the monolingual and crosslingual spaces. In particular, we introduce the definition of the similarity functions Γ_0 and Γ_1 that were referred in §3.

Monolingual Representation The monolingual representation for each document d in language $L(d)$ is a vector in $\mathbb{R}^{k_1}$ constructed from several TF-IDF subvectors with words, word lemmas and named entities. Each subvector is repeated for different sections of the document, the title, the body and both of them together. Besides these text fields and document timestamps, no other metadata was used. To detect named entities, we used Priberam's Text Analysis (Amaral et al., 2008) for English and Spanish, and Turbo Parser (Martins et al., 2013) for German. The extracted entities consist of people, organizations, places and other types.

Crosslingual Representation In the crosslingual space, a document representation is a vector in $\mathbb{R}^{k_2}$. Let $e(d, i)$ be a crosslingual embedding of word i in the document d, which is a vector of length m . Then the document representation $v(d)$ of d consists of subvectors of the form $v(d) = \sum_{i=1}^{n} t_i e(d, i)$, where t_i is the TF-IDF score of the ith word in the relevant section of the document (title, body or both). As detailed further in §5 we compute IDF values from a large pretraining dataset. Furthermore, for both the monolingual and crosslingual cases, we also experiment with using document timestamp features, as explained in §4.1. We use a new set of diverse timestamp features in addition to the simple absolute difference (in hours) between timestamps used by Rupnik et al. (2016).

4.1 Similarity Metrics

Our similarity metric computes weighted cosine similarity on the different subvectors, both in the case of monolingual clustering and crosslingual clustering. Formally, for the monolingual case, the similarity is given by a function defined as:

$$\Gamma_0(d_j, c_l) = \sum_{i=1}^{K} \phi_i(d_j, c_l) \cdot q_i^0 + \sum_{i=1}^{3} \gamma_i(d_j, c_l) \cdot q_i^1. \tag{1}$$

and is computed on the TF-IDF subvectors where K is the number of subvectors for the relevant document representation. For the crosslingual case, we discuss below the function Γ_1, which has a similar structure.

Here, d_j is the jth document in the stream and c_l is a monolingual cluster. The function $\phi_i(d_j, c_l)$ returns the cosine similarity between the document representation of the jth document and the centroid for cluster c_l. The vector q^0 denotes the weights through which each of the cosine similarity values for each subvectors are weighted, whereas q^1 denotes the weights for the timestamp features, as detailed further. Details on learning the weights q^0 and q^1 are discussed in §4.2.

The function $\gamma(d, c)$ that maps a pair of document and cluster to $\mathbb{R}^3$ is defined as follows. Let

$$f(t) = \exp\left(-\frac{(t-\mu)^2}{2\sigma^2}\right) \tag{2}$$

for a given μ and $\sigma > 0$. For each document d and cluster c, we generate the following three-dimensional vector $\gamma(d, c) = (s_1, s_2, s_3)$:

- $s_1 = f(t(d) - n_1(c))$ where $t(d_j)$ is the timestamp for document d and $n_1(c)$ is the timestamp for the newest document in cluster c.
- $s_2 = f(t(d) - n_2(c))$ where $n_2(c)$ is the average timestamp for all documents in cluster c.
- $s_3 = f(t(d) - n_3(c))$ where $n_3(c)$ is the timestamp for the oldest document in cluster c.

These three timestamp[1] features model the time aspect of the online stream of news data and help disambiguate clustering decisions, since time is a valuable indicator that a news story has changed, even if a cluster representation has a reasonable match in the textual features with the incoming document. The same way a news story becomes popular and fades over time (Lerman and Hogg, 2010), we model the probability of a document belonging to a cluster (in terms of timestamp difference) with a probability distribution.

For the case of crosslingual clustering, we introduce Γ_1, which has a similar definition to Γ_0, only instead of passing document/cluster similarity feature vectors, we pass cluster/cluster similarities, across all language pairs. Furthermore, the features are the crosslingual embedding vectors of the sections title, body and both combined (similarly to the monolingual case) and the timestamp features. For denoting the cluster timestamp, we use the average timestamps of all articles in it.

4.2 Learning to Rank Candidates

In §4.1 we introduced q^0 and q^1 as the weight vectors for the several document representation features. We experiment with both setting these weights to just 1 ($q^0_i = 1\,\forall i$ and $q^1_j = 1\,\forall j \in [3]$) and also learning these weights using support vector machines (SVMs). To generate the SVM training data, we simulate the execution of the algorithm on a training data partition (which we do not get evaluated on) and in which the gold standard labels are given. We run the algorithm using only the first subvector $\phi_1(d_j, c_l)$, which is the TF-IDF vector with the words of the document in the body and title. For each incoming document, we create a collection of positive examples, for the document and the clusters which share at least one document in the gold labeling. We then generate 20 negative examples for the document from the 20 best-matching clusters which are not correct. To find out the best-matching clusters, we rank them according to their similarity to the input document using only the first subvector $\phi_1(d_j, c_l)$.

Using this scheme we generate a collection of ranking examples (one for each document in the dataset, with the ranking of the best cluster matches), which are then trained using the SVM-Rank algorithm (Joachims, 2002). We run 5-fold cross-validation on this data to select the best model, and train both a separate model for each language according to Γ_0 and a crosslingual model according to Γ_1.

5 Experiments

Our system was designed to cluster documents from a (potentially infinite) real-word data stream. The datasets typically used in the literature (TDT, Reuters) have a small number of clusters (≈ 20) with coarse topics (economy, society, etc.), and therefore are not relevant to the use case of media monitoring we treat - as it requires much more fine-grained story clusters about particular events. To evaluate our approach, we adapted a dataset constructed for the different purpose of binary classification of joining cluster pairs.[2] We processed it to become a collection of articles annotated with monolingual and crosslingual cluster labels.[3]

Statistics about this dataset are given in Table 1. As described further, we tune the hyper-parameter τ on the development set. As for the hyper-parameters related to the timestamp features, we fixed $\mu = 0$ and tuned σ on the development set, yielding $\sigma = 72$ hours (3 days).[4] To compute IDF scores (which are global numbers computed across a corpus), we used a different and much larger dataset that we collected from Deutsche Welle's news website (`http://www.dw.com/`). The dataset consists of 77,268, 118,045 and 134,243 documents for Spanish, English and German, respectively.

The conclusions from our experiments are: (a) the weighting of the similarity metric features using SVM significantly outperforms unsupervised baselines such as CluStream (Table 2); (b) the SVM approach significantly helps to learn when to create a new cluster, compared to simple grid search

---

[1] Timestamps are given in hours since 1970.

[2] `https://github.com/rupnikj/jair_paper`

[3] The code and data we used is available at `https://github.com/priberam/news-clustering`.

[4] This shows a relative robustness to reordering of the articles – articles within 3 days of each other could appear anywhere in that window, and the algorithm would still perform well.

	Dataset	Size	Avg. L.	C	Avg. S.
train	English	12,233	434	593	21
	German	4,043	282	377	11
	Spanish	4,527	355	416	11
test	English	8,726	521	222	39
	German	2,101	440	118	18
	Spanish	2,177	392	149	15

Table 1: Statistics for the development and evaluation datasets, constructed from the dataset in Rupnik et al. (2016), as explained in §5. "Size" denotes the number of documents in the collection, "Avg. L." is the average number of words in a document, "C" denotes the number of clusters in the collection and "Avg. S." is the average number of documents in each cluster.

	algorithm	F_1	P	R
English	CluStream	79.0	**98.6**	65.9
	Tokens+Lemmas+Ents	92.7	92.9	**92.5**
	+TS	**94.1**	98.2	90.3

	+TS	**94.2**	**97.0**	**91.6**

Table 2: Clustering results on the labeled dataset. We compare our algorithm (with and without timestamps) with the online micro-clustering routine of Aggarwal and Yu (2006) (denoted by CluStream). The F_1 values are for the precision (P) and recall (R) in the following columns. See Table 3 for a legend of the different models. Best result for each language is in bold.

for the optimal τ (Table 4); (c) separating the feature space into one for monolingual clusters in the form of keywords and the other for crosslingual clusters based on crosslingual embeddings significantly helps performance.

Evaluation Method We evaluate clustering in the following manner: let tp be the number of correctly clustered-together document pairs, let fp be the number of incorrectly clustered-together document pairs and let fn be the number of incorrectly not-clustered-together document pairs. Then we report precision as $\frac{\mathrm{tp}}{\mathrm{tp}+\mathrm{fp}}$, recall as $\frac{\mathrm{tp}}{\mathrm{tp}+\mathrm{fn}}$ and F_1 as the harmonic mean of the precision and recall measures. We do the same to evaluate crosslingual clustering, but on a higher level: we count tp, fn and fp for the decisions of clustering clusters, as crosslingual clusters are groups of monolingual gold clusters.

5.1 Monolingual Results

In our first set of experiments, we report results on monolingual clustering for each language separately. Monolingual clustering of a stream of documents is an important problem that has been inspected by others, such as by Ahmed et al. (2011) and by Aggarwal and Yu (2006). We compare our results to our own implementation of the online micro-clustering routine presented by Aggarwal and Yu (2006), which shall be referred to as CluStream. We note that CluStream of Aggarwal and Yu (2006) has been a widely used state-of-the-art system in media monitoring companies as well as academia, and serves as a strong baseline to this day.

In our preliminary experiments, we also evaluated an online latent semantic analysis method, in which the centroids we keep for the function H (see §3) are the average of reduced dimensional vectors of the incoming documents as generated by an incremental singular value decomposition (SVD) of a document-term matrix that is updated after each incoming document. However, we discovered that online LSA performs significantly worse than representing the documents the way is described in §4. Furthermore, it was also significantly slower than our algorithm due to the time it took to perform singular value decomposition.[5]

Clustering experiments Table 2 gives the final monolingual results on the three datasets. For English, we see that the significant improvement we get using our algorithm over the algorithm of Aggarwal and Yu (2006) is due to an increased recall score. We also note that the trained models surpass the baseline for all languages, and that the timestamp feature (denoted by TS), while not required to beat the baseline, has a very relevant contribution in all cases. Although the results for both the baseline and our models seem to differ across languages, one can verify a consistent improvement from the latter to the former, suggesting that the score differences should be mostly tied to the different difficulty found across the datasets for each language. The presented scores show that our learning framework generalizes well to different languages and enables high quality clustering results.

To investigate the impact of the timestamp fea-

---

[5] More specifically, we used an object of type `lsimodel` from the GenSim package that implements algorithms from Řehůřek (2010). The GenSim package can be found at `https://pypi.python.org/pypi/gensim`.

feature	accuracy
TOKENS	85.5
TOKENS+LEMMAS	85.9
TOKENS+LEMMAS+ENTS	86.5
TOKENS+LEMMAS+ENTS+TS	96.9

Table 3: Accuracy of the SVM ranker on the English training set. TOKENS are the word token features, LEMMAS are the lemma features for title and body, ENTS are named entity features and TS are timestamp features. All features are described in detail in §4, and are listed for both the title and the body.

tures, we ran an additional experiment using only the same three timestamp features as used in the best model on the English dataset. This experiment yielded scores of $F_1 = 61.1$, $P = 44.5$ and $R = 97.6$, which lead us to conclude that while these features are not competitive when used alone (hence temporal information by itself is not sufficient to predict the clusters), they contribute significantly to recall with the final feature ensemble.

We note that as described in §3, the optimization of the τ parameter is part of the development process. The parameter τ is a similarity threshold used to decide when an incoming document should merge to the best cluster or create a new one. We tune τ on the development set for each language, and the sensitivity to it is demonstrated in Figure 3 (this process is further referred to as τ_{search}). Although applying grid-search on this parameter is the most immediate approach to this problem, we experimented with a different method which yielded superior results: as described further, we discuss how to do this process with an additional classifier (denoted SVM-merge), which captures more information about the incoming documents and the existing clusters.

Additionally, we also experimented with computing the monolingual clusters with the same embeddings as used in the crosslingual clustering phase, which yielded poor results. In particular, this system achieved F_1 score of 74.8 for English, which is below the bag-of-words baseline presented in Table 2. This result supports the approach we then followed of having two separate feature spaces for the monolingual and crosslingual clustering systems, where the monolingual space is discrete and the crosslingual space is based on embeddings.

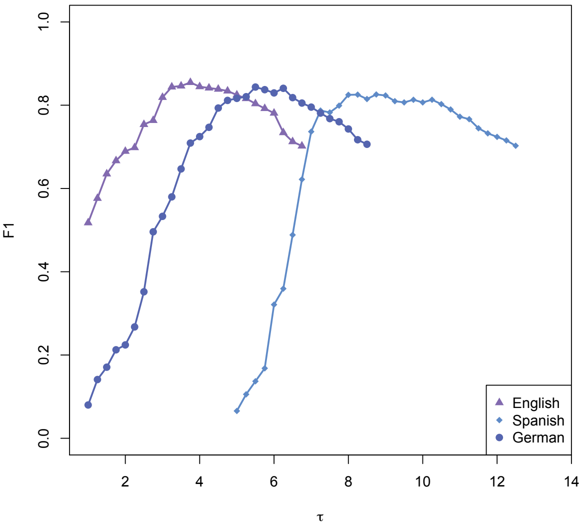

Figure 3: The F_1 score of the different language development sets as a function of the threshold τ. The first point for each language is identified using binary search.

model	F_1	P	R
τ_{search}	82.8	96.5	72.4
SVM-merge	94.1	98.2	90.3

Table 4: Comparison of two different cluster decision techniques for the English SVM model with all features (see Table 2). The first method, τ_{search}, corresponds to executing grid-search to find the optimal clustering τ parameter (see §3). SVM-merge is an alternative method in which we train an SVM binary classifier to decide if a new cluster should be created or not, where we use as features the maximal value of each coordinate for each document in a cluster.

SVM ranker experiments To investigate the importance of each feature, we now consider in Table 3 the accuracy of the SVM ranker for English as described in §4.1. We note that adding features increases the accuracy of the SVM ranker, especially the timestamp features. However, the timestamp feature actually interferes with our optimization of τ to identify when new clusters are needed, although they improve the SVM reranking accuracy. We speculate this is true because high accuracy in the reranking problem does not necessarily help with identifying when *new* clusters need to be opened. To investigate this issue, we experimented with a different technique to learn when to create a new cluster. To this end, we trained another SVM classifier just to learn this decision, this time a binary classifier using LIBLINEAR (Fan et al., 2008), by passing the max of the similarity of each feature between the incoming document and the current clustering pool as the input feature vector. This way, the classifier learns when the current clusters,

crosslingual model	F_1	P	R
τ_{search} (global)	72.7	89.8	61.0
τ_{search} (pivot)	84.0	83.0	85.0

Table 5: Crosslingual clustering results when considering two different approaches to compute distances across crosslingual clusters on the test set for Spanish, German and English. See text for details.

as a whole, are of a different news story than the incoming document. As presented in Table 4, this method, which we refer to as SVM-merge, solved the issue of searching for the optimal τ parameter for the SVM-rank model with timestamps, by greatly improving the F_1 score in respect to the original grid-search approach (τ_{search}).

5.2 Crosslingual Results

As mentioned in §3, crosslingual embeddings are used for crosslingual clustering. We experimented with the crosslingual embeddings of Gardner et al. (2015) and Ammar et al. (2016). In our preliminary experiments we found that the former worked better for our use-case than the latter.

We test two different scenarios for optimizing the similarity threshold τ for the crosslingual case. Table 5 shows the results for these experiments. First, we consider the simpler case of adjusting a global τ parameter for the crosslingual distances, as also described for the monolingual case. As shown, this method works poorly, since the τ grid-search could not find a reasonable τ which worked well for every possible language pair.

Subsequently, we also consider the case of using English as a pivot language (see §3), where distances for every other language are only compared to English, and crosslingual clustering decisions are made only based on this distance.[6] This yielded our best crosslingual score of F_1=84.0, confirming that crosslingual similarity is of higher quality between each language and English, for the embeddings we used. This score represents only a small degradation in respect to the monolingual results, since clustering across different languages is a harder problem.

6 Related Work

Early research efforts, such as the TDT program (Allan et al., 1998), have studied news clustering for some time. The problem of online monolingual clustering algorithms (for English) has also received a fair amount of attention in the literature. One of the earlier papers by Aggarwal and Yu (2006) introduced a two-step clustering system with both offline and online components, where the online model is based on a streaming implementation of k-means and a bag-of-words document representation. Other authors have experimented with distributed representations, such as Ahmed et al. (2011), who cluster news into *storylines* using Markov chain Monte Carlo methods, Řehůřek and Sojka (2010) who used incremental Singular Value Decomposition (SVD) to find relevant topics from streaming data, and Sato et al. (2017) who used the paragraph vector model (Le and Mikolov, 2014) in an offline clustering setting.

More recently, crosslingual linking of clusters has been discussed by Rupnik et al. (2016) in the context of linking existing clusters from the Event Registry (Leban et al., 2014) in a batch fashion, and by Steinberger (2016) who also present a batch clustering linking system. However, these are not "truly" online crosslingual clustering systems since they only decide on the linking of already-built monolingual clusters. In particular, Rupnik et al. (2016) compute distances of document pairs across clusters using nearest neighbors, which might not scale well in an online setting. As detailed before, we adapted the cluster-linking dataset from Rupnik et al. (2016) to evaluate our online crosslingual clustering approach. Preliminary work makes use of deep learning techniques (Xie et al., 2016; Guo et al., 2017) to cluster documents while learning their representations, but not in an online or multilingual fashion, and with a very small number of cluster labels (4, in the case of the text benchmark).

In our work, we studied the problem of monolingual and crosslingual clustering, having experimented several directions and methods and the impact they have on the final clustering quality. We described the first system which aggregates news articles into fine-grained story clusters across different languages in a completely online and scalable fashion from a continuous stream.

---

[6] In this case, all crosslingual clusters will have at least one pivot monolingual cluster, except for clusters which might stay unmerged as single-language degenerated crosslingual clusters.

7 Conclusion

We described a method for monolingual and crosslingual clustering of an incoming stream of documents. The method works by maintaining centroids for the monolingual and crosslingual clusters, where a monolingual cluster groups a set of documents and a crosslingual cluster groups a set of monolingual clusters. We presented an online crosslingual clustering method which auto-corrects past decisions in an efficient way. We showed that our method gives state-of-the-art results on a multilingual news article dataset for English, Spanish and German. Finally, we discussed how to leverage different SVM training procedures for ranking and classification to improve monolingual and crosslingual clustering decisions. Our system is integrated in a larger *media monitoring* project (Liepins et al., 2017; Germann et al., 2018) and solving the use-cases of monitors and journalists, having been validated with qualitative user testing.

Abstract

Multi-task learning in text classification leverages implicit correlations among related tasks to extract common features and yield performance gains. However, a large body of previous work treats labels of each task as independent and meaningless one-hot vectors, which cause a loss of potential label information. In this paper, we propose **Multi-Task Label Embedding** to convert labels in text classification into semantic vectors, thereby turning the original tasks into vector matching tasks. Our model utilizes semantic correlations among tasks and makes it convenient to scale or transfer when new tasks are involved. Extensive experiments on five benchmark datasets for text classification show that our model can effectively improve the performances of related tasks with semantic representations of labels and additional information from each other.

1 Introduction

Text classification is a common *Natural Language Processing* (NLP) issue that tries to infer the most appropriate label for a given sentence or document, for example, sentiment analysis, topic classification and so on. With the developments and prosperities of *Deep Learning* (Bengio et al., 2013), many neural network based models have been exploited by a large body of literature and achieved inspiring performance gains on various text classification tasks. These models are robust at feature engineering and can represent word sequences as fixed-length vectors with rich semantic information, which are notably ideal for subsequent NLP tasks.

Due to numerous parameters to train, neural network based models rely heavily on adequate amounts of annotated corpora, which cannot always be met as constructions of large-scale high-quality labeled datasets are extremely time-consuming and labor-intensive. *Multi-Task Learning* (**MTL**) solves this problem by jointly training multiple related tasks and leveraging potential correlations among them to increase corpora size implicitly, extract common features and yield performance gains. Inspired by (Caruana, 1997), there is a large body of research dedicated to MTL with neural network based models (Collobert and Weston, 2008; Liu et al., 2015b, 2016a,b; Zhang et al., 2017). These models usually contain a pre-trained lookup layer that map words into dense, low-dimension and real-value vectors with semantic implications, namely known as *Word Embedding* (Mikolov et al., 2013b), and utilize some lower layers to capture common features that are further fed to follow-up task-specific layers. However, many existing models may have at least one of the following three disadvantages:

- Lack of **Label Information**. Labels of each task are represented by independent and meaningless one-hot vectors, for example, *positive* and *negative* in sentiment analysis encoded as $[1, 0]$ and $[0, 1]$, which may cause a loss of potential label information.
- Inability to **Scale**. Network structures are elaborately designed to model various correlations for MTL, but many of them are structurally fixed and some can only deal with interactions between two tasks, namely pairwise interactions. When new tasks are involved, the network structures have to be modified and all networks have to be trained again.
- Inability to **Transfer**. Human beings can handle a completely new task without anymore efforts after learning with several related tasks, which can be called the ability

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4545–4553
Brussels, Belgium, October 31 - November 4, 2018.

of *Transfer Learning* (Ling et al., 2008). As discussed above, the network structures of many previous models are fixed and there are no layers specially designed for unannotated new tasks.

In this paper, we proposed **Multi-Task Label Embedding** (**MTLE**) to map labels of each task into semantic vectors, similar to how Word Embedding deals with word sequences, thereby turning the original tasks into vector matching tasks. The idea of embedding label is not new and is primarily designed to improve general neural text classification models (Bengio et al., 2010; Norouzi et al., 2013; Ma et al., 2016), but here we mainly focus on integrating label embedding to enhance MTL. MTLE utilizes semantic correlations among tasks and effectively solves the problems of scaling and transferring when new tasks are involved.

We conduct extensive experiments on five benchmark datasets for text classification. Compared to learning separately, jointly learning multiple related tasks based on MTLE demonstrates significant performance gains for each task.

Our contributions are four-fold:

- Our model efficiently leverages label information of each task by mapping labels into dense, low-dimension and real-value vectors with semantic implications.
- It is particularly convenient for our model to scale for new tasks. The network structures need no modifications and only samples from the new tasks require training.
- After training on several related tasks, our model can also naturally transfer to deal with new tasks without anymore training, while still achieving appreciable performances.
- We consider different scenarios of MTL and demonstrate strong results on several benchmark datasets for text classification. Our model outperforms most of the state-of-the-art baselines.

2 Problem Statements

2.1 Single-Task Learning

For a text classification task, the **Input** is a word sequence $x = \{x_1, x_2, ..., x_T\}$, where T is the sequence length and we need to output the most appropriate **Label** from the set $\{y_1, y_2, ..., y_C\}$, or their one-hot representation $\{\mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_C\}$, where C is the number of classes. In the supervised case, we have the **Annotation**, that is, the corresponding ground truth label $\tilde{\mathbf{y}}$ for each input, while in the unsupervised case, we only know the label set but lack the specific annotations.

A pre-trained lookup layer is used to get the embedding vector $\mathbf{x}_t \in \mathbb{R}^d$ for each word x_t. A text classification model f is trained to produce the predicted distribution $\hat{\mathbf{y}}$ for each $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_T\}$.

$$f(\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_T) = \hat{\mathbf{y}} \tag{1}$$

and the learning objective is to minimize the overall cross-entropy on the training set.

$$l = -\sum_{i=1}^{N}\sum_{j=1}^{C} \tilde{y}_{ij} \log \hat{y}_{ij} \tag{2}$$

where N denotes the number of training samples.

2.2 Multi-Task Learning

Given K supervised text classification tasks, $T_1, T_2, ..., T_K$, a multi-task learning model F is trained to transform each $\mathbf{x}^{(k)}$ from T_k into multiple predicted distributions $\{\hat{\mathbf{y}}^{(1)}, ..., \hat{\mathbf{y}}^{(K)}\}$.

$$F(\mathbf{x}_1^{(k)}, ..., \mathbf{x}_T^{(k)}) = \{\hat{\mathbf{y}}^{(1)}, ..., \hat{\mathbf{y}}^{(K)}\} \tag{3}$$

where only $\hat{\mathbf{y}}^{(k)}$ is used for loss computation. The overall training loss is a weighted combination of costs for each task.

$$L = -\sum_{k=1}^{K} \lambda_k \sum_{i=1}^{N_k}\sum_{j=1}^{C_k} \tilde{y}_{ij}^{(k)} \log \hat{y}_{ij}^{(k)} \tag{4}$$

where λ_k, N_k and C_k denote the weight, the number of training samples and the number of classes for each task T_k.

2.3 Ability to Scale

When new tasks are involved, for example, given K' more supervised tasks $T_{K+1}, T_{K+2}, ..., T_{K+K'}$, the MTL model F, which has been trained on the old K tasks, should be able to scale with few structural modifications.

$$F(\mathbf{x}_1^{(k)}, ..., \mathbf{x}_T^{(k)}) = \{\hat{\mathbf{y}}^{(1)}, ..., \hat{\mathbf{y}}^{(K+K')}\} \tag{5}$$

where $\mathbf{x}^{(k)}$ denotes samples from not only the old tasks but also the new ones.

There are mainly two scaling methods for F to deal with the new tasks. We can continue training F and further tune the model parameters based on samples from the new tasks, which we define as **Hot Update**, or re-train F again based on training samples from all tasks, which is defined as **Cold Update**.

2.4 Ability to Transfer

Given K'' more completely unannotated new tasks $T^{\circ}_{K+1}, T^{\circ}_{K+2}, ..., T^{\circ}_{K+K''}$, F should be able to transfer what it learned from the old tasks, which is defined as **Zero Update**, as no more training samples are available and the model parameters are not updated anymore.

For each $\mathbf{x}^{(k)}$ from the K'' tasks, F should produce the corresponding predicted distributions for the new tasks, even if the annotations of these new tasks are not provided at all.

$$F(\mathbf{x}^{(k)}_1, ..., \mathbf{x}^{(k)}_T) = \{\hat{\mathbf{y}}^{(K+1)}, ..., \hat{\mathbf{y}}^{(K+K'')}\} \quad (6)$$

which requires that F should be able to understand the meanings of each label from the new tasks and infer the most appropriate one.

3 Methodology

In text classification tasks, labels can be single-word or double-word, for example, *positive* and *negative* in binary sentiment classification, *very positive*, *positive*, *neutral*, *negative* and *very negative* in 5-category sentiment classification, but there are few labels that contain three words or more. Inspired by Word Embedding, we propose **Multi-Task Label Embedding (MTLE)** to convert labels of each task of MTL into dense, low-dimension and real-value vectors with semantic implications, thereby disclosing potential intra-task and inter-task correlations from both texts and labels.

3.1 Architecture

Figure 1 illustrates the general idea of MTLE, which mainly consists of three parts, the **Input Encoder**, the **Label Encoder** and the **Matcher**.

In the Input Encoder, each input sequence $x^{(k)}$ from T_k is transformed into embedding representation $\mathbf{x}^{(k)} = \{\mathbf{x}^{(k)}_1, \mathbf{x}^{(k)}_2, ..., \mathbf{x}^{(k)}_T\}$ by the Embedding Layer (E_I). The Learning Layer (L_I) is applied to recurrently comprehend $\mathbf{x}^{(k)}$ and generate a fixed-length vector $\mathbf{X}^{(k)}$, which can be regarded as an overall representation of the original input sequence $x^{(k)}$.

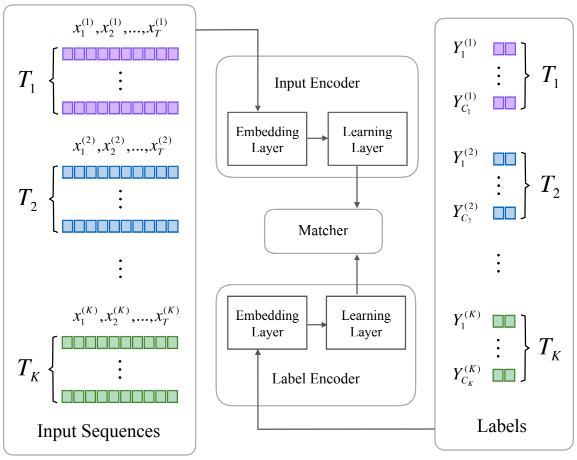

Figure 1: General Architecture of MTLE

In the Label Encoder, there are C_k labels in T_k, where each $y^{(k)}_j (1 \leq j \leq C_k)$ consists of one word or two words, and is mapped into the vector representation $\mathbf{y}^{(k)}_j$ by the Embedding Layer (E_L). The Learning Layer (L_L) absorbs $\mathbf{y}^{(k)}_j$ to generate a fixed-length vector $\mathbf{Y}^{(k)}_j$, which can be utilized as an overall semantic representation of the original label $y^{(k)}_j$.

In order to classify a sample $x^{(k)}$ from T_k, the Matcher obtains the corresponding $\mathbf{X}^{(k)}$ from the Input Encoder, all $\mathbf{Y}^{(k)}_j (1 \leq j \leq C_k)$ from the Label Encoder, and conducts vector matching to select the most appropriate class label.

In MTLE, E_I and E_L obtain understandings of words from texts and labels respectively, while L_I and L_L achieve representation abilities of vector sequences. All these four modules are learned within and shared among tasks.

3.2 Implementation Details

We can explore different embedding methods and neural networks to achieve E_I, E_L and L_I, L_L respectively, but here we choose to implement them in an easier way and spend more efforts to investigate the effectiveness of MTLE.

The implementation details of MTLE are illustrated in Figure 2. L_I and L_L are both fully-connection layers with the weights $\mathbf{W}_I$ and $\mathbf{W}_L$ of $|V| \times d$, where $|V|$ denotes the vocabulary size and d is the embedding size. We can get a pre-trained lookup table based on open domain corpora to initialize $\mathbf{W}_I, \mathbf{W}_L$ and further tune them during training.

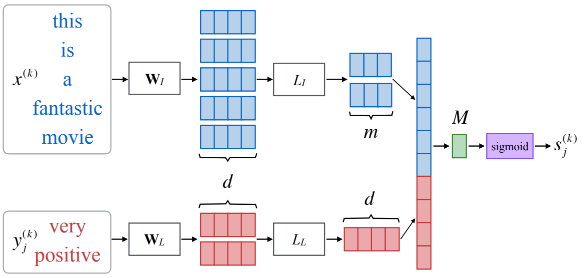

Figure 2: Implementation Details of MTLE

L_I and L_L should be trainable models that can transform a vector sequence of arbitrary length into a fixed-length vector, which can be implemented by a *Bi-directional Long Short-Term Memory Network* (**BiLSTM**) that can recurrently process vector sequences and learn long-term dependencies.

While there are numerous variants of the standard LSTM (Hochreiter and Schmidhuber, 1997), here we follow the implementation of (Graves, 2013). At each time step t, states of the LSTM can be fully described by five vectors in $\mathbb{R}^m$, an input gate $\mathbf{i}_t$, a forget gate $\mathbf{f}_t$, an output gate $\mathbf{o}_t$, the hidden state $\mathbf{h}_t$ and the memory cell $\mathbf{c}_t$, which adhere to the following transition equations.

$$\mathbf{i}_t = \sigma(\mathbf{W}_i\mathbf{x}_t + \mathbf{U}_i\mathbf{h}_{t-1} + \mathbf{V}_i\mathbf{c}_{t-1} + \mathbf{b}_i) \quad (7)$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_f\mathbf{x}_t + \mathbf{U}_f\mathbf{h}_{t-1} + \mathbf{V}_f\mathbf{c}_{t-1} + \mathbf{b}_f) \quad (8)$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_o\mathbf{x}_t + \mathbf{U}_o\mathbf{h}_{t-1} + \mathbf{V}_o\mathbf{c}_{t-1} + \mathbf{b}_o) \quad (9)$$

$$\tilde{\mathbf{c}}_t = \tanh(\mathbf{W}_c\mathbf{x}_t + \mathbf{U}_c\mathbf{h}_{t-1}) \quad (10)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \quad (11)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \quad (12)$$

where $\mathbf{x}_t$ is the current input, σ denotes logistic sigmoid function and $\odot$ denotes element-wise multiplication.

A BiLSTM consists of two LSTM layers that process the input sequences in original and reversed orders, and its output is the concatenation of hidden states from the forward and backward LSTM at each time step.

$$\mathbf{h}_t = \overrightarrow{\mathbf{h}}_t \oplus \overleftarrow{\mathbf{h}}_t \quad (13)$$

where $\oplus$ denotes vector concatenation.

We apply the above equations to implement L_I with hidden size m. However, it is inappropriate to apply a BiLSTM for L_L, as most labels contain only one or two words. Instead, L_L accepts the embedding vectors of each word from a label and calculate the average.

For an input sample $x^{(k)}$ and all C_k labels $y_j^{(k)}$ from T_k, the corresponding $\mathbf{X}^{(k)} \in \mathbb{R}^{2m}$ and $\mathbf{Y}_j^{(k)} \in \mathbb{R}^d$ are calculated as follows.

$$\mathbf{X}^{(k)} = L_I(\mathbf{W}_I(x^{(k)})) \quad (14)$$

$$\mathbf{Y}_j^{(k)} = L_L(\mathbf{W}_L(y_j^{(k)})) \quad (15)$$

In this paper, we mainly focus on the idea and effects of MTLE, so rather than exploring some useful mechanisms like gating, external memory or attention for stronger abilities of sequence learning, we choose the vanilla BiLSTM for quick implementations and spend most of our efforts on investigating the effectiveness of MTLE.

We concatenate $\mathbf{X}^{(k)}, \mathbf{Y}_j^{(k)}$ and apply another fully-connection layer with only one neuron, denoted by M, to implement the Matcher, which accepts outputs from L_I and L_L to produce a score of matching. Given the matching scores of each label, we refer to the idea of cross-entropy and calculate the loss function for a sample $x^{(k)}$ from T_k as follows.

$$s_j^{(k)} = \sigma(M(\mathbf{X}^{(k)} \oplus \mathbf{Y}_j^{(k)})) \quad (16)$$

$$\hat{y}_j^{(k)} = \frac{\exp(s_j^{(k)})}{\sum_{c=1}^{C_k} \exp(s_c^{(k)})} \quad (17)$$

$$l^{(k)} = -\sum_{j=1}^{C_k} \tilde{y}_j^{(k)} \log \hat{y}_j^{(k)} \quad (18)$$

The overall training objective is to minimize the weighted linear combination of costs for each task.

$$L = -\sum_{k=1}^{K} \lambda_k \sum_{i=1}^{N_k} l_i^{(k)} \quad (19)$$

MTLE provides an easy and intuitive way to realize MTL, where input texts and class labels from different tasks are jointly learned and compactly fused. During training, E_I and E_L learn better understanding of word semantics for different tasks, L_I and L_L obtain stronger abilities of sequence representation, while M produces more accurate scores for vector matching.

3.3 Scaling and Transferring

When new tasks are involved, it is particularly convenient for MTLE to scale or transfer as the network structure needs no modifications. For input samples $x^{(k)}$ and class labels $y_j^{(k)}$ from the new tasks, we can apply E_I, E_L, L_I, L_L to get their vector representations $\mathbf{X}^{(k)}$ and $\mathbf{Y}_j^{(k)}$, calculate the matching scores and find the most appropriate label.

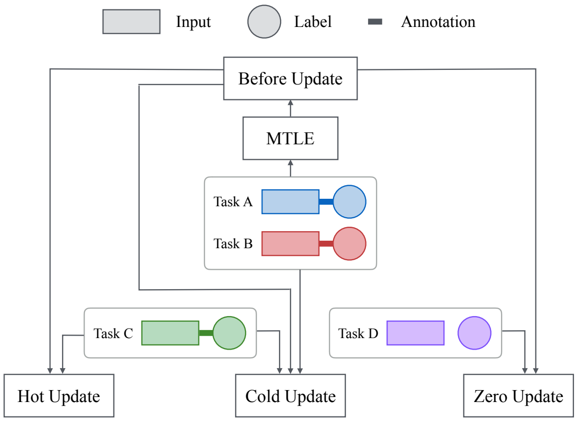

Figure 3: Three different updating methods

If the new tasks are annotated, we can apply Hot Update or Cold Update for scaling and better tune the parameters. If the new tasks are completely unannotated, we can use Zero Update for transferring and produce reasonable predictions.

The differences among Hot Update, Cold Update and Zero Update are illustrated in Figure 3, where **Before Update** denotes the state of MTLE trained on the old tasks before the new tasks are introduced. We will further compare these updating methods in the Experiment Section.

4 Experiment

In this section, we design extensive experiments with multi-task learning based on five benchmark datasets for text classification. We investigate the empirical performances of MTLE and compare them with existing state-of-the-art baselines.

4.1 Datasets

As Table 1 shows, we select five benchmark datasets for text classification, which are commonly used in a large body of research on MTL. We design three experiment scenarios to evaluate the performances of MTLE. Larger text classification datasets (Zhang et al., 2015) are not chosen as there are already enough samples to train and MTL may increase computation workloads. We use the accuracy for evaluations as samples from these datasets are mostly well balanced.

- **Multi-Cardinality** Movie review datasets with different average lengths and class numbers, including **SST-1** (Socher et al., 2013), **SST-2**, **IMDB** (Maas et al., 2011).
- **Multi-Domain** Product review datasets on different domains from *Multi-Domain Sentiment Dataset* (Blitzer et al., 2007).
- **Multi-Objective** Text classification datasets with different objectives, including **IMDB**, **RN** (Apté et al., 1994), **QC** (Li and Roth, 2002).

4.2 Hyperparameters and Training

Training of MTLE is conducted through back propagation with batch gradient descent (Amari, 1993). We obtain a pre-trained lookup table by applying *Word2Vec* (Mikolov et al., 2013a) on the Google News corpus, which contains more than 100B words with a vocabulary size of about 3M. During each epoch, we randomly divide training samples from different tasks into batches of fixed size. For each iteration, we randomly select one task and choose an untrained batch, calculate the gradient and update the parameters accordingly.

Parameters of the neural layers are randomly initialized with the Xavier initializer (Glorot and Bengio, 2010). We apply 10-fold cross-validation and different combinations of hyperparameters are investigated, of which the best one is described in Table 2.

4.3 Results of MTLE vs. Single Task

In Table 3, we compare the performances of MTLE with single-task learning, where only a BiLSTM layer is applied.

MTLE achieves significant performance gains with label information and additional correlations from related tasks. Multi-Domain, Multi-Cardinality and Multi-Objective benefit from MTLE with average improvements of 5.5%, 2.7% and 1.2%, as they contain increasingly weaker relevance among tasks. The result of IMDB in Multi-Cardinality is slightly better than that in Multi-Objective (91.3 against 90.9), as SST-1 and SST-2 share more semantically useful information with IMDB than RN and QC.

4.4 Abilities to Scale and Transfer

In order to investigate the abilities of MTLE to scale and transfer, we use $A + B \rightarrow C$ to denote the case where MTLE is trained on task A and B, while C is the newly involved one. We design three cases based on different scenarios and

Table 1: Five benchmark text classification datasets

Dataset	Description	Type	Average Length	Class	Objective
SST	Movie reviews in Stanford Sentiment Treebank including **SST-1** and **SST-2**	Sentence	19 / 19	5 / 2	Sentiment
IMDB	Internet Movie Database	Document	279	2	Sentiment
MDSD	Product reviews on books, DVDs, electronics and kitchen (**BDEK**)	Document	176 / 189 / 115 / 97	2	Sentiment
RN	Reuters Newswire topics classification	Document	146	46	Topics
QC	Question Classification	Sentence	10	6	Question Types

Table 2: Hyperparameter settings

Embedding size	$d = 300$
Hidden layer size of LSTM	$m = 100$
Batch size	$\delta = 32$
Initial learning rate	$\eta = 0.1$
Regularization weight	$\lambda = 10^{-5}$

compare the influences of Hot Update, Cold Update, Zero Update on each task.

- **Case 1** SST-1 + SST-2 → IMDB.
- **Case 2** B + D + E → K.
- **Case 3** RN + QC → IMDB.

where in Zero Update, we ignore the training set of C and just evaluate our model on the testing set.

As Table 4 shows, Before Update denotes the model trained on the old tasks before the new tasks are involved, so only evaluations on the old tasks are conducted.

Cold Update re-trains the model of Before Update with both the old tasks and the new tasks, thus achieving similar performances with the last line in Table 3. Different from Cold Update, Hot Update resumes training only on the new tasks, requires much less training time, while still obtains competitive results for all tasks. The new tasks like IMDB and Kitchen benefit more from Hot Update than the old tasks, as the parameters are further tuned according to annotations from these new tasks.

Zero Update provides inspiring possibilities for completely unannotated tasks. There are no more annotations for additional training from the new tasks, so we just apply the model of Before Update for evaluations on the testing sets of the new tasks. Zero Update achieves competitive performances in Case 1 (90.9 for IMDB) and Case 2 (86.7 for Kitchen), as tasks from these two cases all belong to sentiment datasets of different cardinalities or domains that contain rich semantic correlations with each other. However, the result for IMDB in Case 3 is only 74.2, as sentiment shares less relevance with topic and question type, thus leading to poor transferring performances.

4.5 Multi-Task or Label Embedding

MTLE mainly employs two mechanisms, label embedding and multi-task learning, so both implicit information from labels and potential correlations from other tasks make differences. In this section, we conduct experiments to explore the contributions of label embedding and multi-task learning respectively.

We choose the four tasks from Multi-Domain scenario and train MTLE on each task separately, so their performances are only influenced by label embedding. Then we re-train MTLE from scratch for every two tasks, every three tasks from them and record the performances of each task in different cases, where both label embedding and multi-task learning matter.

The results are illustrated in Figure 4. The first three graphs show the results of MTLE trained on every one, every two and every three tasks. In the first graph, the four tasks are trained separately and achieve improvements of 3.0%, 3.1%, 3.3%, 2.3% compared to the single task in Table 3. As more tasks are added step by step, MTLE produces increasing performance gains for each task and achieves an average improvement of 5.5% when all the four tasks are trained together. So it can

Table 3: Results of MTLE on different scenarios

Model	**Multi-Cardinality**			**Multi-Domain**				**Multi-Objective**			AvgΔ
	SST-1	SST-2	IMDB	B	D	E	K	IMDB	RN	QC	
Single Task	46.2	86.1	88.9	78.3	79.8	81.5	82.3	89.0	84.2	92.7	-
MTLE	**49.8**	**88.4**	**91.3**	**84.5**	**85.2**	**87.3**	**86.9**	**90.9**	**85.5**	**93.2**	+3.4

Table 4: Results of Hot Update, Cold Update and Zero Update in different cases

Model	**Case 1**			**Case 2**				**Case 3**		
	SST-1	SST-2	IMDB	B	D	E	K	RN	QC	IMDB
Before Update	48.6	87.6	-	83.7	84.5	85.9	-	84.8	**93.4**	-
Cold Update	**49.8**	**88.5**	91.2	**84.4**	**85.2**	**87.2**	86.9	**85.5**	93.2	91.0
Hot Update	49.6	88.1	**91.4**	84.2	84.9	87.0	**87.1**	85.2	92.9	**91.1**
Zero Update	-	-	90.9	-	-	-	86.7	-	-	74.2

be concluded that both information from labels as well as correlations from other tasks account for considerable parts of contributions.

In the last graph, diagonal cells denote improvements of every one task, while off-diagonal cells denote average improvements of every two tasks, so an off-diagonal cell of darker color indicates stronger correlation between the two tasks. An interesting finding is that Books is more related with DVDs and Electronics is more relevant to Kitchen. A possible reason may be that Books and DVDs are products targeted for reading or watching, while customers care more about appearances and functionalities when talking about Electronics and Kitchen.

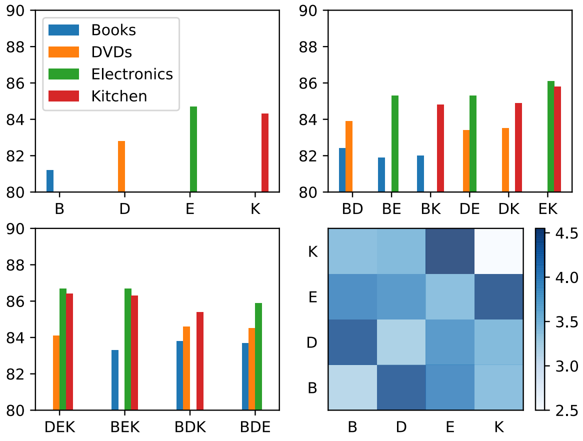

Figure 4: Performance gains of each task in different cases

4.6 Comparisons with State-of-the-art Models

We compare MTLE against the following models.

- **NBOW** Neural Bag-of-Words that sums up embedding vectors of all words and applies a non-linearity followed by a softmax layer.
- **PV** Paragraph Vectors followed by logistic regression (Le and Mikolov, 2014).
- **CNN** Convolutional Neural Networks for Sentence Classification (Kim, 2014).
- **MT-CNN** Multi-Task learning with Convolutional Neural Networks (Collobert and Weston, 2008) where lookup tables are partially shared.
- **MT-DNN** Multi-Task learning with Deep Neural Networks (Liu et al., 2015b) that utilizes bag-of-word representations and a hidden shared layer.
- **MT-RNN** Multi-Task learning with Recurrent Neural Networks with a shared-layer (Liu et al., 2016b).
- **DSM** Deep multi-task learning with Shared Memory (Liu et al., 2016a) where a external memory and a reading/writing mechanism are introduced.
- **GRNN** Gated Recursive Neural Network for sentence modeling and text classification (Chen et al., 2015).
- **Tree-LSTM** A generalization of LSTMs to tree-structured network topologies (Tai et al., 2015).

As Table 5 shows, MTLE achieves competitive or better performances on most tasks except

Table 5: Comparisons of MTLE against state-of-the-art models

Model	SST-1	SST-2	IMDB	Books	DVDs	Electronics	Kitchen	QC
NBOW	42.4	80.5	83.6	-	-	-	-	88.2
PV	44.6	82.7	**91.7**	-	-	-	-	91.8
CNN	48.0	88.1	-	-	-	-	-	93.6
MT-CNN	-	-	-	80.2	81.0	83.4	83.0	-
MT-DNN	-	-	-	79.7	80.5	82.5	82.8	-
MT-RNN	49.6	87.9	91.3	-	-	-	-	-
DSM	49.5	87.8	91.2	82.8	83.0	85.5	84.0	-
GRNN	47.5	85.5	-	-	-	-	-	**93.8**
Tree-LSTM	**50.6**	86.9	-	-	-	-	-	-
MTLE	49.8	**88.4**	91.3	**84.5**	**85.2**	**87.3**	**86.9**	93.2

for QC, as it contains less correlations with other tasks. Tree-LSTM outperforms our model on SST-1 (50.6 against 49.8), but it requires an external parser to get the sentence topological structure and utilizes treebank annotations. PV slightly surpasses MTLE on IMDB (91.7 against 91.3), as sentences from IMDB are much longer than SST and MDSD, which require stronger abilities of long-term dependency learning.

In this paper, we mainly focus the idea and effects of integrating label embedding to enhance multi-task learning, so we apply the BiLSTM to realize L_I, which can be further implemented by other more powerful sequence learning models (Liu et al., 2015a; Chen et al., 2015; Tai et al., 2015) and produce better performances. Explorations of other embedding layers and learning layers may be appreciated, but due to limited pages we choose to research these contents in future work.

5 Related Work

There is a large body of literature related to multi-task learning with neural networks in NLP (Collobert and Weston, 2008; Liu et al., 2015b, 2016a,b; Zhang et al., 2017).

(Collobert and Weston, 2008) use a shared lookup layer for common features, followed by task-specific layers for several traditional NLP tasks including part-of-speech tagging and semantic parsing. They use a fix-size window to solve the problem of variable-length input sequences, which can be better addressed by RNN.

(Liu et al., 2015b, 2016a,b; Zhang et al., 2017) all investigate MTL for text classification. (Liu et al., 2015b) apply bag-of-word representation, but information on word order is lost. (Liu et al., 2016a) introduce an external memory for information sharing with a reading/writing mechanism for communications. (Liu et al., 2016b) propose three different models for MTL with RNN and (Zhang et al., 2017) constructs a generalized architecture for RNN based MTL. However, models of these papers ignore essential information of labels and mostly can only address pairwise interactions between two tasks. Their network structures are also fixed, thereby failing to scale or transfer when new tasks are involved.

Different from the above work, MTLE maps labels of text classification tasks into semantic vectors and provide a more intuitive way to realize MTL with the abilities to scale and transfer. Input sequences from three or more tasks are jointly learned together with their labels, benefitting from each other and obtaining better sequence representations.

6 Conclusion and Future Work

In this paper, we propose Multi-Task Label Embedding to map labels of text classification tasks into semantic vectors. MTLE utilizes semantic correlations among tasks and effectively solves the problems of scaling and transferring when new tasks are involved. We explore three different scenarios of MTL and MTLE can improve performances of most tasks with semantic representations of labels and additional information from others in all scenarios.

In future work, we would like to explore other learning layers and generalize MTLE to address other NLP tasks, for example, sequence labeling and sequence-to-sequence learning.

Abstract

We propose a novel model for multi-label text classification, which is based on sequence-to-sequence learning. The model generates higher-level semantic unit representations with multi-level dilated convolution as well as a corresponding hybrid attention mechanism that extracts both the information at the word-level and the level of the semantic unit. Our designed dilated convolution effectively reduces dimension and supports an exponential expansion of receptive fields without loss of local information, and the attention-over-attention mechanism is able to capture more summary relevant information from the source context. Results of our experiments show that the proposed model has significant advantages over the baseline models on the dataset RCV1-V2 and Ren-CECps, and our analysis demonstrates that our model is competitive to the deterministic hierarchical models and it is more robust to classifying low-frequency labels[1].

1 Introduction

Multi-label text classification refers to assigning multiple labels for a given text, which can be applied to a number of important real-world applications. One typical example is that news on the website often requires labels with the purpose of the improved quality of search and recommendation so that the users can find the preferred information with high efficiency with less disturbance of the irrelevant information. As a significant task of natural language processing, a number of methods have been applied and have gradually achieved satisfactory performance. For instance, a series of methods based on machine learning have been extensively utilized in the industries, such as Binary Relevance (Boutell et al., 2004). BR treats the task as multiple single-label classifications and can achieve satisfactory performance. With the development of Deep Learning, neural methods are applied to this task and achieved improvements (Zhang and Zhou, 2006; Nam et al., 2013; Benites and Sapozhnikova, 2015).

However, these methods cannot model the internal correlations among labels. To capture such correlations, the following work, including ML-DT (Clare and King, 2001), Rank-SVM (Elisseeff and Weston, 2002), LP (Tsoumakas and Katakis, 2006), ML-KNN (Zhang and Zhou, 2007), CC (Read et al., 2011), attempt to capture the relationship, which though demonstrated improvements yet simply captured low-order correlations. A milestone in this field is the application of sequence-to-sequence learning to multi-label text classification (Nam et al., 2017). Sequence-to-sequence learning is about the transformation from one type of sequence to another type of sequence, whose most common architecture is the attention-based sequence-to-sequence (Seq2Seq) model. The attention-based Seq2Seq (Sutskever et al., 2014) model is initially designed for neural machine translation (NMT) (Bahdanau et al., 2014; Luong et al., 2015). Seq2Seq is able to encode a given source text and decode the representation for a new sequence to approximate the target text, and with the attention mechanism, the decoder is competent in extracting vital source-side information to improve the quality of decoding. Multi-label text classification can be regarded as the prediction of the target label sequence given a source text, which can be modeled by the Seq2Seq. Moreover, it is able to model the high-order correlations among the source text as well as those among the label sequence with deep recurrent neural networks (RNN).

Nevertheless, we study the attention-based Seq2Seq model for multi-label text classification

Brussels, Belgium, October 31 - November 4, 2018.

(Nam et al., 2017) and find that the attention mechanism does not play a significant role in this task as it does in other NLP tasks, such as NMT and abstractive summarization. In Section 3, we demonstrate the results of our ablation study, which show that the attention mechanism cannot improve the performance of the Seq2Seq model. We hypothesize that compared with neural machine translation, the requirements for neural multi-label text classification are different. The conventional attention mechanism extracts the word-level information from the source context, which makes little contribution to a classification task. For text classification, human does not assign texts labels simply based on the word-level information but usually based on their understanding of the salient meanings in the source text.

For example, regarding the text “The young boys are playing basketball with great excitement and apparently they enjoy the fun of competition”, it can be found that there are two salient ideas, which are “game of the young” and “happiness of basketball game”, which we call “semantic units” of the text. The semantic units, instead of word-level information, mainly determine that the text can be classified into the target categories “youth” and “sports”.

Semantic units construct the semantic meaning of the whole text. To assign proper labels for text, the model should capture the core semantic units of the source text, the higher-level information compared with word-level information, and then assign the text labels based on its understanding of the semantic units. However, it is difficult to extract information from semantic units as the conventional attention mechanism focuses on extracting word-level information, which contains redundancy and irrelevant details.

In order to capture semantic units in the source text, we analyze the texts and find that the semantic units are often wrapped in phrases or sentences, connecting with other units with the help of contexts. Inspired by the idea of global encoding for summarization (Lin et al., 2018), we utilize the power of convolutional neural networks (CNN) to capture local interaction among words and generate representations of information of higher levels than the word, such as phrase or sentence. Moreover, to tackle the problem of long-term dependency, we design a multi-level dilated convolution for text to capture local correlation and long-term dependency without loss of coverage as we do not apply any form of pooling or strided convolution. Based on the annotations generated by our designed module and those by the original recurrent neural networks, we implement our hybrid attention mechanism with the purpose of capturing information at different levels, and furthermore, it can extract word-level information from the source context based on its attention on the semantic units.

In brief, our contributions are illustrated below:

- We analyze that the conventional attention mechanism is not useful for multi-label text classification, and we propose a novel model with multi-level dilated convolution to capture semantic units in the source text.
- Experimental results demonstrate that our model outperforms the baseline models and achieves the state-of-the-art performance on the dataset RCV1-v2 and Ren-CECps, and our model is competitive with the hierarchical models with the deterministic setting of sentence or phrase.
- Our analysis shows that compared with the conventional Seq2Seq model, our model with effective information extracted from the source context can better predict the labels of low frequency, and it is less influenced by the prior distribution of the label sequence.

2 Attention-based Seq2Seq for Multi-label Text Classification

As illustrated below, multi-label text classification has the potential to be regarded as a task of sequence prediction, as long as there are certain correlation patterns in the label data. Owing to the correlations among labels, it is possible to improve the performance of the model in this task by assigning certain label permutations for the label sequence and maximizing subset accuracy, which means that the label permutation and the corresponding attention-based Seq2Seq method are competent in learning the label classification and the label correlations. By maximizing the subset accuracy, the model can improve the performance of classification with the assistance of the information about the label correlations. Regarding label permutation, a straightforward method is to reorder the label data in accordance with the descending order by frequency, which shows satisfactory effects (Chen et al., 2017).

Multi-label text classification can be regarded as a Seq2Seq learning task, which is formulated as below. Given a source text $x = \{x_1, ..., x_i, ..., x_n\}$ and a target label sequence $y = \{y_1, ..., y_i, ..., y_m\}$, the Seq2Seq model learns to approximate the probability $P(y|x) = \prod_{t=1}^{m} P(y_t|y_{<t}, x)$, where $P(y_t|y_{<t}, x)$ is computed by the Seq2Seq model, which is commonly based on recurrent neural network (RNN).

The encoder, which is bidirectional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1996), encodes the source text x from both directions and generates the source annotations h, where the annotations from both directions at each time step are concatenated ($h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$). To be specific, the computations of $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ are illustrated below:

$$\overrightarrow{h_i} = LSTM(x_i, \overrightarrow{h_{i-1}}, C_{i-1}) \quad (1)$$

$$\overleftarrow{h_i} = LSTM(x_i, \overleftarrow{h_{i-1}}, C_{i-1}) \quad (2)$$

We implement a unidirectional LSTM decoder to generate labels sequentially. At each time step t, the decoder generates a label y_t by sampling from a distribution of the target label set P_{vocab} until sampling the token representing the end of sentence, where:

$$P_{vocab} = g(y_{t-1}, c_t, s_{t-1}) \quad (3)$$

where $g(\cdot)$ refers to non-linear functions including the LSTM decoder, the attention mechanism as well as the softmax function for prediction. The attention mechanism generates c_t as shown in the following:

$$c_t = \sum_{i=1}^{n} \alpha_{t,i} h_i \quad (4)$$

$$\alpha_{t,i} = \frac{exp(e_{t,i})}{\sum_{j=1}^{n} exp(e_{t,j})} \quad (5)$$

$$e_{t,i} = s_{t-1}^{\top} W_a h_i \quad (6)$$

3 Problem

As we analyze the effects of the attention mechanism in multi-label text classification, we find that it contributes little to the improvement of the model's performance. To verify the effects of the attention mechanism, we conduct an ablation test to compare the performance of the Seq2Seq model without the attention mechanism and the attention-based SeqSeq model on the multi-label text classification dataset RCV1-v2, which is introduced in detail in Section 5.

Models	**HL(-)**	**P(+)**	**R(+)**	**F1(+)**
w/o attention	0.0082	0.883	0.849	0.866
+attention	0.0081	0.889	0.848	0.868

Table 1: Performances of the Seq2Seq models with and without attention on the RCV1-v2 test set, where HL, P, R, and F1 refer to hamming loss, micro-precision, micro-recall and micro-F_1. The symbol "+" indicates that the higher the better, while the symbol "-" indicates that the lower the better.

As is shown in Table 1, the Seq2Seq models with and without the attention mechanism demonstrate similar performances on the RCV1-v2 according to their scores of micro-F_1, a significant evaluation metric for multi-label text classification. This can be a proof that the conventional attention mechanism does not play a significant role in the improvement of the Seq2Seq model's performance. We hypothesize that the conventional attention mechanism does not meet the requirements of multi-label text classification. A common sense for such a classification task is that the classification should be based on the salient ideas of the source text. The semantic units, instead of word-level information, mainly determine that the text can be classified into the target categories "youth" and "sports". For each of a variety of texts, there are always semantic units that construct the semantic meaning of the whole text. Regarding an automatic system for multi-label text classification, the system should be able to extract the semantic units in the source text for better performance in classification. Therefore, we propose our model to tackle this problem.

4 Proposed Method

In the following, we introduce our proposed modules to improve the conventional Seq2Seq model for multi-label text classification. In general, it contains two components: multi-level dilated convolution (MDC) as well as hybrid attention mechanism.

4.1 Multi-level Dilated Convolution

On top of the representations generated by the original encoder, which is an LSTM in our model, we apply the multi-layer convolutional neural networks to generate representations of semantic units by capturing local correlations and long-term dependencies among words. To be specific, our CNN is a three-layer one-dimensional CNN. Fol-

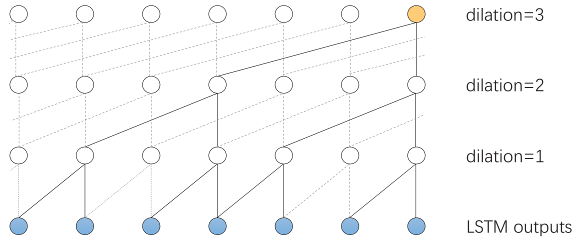

Figure 1: **Structure of Multi-level Dilated Convolution (MDC).** A example of MDC with kernel size $k = 2$ and dilation rates $[1, 2, 3]$. To avoid gridding effects, the dilation rates do not share a common factor other than 1.

lowing the previous work (Kalchbrenner et al., 2014) on CNN for NLP, we use one-dimensional convolution with the number of channels equal to the number of units of the hidden layer, so that the information at each dimension of a representation vector will not be disconnected as 2-dimension convolution does. Besides, as we are to capture semantic units in the source text instead of higher-level word representations, there is no need to use padding for the convolution.

A special design for the CNN is the implementation of dilated convolution. Dilation has become popular in semantic segmentation in computer vision in recent years (Yu and Koltun, 2015; Wang et al., 2018), and it has been introduced to the fields of NLP (Kalchbrenner et al., 2016) and speech processing (van den Oord et al., 2016). Dilated convolution refers to convolution inserted with "holes" so that it is able to remove the negative effects such as information loss caused by common down-sampling methods, such as max-pooling and strided convolution. Besides, it is able to expand the receptive fields at the exponential level without increasing the number of parameters. Thus, it becomes possible for dilated convolution to capture longer-term dependency. Furthermore, with the purpose of avoiding gridding effects caused by dilation (e.g., the dilated segments of the convolutional kernel can cause missing of vital local correlation and break the continuity between word representations), we implement a multi-level dilated convolution with different dilation rates at different levels, where the dilation rates are hyperparameters in our model.

Instead of using the same dilation rate or dilation rates with the common factor, which can cause gridding effects, we apply multi-level dilated convolution with different dilation rates, such as [1,2,3]. Following Wang et al. (2018), for N layers of 1-dimension convolution with kernel size K with dilation rates $[r_1, ..., r_N]$, the maximum distance between two nonzero values is $max(M_{i+1} - 2r_i, M_{i+1} - 2(M_{i+1} - r_i), r_i)$ with $M_N = r_N$, and the goal is $M_2 \leq K$. In our experiments, we set the dilation rates to [1, 2, 3] and K to 3, and we have $M_2 = 2$. The implementations can avoid the gridding effects and allows the top layer to access information between longer distance without loss of coverage. Moreover, as there may be irrelevant information to the semantic units at a long distance, we carefully design the dilation rates to [1, 2, 3] based on the performance in validation, instead of others such as [2, 5, 9], so that the top layer will not process the information among overlong distance and reduce the influence of unrelated information. Therefore, our model can generate semantic unit representations from the information at phrase level with small dilation rates and those at sentence level with large dilation rates.

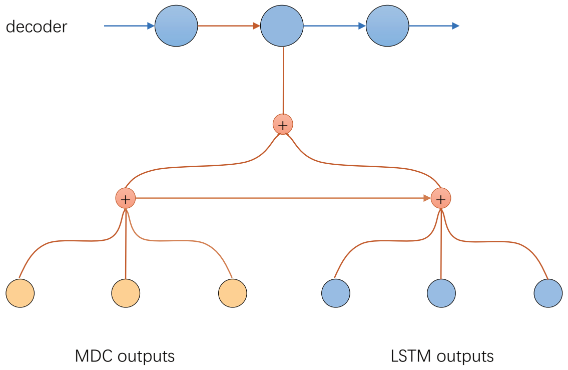

Figure 2: **Structure of Hybrid Attention.** The blue circles at the left bottom represent the source annotations generated by the LSTM encoder, the yellow circles at the right bottom represent the semantic unit representations generated by MDC, and the blue circles at the top represent the LSTM decoder outputs. At each decoding time step, the output of the LSTM attends to the semantic unit representations first, and then the new representation incorporated with high-level information attends to the source annotations.

4.2 Hybrid Attention

As we have annotations from the RNN encoder and semantic unit representations from the MDC, we design two types of attention mechanism to evaluate the effects of information of different levels. One is the common attention mechanism, which attends to the semantic unit representations instead of the source word annotations as the conventional does, the other is our designed hybrid attention mechanism to incorporate information of the two levels.

The idea of hybrid attention is motivated by memory networks (Sukhbaatar et al., 2015) and multi-step attention (Gehring et al., 2017). It can be regarded as the attention mechanism with multiple "hops", with the first hop attending to the higher-level semantic unit information and the second hop attending to the lower-level word unit information based on the decoding and the first attention to the semantic units. Details are presented below.

For the output of the decoder at each time step, it not only attends to the source annotations from the RNN encoder as it usually does but also attends to the semantic unit representations from the MDC. In our model, the decoder output first pays attention to the semantic unit representations from the MDC to figure out the most relevant semantic units and generates a new representation based on the attention. Next, the new representation with both the information from the decoding process as well as the attention to the semantic units attends to the source annotations from the LSTM encoder, so it can extract word-level information from the source text with the guidance of the semantic units, mitigating the problem of irrelevance and redundancy.

To be specific, for the source annotations from the LSTM encoder $h = \{h_1, ..., h_i, ..., h_n\}$ and the semantic unit representations $g = \{g_1, ..., g_i, ..., g_m\}$, the decoder output s_t first attends to the semantic unit representations g and generates a new representation s'_t. Then the new representation s'_t attends to the source annotations h and generates another representation $\tilde{s}_t$ following the identical attention mechanism as mentioned above. In the final step, the model generates o_t for the prediction of y_t, where:

$$o_t = s'_t \oplus \tilde{s}_t \tag{7}$$

For comparison, we also propose another type of attention called "additive attention", whose experimental results are in the ablation test. In this mechanism, instead of paying attention to the two types of representations step by step as mentioned above, the output of the LSTM decoder s_t attends to the semantic unit representations g and the source annotations h respectively to generate s'_t and $\tilde{s}_t$, which are finally added element-wisely for the final output o_t.

5 Experiment Setup

In the following, we introduce the datasets and our experiment settings as well as the baseline models that we compare with.

5.1 Datasets and Preprocessing

Reuters Corpus Volume I (RCV1-v2)[2]: The dataset (Lewis et al., 2004) consists of more than 800k manually categorized newswire stories by Reuters Ltd. for research purpose, where each story is assigned with multiple topics. The total number of topics is 103. To be specific, the training set contains around 802414 samples, while the development set and test set contain 1000 samples respectively. We filter the samples whose lengths are over 500 words in the dataset, which removes about 0.5% of the samples in the training, development and test sets. The vocabulary size is set to 50k words. Numbers as well as out-of-vocabulary words are masked by special tokens "#" and "UNK". For label permutation, we apply the descending order by frequency following Kim (2014).

Ren-CECps: The dataset is a sentence corpus collected from Chinese blogs, annotated with 8 emotion tags *anger*, *anxiety*, *expect*, *hate*, *joy*, *love*, *sorrow* and *surprise* as well as 3 polarity tags *positive*, *negative* and *neutral*. The dataset contains 35096 sentences for multi-label text classification. We apply preprocessing for the data similar to that for the RCV1-v2, which are filtering samples of over 500 words, setting the vocabulary size to 50k and applying the descending order by frequency for label permutation.

5.2 Experiment Settings

We implement our experiments in PyTorch on an NVIDIA 1080Ti GPU. In the experiments, the batch size is set to 64, and the embedding size and the number of units of hidden layers are 512. We use Adam optimizer (Kingma and Ba, 2014) with the default setting $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1 \times 10^{-8}$. The learning rate is initialized to 0.0003 based on the performance on the development set, and it is halved after every epoch

of training. Gradient clipping is applied with the range [-10, 10].

Following the previous studies (Zhang and Zhou, 2007; Chen et al., 2017), we choose hamming loss and micro-F_1 score to evaluate the performance of our model. Hamming loss refers to the fraction of incorrect prediction (Schapire and Singer, 1999), and micro-F_1 score refers to the weighted average F_1 score. For reference, the micro-precision as well as micro-recall scores are also reported. To be specific, the computations of Hamming Loss (HL) micro-F_1 score are illustrated below:

$$HL = \frac{1}{L} \sum \mathbb{I}(y \neq \hat{y}) \tag{8}$$

$$microF_1 = \frac{\sum_{j=1}^{L} 2tp_j}{\sum_{j=1}^{L} 2tp_j + fp_j + fn_j} \tag{9}$$

where tp_j, fp_j and fn_j refer to the number of true positive examples, false positive examples and false negative examples respectively.

5.3 Baseline Models

In the following, we introduce the baseline models for comparison for both datasets.

- **Binary Relevance (BR)** (Boutell et al., 2004) transforms the MLC task into multiple single-label classification problems.
- **Classifier Chains (CC)** (Read et al., 2011) transforms the MLC task into a chain of binary classification problems to model the correlations between labels.
- **Label Powerset (LP)** (Tsoumakas and Katakis, 2006) creates one binary classifier for every label combination attested in the training set.
- **CNN** (Kim, 2014) uses multiple convolution kernels to extract text feature, which is then input to the linear transformation layer followed by a sigmoid function to output the probability distribution over the label space.
- **CNN-RNN** (Chen et al., 2017) utilizes CNN and RNN to capture both global and local textual semantics and model label correlations.
- **S2S** and **S2S+Attn** (Sutskever et al., 2014; Bahdanau et al., 2014) are our implementation of the RNN-based sequence-to-sequence models without and with the attention mechanism respectively.

6 Results and Discussion

In the following sections, we report the results of our experiments on the RCV1-v2 and Ren-CECps. Moreover, we conduct an ablation test and the comparison with models with hierarchical models with the deterministic setting of sentence or phrase, to illustrate that our model with learnable semantic units possesses a clear advantage over the baseline models. Furthermore, we demonstrate that the higher-level representations are useful for the prediction of labels of low frequency in the dataset so that it can ensure that the model is not strictly learning the prior distribution of the label sequence.

6.1 Results

We present the results of our implementations of our model as well as the baselines on the RCV1-v2 on Table 2. From the results of the conventional baselines, it can be found that the classical methods for multi-label text classification still own competitiveness compared with the machine-learning-based and even deep-learning-based methods, instead of the Seq2Seq-based models. Regarding the Seq2Seq model, both the S2S and the S2S+Attn achieve improvements on the dataset, compared with the baselines above. However, as mentioned previously, the attention mechanism does not play a significant role in the Seq2Seq model for multi-label text classification. By contrast, our proposed mechanism, which is label-classification-oriented, can take both the information of semantic units and that of word units into consideration. Our proposed model achieves the best performance in the evaluation of Hamming loss and micro-F_1 score, which reduces 9.8% of Hamming loss and improves 1.3% of micro-F_1 score, in comparison with the S2S+Attn.

We also present the results of our experiments on Ren-CECps. Similar to the models' performance on the RCV1-v2, the conventional baselines except for Seq2Seq models achieve lower performance on the evaluation of micro-F_1 score compared with the Seq2Seq models. Moreover, the S2S and the S2S+Attn still achieve similar performance on micro-F_1 on this dataset, and our proposed model achieves the best performance with the improvement of 0.009 micro-F_1 score. An interesting finding is that the Seq2Seq models do not possess an advantage over the conventional baselines on the evaluation of Hamming Loss. We observe that there are fewer labels in the Ren-CECps than in the RCV1-v2 (11 and 103). As our label data are reordered according to the descending order of label frequency, the Seq2Seq model is inclined to learn the frequency distribution, which is similar to a long-tailed distribution. However, regarding the low-frequency labels with only a few samples, their amounts are similar, whose distributions are much more uniform than that of the whole label data. It is more difficult for the Seq2Seq model to classify them correctly while the model is approximating the long-tailed distribution compared with the conventional baselines. As Hamming loss reflects the average incorrect prediction, the errors in classifying into low-frequency labels will lead to a sharper increase in Hamming Loss, in comparison with micro-F_1 score.

6.2 Ablation Test

To evaluate the effects of our proposed modules, we present an ablation test for our model. We remove certain modules to control variables so that their effects can be fairly compared. To be specific, besides the evaluation of the conventional attention mechanism mentioned in Section 3, we evaluate the effects of hybrid attention and its modules. We demonstrate the performance of five models with different attention implementation for comparison, which are model without attention, one with only attention to the source annotations from LSTM, one with only attention to the semantic unit representations from the MDC, one with the attention to both the source annotations and semantic unit representations (additive) and hybrid attention, respectively. Therefore, the effects of each of our proposed modules, including MDC and hybrid attention, can be evaluated individually without the influence of the other modules.

Models	HL(-)	P(+)	R(+)	F1(+)
w/o attention	0.0086	**0.904**	0.816	0.871
attention	0.0087	0.887	0.828	0.869
MDC	0.0074	0.889	0.871	0.880
additive	0.0073	0.888	0.871	0.879
hybrid	**0.0072**	0.891	**0.873**	**0.882**

Table 4: Performance of the models with different attention mechanisms on the RCV1-V2 test set. HL, P, R, and F1 denote hamming loss, micro-precision, micro-recall and micro-F_1, respectively ($p < 0.05$).

Results in Table 4 reflect that our model still performs the best in comparison with models with the other types of attention mechanism. Except for the insignificant effect of the conventional attention mechanism mentioned above, it can be found that the high-level representations generated by the MDC contribute much to the performance of the Seq2Seq model for multi-label text classification, which improves about 0.9 micro-F_1 score. Moreover, simple additive attention mechanism, which is equivalent to the element-wise addition of the representations of MDC and those of the conventional mechanism, achieves similar performance to the single MDC, which also demonstrates that conventional attention mechanism in this task makes little contribution. As to our proposed hybrid attention, which is a relatively complex combination of the two mechanisms, can improve the performance of MDC. This shows that although conventional attention mechanism for word-level information does not influence the performance of the SeqSeq model significantly, the hybrid attention which extracts word-level infor-

mation based on the generated high-level semantic information can provide some information about important details that are relevant to the most contributing semantic units.

6.3 Comparison with the Hierarchical Models

Another method that can extract high-level representations is a heuristic method that manually annotates sentences or phrases first and applies a hierarchical model for high-level representations. To be specific, the method does not only apply an RNN encoder to the word representations but also to sentence representations. In our reimplementation, we regard the representation from the LSTM encoder at the time step of the end of each sentence as the sentence representation, and we implement another LSTM on top of the original encoder that receives sentence representations as input so that the whole encoder can be hierarchical. We implement the experiment on the dataset RCV1-v2. As there is no sentence marker in the dataset RCV1-v2, we set a sentence boundary for the source text and we apply a hierarchical model to generate sentence representations.

Compared with our proposed MDC, the hierarchical model for the high-level representations is relatively deterministic since the sentences or phrases are predefined manually. However, our proposed MDC learns the high-level representations through dilated convolution, which is not restricted by the manually-annotated boundaries. Through the evaluation, we expect to see if our model with multi-level dilated convolution as well as hybrid attention can achieve similar or better performance than the hierarchical model. Moreover, we note that the number of parameters of the hierarchical model is more than that of our model, which are 47.24M and 45.13M respectively. Therefore, it is obvious that our model does not possess the advantage of parameter number in the comparison.

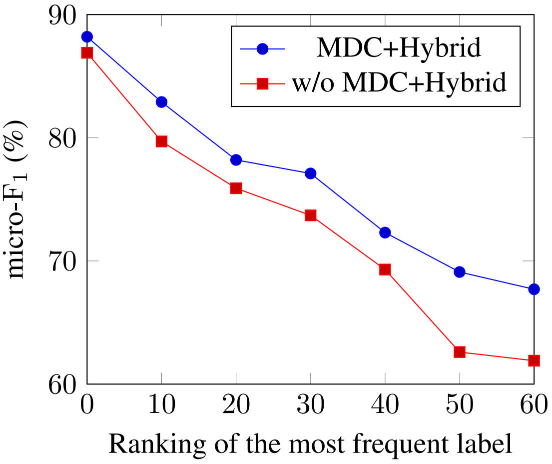

Figure 3: **Micro-F$_1$ scores of our model and the baseline on the evaluation of labels of different frequency.** The x-axis refers to the ranking of the most frequent label in the labels for classification, and the y-axis refers to the micro-F$_1$ score performance.

We present the results of the evaluation on Table 5, where it can be found that our model with fewer parameters still outperforms the hierarchical model with the deterministic setting of sentence or phrase. Moreover, in order to alleviate the influence of the deterministic sentence boundary, we compare the performance of different hierarchical models with different boundaries, which sets the boundaries at the end of every 5, 10, 15 and 20 words respectively. The results in Table 5 show that the hierarchical models achieve similar performances, which are all higher than the performances of the baselines. This shows that high-level representations can contribute to the performance of the Seq2Seq model on the multi-label text classification task. Furthermore, as these performances are no better than that of our proposed model, it can reflect that the learnable high-level representations can contribute more than deterministic sentence-level representations, as it can be more flexible to represent information of diverse levels, instead of fixed phrase or sentence level.

6.4 Error Analysis

Another finding in our experiments is that the model's performance on low-frequency label classification is lower than that on high-frequency label classification. This problem is also reflected in our report of the experimental results on the Ren-CECps. The decrease in performance is reasonable since the model is sensitive to the amount of data, especially on small datasets such as Ren-CECps. We also hypothesize that this error comes from the essence of the Seq2Seq model. As the frequency of our label data is similar to a long-tailed distribution and the data are organized by descending order of label frequency, the Seq2Seq model is inclined to model the distribution. As the frequency distribution of the low-frequency labels is relatively uniform, it is much harder for it to model the distribution.

In contrast, as our model is capable of capturing deeper semantic information for the label classification, we believe that it is more robust to the classification of low-frequency labels with the help of the information from multiple levels. We remove the top 10, 20, 30, 40, 50 and 60 most frequent labels subsequently, and we evaluate the performance of our model and the baseline Seq2Seq model on the classification of these labels. Figure 3 shows the results of the models on label data of different frequency. It is obvious that although the performances of both models decrease with the decrease of the label frequency, our model continues to perform better than the baseline on all levels of label frequency. In addition, the gap between the performances of the two models continues to increase with the decrease of label frequency, demonstrating our model's advantage over the baseline on classifying low-frequency labels.

7 Related Work

The current models for the multi-label classification task can be classified into three categories: problem transformation methods, algorithm adaptation methods, and neural network models.

Problem transformation methods decompose the multi-label classification task into multiple single-label learning tasks. The BR algorithm (Boutell et al., 2004) builds a separate classifier for each label, causing the label correlations to be ignored. In order to model label correlations, Label Powerset (LP) (Tsoumakas and Katakis, 2006) creates one binary classifier for every label combination attested in the training set and Classifier Chains (CC) (Read et al., 2011) connects all classifiers in a chain through feature space.

Algorithm adaptation methods adopt specific learning algorithms to the multi-label classification task without requiring problem transformations. Clare and King (2001) constructed decision tree based on multi-label entropy to perform classification. Elisseeff and Weston (2002) adopted a Support Vector Machine (SVM) like learning system to handle multi-label problem. Zhang and Zhou (2007) utilized the k-nearest neighbor algorithm and maximum a posteriori principle to determine the label set of each sample. Fürnkranz et al. (2008) made ranking among labels by utilizing pairwise comparison. Li et al. (2015) used joint learning predictions as features.

Recent studies of multi-label text classification have turned to the application of neural networks, which have achieved great success in natural language processing. Zhang and Zhou (2006) implemented the fully-connected neural networks with pairwise ranking loss function. Nam et al. (2013) changed the ranking loss function to the cross-entropy loss to better the training. Kurata et al. (2016) proposed a novel neural network initialization method to treat some neurons as dedicated neurons to model label correlations. Chen et al. (2017) incorporated CNN and RNN so as to capture both global and local semantic information and model high-order label correlations. (Nam et al., 2017) proposed to generate labels sequentially, and Yang et al. (2018); Li et al. (2018) both adopted the Seq2Seq, one with a novel decoder and one with a soft loss function respectively.

8 Conclusion

In this study, we propose our model based on the multi-level dilated convolution and the hybrid attention mechanism, which can extract both the semantic-unit-level information and word-level information. Experimental results demonstrate that our proposed model can significantly outperform the baseline models. Moreover, the analyses reflect that our model is competitive with the deterministic hierarchical models and it is more robust to classifying the low-frequency labels than the baseline.

Abstract

Multi-task learning has an ability to share the knowledge among related tasks and implicitly increase the training data. However, it has long been frustrated by the interference among tasks. This paper investigates the performance of capsule network for text, and proposes a capsule-based multi-task learning architecture, which is unified, simple and effective. With the advantages of capsules for feature clustering, proposed task routing algorithm can cluster the features for each task in the network, which helps reduce the interference among tasks. Experiments on six text classification datasets demonstrate the effectiveness of our models and their characteristics for feature clustering.

1 Introduction

Multi-task learning (MTL) has achieved a great success in the field of natural language processing, which can share the knowledge among multiple tasks, implicitly increasing the volume of training data. The combination of multi-task learning and deep neural networks (DNNs) generates a further synergy via the regularization effect on the DNNs (Collobert and Weston, 2008), which helps alleviate the overfitting and learn a more universal presentation.

Inspired by this, more DNN-based multi-task learning models are proposed to improve the performance. As depicted in Figure 1, they can be categorized into three groups by structure: tree scheme (Collobert and Weston, 2008; Liu et al., 2015), parallel scheme (Liu et al., 2016) and mediate scheme (Zhang et al., 2017). Tree scheme reuses some shallow layers of network and separates the higher layers for different tasks, which is the most common architecture for MTL but can only share the low-level knowledge. To share deeper level knowledge among the tasks, more layers are linked in parallel and mediate schemes. But this would severely suffer from the interference among tasks. Useless features following the helpful ones are fully shared among tasks, which may contaminate the feature spaces of tasks by useless ones. Besides, models under these two schemes usually employ multiple subnets in the structures, which would contain more parameters and are hard to train.

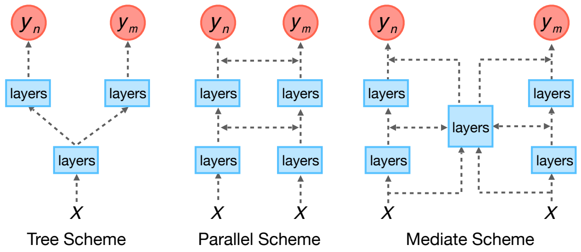

Figure 1: Three schemes of multi-task learning

Apparently, there is a contradiction between knowledge sharing and interference. Sharing too much between tasks would inevitably bring about the interference that feature space for each task may be contaminated by others. Shared useless features may mislead the prediction of network. This dilemma is caused by the lack of management for sharing process, in which the network can not discriminate the features and collect the appropriate features for each task.

Capsule network (Hinton et al., 2011; Mousa et al., 2017; Hinton et al., 2018) embeds the features into capsules and connects the neighbor layers via "routing-by-agreement". The *dynamic routing* algorithm has an ability to decide the routes of capsules, namely, to cluster the features for each category. So, intuitively this property of capsule network can be employed in MTL to discriminate the features for tasks.

In this paper, we explore the performance of capsule network for text (**CapsNet-1**, **CapsNet-1**) and show the benefits and potential of cap-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4565–4574
Brussels, Belgium, October 31 - November 4, 2018.

sule network for NLP. Then we mainly propose a capsule-based architecture for multi-task learning (**McapsNet**), which is unified, simple, effective and can cluster the feature for tasks. We designed a **Task Routing** algorithm to route the feature flows to tasks and vote for the classes, which can reduce the interference. In extensive experiences, our approach achieves competitive results in single-task scenario and shows obvious improvement in multi-task scenario, which proves our approach effective and its ability to reduce the interference among multiple tasks. Also, our visualization experiments intuitively show the feature clustering mechanism and how it helps make right predictions.

The contribution of this paper are three-folds:

- This paper investigates the performance of capsule network on text and designs two effective capsule-based models for text classification, which give clear improvement to several benchmarks.
- We novelly combine the capsule and multi-task learning, which can help reduce the interference among tasks.
- Proposed task routing algorithm can route the capsules to multiple tasks, by which the features is clustered into groups for tasks.

2 Convolutional Neural Network and Multi-Task Learning

Capsule network is based on the convolutional neural network (CNN) and uses a lot of convolution operations. The main differences between them are that capsule network uses vectors to represent the features and discards the pooling operation. CNN is good at feature extraction and can capture short and long range relations through the feature graph over text sequence (Kalchbrenner et al., 2014; Kim, 2014). In this section, we provide some formulations for CNN and some background knowledge for multi-task learning.

2.1 Single-Task CNN for Text Classification

Given a text sequence $x_{1:l} = x_1 x_2 \cdots x_l$ of length l, the target of CNN is to predict the category $\hat{y}$ of $x_{1:l}$ from a set $\{y_1, y_2, \cdots, y_C\}$, or a one-hot form of $\hat{\mathbf{y}}$, where C is the class number. Using $f(\cdot)$ denote the network, the prediction process can be formalized as $f(x_1, x_2, \cdots, x_l) = \hat{y}$.

For details, convolutional neural network $f(\cdot)$ first uses a lookup table to embed the word sequence $x_{1:l}$ into vectors $\mathbf{x}$. Then CNN produces the representation of the input sequence by stacking the layers of convolution, pooling and fully-connected in order.

$$\mathbf{F} = \mathbf{K} * \mathbf{x} \tag{1}$$

$$\hat{\mathbf{F}} = p(\mathbf{F}) \tag{2}$$

$$\hat{\mathbf{y}} = \mathbf{w}\hat{\mathbf{F}} + \mathbf{b}, \tag{3}$$

where $\mathbf{K}$ is the kernel of convolution operation $*$; $p(\cdot)$ denotes the pooling operation; $\mathbf{F}$ and $\hat{\mathbf{F}}$ represent the feature maps; $\mathbf{w}$ and $\mathbf{b}$ denote the weight and bias respectively in fully connected layer.

The parameters of the network are optimized via all kinds of SGD (stochastic gradient decent) algorithms to minimize the loss between prediction $\hat{\mathbf{y}}$ and ground truth label $\tilde{\mathbf{y}}$

$$l(\hat{\mathbf{y}}, \tilde{\mathbf{y}}) = -\sum_{i=1}^{N}\sum_{j=1}^{C} \tilde{\mathbf{y}}_j^i \log(\hat{\mathbf{y}}_j^i), \tag{4}$$

where i, j enumerate the training samples and classes respectively.

2.2 Multi-Task Learning

Multi-task learning model is usually the variant or combination of single-task ones (CNNs, RNNs or DNNs) like the architectures illustrated in Figure 1. Given K text classification tasks $\{T_1, T_2, \cdots, T_K\}$, a multi-task learning model $f(\cdot)$ shall have the ability to make prediction for samples $\mathbf{x}_i^{(k)}$ from each task T_k.

$$\hat{\mathbf{y}}_i^{(k)} = f(\mathbf{x}_i^{(k)}) \tag{5}$$

And the overall loss for all the tasks is usually a linear combination of the costs for each.

$$L = -\sum_{k=1}^{K} \lambda_k \sum_{i=1}^{N_k}\sum_{j=1}^{C_k} \tilde{\mathbf{y}}_{i,j}^{(k)} \log \hat{\mathbf{y}}_{i,j}^{(k)} \tag{6}$$

where λ_k,N_k and C_k denote the weight, number of training samples and class number of task T_k.

3 Capsule Networks for Text

Capsule network (CapsNet) is first proposed by Sabour et al. (2017) for image classification, which is position sensitive and shows strong performance on some classification tasks. As depicted in Figure 2, we propose several capsule networks for text, which are suitable for text representation and multi-task learning. They are comprised of convolutional layer, primary capsule layer and class capsule layer. In the rest of this section, we will first give the formulation of single-task capsule networks (CapsNet-1 and CapsNet-2) for text classification, and then transfer it into a multi-task version (McapsNet).

3.1 Primary Capsule Layer

Given an embedded sample of $\mathbf{x} \in \mathbb{R}^{l \times d}$ with length of l and word vectors of d-dimension, capsule network first employs a plain convolution layer to extract the local features from N-grams. Each kernel $\mathbf{K}_i$ with a bias $\mathbf{b}$ emits a feature maps $\mathbf{F}_i$ by convolution.

$$\mathbf{F}_i = \mathbf{x} * \mathbf{K}_i + \mathbf{b} \tag{7}$$

By assembling I feature maps together, we have a I-channel layer

$$\mathbf{F} = [\mathbf{F}_1, \mathbf{F}_2, \cdots, \mathbf{F}_I] \tag{8}$$

The generated feature maps are then fed into the primary capsule layer, piecing the instantiated parts together via another convolution. Primary capsules use vectors instead of scales to preserve the instantiated parameters for each feature, which can not only represent the intensity of activation but also record some details of the instantiated parts in input. In this way, capsule can be regarded as a short representation of instantiated parts that are detected by kernel.

Sliding over the feature map $\mathbf{F}$, each kernel $\mathbf{K}_j$ would output a series of capsules $p_j \in \mathbb{R}^d$ of d-dimension. These capsules comprise a channel $\mathbf{P}_j$ of primary capsule layer.

$$\mathbf{P}_j = g(\mathbf{K}_j * \mathbf{F} + \mathbf{b}) \tag{9}$$

where g is the nonlinear squash function and b is the capsule bias term. All the J channels can be arranged as

$$\mathbf{P} = [\mathbf{P}_1, \mathbf{P}_2, \cdots, \mathbf{P}_J] \tag{10}$$

3.2 Connection Between Capsule Layers

Capsule network generates the capsules in next layer using "routing-by-agreement". This process takes the place of pooling operation that usually discards the location information, which helps augment the robust of the network and also helps cluster features for prediction.

Between two neighbor layers l and $l + 1$, a "prediction vectors" $\hat{\mathbf{u}}_{j|i}$ is first computed from the capsule $\mathbf{u}_i$ in lower layer l, by multiplying a weight matrix $\mathbf{W}_{ij}$

$$\hat{\mathbf{u}}_{j|i} = \mathbf{W}_{ij}\mathbf{u}_i \tag{11}$$

Then, in the higher layer $l+1$ a capsule $\mathbf{s}_j$ is generated by the linear combination of all the prediction vectors with weights c_{ij}

$$\mathbf{s}_j = \sum_i c_{ij}\mathbf{u}_{j|i} \tag{12}$$

where c_{ij} are coupling coefficients decided by the iterative **dynamic routing** process.

Coupling coefficients are calculated by a "routing softmax" function on original logits b_{ij}, which are the log prior probability that capsule i should be coupled to capsule j.

$$c_{ij} = \frac{\exp(b_{ij})}{\sum_j exp(b_{ij})} \tag{13}$$

This process of "routing softmax" guarantee the sum of all the coefficients for capsule j is 1.

The length of capsule represents the probability that the input sample has the object capsule describes, that is the activation of capsule. So the length of capsule is limited in range $[0, 1]$ with a non-linear squashing function.

$$\mathbf{v}_j = \frac{\|\mathbf{s}_j\|^2}{1 + \|\mathbf{s}_j\|} \frac{\mathbf{s}_j}{\|\mathbf{s}_j\|^2} \tag{14}$$

By that, the short vectors are pushed to shrink to zero length, and long ones are pushed to one.

3.3 Dynamic Routing

Suppose capsule layer l has been generated. We have to decide the intensity of the connections between capsule i and j from l-th layer to $(l + 1)$-th layer, that is the coupling coefficient c_{ij}. The initial digit of coupling coefficient b_{ij} is updated with routing by agreement a_{ij}, which is calculated by a scale product between capsules in two layers.

$$a_{ij} = \hat{\mathbf{u}}_{j|i} \cdot \mathbf{v}_j \tag{15}$$

Value of agreement a_{ij} is added to the digit to calculated the capsules in the next layer.

$$b_{ij} \leftarrow b_{ij} + a_{ij} \tag{16}$$

And the whole process for update (Eq.(13)→(12) →(14)→(15)→(16)) is conducted iteratively to optimize the coupling coefficients and the capsules in the next layer.

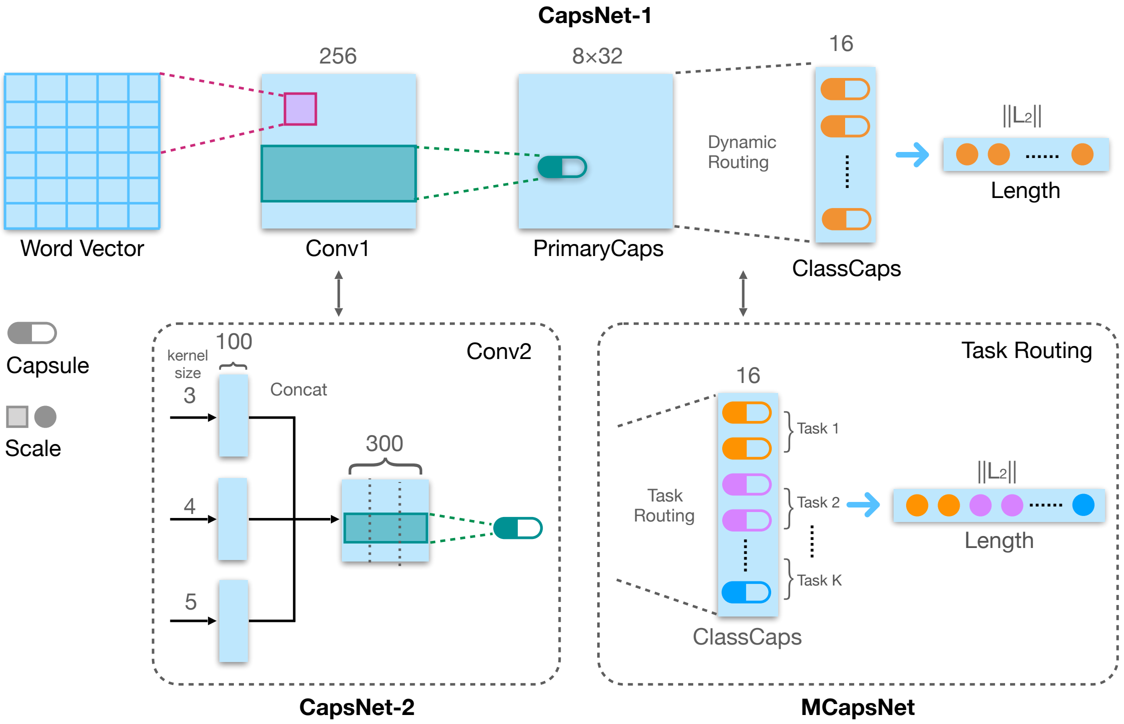

Figure 2: Architectures of capsule networks for text

3.4 Class Capsule Layer and Loss

Class capsule layer, as the top-level layer, is comprised of C class capsules, in which each one corresponds to a category. The length of instantiated parameters in each capsule represents the probability that the input sample belongs to this category, and the direction of each set of instantiated parameters preserves the characteristics of the features, which could be regarded as an encoded vector for the input sample.

Margin Loss To increase the difference between the lengths of classes, CapsNet utilizes a separated margin loss:

$$\begin{aligned} L_j =& G_j \max(0, m^+ - \|\mathbf{v}_j\|)^2 + \\ & \lambda(1-G_j)\max(0, m^- - \|\mathbf{v}_j\|)^2 \end{aligned} \tag{17}$$

where $\mathbf{v}_j$ is the capsule for class j; m^+ and m^- is the top and bottom margins respectively, which help push the length to shrink beyond two margins; $G_j = 1$ if and only if class j is the ground truth:

$$G_j = \begin{cases} 1 & \tilde{\mathbf{y}}_j = 1 \\ 0 & \tilde{\mathbf{y}}_j = 0 \end{cases} \tag{18}$$

λ is the weight for the absent classes, which reduces the weight of absent classes, avoiding shrinking the lengths of all the capsules too much at prophase training. In this paper, λ is set to 0.5.

Orphan Category A drawback of CapsNet is that it tends to account for everything in the input sampling, including some "background" information such as stop word and punctuations that would interfere the prediction. So an orphan category is added in class capsules in the output layer, which belongs to none of the categories of the task. The orphan category would help collect the less contributive capsules that contain too much "background" information, which reduces the interference for normal categories.

3.5 Substitutional Modules for Multi-Task

Task Routing

Dynamic routing algorithm is first proposed by Sabour et al. (2017), which displaces the pooling operation used in conventional convolution neural network. It maintains the position information for features, which is beneficial to both image and text representation. More importantly, this routing-by-agreement method has an ability to cluster the features into each class.

Inspirited by this, we employ this thought to cluster the features for different tasks and propose the **Task Routing** algorithm, which gives a simple and efficient solution to the problem that existing

Algorithm 1 Task Routing Algorithm

```
function ROUTING($\hat{\mathbf{u}}^{(k)}_{j|i}$, $a^{(k)}_{ij}$, $r$, $l$ )
    for $i = 0 \to r$ do
        for all capsule $i$ in layer $l$ and capsule $j$ in task $k$:
            $\mathbf{c}^{(k)}_i = softmax(\mathbf{b}^{(k)}_i)$
        for all capsule $j$ in layer $l + 1$:
            $\mathbf{v}^{(k)}_j = g(\sum_i c^{(k)}_{j|i} \hat{\mathbf{u}}^{(k)}_{j|i})$
        for all capsule $i$ in layer $l$ and capsule $j$ in task $k$:
            $b^{(k)}_{ij} = b^{(k)}_{ij} + a^{(k)}_{ij}$, $a^{(k)}_{ij} = \hat{\mathbf{u}}^{(k)}_{j|i} \cdot \mathbf{v}^{(k)}_j$
    end for
    return $\mathbf{v}^{(k)}_j$
end function
```

MTL models (Liu et al., 2017; Ruder et al., 2017; Fang et al., 2017) want to address: *"What feature should be shared and what should not among tasks?"* By that, network can decide the contribution of the features for each tasks and set the appropriate coupling coefficients between features and tasks.

More concretely, we introduce a coupling coefficient $c^{(k)}_{ij}$ between capsule i in l-th layer and capsule j in class capsule $(l + 1)$-th layer for task k, which is the result of a softmax function on $\mathbf{b}^{(k)}_{ij}$.

$$c^{(k)}_{ij} = softmax(\mathbf{b}^{(k)}_{ij}) \tag{19}$$

Then, instantiated parameter $\mathbf{v}^{(k)}_j$ of capsule j in task k is calculated by

$$\mathbf{v}^{(k)}_j = \sum_i c^{(k)}_{ij} \cdot \hat{\mathbf{u}}^{(k)}_{j|i} \tag{20}$$

where $\hat{\mathbf{u}}^{(k)}_{j|i} = \mathbf{W}_{k,j,i}\mathbf{u}_i$

Coupling coefficient $c^{(k)}_{ij}$ is restricted in range $[0, 1]$, which represents the probability that capsule i belongs to class capsule j in task k. And it is update by the algorithm is described in Algorithm 3.5.

Multi-Task Loss

The loss for each task is the sum of margin losses for all the classes $\sum_{j=1}^{C} L^{(k)}_j$. By linearly combining the loss for every task, we get multi-task loss

$$L = \sum_{k=1}^{K} \beta^{(k)} \sum_{j=1}^{C} L^{(k)}_j. \tag{21}$$

where $\beta^{(k)}$ is the weight for each loss and $\sum_{k=1}^{K} \beta^{(k)} = 1$. In this paper, all the $\beta^{(k)}$ are set to be $1/K$ to make a balance among K tasks.

Multi-Task Training

In order to juggle several tasks in a unified network, following (Collobert and Weston, 2008), each task is trained alternatively in a stochastic manner. The steps can be described as follows: 1. Pick up a task k randomly; 2. Select an arbitrary sample s from the task k; 3. Feed the sample s into the McapsNet and update the parameters; 4. Go back to 1.

3.6 Architectures of CapsNets for Text

As illustrated in Figure 2, we propose a capsule-based multi-task learning architecture McapsNet, which is base on the single-task structures CapsNet-1 and CapsNet-2. Architectures for them are detailed as following.

CapsNet-1 As depicted in Figure 2, CapsNet-1 is a fundamental framework with three layers. The first layer is a plain convolution operation with 256 kernels with window size of 3 and stride of 1. For activation function, we use ReLU to augment non-linearity. This layer helps extract local features from the input sequences, which is the base to construct primary capsules.

Primary capsule layer employs 32 kernels with window size of 3 and stride of 1. The emitted primary capsules are 8-dimensional, which have bigger respective field, helping reassemble the piece features into wholes.

Last one is the class capsule layer, which is comprised of 16-dimensional capsules for the classes. They are connected to PrimaryCaps with routing-by-agreement and the coupling coefficients are updated by dynamic routing algorithm.

CapsNet-2 On this basis of CapsNet-1, CapsNet-2 upgrades the convolutional layer and uses multiple kernel sizes, which enriches the features. And concatenating[1] them up allows primary capsule see the features with different kernel sizes in the same time.

MCapsNet McapsNet is a unified multi-task structure based on CapsNet-2. It replaces the dynamic routing with task routing (Algorithm 3.5), which enables the network to route the features to

each tasks. And the whole network is optimized in a stochastic way with multi-task training (Section 3.5).

Implement Details For word embedding, we use the word vectors in *Word2Vec* (Mikolov et al., 2013), which is 300-dimensional and has 3M vocabularies. And all the routing logits $b_{ij}^{(k)}$ is initialized to zero, so that all the capsules in adjacent layers ($\hat{\mathbf{u}}_{j|i}, \mathbf{v}_j$) are connected with equal possibility c_{ij}. The coupling coefficients are updated by routing with 3 iterations, which performs best for our approach. For training, we use Adam optimizer (Kingma and Ba, 2014) with exponentially decaying learning rate. Moreover, we use mini-batch with size of 8 for all the datasets.

4 Experiment

We test our capsule-based models on six datasets in both single-task and multi-task scenarios to demonstrate the effectiveness of our approaches. We also in this section conduct some investigations like ablation study and visualization to give a comprehensive understanding to the characteristics of our models.

4.1 Datasets

For both single-task and multi-task scenarios, we conduct extensive experiments on six benchmarks: movie reviews (MR) (Bo and Lee, 2005), Stanford Sentiment Treebank (SST-1 and SST-2) (Socher et al., 2013), subjectivity classification (Subj) (Pang et al., 2004), question dataset (TREC) (Li and Roth, 2002), AG's news corpus (Mousa et al., 2017). These datasets cover a wide range of text classification tasks, which can fully test a model and the details are listed in Table 1.

4.2 Competitors

To demonstrate the effectiveness of our capsule network, we compare the single-task architectures with several state-of-the-art models, involving LSTM/BiLSTM (Cho et al., 2014), LSTM regularized by linguistic knowledge (LR-LSTM) (Qian et al., 2016), very deep network (VD-CNN) (Conneau et al., 2016), dynamic CNN (DCNN) (Kalchbrenner et al., 2014), CNN with multiple channels (CNN-MC) (Kim, 2014). Also, we compare the multi-task architecture (Figure 2) with several strong baselines of multi-task learning, including a general architecture for multi-task learning (MT-GRNN) (Zhang et al., 2017), recurrent neural network based multi-task learning (MT-RNN) (Liu et al., 2016), convolutional neural network with multi-task learning (MT-DNN) (Collobert and Weston, 2008), deep neural network with multi-task learning (MT-CNN) (Liu et al., 2015).

4.3 Single-Task Learning Results

We first test our approach on six datasets for text classification under the scheme of single-task. As Table 2 shows, our single-task network enhanced by capsules is already a strong model. CapsNet-1 that has one kernel size obtains the best accuracy on 2 out of 6 datasets, and gets competitive results on the others. And CapsNet-2 with multiple kernel sizes further improves the performance and get best accuracy on 4 datasets. This proves our capsule networks are effective for text. Particularly, our capsule network outperforms conventional CNNs like DCNN, CNN-MC and VD-CNN with a large margin (by average 1.1%, 0.7% and 1.0% respectively), which shows the advantages of capsule network over conventional CNNs for clustering features and leveraging the position information.

Routing Iteration The coupling coefficients c_{ij} are updated by dynamic routing algorithm, which determines the connections between the capsules. To find the best updating iteration for coupling co-

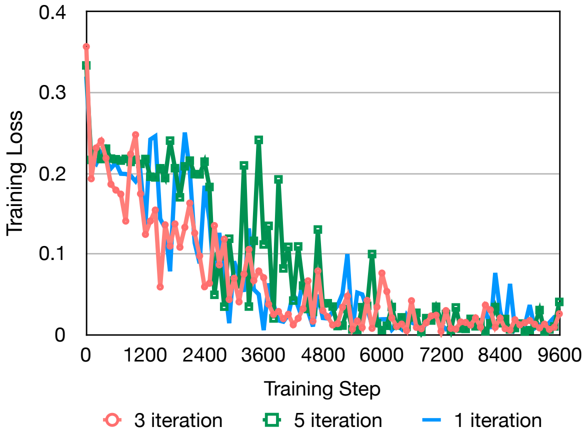

Figure 3: Influence of routing iteration

efficients, we test the CapsNet-2 with a series of iterations (1, 3 and 5) on MR dataset. As shown in Figure 3, network with 3 iterations convergences fast and performs best, which stays in line with the conclusion in (Sabour et al., 2017). So we utilize 3 iterations in all our experiments.

Ablation Study on Orphan Category Orphan category in class capsule layer helps collect the noise capsules that contain the 'background' information like stop words, punctuations or any unrelated words. We conduct the ablation experiment on orphan category, and result (Table 2) shows that network with orphan category perform better than the without one by 0.4%. This demonstrates the effectiveness of orphan category.

4.4 Multi-Task Learning Results

Up to now, we have obtained an optimized single-task architecture. In this section, we equip CapsNet-2 with the *task routing* and multi-task training procedure, namely the model MCapsNet, so that this capsule based architecture can learn several datasets in a unified network. Extensive experiments are conducted in this section to demonstrate the effectiveness of our multi-task learning architecture, as well as its ability for feature clustering.

Multi-Task Performance

We simultaneously train our model McapsNet on six tasks in Table 1 and compare it with single-task scenario (Table 3). We can see that our multi-task architecture clearly improves the performance over the single task models, which demonstrates the benefits of our multi-task architecture.

Dataset	MR	SST-1	SST-2	Subj	TREC	AG's	Avg.△
BiLSTM	79.3	46.2	83.2	90.5	89.6	88.2	+0
MT-GRNN	-	49.2	87.7	89.3	93.8	-	+2.6
MT-RNN	-	49.6	87.9	94.1	91.8	-	+3.5
MT-DNN	82.1	48.1	87.3	93.9	92.2	91.8	+2.9
MT-CNN	81.6	49.0	86.9	93.6	91.8	91.9	+3.0
CapsNet-1	81.5	48.1	86.4	93.3	91.8	91.1	+2.5
CapsNet-2	82.4	48.7	87.8	93.6	92.9	92.3	+3.3
MCapsNet	83.5	49.7	88.6	94.5	94.2	93.8	+4.6

Table 3: Multi-task results of MCapsNet. In column Avg.△, we use BiLSTM as baseline and calculate the average improvements over it.

As Table 3 shows, MCapsNet also outperforms the state-of-the-art multi-task learning models by at least 1.1%. This shows the advantages of our task routing algorithm, which can cluster the features for each task, instead of freely sharing the features among tasks.

4.5 Routing Visualization

To show the mechanism how capsule benefits the multi-task learning, we visualize the coupling coefficient $c_{ij}^{(k)} \in [0, 1]$ between primary and class capsules. We use kernel with size 1 for primary capsule layer so that every capsule represents only one 3-gram phrase. The strength of these connections indicates the importance of these 3-grams to their corresponding task and class.

We feed a random sample from the dataset MR into MCapsNet. In the first row of Table 4, we show the most important 3-gram phrases for two tasks MR and Subj (two classes for each) with word cloud. The sizes of the grams represent the weights of coupling coefficients. We can see that task routing algorithm helps lead the grams into the most related tasks, which allows each task only consider the helpful features for them. In another word, task routing builds a feature space for each task and avoids they contaminate each other. This demonstrates that MCapsNet has the ability of feature clustering, which can benefit MTL by reducing the interference.

We also illustrate the coupling coefficients sequentially for each task. The height of the blue and gray lines represents the polarity of positivity and subjectivity respectively. It is clear that MCapsNet can focus on the appropriate positions for each task, which helps make the final correct predication for every task.

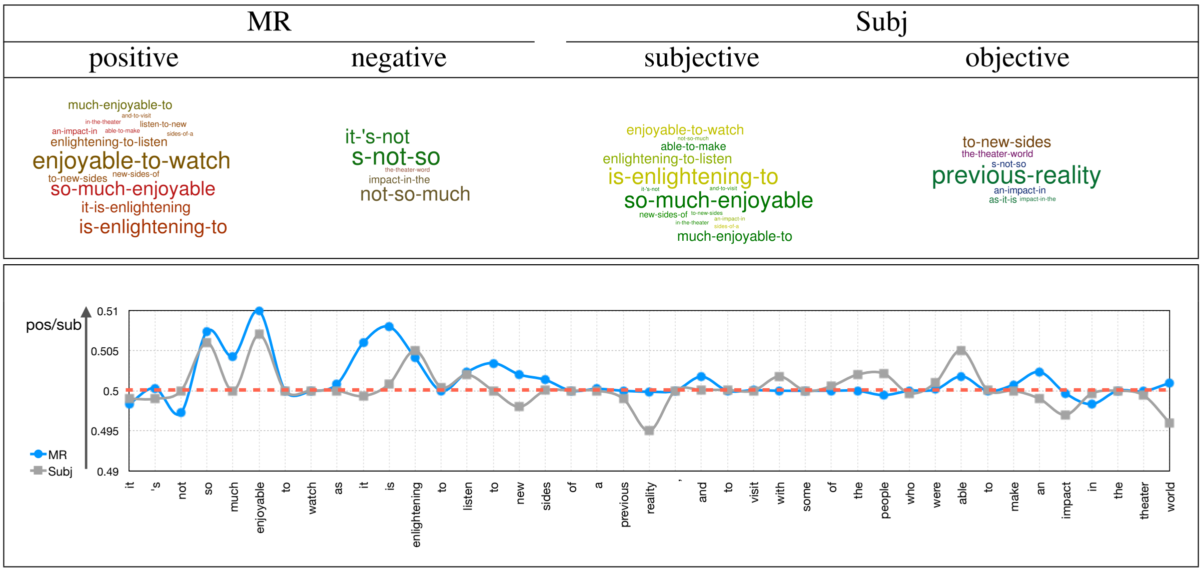

Table 4: Visualization of the task routing for a positive sample from MR, "it 's not so much enjoyable to watch as it is enlightening to listen to new sides of a previous reality , and to visit with some of the people who were able to make an impact in the theater world"

5 Related Work

Related work can be divided into two threads. The first thread is capsule network, which has been proven effective on many classification tasks.

Concept of capsule is first proposed by Hinton et al. (2011), which first use vector to describe the pose of object. This work improves the representation ability of the neural networks against the vanilla CNNs and also enhances the robust of network for transformation. Then dynamic routing algorithm is proposed in (Sabour et al., 2017), which is aimed to displace the pooling operation, building a part-whole relationship for object recognition. Dynamic routing can maintain the position information of features for objects that pooling operations generally discard. And the result shows the proposed method improves the state-of-the-art performance for MNIST dataset. Next, Hinton et al. (2018) employs the matrix to depict the pose and, based on EM algorithm designs a new routing procedure between capsule layers. This work shows strong ability for addressing transformation problem and gains significant improvement on smallNORB dataset.

All these methods are proposed for computer vision, while in this paper we investigate the benefits of capsules for text.

The other thread is about multi-task learning. The earliest idea can be traced back to (Caruana, 1997) and there have been some work completed in this field to augment the performance. Collobert and Weston (2008) develop a multi-task learning model based on CNN. It shares only one lookup table to train a better word embedding. And Liu et al. (2015) propose a DNN-based model for multi-task learning, which shares some low layers but separate the high-level layers to complete several different tasks.

Some models are proposed to share deeper layers of networks, which can exchange high-level knowledge among tasks and gain better performance. (Zhang et al., 2017) and (Liu et al., 2016) introduce some RNN architectures and design different schemes for knowledge sharing. These trials promote the performance of models, but they give no consideration to the interference in multi-task learning. Liu et al. (2017) add the adversarial losses in multi-task RNNs, which can alleviate the interference among tasks by finding a common feature space for tasks. However, the model has multiple subnets and various losses, which requires more computation and training skills.

Different from these methods, we use the thought of capsule in natural language processing (NLP) field. And proposed a capsule based multi-task learning architecture with task routing algorithm. This approach can cluster the features for each task, reducing the interference among them.

6 Conclusion and Future Work

This paper investigates the performance of capsule network for text representation, and proposes several effective architectures. By means of the characteristics of capsule network, we design a unified, sample yet effective architecture with task routing for multi-task learning, which has the ability to clustering the features, building a private feature space for every task.

In future work, we would like to investigate the relations of various tasks in multi-task learning by exploiting the potential of capsule network.

Uncertainty-aware generative models for inferring document class prevalence

Katherine A. Keith and **Brendan O'Connor**
College of Information and Computer Sciences
University of Massachusetts Amherst
`{kkeith,brenocon}@cs.umass.edu`

Abstract

Prevalence estimation is the task of inferring the relative frequency of classes of unlabeled examples in a group—for example, the proportion of a document collection with positive sentiment. Previous work has focused on aggregating and adjusting discriminative individual classifiers to obtain prevalence point estimates. But imperfect classifier accuracy ought to be reflected in uncertainty over the predicted prevalence for scientifically valid inference. In this work, we present (1) a generative probabilistic modeling approach to prevalence estimation, and (2) the construction and evaluation of prevalence confidence intervals; in particular, we demonstrate that an off-the-shelf discriminative classifier can be given a *generative re-interpretation*, by backing out an implicit individual-level likelihood function, which can be used to conduct fast and simple group-level Bayesian inference. Empirically, we demonstrate our approach provides better confidence interval coverage than an alternative, and is dramatically more robust to shifts in the class prior between training and testing.[1]

1 Introduction

The goal of *prevalence estimation* is to infer the relative frequency of classes y_i associated with unlabeled examples (e.g. documents) from a group, $x_i \in \mathcal{D}$. For example, one might want to estimate the proportion of blogs with a positive sentiment towards a political candidate (Hopkins and King, 2010), sentiment of responses to natural disasters on social media (Mandel et al., 2012), or prevalence of car types in street photos to infer neighborhood demographics (Gebru et al., 2017). Often, an analyst wants to compare prevalence between multiple groups, such as inferring prevalence variation over time (e.g., changes to online abuse content (Bissias et al., 2016)), or across other covariates (e.g., changes in police officers' "respect" when speaking to minorities (Voigt et al., 2017)). This problem has been re-introduced in many different fields: as "quantification" in data mining (Forman, 2005, 2008), "prevalence estimation" in statistics and epidemiology (Gart and Buck, 1966), and "class prior estimation" in machine learning (Vucetic and Obradovic, 2001; Saerens et al., 2002). In NLP, SemEval 2016 and 2017 included Twitter sentiment class prevalence tasks (Nakov et al., 2016; Rosenthal et al., 2017).

Prevalence estimation assumes access to a (potentially small) set of labeled examples to train a classifier; but unlike the task of individual classification, the goal is to estimate the proportion of a class among examples in a group. If a perfectly accurate classifier is available, it is trivial to construct a perfect prevalence estimate by counting the classification decisions (§3.1). In fact, most application papers in the previous paragraph use this or a similar aggregation rule to conduct their prevalence estimates. However, classifiers often exhibit errors from different sources, including:

- Shifts in the class distribution from training to testing ($P_{train}(y) \neq P_{test}(y)$). A classifier may be biased toward predicting $P_{train}(y)$.
- Difficult classification tasks (such as predicting sentiment or sarcasm) that result in low accuracy classifiers; this can be exacerbated by limited training data, as is common in social science or industry settings that require manual human annotation for labels.

It is typically assumed (and sometimes confirmed) that when an individual classifier has less than 100% accuracy, it can still give reasonable preva-

Brussels, Belgium, October 31 - November 4, 2018.

lence estimates.[2] However, there is relatively little understanding to what extent the quality of the document-level model impacts prevalence estimates. Imperfect classifier accuracy ought to be reflected in uncertainty over the predicted prevalence.

In this work, we tackle both of these challenges simultaneously, using a generative probabilistic modeling approach to prevalence estimation. This model directly parameterizes and conducts inference for the unknown prevalence, naturally accommodating shifts between training and testing, and also allows us to infer confidence intervals for the prevalence. We show that our best model can be seen as an *implicit likelihood* generative re-interpretation of an off-the-shelf discriminative classifier (§4.2); this unifies it with previous work, and also is easy for a practitioner to apply.

We additionally review several types of class prevalence estimators from the literature (§3), and conduct a robust empirical evaluation on sentiment analysis over hundreds of document groups, illustrating the methods' biases and robustness to class prior shift between training and testing. Our method provides better confidence interval coverage and is more robust to class prior shift than previous methods, and is substantially more accurate than an algorithm in widespread use in political science.

2 Problem definition

We consider two prevalence estimation problems: (1) point prediction and (2) confidence interval prediction. In this work, we are most interested in supervised learning for discrete-valued document labels, with access to a small to moderate number (e.g. around 1000) of labeled documents with text x and label y: $(x_i, y_i) \in \mathcal{D}^{train}$. We restrict attention to binary-valued labels $y \in \{0, 1\}$. At test time, there are one or more groups of unlabeled test documents, $\mathcal{D}^{(1)}, \cdots, \mathcal{D}^{(G)}$; for example, one group might be a set of tweets sent during a certain month, or a set of online reviews associated with a particular product. For each group $\mathcal{D}$, let $\theta^* \equiv (1/n) \sum_i^n y_i$ be the true proportion of positive labels (where $n = |\mathcal{D}|$).

The *prevalence point prediction* problem is to take an unlabeled document group $\mathcal{D}$ as input and infer an estimated $\hat{\theta} \in [0, 1]$. Ideally, this point estimate should be close to the true prevalence θ^*; we evaluate this by mean absolute error.

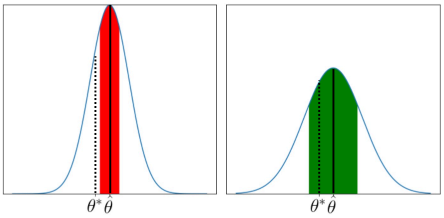

Figure 1: Example posterior distributions with MAP prevalence estimates, $\hat{\theta}$ (solid line) and the true prevalence, θ^* (dashed line). A desirable property is that confidence intervals, technically Bayesian credible intervals, (shaded regions) will be wider for more uncertain models. For example, the wider CI on the right (green) contains θ^* whereas the narrower CI interval on the left (red) does not.

In this work, we are the first (that we know of) to introduce the question of *uncertainty* in prevalence estimation. Since document classifiers are typically far from perfectly accurate, we should expect substantial error in prevalence prediction, and inference methods should quantify such uncertainty. We formalize this as a *prevalence confidence interval* (CI) inference, which takes as input a desired nominal coverage level $(1 - \alpha)$, and predicts a real-valued interval $[\hat{\theta}_{lo}, \hat{\theta}_{hi}] \subseteq [0, 1]$. Ideally, a CI prediction algorithm should have frequentist coverage semantics: over a large number of test groups,[3] $(1-\alpha)\%$ of the predicted intervals ought to contain the true value θ^*. If the problem is hard—for example, the relationship between document features and the label is not captured well by the model—the CI should be wide. We empirically evaluate coverage of CI-aware prevalence inference models. See Fig. 1 for an intuitive example.

3 Review and baselines: Discriminative individual classification aggregation

The most straightforward baseline approach to prevalence estimation is to build on discriminative, supervised learning for individual-level labels, such as binary logistic regression with bag-of-words features, randomized feature hashing

---

[2] For example, Bissias et al. find a relative mean absolute error of less than 0.01 when the individual classifier has ROC AUC of 0.91.

[3] Or in fact, across many experiments in which the model or algorithm is applied (Wasserman, 2011).

(Weinberger et al., 2009), or neural networks (Goldberg, 2016). Such a model defines an individual document's label probability $p_i \equiv p_\beta(y_i = 1 \mid x_i)$ where parameters β are fit by maximizing regularized likelihood on the labeled training data.

3.1 Classify and Count (CC)

For prevalence point estimation, Forman (2005) defines the "classify and count" (CC) method as simply averaging the most-likely individual label predictions,

$$\hat{\theta}^{CC} = \frac{1}{n} \sum_i 1\{p_i > 0.5\}. \tag{1}$$

This is the most obvious approach for practitioners, but it has at least two weaknesses, which have been addressed in different groups of prior work. First, the class proportions may change between training and test groups, which the Adjusted CC and ReadMe algorithms attempt to fix (§3.2–3.3). Second, it discards probabilistic information, which is remedied by the Probabilistic CC method, and an extension we propose (§3.4–3.5).

3.2 Adjusted Classify and Count (ACC)

CC may encounter problems if the test class distribution is different than the training's. The "adjusted classify-and-count" method (Gart and Buck, 1966; Forman, 2005) treats the classifier output as a proxy variable, and estimates a separate confusion model of classifier output $\hat{y}_i \equiv 1\{p_i > 0.5\}$ conditional on the true label, $p(\hat{y} \mid y)$, from cross-validation within the training set. Assuming the confusion model extends to the test data, a moment-matching approach is then used to infer the true label proportions, by first observing $p_{test}(\hat{y}) = \sum_y p(\hat{y} \mid y) p_{test}(y)$ and solving the linear system for $p_{test}(y)$, the test-time expected class prevalence. Using empirical estimates for the true positive rate TPR $= p(\hat{y} = 1 \mid y = 1)$, and false positive rate FPR $= p(\hat{y} = 1 \mid y = 0)$, and $\hat{\theta}^{CC} = p(\hat{y} = 1)$, it has the closed form

$$\hat{\theta}^{ACC} = \frac{\hat{\theta}^{CC} - \text{FPR}}{\text{TPR} - \text{FPR}}. \tag{2}$$

By design, ACC is more robust to a new test-time prevalence, but it relies on the accuracy of its TPR and FPR estimates, and its lack of probabilistic semantics makes it unclear how to infer confidence intervals.

3.3 ReadMe algorithm

An interesting extension to ACC is to remove the need for a discriminative classifier, by directly modeling text conditional on the latent document class. The ReadMe algorithm, developed in political science (Hopkins and King, 2010), extends ACC's linear system for every term type in a (subsampled and augmented) term vocabulary $\mathcal{V}$, and calculates their class-conditional probabilities from the training data. Assuming these conditional models also hold in the test data, that implies $p_{test}(w) = \sum_y \hat{p}(w \mid y) p_{test}(y)$; the algorithm infers $p_{test}(y)$ by minimizing the squared error of predicted versus empirical term frequencies in the test set. The open-source ReadMe software package[4] has been used in numerous political science studies, including inferring proportions of types of censored Chinese news (King et al., 2013), credit claiming in Congressional press releases (Grimmer et al., 2012), and voter intentions among Twitter messages (Ceron et al., 2015).

ReadMe is theoretically appealing in that it infers latent class prevalences to explain the test group's textual evidence; but as a non-probabilistic model, it does not directly imply a method for confidence intervals (Hopkins and King use the bootstrap). Furthermore, our experiments (§5), contra the original paper, show its implementation exhibits poor performance.

3.4 Probabilistic Classify and Count (PCC)

Both the CC and ACC methods discard uncertainty information from the classification model. In a difficult classification setting, for example, we might expect many probabilities to be near, say, 0.6, in which case the CC method may undercount the negative class. This suggests an alternative method, "probabilistic classify and count" (PCC):

$$\hat{\theta}^{PCC} = \frac{1}{n} \sum_i p_i \tag{3}$$

which is the expected prevalence, $(1/n) \sum_i y_i$, assuming each y_i is distributed according to the original probabilistic classifier.

3.5 PCC Poisson-Binomial distribution (PB-PCC)

If we assume each y_i is conditionally independent given text x_i and model parameters β, this

---

[4] `https://gking.harvard.edu/readme`

defines a fully probabilistic model for the class prevalence. Let the latent variable $S = \sum_i y_i$; its distribution is thus Poisson-Binomial (Chen and Liu, 1997). The modeled prevalence distribution $p(\frac{S}{n} \mid \mathcal{D})$ can be exactly inferred by Monte Carlo inference: each iteration samples every y_i and sums for an S sample. The S/n distribution over many iterations can be used to construct a Monte Carlo CDF $\hat{F}$, from which any $[\hat{F}(t), \hat{F}(t+1-\alpha)]$ is an $(1-\alpha)$-sized credible interval (where $0 \leq t \leq t+1-\alpha \leq 1$). This model has prevalence expectation $E[\frac{S}{n}] = \hat{\theta}^{PCC}$, and variance

$$\text{Var}\left[\frac{S}{n}\right] = \frac{1}{n^2}\sum_i p_i(1-p_i). \tag{4}$$

To a certain degree, this model captures uncertainty in the classifier since per-document variance, $p_i(1-p_i)$, is high when $p_i = 0.5$ and low when near 0 or 1. However, it also has a major weakness—the variance concentrates with a large test group size n, which is the wrong behavior when a classifier is truly noisy, for example, when a classifier is genuinely uncertain and predicts the same constant $p_i = q$ for each document. In this case, the correct behavior would be to maintain a flat, wide posterior belief about θ, which is better accomplished by the generative model we introduce in the subsequent section.

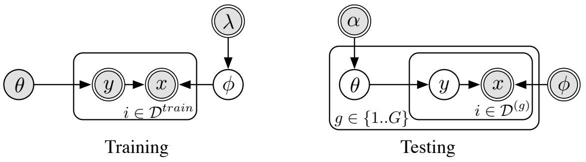
4 Our approach: generative probabilistic modeling

We turn to generative modeling, that seeks to to jointly model the probability of labels and text in both the training and test groups, by assuming a document's text is generated conditional on the document label. Language models have widespread use in natural language processing, and class-conditional models have been used for document classification (e.g. multinomial Naive Bayes; McCallum and Nigam (1998)). We use a similar generative setup to explicitly model a class prevalence for test group g, with a generative story for each (bag-of-words) document i in the group:

$$\theta_g \sim \text{Dist}(\alpha) \tag{5}$$

$$y_{i,g} \sim \text{Bernoulli}(\theta_g) \tag{6}$$

$$x_{i,g} \sim \text{Multinomial}(\phi_{y_{i,g}}) \tag{7}$$



Training Testing

Figure 2: Our generative model for prevalence estimation. **Left:** Class-conditional language models (ϕ) are learned at training time. **Right:** Test-time inference for multiple groups' latent prevalences (θ).

The test group is assumed to have a latent class prior θ_g, which itself has a prior distribution (we assume $\text{Dist}(\alpha) = \text{Unif}(0,1)$ in this work). For each class k, ϕ_k is a class-conditional unigram language model, which is learned from the training data but fixed at test time. We then perform inference to find θ_g that gives a high probability to text data $\{x_i \in \mathcal{D}^{(g)}\}$. Figure 2 shows the probabilistic graphical model.

4.1 MNB and Loglin language models

We experiment with two explicit language models in this generative framework: (1) multinomial Naive Bayes (**MNB**), using a training-time symmetric Dirichlet prior $\phi_y \sim \text{Dir}(\lambda/V)$ for vocabulary size V and "pseudocount" λ, and (2) an additive log linear model (**Loglin**, a.k.a. SAGE (Eisenstein et al., 2011)). Loglin estimates words' probabilities as deviations from a background log-probability m,

$$\eta_{y,w} \sim \text{Laplace}(\lambda) \tag{8}$$

$$\phi_{y,w} = \exp(m_w + \eta_{y,w}) / \sum_j \exp(m_j + \eta_{y,j})$$

where m_w is the empirical log probability of a word w among all training documents, and $\eta_{y,w}$ denotes class-specific deviations of the log-probability of a word w, MAP estimated under a sparsity-inducing L1 penalty. Such sparse additive models have been used in both supervised and unsupervised document modeling; for example, as a document-level posterior classifier it outperforms MNB (Eisenstein et al., 2011), or even discriminative models (Taddy, 2013), and its sparsity helps interpretability for analyzing political, literary, and legal texts (Monroe et al., 2008; Sim et al., 2013; Bamman et al., 2014; Wang et al., 2012).

4.2 Implicit likelihoods from discriminative classifiers (LR-Implicit)

This generative formulation has a major advantage over the discriminative, CC-style aggregation models because it sets up a likelihood and posterior distribution over θ. But in terms of document modeling for classification purposes, the independence assumptions of the generative model are typically too strong, and for document-level classification, discriminative models tend to outperform similarly parameterized generative ones, especially when the training set is sufficiently large (Ng and Jordan, 2002). Thus, discriminative models may have information better suited to class prevalence inference. Also, since the most common practice for document classification is to use discriminative models, it would be helpful to more effectively use discriminative posteriors within our generative context.

In Naive Bayes-style generative document classification, the model defines $p_{gen}(x \mid y)$ and class prior $p(y)$, which are combined to calculate the posterior $p_{gen}(y \mid x) \propto p_{gen}(x \mid y)p(y)$. Discriminative models, by contrast, directly define a $p_{disc}(y \mid x)$. We can, however, expand this quantity via Bayes Rule:

$$p_{\text{disc}}(y \mid x) = p_{\text{implicit}'}(x \mid y) p_{\text{train}}(y)/p(x). \quad (9)$$

The "implicit document likelihood" $p_{\text{implicit}'}(x \mid y)$ is a likelihood function that, combined with a particular class prior $p(y)$, would have resulted in the same posterior predicted by the discriminative model. Given the discriminative posterior predictions and the training-time class prior $p_{\text{train}}(y) = \hat{\theta}_{\text{train}}$, an implicit likelihood function can be backed out for any particular document x; we define the "simple implicit" likelihood for document x to be:

$$p_{\text{implicit}}(x \mid y) = p_{\text{disc}}(y \mid x)/\hat{\theta}_{\text{train}}. \quad (10)$$

This takes the form of a correction of the discriminative posterior, by dividing out the training-time class prevalence.[5]

Our **LR-Implicit** generative model uses the same class prevalence and document label generation setup as before, but to calculate the individual documents' $p(x \mid y)$ probabilities, it uses p_{implicit} based on a logistic regression p_{disc}.[6]

This model is inspired by Saerens et al. (2002)'s EM algorithm for adjusting a classifier for a test set's class prior; they derive it differently by applying the assumption $p_{\text{train}}(x \mid y) = p_{\text{test}}(x \mid y)$, expanding each side with Bayes' Rule, solving for $p_{\text{test}}(y \mid x)$, then estimating $p_{\text{test}}(y)$ via EM. This in fact optimizes the same marginal likelihood function in the next section under the implicit-discriminative generative model; our formulation broadens it as a fully Bayesian or likelihood-based model.

4.3 Inference

To estimate class prevalence, we use the marginal log likelihood over θ to obtain a posterior over θ. For each each test group g, we have the marginal log probability of all document texts,

$$\begin{aligned} \text{MLL}_g(\theta) &\equiv \log p(\mathcal{D}^{(g)} \mid \theta) \quad (11) \\ &= \sum_{i \in \mathcal{D}^{(g)}} \log \sum_{y \in \{0,1\}} p(x_i, y_i = y \mid \theta) \\ &= \sum_{i \in \mathcal{D}^{(g)}} \log \left(\theta L_i^+ + (1-\theta) L_i^- \right), \end{aligned}$$

where we denote the class-conditional document text likelihoods $L_i^+ \equiv p(x_i \mid y_i = 1)$ and $L_i^- \equiv p(x_i \mid y_i = 0)$. The gradient for an individual document is $(L_i^+ - L_i^-)/(\theta L_i^+ + (1-\theta)L_i^-)$; intuitively, the sign of the numerator says that documents that are more likely under the positive than negative class encourage higher likelihood for larger values of θ. When the model is uncertain about a document—that is, when $L_i^+ \approx L_i^-$—that document contributes a relatively flat likelihood curve, expressing little preference for likely values of θ. If a model is more heavily regularized—for example, when the log-linear additive model is more dominated by the background language model—this condition tends to hold for the documents, leading to a flat, highly uncertain likelihood curve.

The marginal log likelihood is unimodal over $\theta \in [0,1]$, since it is concave, being a sum of concave log-linear functions, and having negative curvature:

$$\frac{\partial^2 \text{MLL}_g}{\partial \theta^2} = - \sum_{i \in \mathcal{D}^{(g)}} \left(\frac{L_i^+ - L_i^-}{\theta L_i^+ + (1-\theta)L_i^-} \right)^2. \quad (12)$$

Since it is concave and there is only one parameter, a very wide variety of techniques could be

---

[5] Technically, $p_{\text{implicit}'}$ is retrievable only up to a constant, and p_{implicit} is one particular compatible implicit likelihood, since it can be multiplied by any constant and is still consistent with Eq. 9, and would give rise to the same document- and group-level posteriors.

[6] The implicit likelihood still has the form of a logistic regression, adjusting its bias term: if $p_{\text{disc}}(y \mid x) = \sigma(\beta' x + \beta_0)$, then $p_{\text{implicit}}(x \mid y) = \sigma(\beta' x + \beta_0 - \log(\theta_{\text{train}}/(1-\theta_{\text{train}})))$.

used to reliably find a mode, including EM or first- or second-order methods. At least two approaches to inferring confidence intervals are possible. One is to use a central limit theorem-style approximation, assuming the sampling distribution is approximated by a normal with mean θ^{MLE} and variance $-[\partial^2 \text{MLL}_g / \partial\theta^2]^{-1}$. The second, which we focus on, is Bayesian estimation for $\log p(\theta_g \mid \mathcal{D}^{(g)}) \propto \log p(\theta_g) + \text{MLL}_g(\theta_g)$ by simply using a grid search over values $\theta \in \{0.001, 0.002, ...0.999\}$ to infer both the posterior mode θ^{MAP} as well as a 90% highest posterior density interval.[7] In small-scale experiments, this model had very similar results to the central limit theorem (with EM for θ^{MLE}).

5 Experiments

5.1 Data

In order to compare document class prevalence estimators, we desire datasets that (1) have natural document groups that correspond to realistic, real-world applications, (2) have a large number of test groups (hundreds or more), and (3) are freely available for academic research. It has been a challenge to fulfill these criteria in previous work. Nakov et al. (2016) conduct large-scale manual annotation of Twitter sentiment for SemEval 2016 Task 4, with topic-based test groups; unfortunately, redistribution is restricted to message IDs, making the original dataset difficult to reconstruct under Twitter's terms of service if messages have since been deleted. Bella et al. (2010) and Esuli and Sebastiani (2015) use large, pre-existing labeled document corpora, but they do not contain natural groups; evaluations utilize randomly sampled synthetic groups.

To better fulfill these criteria, we select the task of business review sentiment prevalence, where the goal is to estimate the proportion of reviews that are positive for one particular business; specifically, we use labeled data from the Yelp Dataset Challenge Round Nine[8] corpus, which consists of 4.1M reviews by 1M users for 144K businesses. We sample 500 businesses with at least 200 reviews each as the test groups. We treat the task as binary classification, and assign $y_i = 1$ to reviews with 3 or more stars. This task seems reasonably representative of real-world sentiment analysis problems, and this type of dataset can easily be collected and reproduced from Yelp or other widely available review data.

For training, we simulate a small-scale annotation project by sampling 2000 labeled documents from the rest of the corpus. This is a **natural** prevalence that on average is about the same as the test groups, though individual test groups may have a much different prevalence (ranging from 0.096 to 0.997, mean (stdev) 0.823 (0.136)). We also construct a **synthetic** training setting with a highly skewed class prior, selecting 2000 documents with a 0.1 class prevalence (i.e. 200 positive documents in the group). In each case, for every model, we re-run and average results over 10 different samples of the training set. For preprocessing, we tokenize with NLTK[9] and lowercase.

5.2 Model training

We use L1 regularization for logistic regression based on the vector of a documents' word counts, to be most directly comparable to the generative models; for each model, we select its hyperparameter (LR and Loglin's λ, or MNB's pseudocount) by minimizing cross-validated cross-entropy of individual document posteriors (within the labeled training set), over a grid search of powers of 2. The log-linear additive model is trained with OWL-QN (Andrew and Gao, 2007)[10] and the logistic regression model is trained with the default implementation in scikit-learn (Pedregosa et al., 2011).[11] We used ReadMe with its default parameters.[12]

5.3 Results

For each of the 500 test groups, we calculate a prevalence point estimate $\hat{\theta}$ with each method, and evaluate by averaging across groups for mean absolute error $\sum_g |\hat{\theta}_g - \theta^*_g|$ and bias $\sum_g (\hat{\theta}_g - \theta^*_g)$.[13] For the models that allow for confidence interval

---

[7] Since we use a uniform prior, this is just the MLE. Technically, we used a prior of Beta(1.0001, 1.0001) to avoid certain issues with tie-breaking, but it was not necessary.

[11] Version 0.18.2

[12] Version 0.99837 from `https://gking.harvard.edu/readme`, with default parameters features=15, n.subset=300, prob.wt=1. We bypass the ReadMe software's text preprocessing pipeline, and instead have it use nearly the same document-term matrices as the other models. Since it only handles binary document-term matrices, we transformed counts to indicators; with other models this change only made a minor difference in results.

[13] For the generative (MLL) models, $\hat{\theta}$ is the MAP estimate; the posterior mean gives similar results.

Table 1: Mean absolute error (MAE), bias, nominal 90% confidence interval coverage, and average CI width for the 500 Yelp data test groups, averaged over 10 simulations of resampled training (2000 document) sets. We examine both the natural positive class training prevalence ($E[\theta_{train}] = 0.7783$), and a synthetic fixed prevalence of 0.1. Dashes indicate the methods that are not able to calculate confidence intervals.

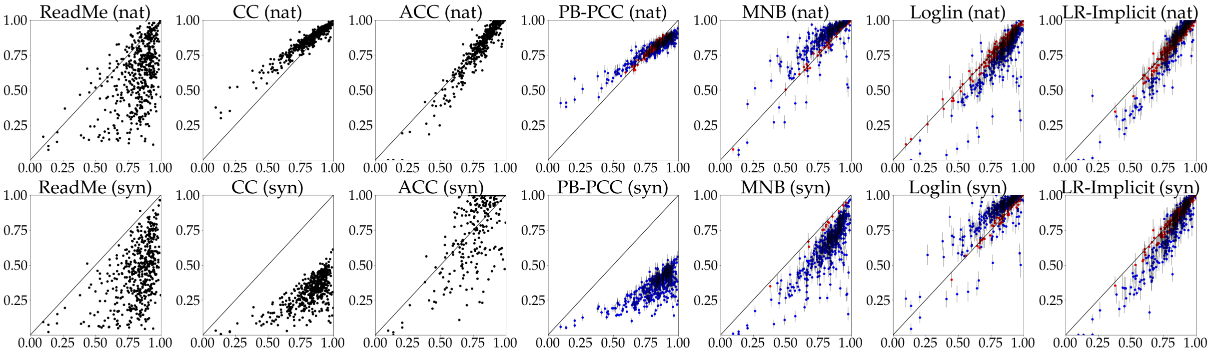

Figure 3: Gold prevalence θ^* (x-axis) versus predicted prevalence $\hat{\theta}$ (y-axis) for each of the 500 test groups with **natural** (nat) training prevalence (top row) and **synthetic** (syn) 0.1 training prevalence (bottom row). A black $y = x$ line is plotted for visualization. For the models that allow for confidence intervals, 90% CIs for each group are given by the faint grey lines. Blue dots indicate the CI does not contain θ^* and red dots indicate the CI does contain θ^*. For each setting, we show the the model with median MAE across training resamplings.

prediction, we infer 90% intervals and calculate coverage, which is best if it is 0.90. We also report average CI width; a narrower interval indicates more confidence (even if misplaced). Results are in Table 1; every result is averaged over 10 resamplings of the training set.

The ReadMe software did not have competitive performance; we hope in follow-up work to understand why Hopkins and King found it had considerably stronger performance than SVM-based CC.

For the natural training class prevalence setting (first column, Table 1), the discriminative-based models (CC, PCC and the adjusted variants ACC and LR-Implicit) all have very similar point estimate performance, outperforming the purely generative models (MNB and Loglin). For CI coverage, the log-linear and LR-Implicit generative models have significantly better coverage than the discriminative model (PB-PCC) or MNB. Future work is required to improve coverage to be closer to the nominal ideal of 90%.

By contrast, when the class prevalences are mismatched (second column, Table 1), the non-adjusted CC and PCC methods give extremely poor and biased point estimates, and PB-PCC has incredibly poor CI coverage. ACC and the generative models do much better, presumably because their models directly allow for variability in the test class prior. While Loglin has somewhat higher coverage in this setting, overall, LR-Implicit has

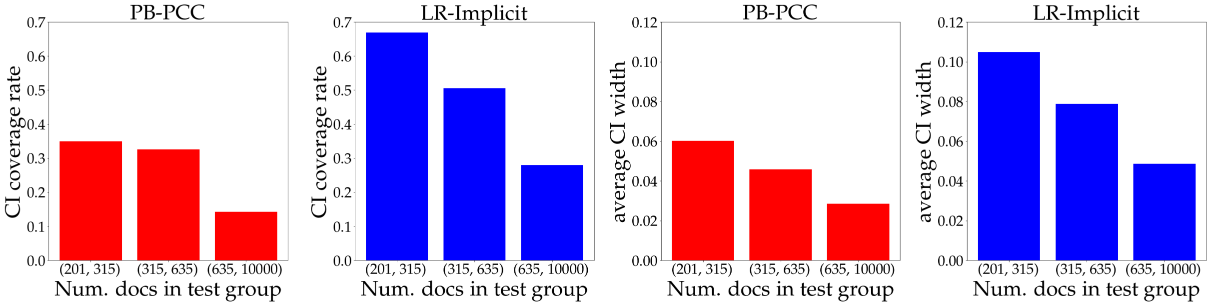

Figure 4: CI coverage rate (left two graphs) and average CI width (right two graphs) for three bins of the test groups, binned by number of documents.

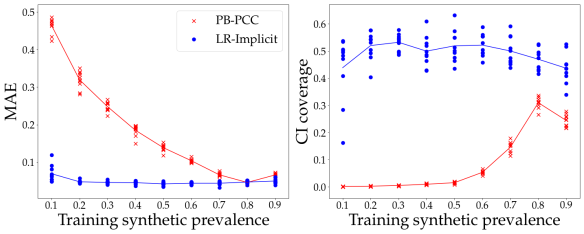
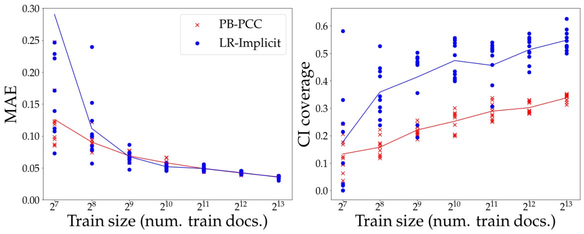


(a) Varying training prevalence



(b) Varying training size

Figure 5: MAE and 90% CI coverage for PB-PCC while varying **(a)** training prevalence (the proportion of the 2000 training documents with positive reviews) and **(b)** training size (number of documents in the training data) with natural prevalence. Lines are the averages over 10 resamplings of training sets and points represent one resampling.

consistently strong performance in both training settings, and for both point estimation and (relatively, at leas) confidence intervals.

Figure 3 shows θ^* versus $\hat{\theta}$ for each of the 500 test groups for each of the models, including predicted CIs. CC's and PCC's erroneous assumptions are directly viewable: in the natural prevalence setting, the slope shallower than 1, indicating a persistent under-sensitivity to the true class prevalence—unlike ACC and the generative models. In the synthetic training case, CC and PCC wildly underpredict, presumably because they are biased by the low training-time prevalence $\theta_{\text{train}} = 0.1$.

5.4 Comparison of PB-PCC and LR-Implicit

Since PB-PCC and LR-Implicit represent the strongest members of non-adjusted classification aggregation and generative modeling, respectively, we further compare their results. When varying synthetic training prevalence across 0.1 to 0.9 (Figure 5a), LR-Implicit has much better MAE in all settings except near the natural prevalence (the test groups have, on average, 0.82 positive prevalence), and consistently stronger CI coverage.

Figure 5b shows results for natural class prevalence when varying the training set size. Unfortunately, LR-Implicit is disadvantaged at very small test sizes—its MAE is higher when there are only a few hundred training documents ($\leq 2^8 = 256$), though performance converges after that. We suspect this may occur because, when textual evidence is weak, the classifier learns to more heavily rely on its bias term, which can be a useful form of bias when the training class prevalence matches the test groups (on average). However, at all levels, LR-Implicit's coverage is better.

Since we hypothesized that PB-PCC may be overconfident for large test groups (§3.5), we test this by binning test groups by the number of documents per group. Figure 4 confirms that PB-PCC exhibits overconfidence for larger groups (smaller CI width alongside lower CI coverage), but LR-Implicit suffers from the same problem as well.

6 Additional Related Work

González et al. (2017a) reviews the class prevalence estimation literature, and we note a few threads of work here. Bella et al. (2010) propose a probabilistic variant of ACC, and Esuli and Sebastiani (2015) compare many methods on news article topics (RCV1) and medical record subject heading (OHSUMED-S) class prevalence tasks, finding varying results among CC, ACC, and PCC. A number of other empirical evaluations were conducted in two SemEval Twitter sentiment prevalence shared tasks, with varying results among these and other methods with a range of classifiers (Nakov et al., 2016; Rosenthal et al., 2017); Nakov et al. note that CC was often one of the strongest methods. Esuli and Sebastiani as well as Xue and Weiss (2009) present semi-supervised loss-augmented classifier training methods to improve prevalence estimation. Tasche (2017) presents theoretical results for ACC and Saerens et al.'s EM method (what we call the LR-Implicit MLE), arguing they correctly predict θ^* under class prior shift; we confirm that those two methods are indeed better than many alternatives in our empirical evaluation. While we focus on inference of the test-time class prior as a class prevalence estimate, Saerens et al. (2002) also show their method can improve individual-level classification accuracy, which Sulc and Matas (2018) use for image classification. (From the viewpoint of individual classification, this phenomenon is known as prior probability shift (Moreno-Torres et al., 2012).) González et al. (2017b) and Card and Smith (2018), similarly to our results, find that CC is much poorer than ACC under class shift. Card and Smith also show that PCC can be sensitive to properties of the classifier, finding that well-calibrated classifiers can give strong performance. They argue that discriminative aggregation models are appropriate for tasks where humans respond to text. Jerzak et al. (2018) analyze issues in class prevalence estimation and propose the ReadMe2 algorithm, which adds external word embeddings, optimization-based dimension reduction, and similarity matching to ReadMe's moment-matching framework.

7 Conclusion

Document class prevalence estimation is a widespread and much understudied task. We show that simple and obvious classifier aggregation methods display consistent biases, especially under class prior shift. Given how widely some of the less effective methods are used, machine learning and natural language processing research could have real impact in this space.

We also call attention to the need for *uncertainty aware* inference—methods that give confidence intervals to summarize their uncertainty. While our method is a first step, future work is necessary to better understand the problem and develop methods with improved coverage. Also, our framework can accommodate a wide array of document and language models—while we focus on bag-of-words models, recent advances in sequence, neural, and attention-based document models could be added directly to our generative model, or used as a discriminative-implicit component. The overall framework could also be extended to multiclass, and potentially, structured prediction settings.

Abstract

Causal understanding is essential for many kinds of decision-making, but causal inference from observational data has typically only been applied to structured, low-dimensional datasets. While text classifiers produce low-dimensional outputs, their use in causal inference has not previously been studied. To facilitate causal analyses based on language data, we consider the role that text classifiers can play in causal inference through established modeling mechanisms from the causality literature on missing data and measurement error. We demonstrate how to conduct causal analyses using text classifiers on simulated and Yelp data, and discuss the opportunities and challenges of future work that uses text data in causal inference.

1 Introduction

Most scientific analyses, in domains from economics to medicine, focus on low-dimensional structured data. Many such domains also have unstructured text data; advances in natural language processing (NLP) have led to an increased interest in incorporating language data into scientific analyses. While language is inherently unstructured and high dimensional, NLP systems can be used to process raw text to produce structured variables. For example, work on identifying undiagnosed side effects from electronic health records (EHR) uses text classifiers to produce clinical variables from the raw text (Hazlehurst et al., 2009).

NLP tools may also benefit the study of causal inference, which seeks to identify causal relations from observational data. Causal analyses traditionally use low-dimensional structured variables, such as clinical markers and binary health outcomes. Such analyses require assumptions about the data-generating process, which are often simpler with low-dimensional data. Unlike prediction tasks which are validated by held-out test sets, causal inference involves modeling counterfactual random variables (Neyman, 1923; Rubin, 1976) that represent the outcome of some hypothetical intervention. To rigorously reason about hypotheticals, we use causal models to link our counterfactuals to observed data (Pearl, 2009).

NLP provides a natural way to incorporate text data into causal inference models. We can produce low-dimensional variables using, for example, text classifiers, and then run our causal analysis. However, this straightforward integration belies several potential issues. Text classification is not perfect, and errors in a NLP algorithm may bias subsequent analyses. Causal inference requires understanding how variables influence one another and how correlations are confounded by common causes. Classic methods such as stratification provide a means for handling confounding of categorical or continuous variables, but it is not immediately obvious how such work can be extended to high-dimensional data.

Recent work has approached high-dimensional domains by using random forests (Wager and Athey, 2017) and other methods borrowed from machine learning (Chernozhukov et al., 2016). But even compared to an analysis that requires hundreds of confounders (Belloni et al., 2014), NLP models with millions of variables are very high-dimensional. While physiological symptoms reflect complex biological realities, many symptoms such as blood pressure are one-dimensional variables. While doctors can easily quantify the effect of high blood pressure on some outcome, can we use the “positivity” of a restaurant review to estimate a causal effect? More broadly, is it possible to employ text classification methods in a causal analysis?

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4586–4598
Brussels, Belgium, October 31 - November 4, 2018.

We explore methods for the integration of text classifiers into causal inference analyses that consider confounds introduced by imperfect NLP. We show what assumptions are necessary for causal analyses using text, and discuss when those assumptions may or may not be reasonable. We draw on the causal inference literature to consider two modeling aspects: missing data and measurement error. In the missing data formulation, a variable of interest is sometimes unobserved, and text data gives us a means to model the missingness process. In the measurement error formulation, we use a text classifier to generate a noisy proxy of the underlying variable.

We highlight practical considerations of a causal analysis with text data by conducting analyses with simulated and Yelp data. We examine the results of both formulations and show how a causal analysis which properly accounts for possible sources of bias produces better estimates than naïve methods which make unjustified assumptions. We conclude by examining how our approach may enable new research avenues for inferring causality with text data.

2 Causal Inference, Briefly

While randomized control trials (RCT) are the gold standard of determining causal effects of treatments on outcomes, they can be expensive or impossible in many settings. In contrast, the world is filled with observational data collected without randomization. While most studies simply report correlations from observational data, the field of causal inference examines what assumptions and analyses make it possible to identify causal effects.

We formalize a causal statement like "smoking causes cancer" as "if we were to conduct a RCT and assign smoking as a treatment, we would see a higher incidence of cancer among those assigned smoking than among the control group." In the framework of Pearl (1995), we consider a counterfactual variable of interest: what *would have* been the cancer incidence among smokers if smoking *had been* randomized? Specifically, we consider a causal effect as the counterfactual outcome of a hypothetical intervention on some treatment variable. If we denote smoking as our treatment variable A and cancer as our outcome variable Y, then we are interested in the counterfactual distribution, denoted $p(Y(a))$ or $p(Y \mid \text{do}(a))$. We interpret this as "the distribution over Y had A been set, possibly contrary to fact, to value a." For a binary treatment A, the causal effect of A on Y is denoted $\tau = E[Y(1)] - E[Y(0)]$; the average difference between if you had received the treatment and if you had not. Throughout, we use causal directed acyclic graphs (DAG), which assumes that an intervention on A is well-defined and results in a counterfactual variable $Y(a)$ (Pearl, 1995; Dawid, 2010).

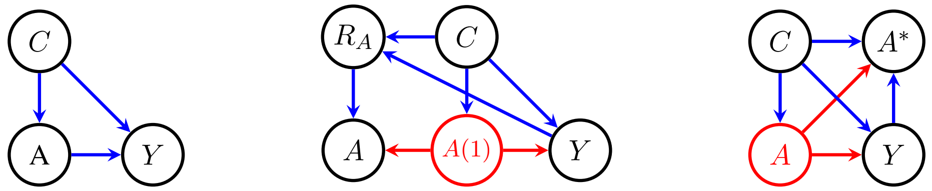
Figure 1a shows an example of simple confounding. This is the simplest DAG in which counterfactual distribution $p(Y(a))$ is not simply $p(Y \mid A)$, as C influences both the treatment A and the outcome Y. To recover the counterfactual distribution $p(Y(a))$ that would follow an intervention upon A, we must "adjust" for C, applying the so-called "back-door criterion" (Pearl, 1995). We can then derive the counterfactual distribution $p(Y(a))$ and desired causal effect, τ_S as a function of the observed data, (Fig. 4 Eq. 1.) This derivation is shown in Appendix A.

Note that $p(Y(a))$ and τ_S require data on C, and if C is not in fact observed, it is impossible to recover the causal effect. Formally, we say that $p(Y(a))$ is *not identified* in the model, meaning there is no function f such that $p(Y(a)){=}f(p(A,Y))$. Identifiability is a primary concern of causal inference (Shpitser and Pearl, 2008).

Throughout, we assume for simplicity that A, C, and Y are binary variables. While text classifiers can convert high-dimensional data into binary variables for such analyses, we need to make further assumptions about how classification errors affect causal inferences. We cannot assume that the output of a text classifier can be treated as if it were ground truth. To conceptualize the ways in which a text classifier may be biased, we will consider them as a way to recover from missing data or measurement error.

3 Causal Models

Real-world observational data is messy and often imperfectly collected. Work in causal inference has studied how analyses can be made robust to missing data or data recorded with systematic measurement errors.



(a) Simple Confounding (b) Missing Data (c) Measurement Error

3.1 Missing Data

Our dataset has "missing data" if it contains individuals (instances) for which some variables are unobserved, even though these variables are typically available. This may occur if some survey respondents choose not to answer certain questions, or if certain variables are difficult to collect and thus infrequently recorded. Missing data is closely related to causal inference – both are interested in hypothetical distributions that we cannot directly observe (Robins et al., 2000; Shpitser et al., 2015).

Consider a causal model where A is sometimes missing (Figure 1b). The variable R_A is a binary indicator for whether A is observed ($R_A = 1$) or missing. The variable $A(R_A = 1)$, written as $A(1)$, represents the counterfactual value of A were it never missing. Finally, A is the observed proxy for $A(1)$: it has the same value as $A(1)$ if $R_A = 1$, and the special value "?" if $R_A = 0$.

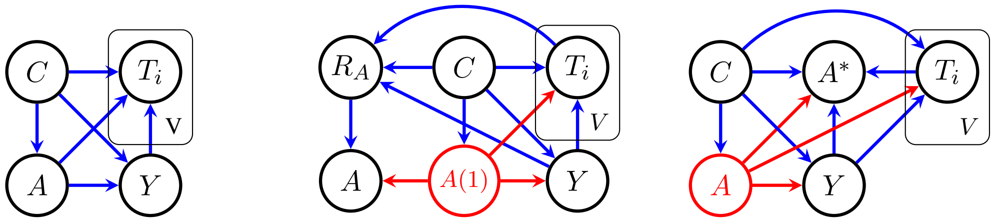
Solving missingness can seen as intervening to set R_A to 1. Given $p(A, R_A, C, Y)$, we want to recover $p(A(1), C, Y)$. We may need to make a "Missing at Random" (MAR) assumption, which says that the missingness process is independent of the true missing values, conditional on observed values. Figure 1b reflects the MAR assumption; R_A is independent of $A(1)$ given fully-observed C and Y. If an edge existed from $A(1)$ to R_A, we have "Missing Not at Random" (MNAR) and would not be identified except in special cases (Shpitser et al., 2015).

3.2 Measurement Error

Sometimes a necessary variable is never observed, but is instead proxied by a variable which differs from the truth by some error. Consider the example of body mass index (BMI) as a proxy for obesity in a clinical study. Obesity is a known risk factor for many health outcomes, but has a complex clinical definition and is nontrivial to measure. BMI is a simple deterministic function of height and weight. To conduct a causal analysis of obesity on cancer when only BMI and cancer are measured, we can proceed as if we had measured obesity and then correct our analysis for the known error that comes from using BMI as a proxy for obesity (Hernán and Cole, 2009; Michels et al., 1998).

To generalize this concept, we can replace obesity with our ground truth variable A and replace BMI with a noisy proxy A^*. Figure 1c gives the DAG for this model. Unlike missing data problems, there is no hypothetical intervention which recovers the true data distribution $p(A, C, Y)$. Instead, we manipulate the observed distribution $p(A^*, C, Y)$ with the known relationship $p(A^*, A)$ to recover the desired $p(A, C, Y)$.

Unlike missing data, measurement error conceptualization can be used even when we never observe A (e.g. the table in Figure 2c) as long as we have knowledge about the error mechanism $p(A^*, A)$. Using this knowledge, we can correct for the error using 'matrix



(a) Simple Confounding with Text (b) Missing Data with Text (c) Measurement Error with Text

Figure 3: DAGs for causal inference with text data. In the Yelp experiments we discuss, T_i influences Y and not the other way around.

$$\tau_S = \sum_C \left(p(Y=1 \mid A=1, C) - p(Y=1 \mid A=0, C)\right) p(C) \tag{1}$$

$$\begin{aligned}\tau_{\text{MD}} = \sum_C \Bigg(& \frac{p(A=1 \mid \mathbf{T}, C, Y=1, R_A=1)}{\sum_y' p(A=1 \mid \mathbf{T}, C, y', R_A=1) p(Y=y' \mid C)} \\ & - \frac{p(A=0 \mid \mathbf{T}, C, Y=1, R_A=1)}{\sum_y' p(A=0 \mid \mathbf{T}, C, Y=y', R_A=1) p(Y=y' \mid C)} \Bigg) p(Y=1, C)\end{aligned} \tag{2}$$

$$\tau_{\text{ME}} = \sum_C \left(\frac{\frac{-\delta_{c,y=1} q_{c,y=1}(0) + (1-\delta_{c,y=1}) q_{c,y=1}(1)}{(1-\epsilon_{c,y=1}-\delta_{c,y=1})}}{\sum_{y'} \frac{-\delta_{c,y'} q_{c,y'}(0) + (1-\delta_{c,y'}) q_{c,y'}(1)}{(1-\epsilon_{c,y'}-\delta_{c,y'})}} - \frac{\frac{(1-\epsilon_{c,y=1}) q_{c,y=1}(0) - \epsilon_{c,y=1} q_{c,y=1}(1)}{(1-\epsilon_{c,y=1}-\delta_{c,y=1})}}{\sum_{y'} \frac{(1-\epsilon_{c,y'}) q_{c,y'}(0) - \epsilon_{c,y'} q_{c,y'}(1)}{(1-\epsilon_{c,y'}-\delta_{c,y'})}} \right) p(C) \tag{3}$$

Define $\epsilon_{c,y} = p(A=0 \mid A^*=1, C=c, Y=y)$, $\delta c, y = p(A=1 \mid A^*=0, C=c, Y=y)$,
$q_{c,y}(0) = p(C=c, Y=y, A^*=0)$, and $q_{c,y}(1) = p(C=c, Y=y, A^*=1)$.

Figure 4: Functionals for the Causal Effects for Simple Confounding (τ_{SC}), Missing Data (τ_{MD}) and Measurement Error (τ_{ME}). Derivations are in Appendices A, B, and C.

adjustment' (Pearl, 2010). In practice we might learn $p(A^*, A)$ from data such as that found in Figure 2d. Recent work has also considered how multiple independent proxies of A could allow identification without any data on $p(A^*, A)$ (Kuroki and Pearl, 2014).

4 Causal Models for Text Data

We can use conceptualizations for missing data and measurement error to support causal analyses with text data. The choice of model depends on the assumptions we make about the data-generation process.

We add new variables to our models (Figure 1a) to represent text, which produces the data-generating distribution shown in Figure 3a. This model assumes that the underlying A, C, and Y variables are generated before the text variables; we use text to recover the true relationship between A and Y.

We represent text as an arbitrary set of V variables, which are independent of one another given the non-text variables. In our implemented analyses we will represent text as a bag-of-words, wherein each T_i is simply the binary indicator of the presence of the i-th word in our vocabulary of V words, and $\mathbf{T} = \cup_i T_i$. The restriction to simple text models allows us to explore connections to causal inference applications, though future work could relax assumptions of the text models to be inclusive of more sophisticated text models (e.g. neural sequence models (Lai et al., 2015; Zhang et al., 2015)), or consider causal relationships between two text variables.

To motivate our explanations, consider the task of predicting an individuals' smoking status from free-text hospital discharge notes (Uzuner et al., 2008; Wicentowski and Sydes, 2008). Some hospitals do not explicitly record patient smoking status as structured data, making it difficult to use such data in a study on the outcomes of smoking. We will suppose that we are given a dataset with patient data on lung cancer outcome (Y) and age (C), that our data on smoking status (A) is affected by either missing data or measurement error, but that we have text data ($\mathbf{T}$) from discharge records that will allow us to infer smoking status with reasonable accuracy.

4.1 Missing Data

To show how we might use text data to recover from missing data, we introduce missingness for A from Figure 3a to get the model in Figure 3b. The missing arrow from $A(1)$ to R_A encodes the MAR assumption, which is sufficient to make it possible to identify the full data distribution from the observed data.

Suppose our motivation is to estimate the causal effect of smoking status (A) on lung cancer (Y) adjusting for age (C). Imagine that missing data arises because hospitals sometimes – but not always – delete explicit data on smoking status from patient records. If we have access to patients' discharge notes ($\mathbf{T}$) and know whether a given patient had smoking status recorded (R_A), then the DAG in Figure 3b may be a reasonable model for our setting. Note that we must again assume that A does not directly affect R_A.

The causal effect of A on Y in Figure 3b is identified as τ_{MD}, given in Eq. 2 in Figure 4. The derivation is given in Appendix B.

4.2 Measurement Error

We model text data with measurement error by introducing a proxy A^* to the model in Figure 3c. We assume that the proxied value of A^* can depend upon all other variables, and that we will be able to estimate $p(A^*, A)$ given an external dataset, e.g. text classifier accuracy on held-out data.

Suppose we again want to estimate the causal effect from §4.1, but this time none of our hospital records contain explicit data on smoking status. However, imagine that we have a separate training dataset of medical discharge records annotated by expert pulmonologists for patients' smoking status. We could then train a classifier to predict smoking status using discharge record text[1].

Working from the derivation for matrix adjustment in binary models given by Pearl (2010), we identify the causal effect of A on Y (Figure 3c) as τ_{ME} (Eq 3 in Figure 4.) The derivation is in Appendix C.

5 Experiments

We now empirically evaluate the effectiveness of our two conceptualizations (missing data and measurement error) for including text data in causal analyses. We induce missingness or mismeasurement of the treatment variable and use text data to recover the true causal relationship of that treatment on the outcome. We begin with a simulation study with synthetic text data, and then conduct an analysis using reviews from `yelp.com`.

5.1 Synthetic Data

We select synthetic data so that we can control the entire data-generation process. For each data row, we first sample data on three binary variables (A, C, Y) and then sample V different binary variables T_i representing a V-vocabulary bag-of-words. A graphical model for this distribution appears in Figure 3a. We augment this distribution to introduce either missing data (Figure 3b) or measurement error (Figure 3c.) For measurement error, we sample two datasets. A small training set which gives data on $p(A, C, Y, \mathbf{T})$ and a large test set which gives data on $p(C, Y, \mathbf{T})$.

The full data generating process appears in Appendix D, and the implementation (along with all our code) is provided online[2].

5.2 Yelp Data

We utilize the 2015 Yelp Dataset Challenge[3] which provides 4.7M reviews of local businesses. Each review contains a one- to five-star rating, up to 5,000 characters of text. Yelp users can flag reviews as "Useful" as a mark of quality.

We extract treatment, outcome, and confounder variables from the structured data. The treatment is a binarized user rating that takes value 1 if the review has four or five stars and value 0 if the review has one or two stars. Three-star reviews are discarded from our analysis. The outcome is whether the review received at least one "Useful" flag. The confounder is whether the review's author has received at least two "Useful" flags across all reviews, according to their user object. In our data, 74.2% of reviews were positive, 42.6% of reviews were flagged as "Useful," and 56.7% users had received at least

---

[1] This is the precise setting of Uzuner et al. (2008).

[2] `github.com/zachwooddoughty/emnlp2018-causal`

[3] `yelp.com/dataset/challenge`

two such flags. We preprocess the text of each review by lowercasing, stemming, and removing stopwords, before converting to a bag-of-words representation with the 4,334 word vocabulary of all words which appeared at least 1000 times in a sample of 1M reviews.

Based on this $p(A, C, Y, \mathbf{T})$ distribution, we assume the data-generating process that matches Figure 3a and introduce missingness and mismeasurement as before, giving us data-generating processes matching Figures 3b and 3c.

Our intention is not to argue about a true real-world causal effect of Yelp reviews on peer behavior: we do not believe that our confounder is the only common cause of the author's rating and the platform's response. We leave for future work a case study that jointly addresses questions of identifiability and estimation of a real-world causal effect. In this work, our experiments focus on a simpler task: can a correctly-specified model that uses text data effectively estimate a causal effect in the presence of missing data or measurement error.

5.3 Models

We now introduce several baseline methods which, unlike our correctly specified models τ_{MD} and τ_{ME}, are not consistent estimators of our desired causal effect. We would expect that the theoretical bias in these estimators would result in poor performance in our experiments.

5.3.1 Baseline: Naïve Model

In both the missing data and measurement error settings, our models use some rows that are full observed. In missing data, these are rows where $R_A = 1$; in measurement error, the training set is sampled from the true distribution. The simplest approach to handling imperfect data is to throw away all rows without full data, and calculate Eq 1 from that data. In Figure 5, these are labeled as `*.naive`.

5.3.2 Baseline: Textless Model

In Figure 3b, if we do not condition on T_i to d-separate $A(1)$ from its missingness indicator, that influence may bias our estimate. While we know that ignoring text may introduce asymptotic bias into our estimates of the causal effect, we empirically evaluate how much bias is produced by this "Textless" model compared to a correct model. This is labeled as `*.no_text` in Figure 5 (a).

In principle, we could conduct a measurement error analysis using a model that does not include text. In practice, we found we could not impute A^* from C and Y alone. The non-textual classifier had such high error that the adjustment matrix was singular and we could not compute the effect. Thus, we have no such baseline in our measurement error results.

5.3.3 Baseline: `no_y` and `unadjusted` Models

In Figure 3b, we must also condition on C and Y to d-separate $A(1)$ from its missingness indicator. In our misspecified model for missing data, we do not condition on Y, leaving open a path for $A(1)$ to influence its missingness. In Figure 5 (a), this model is labeled as `*.no_y`.

When correcting for measurement error, a crucial piece of the estimation is the matrix adjustment using the known error between the proxy and the truth. A straightforward misspecified model for measurement error is to impute a proxy for each row in our dataset and then calculate the causal effect assuming no error between the proxy and truth. This approach, while simplistic, can be thought of as using a text classifier as a proxy without regard for the text classifier's biases. In Figure 5 (b), this approach is labeled as `*.unadjusted`.

5.3.4 Correct Models

Finally, we consider the estimation approaches presented in §4.1 and §4.2. For the missing data causal effect (τ_{MD} from Eq 2) we use a multiple imputation estimator which calculates the average effect across 20 samples from $p(A|\mathbf{T}, C, Y)$ for each row where $R_A = 0$. For the measurement error causal effect (τ_{ME} from Eq 3), we use the training set of $p(A, C, Y, \mathbf{T})$ data to estimate $\epsilon_{c,y}$ and $\delta c, y$ and the larger set of $p(C, Y, \mathbf{T})$ data to estimate $q_{c,y}$ and $p(C)$.

These models are displayed in Figure 5 (a) as `*.full` and in Figure 5 (b) `*.adjusted`.

5.4 Evaluation

Each model takes in a data sample with missingness or mismeasurement, and outputs an estimate of the causal effect of A on Y in the underlying data. Rather than comparing models' estimates against a population-level estimate, we compare against an estimate of the effect computed on the same data sample, but without any missing data or measurement error. This 'perfect data estimator' may still make errors given the finite data sample. We compare against this estimator to avoid a small-sample case where an estimator gets lucky. In Figure 5, we plot data sample size against the squared distance of each model's estimate from a perfect data estimator's estimate, averaged over ten runs. Figure 6 in Appendix E contains a second set of experiments using a larger vocabulary.

6 Results

Given that our correctly-specified models are proven to be asymptotically consistent, we would expect them to outperform misspecified models. However, for any given dataset, asymptotic consistency provides no guarantees.

6.1 Missing Data

The missing data (MD) experiments suggest that the correct `full` model does perform best. The `no_y` model performs approximately as well as the correct model on the synthetic data, but not on the Yelp data. The difference between the `no_y` and `full` missing data models is simply a function of the effect of Y on R_A. We could tweak our synthetic data distribution to increase the influence of Y to make the `no_y` model perform worse.

When we initially considered other data-generating distributions for missing data, we found that when we reduced the influence of the text variables on R_A, the `no_text` and `naive` models approached the performance of the correctly-specified model. While intuitive, this reinforces that the underlying distribution matters a great deal in how modeling choices may introduce biases if incorrectly specified.

6.2 Measurement error

The measurement error results tell a more interesting story. We see enormous fluctuations of the `adjusted` model, and in the synthetic data, the `unadjusted` model appears to be quite superior.

In the synthetic dataset, this is likely because our text classifier had near-perfect accuracy, and so simple approach of assuming its predictions were ground-truth introduced less bias. A broader issue with the `adjusted` model is that the matrix adjustment approach requires dividing by (potentially very small) probabilities, this sometimes resulted in huge over-corrections. In addition, since those probabilities are estimated from a relatively small training dataset, small changes to the error-estimate can propagate to huge changes in the final casual estimate.

This instability of the matrix adjustment approach may be a bigger problem for text and other high-dimensional data: unlike in our earlier example of BMI and obesity, there are likely no simple relationships between text and clinical variables. However, instead of using matrix adjustment as a way to recover the true effect, we may instead use it to bound the error our proxy may introduce. As mentioned by Pearl (2010), when $p(A \mid A^*)$ is not known exactly, we can use a Bayesian analysis to bound estimates of a causal effect. In a downstream task, this would let us explore the stability of our `adjusted` results.

7 Related Work

A few recent papers have considered the possibilities for combining text data with approaches from the causal inference literature. Landeiro and Culotta (2016) and Landeiro and Culotta (2017) explored text classification when the relationship between text data and class labels are confounded. Other work has used propensity scores as a way to extract features from text data (Paul, 2017) or to match social media users based on what words they write (De Choudhury et al., 2016). The only work we know of which seeks to estimate causal effects using text data focuses on effects *of* text or effects *on* text (Egami et al., 2018; Roberts et al., 2018). In our work, our causal effects do not include text variables: we use text variables to recover an underlying distribution and then estimate a causal effect within that distribution.

There is a conceptually related line of work in the NLP community on inferring causal relationships expressed in text (Girju, 2003; Kaplan and Berry-Rogghe, 1991). However, our work is fundamentally different. Rather than identify casual relations expressed via language, we are using text data in a causal model to identify the strength of an underlying causal effect.

Figure 5: Experimental results. Squared distance (y-axis, lower is better) of the estimated causal effect from τ_{SC} calculated from the full data with no missing data or measurement error. Error bars (negligible for larger datasets) are 1.96 times standard error across 10 experiments. Additional experiments with a larger vocabulary are shown in Appendix E.

8 Future Directions

While this paper addresses some initial issues arising from using text classifiers in causal analyses, many challenges remain. We highlight some of these issues as directions for future research.

We provided several proof-of-concept models for estimating effects, but our approach is flexible to more sophisticated models. For example, a semi-parametric estimator would make no assumptions about the text data distribution by wrapping the text classifier into an infinite-dimensional nuisance model (Tsiatis, 2007). This would enable estimators robust to partial model misspecification (Bang and Robins, 2005).

Choices in the design of statistical models of text consider issues like accuracy and tractability. Yet if these models are to be used in a causal framework, we need to understand how modeling assumptions introduce biases and other issues that can interfere with a downstream causal analysis. To take an example from the medical domain, we know that doctors write clinical notes throughout the healthcare process, but it is not obvious how to model this data-generating process. We could assume that the doctor's notes passively record a patient's progression, but in reality it may be that the content of the notes themselves actively change the patient's care; causality could work in either direction.

New lines of work in causality may be especially helpful for NLP. In this work, we used simple logistic regression on a bag-of-words representation of text; using state-of-the-art text models will likely require more causal assumptions. Nabi and Shpitser (2017) develops causality-preserving dimensionality reduction, which could help develop text representations that preserve causality.

Finally, we are interested in case studies on incorporating text classifiers into real-world causal analyses. Many health studies have used text classifiers to extract clinical variables from EHR data (Meystre et al., 2008). These works could be extended to study causal effects involving those extracted variables, but such extensions would require an understanding of the underlying assumptions. In any given study, the necessity and appropriateness of assumptions will hinge on domain expertise. The conceptualizations outlined in this paper, while far from solving all issues of causality and text, will help those using text classifiers to more easily consider research questions of cause and effect.

A Simple Confounding

$$p(Y(a)) = \sum_C p(Y(a) \mid C)p(C) \tag{4}$$
$$= \sum_C p(Y(a) \mid A, C)p(C) \tag{5}$$
$$= \sum_C p(Y \mid A, C)p(C) \tag{6}$$

Eq 5 holds because $Y(a) \perp A \mid C$, as seen in Figure 1a. Plugging this distribution into $\tau_S = E[Y(1)] - E[Y(0)]$ gives us the causal effect presented in Figure 4, Eq 1.

This assumes that an intervention on A is well-defined; if we *did* conduct a randomized control trial, we *could* assign $A = a$ and break A's dependence on C.

In general, this step requires that we condition on all "back-door" paths between the treatment and the outcome. In Figure 1(a), if we did not have data on C, we could not block the back-door path between A and Y.

Eq 6 holds due to consistency. We assume that, given we intervened to set $A = a$, if that individual would have been assigned $A = a$ in nature, then the distribution over Y is the same.

B Missing Data

Denote $p(Y(A(1) = a)) = p(Y(a))$.

First, we identify the causal effect in terms of the true $A(1)$.

$$p(Y(a))$$
$$= \sum_C p(Y(a) \mid C)p(C) \tag{7}$$
$$= \sum_C p(Y(a) \mid A(1), C)p(C) \tag{8}$$
$$= \sum_C p(Y \mid A(1), C)p(C) \tag{9}$$

Where 7 holds by chain rule, 8 holds by $A(1) \perp Y(a) \mid C$, and 9 by consistency.

Now, we identify $A(1)$ in terms of observed data.

$$p(A(1), C, Y)$$
$$= p(A(1) \mid C, Y)p(C, Y) \tag{10}$$
$$= p(A(1) \mid C, Y, R_A = 1)p(C, Y) \tag{11}$$
$$= p(A \mid C, Y, R_A = 1)p(C, Y) \tag{12}$$

Where 10 holds by chain rule, 11 by $A(1) \perp R_A \mid C, Y$, and 12 by consistency.

Now, use Eq 12 to identify $p(Y \mid A(1), C)$ from Eq 9 in terms of observed data.

$$p(Y \mid A(1), C)$$
$$= \frac{p(Y, A(1), C)}{p(A(1), C)} \tag{13}$$
$$= \frac{p(Y, A(1), C)}{\sum_Y p(Y, A(1), C)} \tag{14}$$
$$= \frac{p(A \mid C, Y, R_A = 1)p(C, Y)}{\sum_Y p(A \mid C, Y, R_A = 1)p(C, Y)} \tag{15}$$
$$= \frac{p(A \mid C, Y, R_A = 1)p(Y \mid C)}{\sum_Y p(A \mid C, Y, R_A = 1)p(Y \mid C)} \tag{16}$$

Where 13 holds by definition, 14 holds by marginalization, 15 holds by an application of 12 twice, and 16 holds by canceling out p(C).

If we include text in this derivation, we simply replace $p(A \mid C, Y, R_A = 1)$ with $p(A \mid \mathbf{T}, C, Y, R_A = 1)$, where $\mathbf{T}$ is all our text variables.

Finally, combine Eq 9 and Eq 16 to get:

$$p(Y(A(1) = a))$$
$$= \sum_C \frac{p(A \mid C, Y, R_A = 1)p(Y \mid C)}{\sum_Y p(A \mid C, Y, R_A = 1)p(Y \mid C)} p(C) \tag{17}$$

Plugging this distribution into $\tau_{\text{MD}} = E[Y(1)] - E[Y(0)]$ gives us the causal effect presented in Figure 4, Eq 2.

C Measurement Error

Define the following terms for convenience:

$$\epsilon_{c,y} = p(A = 0 \mid A^* = 1, C = c, Y = y) \tag{18}$$
$$\delta c, y = p(A = 1 \mid A^* = 0, C = c, Y = y) \tag{19}$$
$$q_{c,y}(0) = p(C = c, Y = y, A^* = 0) \tag{20}$$
$$q_{c,y}(1) = p(C = c, Y = y, A^* = 1) \tag{21}$$

Eq (5) and (7) from Pearl 2010 gives us:

$$p(A = 1, C = c, Y = y)$$
$$= \frac{-\delta_{c,y} q_{c,y}(0) + (1 - \delta_{c,y}) q_{c,y}(1)}{(1 - \epsilon_{c,y} - \delta_{c,y})} \tag{22}$$
$$p(A = 0, C = c, Y = y)$$
$$= \frac{(1 - \epsilon_{c,y}) q_{c,y}(0) - \epsilon_{c,y} q_{c,y}(1)}{(1 - \epsilon_{c,y} - \delta_{c,y})} \tag{23}$$

Now,

$$
\begin{aligned}
& p(Y \mid A=1, C) \\
& \quad = \frac{p(Y, A=1, C)}{p(A=1, C)} && (24) \\
& \quad = \frac{p(Y, A=1, C)}{\sum_Y p(Y, A=1, C)} && (25) \\
& \quad = \frac{\dfrac{-\delta_{c,y} q_{c,y}(0) + (1-\delta_{c,y}) q_{c,y}(1)}{(1-\epsilon_{c,y}-\delta_{c,y})}}{\sum_{y'} \dfrac{-\delta_{c,y'} q_{c,y'}(0) + (1-\delta_{c,y'}) q_{c,y'}(1)}{(1-\epsilon_{c,y'}-\delta_{c,y'})}} && (26)
\end{aligned}
$$

and then,

$$
\begin{aligned}
& p(Y \mid A=0, C) \\
& \quad = \frac{p(Y, A=0, C)}{p(A=0, C)} && (27) \\
& \quad = \frac{p(Y, A=0, C)}{\sum_Y p(Y, A=0, C)} && (28) \\
& \quad = \frac{\dfrac{(1-\epsilon_{c,y}) q_{c,y}(0) - \epsilon_{c,y} q_{c,y}(1)}{(1-\epsilon_{c,y}-\delta_{c,y})}}{\sum_{y'} \dfrac{(1-\epsilon_{c,y'}) q_{c,y'}(0) - \epsilon_{c,y'} q_{c,y'}(1)}{(1-\epsilon_{c,y'}-\delta_{c,y'})}} && (29)
\end{aligned}
$$

Plugging this distribution into $\tau_{\text{ME}} = E[Y(1)] - E[Y(0)]$ gives us the causal effect presented in Figure 4, Eq 3.

D Synthetic Data Distribution

In the distributions below, Ber(p) is used as the abbreviation a Bernoulli distribution with probability p.

Below, s_i, u_i and v_i are the effect of C, A, and Y on the probability of word T_i; each is drawn from $\mathcal{N}(0, \zeta)$, a parameter which controls how correlated words are with the underlying variables. When ζ is close to 0, the words are essentially random. When ζ is large, the words are essentially deterministic functions of the underlying variables. Similarly w_i is the effect of word T_i on R_A, and is drawn from $\mathcal{N}(0, \eta)$.

For both settings, we set vocabulary size to 4,334 (to match Yelp experiments) and ζ = 0.5. For the missing data setting, we set η = 0.1. We picked these constants by empirically finding a reasonable middle ground between the text data providing only noise and being a deterministic function of their parents. We picked all other constants such that the naïve correlation $p(Y \mid A)$ was a poor estimate of the counterfactual $p(Y(a))$ in the full-data setting.

D.1 Missing data data-generation

$$
\begin{aligned}
C &\sim \text{Ber}(0.4) \\
A(1) &\sim \text{Ber}(-0.3C + 0.4) \\
Y &\sim \text{Ber}(0.2C + 0.1A + 0.5) \\
T_i &\sim \text{Ber}(0.5 + u_i A + v_i C) \\
R_A &\sim \text{Ber}\left(0.7 + 0.2C - 0.4Y + \sum_i w_i T_i\right)
\end{aligned}
$$

D.2 Measurement error data-generation

$$
\begin{aligned}
C &\sim \text{Ber}(0.4) \\
A &\sim \text{Ber}(-0.3C + 0.4) \\
Y &\sim \text{Ber}(0.2C + 0.1A + 0.5) \\
T_i &\sim \text{Ber}(0.5 + s_i C + u_i A + v_i Y)
\end{aligned}
$$

Figure 6: Experimental results with a vocabulary of size 53,197. Squared distance (y-axis, lower is better) of the estimated causal effect from τ_{SC} calculated from the full data with no missing data or measurement error. Error bars (negligible for larger datasets) are 1.96 times standard error across 10 experiments.

E Additional Experiments

Figure 6 shows the results of a second set of experiments, which are identical to those described in §5 except the vocabulary size is now 53,197 instead of 4,334. For the Yelp data, the larger vocabulary consists of all words which appear at least ten times in a sample of 1M reviews. As the larger vocabulary introduced greater memory requirements, we did not run these experiments with as large of datasets.

The results of these experiments show roughly the same patterns as those seen in Figure 5. The `adjusted` measurement error models again appear erratic, generally performing worse than the `unadjusted` models though better than the `naive` models.

The `full` missing data model appeared to slightly outperform the `no_y` model on Yelp data but only perform as well on the synthetic data. Both these models appeared better than the `naive` and `no_text` models on both datasets.

Direct Output Connection for a High-Rank Language Model

Abstract

This paper proposes a state-of-the-art recurrent neural network (RNN) language model that combines probability distributions computed not only from a final RNN layer but also from middle layers. Our proposed method raises the expressive power of a language model based on the matrix factorization interpretation of language modeling introduced by Yang et al. (2018). The proposed method improves the current state-of-the-art language model and achieves the best score on the Penn Treebank and WikiText-2, which are the standard benchmark datasets. Moreover, we indicate our proposed method contributes to two application tasks: machine translation and headline generation. Our code is publicly available at: https://github.com/nttcslab-nlp/doc_lm.

1 Introduction

Neural network language models have played a central role in recent natural language processing (NLP) advances. For example, neural encoder-decoder models, which were successfully applied to various natural language generation tasks including machine translation (Sutskever et al., 2014), summarization (Rush et al., 2015), and dialogue (Wen et al., 2015), can be interpreted as conditional neural language models. Neural language models also positively influence syntactic parsing (Dyer et al., 2016; Choe and Charniak, 2016). Moreover, such word embedding methods as Skip-gram (Mikolov et al., 2013) and vLBL (Mnih and Kavukcuoglu, 2013) originated from neural language models designed to handle much larger vocabulary and data sizes. Neural language models can also be used as contextualized word representations (Peters et al., 2018). Thus, language modeling is a good benchmark task for investigating the general frameworks of neural methods in NLP field.

In language modeling, we compute joint probability using the product of conditional probabilities. Let $w_{1:T}$ be a word sequence with length T: $w_1, ..., w_T$. We obtain the joint probability of word sequence $w_{1:T}$ as follows:

$$p(w_{1:T}) = p(w_1) \prod_{t=1}^{T-1} p(w_{t+1}|w_{1:t}). \qquad (1)$$

$p(w_1)$ is generally assumed to be 1 in this literature, that is, $p(w_1) = 1$, and thus we can ignore its calculation. See the implementation of Zaremba et al. (2014)[1], for an example. RNN language models obtain conditional probability $p(w_{t+1}|w_{1:t})$ from the probability distribution of each word. To compute the probability distribution, RNN language models encode sequence $w_{1:t}$ into a fixed-length vector and apply a transformation matrix and the softmax function.

Previous researches demonstrated that RNN language models achieve high performance by using several regularizations and selecting appropriate hyperparameters (Melis et al., 2018; Merity et al., 2018). However, Yang et al. (2018) proved that existing RNN language models have low expressive power due to the *Softmax bottleneck*, which means the output matrix of RNN language models is low rank when we interpret the training of RNN language models as a matrix factorization problem. To solve the *Softmax bottleneck*, Yang et al. (2018) proposed *Mixture of Softmaxes* (MoS), which increases the rank of the matrix by combining multiple probability distributions computed from the encoded fixed-length vector.

In this study, we propose *Direct Output Connection* (DOC) as a generalization of MoS. For stacked RNNs, DOC computes the probability distributions from the middle layers including input embeddings. In addition to raising the rank, the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4599–4609
Brussels, Belgium, October 31 - November 4, 2018.

proposed method helps weaken the vanishing gradient problem in backpropagation because DOC provides a shortcut connection to the output.

We conduct experiments on standard benchmark datasets for language modeling: the Penn Treebank and WikiText-2. Our experiments demonstrate that DOC outperforms MoS and achieves state-of-the-art perplexities on each dataset. Moreover, we investigate the effect of DOC on two applications: machine translation and headline generation. We indicate that DOC can improve the performance of an encoder-decoder with an attention mechanism, which is a strong baseline for such applications. In addition, we conduct an experiment on the Penn Treebank constituency parsing task to investigate the effectiveness of DOC.

2 RNN Language Model

In this section, we briefly overview RNN language models. Let V be the vocabulary size and let $P_t \in \mathbb{R}^V$ be the probability distribution of the vocabulary at timestep t. Moreover, let D_{h^n} be the dimension of the hidden state of the n-th RNN, and let D_e be the dimensions of the embedding vectors. Then the RNN language models predict probability distribution P_{t+1} by the following equation:

$$P_{t+1} = \mathrm{softmax}(W h_t^N), \quad (2)$$

$$h_t^n = f(h_t^{n-1}, h_{t-1}^n), \quad (3)$$

$$h_t^0 = E x_t, \quad (4)$$

where $W \in \mathbb{R}^{V \times D_{h^N}}$ is a weight matrix[2], $E \in \mathbb{R}^{D_e \times V}$ is a word embedding matrix, $x_t \in \{0,1\}^V$ is a one-hot vector of input word w_t at timestep t, and $h_t^n \in \mathbb{R}^{D_{h^n}}$ is the hidden state of the n-th RNN at timestep t. We define h_t^n at timestep $t = 0$ as a zero vector: $h_0^n = \mathbf{0}$. Let $f(\cdot)$ represent an abstract function of an RNN, which might be the Elman network (Elman, 1990), the Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), the Recurrent Highway Network (RHN) (Zilly et al., 2017), or any other RNN variant. In this research, we stack three LSTM layers based on Merity et al. (2018) because they achieved high performance.

3 Language Modeling as Matrix Factorization

Yang et al. (2018) indicated that the training of language models can be interpreted as a matrix factorization problem. In this section, we briefly introduce their description. Let word sequence $w_{1:t}$ be context c_t. Then we can regard a natural language as a finite set of the pairs of a context and its conditional probability distribution: $\mathcal{L} = \{(c_1, P^*(X|c_1)), ..., (c_U, P^*(X|c_U))\}$, where U is the number of possible contexts and $X \in \{0,1\}^V$ is a variable representing a one-hot vector of a word. Here, we consider matrix $A \in \mathbb{R}^{U \times V}$ that represents the true log probability distributions and matrix $H \in \mathbb{R}^{U \times D_{h^N}}$ that contains the hidden states of the final RNN layer for each context c_t:

$$A = \begin{bmatrix} \log P^*(X|c_1) \\ \log P^*(X|c_2) \\ \dots \\ \log P^*(X|c_U) \end{bmatrix}; H = \begin{bmatrix} h_{c_1}^N \\ h_{c_2}^N \\ \dots \\ h_{c_U}^N \end{bmatrix}. \quad (5)$$

Then we obtain set of matrices $F(A) = \{A + \Lambda S\}$, where $S \in \mathbb{R}^{U \times V}$ is an all-ones matrix, and $\Lambda \in \mathbb{R}^{U \times U}$ is a diagonal matrix. $F(A)$ contains matrices that shifted each row of A by an arbitrary real number. In other words, if we take a matrix from $F(A)$ and apply the softmax function to each of its rows, we obtain a matrix that consists of true probability distributions. Therefore, for some $A' \in F(A)$, training RNN language models is to find the parameters satisfying the following equation:

$$HW^\top = A'. \quad (6)$$

Equation 6 indicates that training RNN language models can also be interpreted as a matrix factorization problem. In most cases, the rank of matrix $HW^\top$ is D_{h^N} because D_{h^N} is smaller than V and U in common RNN language models. Thus, an RNN language model cannot express true distributions if D_{h^N} is much smaller than $\mathrm{rank}(A')$.

Yang et al. (2018) also argued that $\mathrm{rank}(A')$ is as high as vocabulary size V based on the following two assumptions:

1. Natural language is highly context-dependent. In addition, since we can imagine many kinds of contexts, it is difficult to assume a basis that represents a conditional probability distribution for any contexts. In other words, compressing U is difficult.

2. Since we also have many kinds of semantic meanings, it is difficult to assume basic meanings that can create all other semantic meanings by such simple operations as addition and subtraction; compressing V is difficult.

---

[2] Actually, we apply a bias term in addition to the weight matrix but we omit it to simplify the following discussion.

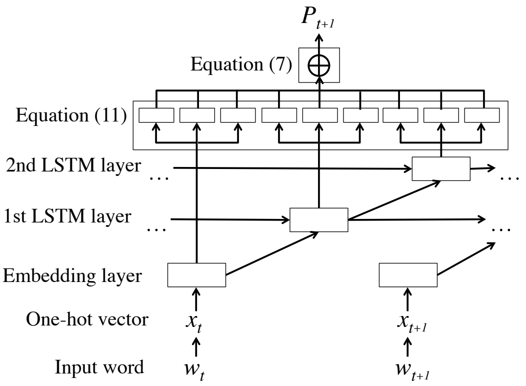

Figure 1: Overview of the proposed method: DOC. This figure represents the example of $N = 2$ and $i_0 = i_1 = i_2 = 3$.

In summary, Yang et al. (2018) indicated that D_{h^N} is much smaller than $\mathrm{rank}(A)$ because its scale is usually 10^2 and vocabulary size V is at least 10^4.

4 Proposed Method: Direct Output Connection

To construct a high-rank matrix, Yang et al. (2018) proposed Mixture of Softmaxes (MoS). MoS computes multiple probability distributions from the hidden state of final RNN layer h^N and regards the weighted average of the probability distributions as the final distribution. In this study, we propose Direct Output Connection (DOC), which is a generalization method of MoS. DOC computes probability distributions from the middle layers in addition to the final layer. In other words, DOC directly connects the middle layers to the output.

Figure 1 shows an overview of DOC, that uses the middle layers (including word embeddings) to compute the probability distributions. Figure 1 computes three probability distributions from all the layers, but we can vary the number of probability distributions for each layer and select some layers to avoid. In our experiments, we search for the appropriate number of probability distributions for each layer.

Formally, instead of Equation 2, DOC computes the output probability distribution at timestep $t+1$ by the following equation:

$$P_{t+1} = \sum_{j=1}^{J} \pi_{j,c_t} \, \mathrm{softmax}(\tilde{W} k_{j,c_t}), \qquad (7)$$

$$s.t. \sum_{j=1}^{J} \pi_{j,c_t} = 1, \qquad (8)$$

where π_{j,c_t} is a weight for each probability distribution, $k_{j,c_t} \in \mathbb{R}^d$ is a vector computed from each hidden state h^n, and $\tilde{W} \in \mathbb{R}^{V \times d}$ is a weight matrix. Thus, P_{t+1} is the weighted average of J probability distributions. We define the $U \times U$ diagonal matrix whose elements are weight $\pi_{j,c}$ for each context c as Φ. Then we obtain matrix $\tilde{A} \in \mathbb{R}^{U \times V}$:

$$\tilde{A} = \log \sum_{j=1}^{J} \Phi \, \mathrm{softmax}(K_j \tilde{W}^\top), \qquad (9)$$

where $K_j \in \mathbb{R}^{U \times d}$ is a matrix whose rows are vector $k_{j,c}$. $\tilde{A}$ can be an arbitrary high rank because the righthand side of Equation 9 computes not only the matrix multiplication but also a nonlinear function. Therefore, an RNN language model with DOC can output a distribution matrix whose rank is identical to one of the true distributions. In other words, $\tilde{A}$ is a better approximation of A' than the output of a standard RNN language model.

Next we describe how to acquire weight π_{j,c_t} and vector k_{j,c_t}. Let $\pi_{c_t} \in \mathbb{R}^J$ be a vector whose elements are weight π_{j,c_t}. Then we compute π_{c_t} from the hidden state of the final RNN layer:

$$\pi_{c_t} = \mathrm{softmax}(W_\pi h_t^N), \qquad (10)$$

where $W_\pi \in \mathbb{R}^{J \times D_{h^N}}$ is a weight matrix. We next compute k_{j,c_t} from the hidden state of the n-th RNN layer:

$$k_{j,c_t} = W_j h_t^n, \qquad (11)$$

where $W_j \in \mathbb{R}^{d \times D_{h^n}}$ is a weight matrix. In addition, let i_n be the number of k_{j,c_t} from h_t^n. Then we define the sum of i_n for all n as J; that is, $\sum_{n=0}^{N} i_n = J$. In short, DOC computes J probability distributions from all the layers, including the input embedding (h^0). For $i_N = J$, DOC becomes identical to MoS. In addition to increasing the rank, we expect that DOC weakens the vanishing gradient problem during backpropagation because a middle layer is directly connected to the output, such as with the auxiliary classifiers described in Szegedy et al. (2015).

For a network that computes the weights for several vectors, such as Equation 10, Shazeer et al. (2017) indicated that it often converges to a state where it always produces large weights for few vectors. In fact, we observed that DOC tends to assign large weights to shallow layers. To prevent this phenomenon, we compute the coefficient of variation of Equation 10 in each mini-batch as a regularization term following Shazeer et al. (2017). In other words, we try to adjust the sum of the weights for each probability distribution with identical values in each mini-batch. Formally, we compute the following equation for a mini-batch consisting of $w_b, w_{b+1}, ..., w_{\tilde{b}}$:

$$B = \sum_{t=b}^{\tilde{b}} \pi_{c_t} \tag{12}$$

$$\beta = \left(\frac{\mathrm{std}(B)}{\mathrm{avg}(B)}\right)^2, \tag{13}$$

where functions $\mathrm{std}(\cdot)$ and $\mathrm{avg}(\cdot)$ are functions that respectively return an input's standard deviation and its average. In the training step, we add λ_β multiplied by weight coefficient β to the loss function.

5 Experiments on Language Modeling

We investigate the effect of DOC on the language modeling task. In detail, we conduct word-level prediction experiments and show that DOC improves the performance of MoS, which only uses the final layer to compute the probability distributions. Moreover, we evaluate various combinations of layers to explore which combination achieves the best score.

5.1 Datasets

We used the Penn Treebank (PTB) (Marcus et al., 1993) and WikiText-2 (Merity et al., 2017) datasets, which are the standard benchmark datasets for the word-level language modeling task. Mikolov et al. (2010) and Merity et al. (2017) respectively published preprocessed PTB[3] and WikiText-2[4] datasets. Table 1 describes their statistics. We used these preprocessed datasets for fair comparisons with previous studies.

5.2 Hyperparameters

Our implementation is based on the averaged stochastic gradient descent Weight-Dropped LSTM (AWD-LSTM)[5] proposed by Merity et al. (2018). AWD-LSTM consists of three LSTMs with various regularizations. For the hyperparameters, we used the same values as Yang et al. (2018) except for the dropout rate for vector k_{j,c_t} and the non-monotone interval. Since we found that the dropout rate for vector k_{j,c_t} greatly influences β in Equation 13, we varied it from 0.3 to 0.6 with 0.1 intervals. We selected 0.6 because this value achieved the best score on the PTB validation dataset. For the non-monotone interval, we adopted the same value as Zolna et al. (2018). Table 2 summarizes the hyperparameters of our experiments.

		PTB	WikiText-2
Vocab		10,000	33,278

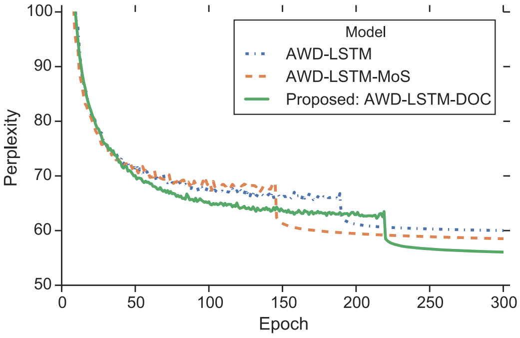

Figure 2: Perplexities of each method on the PTB validation set.

represents the number of probability distributions from hidden state h_t^n. To find the best combination, we varied the number of probability distributions from each layer by fixing their total to 20: $J = 20$. Moreover, the top row of Table 3 shows the perplexity of AWD-LSTM with MoS reported in Yang et al. (2018) for comparison. Table 3 indicates that language models using middle layers outperformed one using only the final layer. In addition, Table 3 shows that increasing the distributions from the final layer ($i_3 = 20$) degraded the score from the language model with $i_3 = 15$ (the top row of Table 3). Thus, to obtain a superior language model, we should not increase the number of distributions from the final layer; we should instead use the middle layers, as with our proposed DOC.

Table 3 shows that the $i_3 = 15, i_2 = 5$ setting achieved the best performance and the other settings with shallow layers have a little effect. This result implies that we need some layers to output accurate distributions. In fact, most previous studies adopted two LSTM layers for language modeling. This suggests that we need at least two layers to obtain high-quality distributions.

Model	Valid	Test
AWD-LSTM†	58.88	56.36
AWD-LSTM-MoS†	56.36	54.26
AWD-LSTM-MoS‡	55.67	53.75
AWD-LSTM-DOC	**54.62**	**52.87**
AWD-LSTM-DOC (fin)	**54.12**	**52.38**

Table 6: Perplexities of our implementations and reruns on the PTB dataset. We set the non-monotone interval to 60. † represents results obtained by original implementations with identical hyperparameters except for non-monotone interval. ‡ indicates the result obtained by our AWD-LSTM-MoS implementation with identical dropout rates as AWD-LSTM-DOC. For (fin), we repeated fine-tuning until convergence.

For the $i_3 = 15, i_2 = 5$ setting, we explored the effect of λ_β in $\{0, 0.01, 0.001, 0.0001\}$. Although Table 3 shows that $\lambda_\beta = 0.001$ achieved the best perplexity, the effect is not consistent. Table 4 shows the coefficient of variation of Equation 10, i.e., $\sqrt{\beta}$ in the PTB dataset. This table demonstrates that the coefficient of variation decreases with growth in λ_β. In other words, the model trained with a large λ_β assigns balanced weights to each probability distribution. These results indicate that it is not always necessary to equally use each probability distribution, but we can acquire a better model in some λ_β. Hereafter, we refer to the setting that achieved the best score ($i_3 = 15, i_2 = 5, \lambda_\beta = 0.001$) as AWD-LSTM-DOC.

Table 5 shows the ranks of matrices containing log probability distributions from each method. In other words, Table 5 describes $\tilde{A}$ in Equation 9 for each method. As shown by this table, the output of AWD-LSTM is restricted to D_3[7]. In contrast, AWD-LSTM-MoS (Yang et al., 2018) and AWD-LSTM-DOC outputted matrices whose ranks equal the vocabulary size. This fact indicates that DOC (including MoS) can output the same matrix as the true distributions in view of a rank.

Figure 2 illustrates the learning curves of each method on PTB. This figure contains the validation scores of AWD-LSTM, AWD-LSTM-MoS, and AWD-LSTM-DOC at each training epoch. We trained AWD-LSTM and AWD-LSTM-MoS by setting the non-monotone interval to 60, as with AWD-LSTM-DOC. In other words, we used hyperparameters identical to the original ones to train AWD-LSTM and AWD-LSTM-MoS, except for the non-monotone interval. We note that the opti-

---

[7] Actually, the maximum rank size of an ordinary RNN language model is $D_N + 1$ when we use a bias term.

Table 8: Perplexities of each method on the WikiText-2 dataset.

mization method converts the ordinary stochastic gradient descent (SGD) into the averaged SGD at the point where convergence almost occurs. In Figure 2, the turning point is the epoch when each method drastically decreases the perplexity. Figure 2 shows that each method similarly reduces the perplexity at the beginning. AWD-LSTM and AWD-LSTM-MoS were slow to decrease the perplexity from 50 epochs. In contrast, AWD-LSTM-DOC constantly decreased the perplexity and achieved a lower value than the other methods with ordinary SGD. Therefore, we conclude that DOC positively affects the training of language modeling.

Table 6 shows the AWD-LSTM, AWD-LSTM-MoS, and AWD-LSTM-DOC results in our configurations. For AWD-LSTM-MoS, we trained our implementation with the same dropout rates as AWD-LSTM-DOC for a fair comparison. AWD-LSTM-DOC outperformed both the original AWD-LSTM-MoS and our implementation. In other words, DOC outperformed MoS.

Since the averaged SGD uses the averaged parameters from each update step, the parameters of the early steps are harmful to the final parameters. Therefore, when the model converges, recent studies and ours eliminate the history of and then retrains the model. Merity et al. (2018) referred to this retraining process as fine-tuning. Although most previous studies only conducted fine-tuning once, Zolna et al. (2018) argued that two fine-tunings provided additional improvement. Thus, we repeated fine-tuning until we achieved no more improvements in the validation data. We refer to the model as AWD-LSTM-DOC (fin) in Table 6, which shows that repeated fine-tunings improved the perplexity by about 0.5.

Tables 7 and 8 respectively show the perplexities of AWD-LSTM-DOC and previous studies on PTB and WikiText-2[8]. These tables show that AWD-LSTM-DOC achieved the best perplexity. AWD-LSTM-DOC improved the perplexity by almost 2.0 on PTB and 3.5 on WikiText-2 from the state-of-the-art scores. The ensemble technique provided further improvement, as described in pre-

---

[8] We exclude models that use the statistics of the test data (Grave et al., 2017; Krause et al., 2017) from these tables because we regard neural language models as the basis of NLP applications and consider it unreasonable to know correct outputs during applications, e.g., machine translation. In other words, we focus on neural language models as the foundation of applications although we can combine the method using the statistics of test data with our AWD-LSTM-DOC.

vious studies (Zaremba et al., 2014; Takase et al., 2017), and improved the perplexity by at least 4 points on both datasets. Finally, the ensemble of the repeated finetuning models achieved 47.17 on the PTB test and 53.09 on the WikiText-2 test.

6 Experiments on Application Tasks

As described in Section 1, a neural encoder-decoder model can be interpreted as a conditional language model. To investigate the effect of DOC on an encoder-decoder model, we incorporate DOC into the decoder and examine its performance.

6.1 Dataset

We conducted experiments on machine translation and headline generation tasks. For machine translation, we used two kinds of sentence pairs (English-German and English-French) in the IWSLT 2016 dataset[9]. The training set respectively contains about 189K and 208K sentence pairs of English-German and English-French. We experimented in four settings: from English to German (En-De), its reverse (De-En), from English to French (En-Fr), and its reverse (Fr-En).

Headline generation is a task that creates a short summarization of an input sentence(Rush et al., 2015). Rush et al. (2015) constructed a headline generation dataset by extracting pairs of first sentences of news articles and their headlines from the annotated English Gigaword corpus (Napoles et al., 2012). They also divided the extracted sentence-headline pairs into three parts: training, validation, and test sets. The training set contains about 3.8M sentence-headline pairs. For our evaluation, we used the test set constructed by Zhou et al. (2017) because the one constructed by Rush et al. (2015) contains some invalid instances, as reported in Zhou et al. (2017).

6.2 Encoder-Decoder Model

For the base model, we adopted an encoder-decoder with an attention mechanism described in Kiyono et al. (2017). The encoder consists of a 2-layer bidirectional LSTM, and the decoder consists of a 2-layer LSTM with attention proposed by Luong et al. (2015). We interpreted the layer after computing the attention as the 3rd layer of the decoder. We refer to this encoder-decoder as EncDec. For the hyperparameters, we followed the setting of Kiyono et al. (2017) except for the sizes of hidden states and embeddings. We used 500 for machine translation and 400 for headline generation. We constructed a vocabulary set by using Byte-Pair-Encoding[10] (BPE) (Sennrich et al., 2016). We set the number of BPE merge operations at 16K for the machine translation and 5K for the headline generation.

Model	En-De	De-En	En-Fr	Fr-En
EncDec	23.05	28.18	34.37	34.07
EncDec+DOC ($i_3 = 2$)	23.62	29.12	36.09	34.41
EncDec+DOC ($i_3 = i_2 = 2$)	**23.97**	**29.33**	**36.11**	**34.72**

Table 9: BLEU scores on test sets in the IWSLT 2016 dataset. We report averages of three runs.

Model	RG-1	RG-2	RG-L
EncDec	46.77	24.87	43.58
EncDec+DOC ($i_3 = 2$)	46.91	24.91	43.73
EncDec+DOC ($i_3 = i_2 = 2$)	**46.99**	**25.29**	**43.83**
ABS (Rush et al., 2015)	37.41	15.87	34.70
SEASS (Zhou et al., 2017)	46.86	24.58	43.53
Kiyono et al. (2017)	46.34	24.85	43.49

Table 10: ROUGE F1 scores in headline generation test data provided by Zhou et al. (2017). RG in table denotes ROUGE. For our implementations (the upper part), we report averages of three runs.

In this experiment, we compare DOC to the base EncDec. We prepared two DOC settings: using only the final layer, that is, a setting that is identical to MoS, and using both the final and middle layers. We used the 2nd and 3rd layers in the latter setting because this case achieved the best performance on the language modeling task in Section 5.3. We set $i_3 = 2$ and $i_2 = 2, i_3 = 2$. For this experiment, we modified a publicly available encode-decoder implementation[11].

6.3 Results

Table 9 shows the BLEU scores of each method. Since an initial value often drastically varies the result of a neural encoder-decoder, we reported the average of three models trained from different initial values and random seeds. Table 9 indicates that EncDec+DOC outperformed EncDec.

Table 10 shows the ROUGE F1 scores of each method. In addition to the results of our implementations (the upper part), the lower part represents the published scores reported in previous studies. For the upper part, we reported the average of three models (as in Table 9). EncDec+DOC outperformed EncDec on all scores. Moreover, EncDec

---

[9] https://wit3.fbk.eu/

[10] https://github.com/rsennrich/subword-nmt

[11] https://github.com/mlpnlp/mlpnlp-nmt/

outperformed the state-of-the-art method (Zhou et al., 2017) on the ROUGE-2 and ROUGE-L F1 scores. In other words, our baseline is already very strong. We believe that this is because we adopted a larger embedding size than Zhou et al. (2017). It is noteworthy that DOC improved the performance of EncDec even though EncDec is very strong.

These results indicate that DOC positively influences a neural encoder-decoder model. Using the middle layer also yields further improvement because EncDec+DOC ($i_3 = i_2 = 2$) outperformed EncDec+DOC ($i_3 = 2$).

7 Experiments on Constituency Parsing

Choe and Charniak (2016) achieved high F1 scores on the Penn Treebank constituency parsing task by transforming candidate trees into a symbol sequence (S-expression) and reranking them based on the perplexity obtained by a neural language model. To investigate the effectiveness of DOC, we evaluate our language models following their configurations.

7.1 Dataset

We used the Wall Street Journal of the Penn Treebank dataset. We used the section 2-21 for training, 22 for validation, and 23 for testing. We applied the preprocessing codes of Choe and Charniak (2016)[12] to the dataset and converted a token that appears fewer than ten times in the training dataset into a special token *unk*. For reranking, we prepared 500 candidates obtained by the Charniak parser (Charniak, 2000).

7.2 Models

We compare AWD-LSTM-DOC with AWD-LSTM (Merity et al., 2018) and AWD-LSTM-MoS (Yang et al., 2018). We trained each model with the same hyperparameters from our language modeling experiments (Section 5). We selected the model that achieved the best perplexity on the validation set during the training.

7.3 Results

Table 11: Bracketing F1 scores on the PTB test set (Section 23). This table includes reranking models trained on the PTB without external data.

Table 11 shows the bracketing F1 scores on the PTB test set. This table is divided into three parts by horizontal lines; the upper part describes the scores by single language modeling based rerankers, the middle part shows the results by ensembling five rerankers, and the lower part represents the current state-of-the-art scores in the setting without external data. The upper part also contains the score reported in Choe and Charniak (2016) that reranked candidates by the simple LSTM language model. This part indicates that our implemented rerankers outperformed the simple LSTM language model based reranker, which achieved 92.6 F1 score (Choe and Charniak, 2016). Moreover, AWD-LSTM-DOC outperformed AWD-LSTM and AWD-LSTM-MoS. These results correspond to the language modeling task.

The middle part shows that AWD-LSTM-DOC also outperformed AWD-LSTM and AWD-LSTM-MoS in the ensemble setting. In addition, we can improve the performance by exchanging the base parser with a stronger one. In fact, we achieved 94.29 F1 score by reranking the candidates from retrained Recurrent Neural Network Grammars (RNNG) (Dyer et al., 2016)[13], that achieved 91.2 F1 score in our configuration. Moreover, the lowest row of the middle part indicates the result by reranking the candidates from the retrained neural encoder-decoder based parser (Suzuki et al., 2018). Our base parser has two different parts from Suzuki et al. (2018). First, we used the sum of the hidden states of the forward and backward RNNs as the hidden layer for each RNN[14]. Second, we tied the embedding matrix to the weight matrix to compute

---

[12] https://github.com/cdg720/emnlp2016

[13] The output of RNNG is not in descending order because it samples candidates based on their scores. Thus, we prepared more candidates (i.e., 700) to be able to obtain correct instances as candidates.

[14] We used the deep bidirectional encoder described at http://opennmt.net/OpenNMT/training/models/ instead of a basic bidirectional encoder.

the probability distributions in the decoder. The retrained parser achieved 93.12 F1 score. Finally, we achieved 94.47 F1 score by reranking its candidates with AWD-LSTM-DOC. We expect that we can achieve even better score by replacing the base parser with the current state-of-the-art one (Kitaev and Klein, 2018).

8 Related Work

Bengio et al. (2003) are pioneers of neural language models. To address the curse of dimensionality in language modeling, they proposed a method using word embeddings and a feed-forward neural network (FFNN). They demonstrated that their approach outperformed n-gram language models, but FFNN can only handle fixed-length contexts. Instead of FFNN, Mikolov et al. (2010) applied RNN (Elman, 1990) to language modeling to address the entire given sequence as a context. Their method outperformed the Kneser-Ney smoothed 5-gram language model (Kneser and Ney, 1995; Chen and Goodman, 1996).

Researchers continue to try to improve the performance of RNN language models. Zaremba et al. (2014) used LSTM (Hochreiter and Schmidhuber, 1997) instead of a simple RNN for language modeling and significantly improved an RNN language model by applying dropout (Srivastava et al., 2014) to all the connections except for the recurrent connections. To regularize the recurrent connections, Gal and Ghahramani (2016) proposed variational inference-based dropout. Their method uses the same dropout mask at each timestep. Zolna et al. (2018) proposed fraternal dropout, which minimizes the differences between outputs from different dropout masks to be invariant to the dropout mask. Melis et al. (2018) used black-box optimization to find appropriate hyperparameters for RNN language models and demonstrated that the standard LSTM with proper regularizations can outperform other architectures.

Apart from dropout techniques, Inan et al. (2017) and Press and Wolf (2017) proposed the word tying method (WT), which unifies word embeddings (E in Equation 4) with the weight matrix to compute probability distributions (W in Equation 2). In addition to quantitative evaluation, Inan et al. (2017) provided a theoretical justification for WT and proposed the augmented loss technique (AL), which computes an objective probability based on word embeddings. In addition to these regularization techniques, Merity et al. (2018) used DropConnect (Wan et al., 2013) and averaged SGD (Polyak and Juditsky, 1992) for an LSTM language model. Their AWD-LSTM achieved lower perplexity than Melis et al. (2018) on PTB and WikiText-2.

Previous studies also explored superior architecture for language modeling. Zilly et al. (2017) proposed recurrent highway networks that use highway layers (Srivastava et al., 2015) to deepen recurrent connections. Zoph and Le (2017) adopted reinforcement learning to construct the best RNN structure. However, as mentioned, Melis et al. (2018) established that the standard LSTM is superior to these architectures. Apart from RNN architecture, Takase et al. (2017) proposed the input-to-output gate (IOG), which boosts the performance of trained language models.

As described in Section 3, Yang et al. (2018) interpreted training language modeling as matrix factorization and improved performance by computing multiple probability distributions. In this study, we generalized their approach to use the middle layers of RNNs. Finally, our proposed method, DOC, achieved the state-of-the-art score on the standard benchmark datasets.

Some studies provided methods that boost performance by using statistics obtained from test data. Grave et al. (2017) extended a cache model (Kuhn and De Mori, 1990) for RNN language models. Krause et al. (2017) proposed dynamic evaluation that updates parameters based on a recent sequence during testing. Although these methods might also improve the performance of DOC, we omitted such investigation to focus on comparisons among methods trained only on the training set.

9 Conclusion

We proposed *Direct Output Connection* (DOC), a generalization method of MoS introduced by Yang et al. (2018). DOC raises the expressive power of RNN language models and improves quality of the model. DOC outperformed MoS and achieved the best perplexities on the standard benchmark datasets of language modeling: PTB and WikiText-2. Moreover, we investigated its effectiveness on machine translation and headline generation. Our results show that DOC also improved the performance of EncDec and using a middle layer positively affected such application tasks.

Abstract

In recent years, the natural language processing community has moved away from task-specific feature engineering, i.e., researchers discovering ad-hoc feature representations for various tasks, in favor of general-purpose methods that learn the input representation by themselves. However, state-of-the-art approaches to disfluency detection in spontaneous speech transcripts currently still depend on an array of hand-crafted features, and other representations derived from the output of pre-existing systems such as language models or dependency parsers. As an alternative, this paper proposes a simple yet effective model for automatic disfluency detection, called an auto-correlational neural network (ACNN). The model uses a convolutional neural network (CNN) and augments it with a new auto-correlation operator at the lowest layer that can capture the kinds of "rough copy" dependencies that are characteristic of repair disfluencies in speech. In experiments, the ACNN model outperforms the baseline CNN on a disfluency detection task with a 5% increase in f-score, which is close to the previous best result on this task.

1 Introduction

Disfluency informally refers to any interruptions in the normal flow of speech, including false starts, corrections, repetitions and filled pauses. Shriberg (1994) defines three distinct parts of a speech disfluency, referred to as the *reparandum*, *interregnum* and *repair*. As illustrated in Example 1, the reparandum *to Boston* is the part of the utterance that is replaced, the interregnum *uh, I mean* (which consists of a filled pause *uh* and a discouse marker *I mean*) is an optional part of a disfluent structure, and the repair *to Denver* replaces the reparandum. The fluent version is obtained by removing reparandum and interregnum words although disfluency detection models mainly deal with identifying and removing reparanda. The reason is that filled pauses and discourse markers belong to a closed set of words and phrases and are trivial to detect (Johnson and Charniak, 2004).

$$\begin{gathered}\textit{I want a flight } \overbrace{\textit{to Boston,}}^{\text{reparandum}} \\ \underbrace{\textit{uh, I mean}}_{\text{interregnum}} \underbrace{\textit{to Denver}}_{\text{repair}} \textit{ on Friday}\end{gathered} \tag{1}$$

In disfluent structures, the repair (e.g., *to Denver*) frequently seems to be a "rough copy" of the reparandum (e.g., *to Boston*). In other words, they incorporate the same or very similar words in roughly the same word order. In the Switchboard training set (Godfrey and Holliman, 1993), over 60% of the words in the reparandum are exact copies of words in the repair. Thus, this similarity is strong evidence of a disfluency that can help the model detect reparanda (Charniak and Johnson, 2001; Johnson and Charniak, 2004). As a result, models which are able to detect "rough copies" are likely to perform well on this task.

Currently, state-of-the-art approaches to disfluency detection depend heavily on hand-crafted pattern match features, specifically designed to find such "rough copies" (Zayats et al., 2016; Jamshid Lou and Johnson, 2017). In contrast to many other sequence tagging tasks (Plank et al., 2016; Yu et al., 2017), "vanilla" convolutional neural networks (CNNs) and long short-term memory (LSTM) models operating only on words or characters are surprisingly poor at disfluency detection (Zayats et al., 2016). As such, the task of disfluency detection sits in opposition to the ongoing trend in NLP away from task-specific feature engineering — i.e., researchers discovering ad-hoc feature representations for various tasks — in favor of general-purpose methods that

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4610–4619
Brussels, Belgium, October 31 - November 4, 2018.

learn the input representation by themselves (Collobert and Weston, 2008).

In this paper, we hypothesize that LSTMs and CNNs cannot not easily learn "rough copy" dependencies. We address this problem in the context of a CNN by introducing a novel auto-correlation operator. The resulting model, called an *auto-correlational neural network (ACNN)*, is a generalization of a CNN with an auto-correlation operator at the lowest layer. Evaluating the ACNN in the context of disfluency detection, we show that introducing the auto-correlation operator increases f-score by 5% over a baseline CNN. Furthermore, the ACNN — operating only on word inputs — achieves results which are competitive with much more complex approaches relying on hand-crafted features and outputs from pre-existing systems such as language models or dependency parsers. In summary, the main contributions of this paper are:

- We introduce the auto-correlational neural network (ACNN), a generalization of a CNN incorporating auto-correlation operations,
- In the context of disfluency detection, we show that the ACNN captures important properties of speech repairs including "rough copy" dependencies, and
- Using the ACNN, we achieve competitive results for disfluency detection without relying on any hand-crafted features or other representations derived from the output of pre-existing systems.

2 Related Work

Approaches to disfluency detection task fall into three main categories: noisy channel models, parsing-based approaches and sequence tagging approaches. Noisy channel models (NCMs) (Johnson and Charniak, 2004; Johnson et al., 2004) use complex tree adjoining grammar (TAG) (Shieber and Schabes, 1990) based channel models to find the "rough copy" dependencies between words. The channel model uses the similarity between the reparandum and the repair to allocate higher probabilities to exact copy reparandum words. Using the probabilities of TAG channel model and a bigram language model (LM) derived from training data, the NCM generates n-best disfluency analyses for each sentence at test time. The analyses are then reranked using a language model which is sensitive to the global properties of the sentence, such as a syntactic parser based LM (Johnson and Charniak, 2004; Johnson et al., 2004). Some works have shown that rescoring the n-best analyses with external n-gram (Zwarts and Johnson, 2011) and deep learning LMs (Jamshid Lou and Johnson, 2017) trained on large speech and non-speech corpora, and using the LM scores along with other features (i.e. pattern match and NCM ones) into a MaxEnt reranker (Johnson et al., 2004) improves the performance of the baseline NCM, although this creates complex runtime dependencies.

Parsing-based approaches detect disfluencies while simultaneously identifying the syntactic structure of the sentence. Typically, this is achieved by augmenting a transition-based dependency parser with a new action to detect and remove the disfluent parts of the sentence and their dependencies from the stack (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Yoshikawa et al., 2016). Joint parsing and disfluency detection can compare favorably to pipelined approaches, but requires large annotated treebanks containing both disfluent and syntatic structures for training.

Our proposed approach, based on an auto-correlational neural network (ACNN), belongs to the class of sequence tagging approaches. These approaches use classification techniques such as conditional random fields (Liu et al., 2006; Ostendorf and Hahn, 2013; Zayats et al., 2014; Ferguson et al., 2015), hidden Markov models (Liu et al., 2006; Schuler et al., 2010) and deep learning based models (Hough and Schlangen, 2015; Zayats et al., 2016) to label individual words as fluent or disfluent. In much of the previous work on sequence tagging approaches, improved performance has been gained by proposing increasingly complicated labeling schemes. In this case, a model with begin-inside-outside (BIO) style states which labels words as being inside or outside of edit region[1] is usually used as the baseline sequence tagging model. Then in order to come up with different pattern matching lexical cues for repetition and correction disfluencies, they extend the baseline state space with new explicit repair states to consider the words at repair region, in addition to edit region (Ostendorf and Hahn,

---

[1] For state labels, edit corresponds to reparandum.

2013; Zayats et al., 2014, 2016). A model which uses such labeling scheme may generate illegal label sequences at test time. As a solution, integer linear programming (ILP) constraints are applied to the output of classifier to avoid inconsistencies between neighboring labels (Georgila, 2009; Georgila et al., 2010; Zayats et al., 2016). This contrasts with our more straightforward approach, which directly labels words as being fluent or disfluent, and does not require any post-processing or annotation modifications.

The most similar work to ours is recent work by Zayats et al. (2016) that investigated the performance of a bidirectional long-short term memory network (BLSTM) for disfluency detection. Zayats et al. (2016) reported that a BLSTM operating only on words underperformed the same model augmented with hand-crafted pattern match features and POS tags by 7% in terms of f-score. In addition to lexically grounded features, some works incorporate prosodic information extracted from speech (Kahn et al., 2005; Ferguson et al., 2015; Tran et al., 2018). In this work, our primary motivation is to rectify the architectural limitations that prevent deep neural networks from automatically learning appropriate features from words alone. Therefore, our proposed model eschews manually engineered features and other representations derived from dependency parsers, language models or tree adjoining grammar transducers that are used to find "rough copy" dependencies. Instead, we aim to capture these kinds of dependencies automatically.

3 Convolutional and Auto-Correlational Networks

In this section, we introduce our proposed auto-correlation operator and the resulting auto-correlational neural network (ACNN) which is the focus of this work.

A convolutional or auto-correlational network computes a series of h feature representations $X^{(0)}, X^{(1)}, \ldots, X^{(h)}$, where $X^{(0)}$ is the input data, $X^{(h)}$ is the final (output) representation, and each non-input representation $X^{(k)}$ for $k > 0$, is computed from the preceding representation $X^{(k-1)}$ using a convolution or auto-correlation operation followed by an element-wise non-linear function.

Restricting our focus to convolutions in one dimension, as used in the context of language processing, each representation $X^{(k)}$ is a matrix of size (n, m_k), where n is the number of words in the input and m_k is the feature dimension of representation k, or equivalently it can be viewed as a sequence of n row vectors $X^{(k)} = (\boldsymbol{x}_1^{(k)}, \ldots, \boldsymbol{x}_n^{(k)})$, where $\boldsymbol{x}_t^{(k)}$ is the row vector of length m_k that represents the tth word at level k.

Consistent with the second interpretation, the input representation $X^{(0)} = (\boldsymbol{x}_1^{(0)}, \ldots, \boldsymbol{x}_n^{(0)})$ is a sequence of word embeddings, where m_0 is the length of the embedding vector and $\boldsymbol{x}_t^{(0)}$ is the word embedding for the tth word.

Each non-input representation $X^{(k)}, k > 0$ is formed by column-wise stacking the output of one or more convolution or auto-correlation operations applied to the preceding representation, and then applying an element-wise non-linear function. Formally, we define:

$$\begin{aligned} Y^{(k)} &= \left(F^{(k,1)}(X^{(k-1)}); \ldots; F^{(k,m_k)}(X^{(k-1)})\right) \\ X^{(k)} &= N^{(k)}(Y^{(k)}) \end{aligned} \tag{2}$$

where $F^{(k,u)}$ is the uth operator applied at layer k, and $N^{(k)}$ is the non-linear operation applied at layer k. Each operator $F^{(k,u)}$ (either convolution or auto-correlation) is a function from $X^{(k-1)}$, which is a matrix of size (n, m_{k-1}), to a vector of length n. A network that employs only convolution operators is a convolutional neural network (CNN). We call a network that utilizes a mixture of convolution and auto-correlation operators an *auto-correlational neural network* (ACNN). In our networks, the non-linear operation $N^{(k)}$ is always element-wise $ReLU$, except for the last layer, which uses a $softmax$ non-linearity.

3.1 Convolution Operator

A one-dimensional convolution operation maps an input matrix $X = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$, where each $\boldsymbol{x}_t$ is a row vector of length m, to an output vector $\boldsymbol{y}$ of length n. The convolution operation is defined by a convolutional kernel A, which is applied to a window of words to produce a new output representation, and kernel width parameters ℓ and r, which define the number of words to the left and right of the target word included in the convolutional window. For example, assuming appropriate input padding where necessary, element y_t in the output vector $\boldsymbol{y}$ is computed as:

$$y_t \quad = \quad A \cdot X_{i:j} + \boldsymbol{b} \tag{3}$$

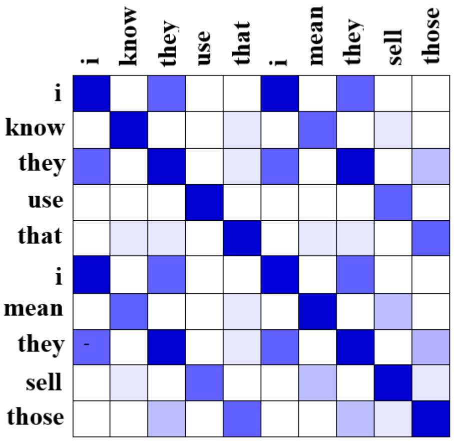

Figure 1: Cosine similarity between word embedding vectors learned by the ACNN model for the sentence "I know they use that I mean they sell those" (with disfluent words highlighted). In the figure, darker shades denote higher cosine values. "Rough copies" are clearly indicated by darkly shaded diagonals, which can be detected by our proposed auto-correlation operator.

where

A is a learned convolutional kernel of dimension $(\ell + r, m)$,

$X_{i:j}$ is the sub-matrix formed by selecting rows i to j from matrix X,

$\cdot$ is the dot product (a sum over elementwise multiplications),

i, j are given by $i = t - \ell$ and $j = t + r$, indicating the left and right extremities of the convolutional window effecting element y_t,

$\ell > 0$ is the left kernel width, and

$r > 0$ is right kernel width.

$\boldsymbol{b}$ is a learned bias vector of dimension n,

3.2 Auto-Correlation Operator

The auto-correlational operator is a generalisation of the convolution operator:

$$y_t = A \cdot X_{i:j} + B \cdot \hat{X}_{i:j,i:j} + \boldsymbol{b} \tag{4}$$

where y_t, A, X, $\boldsymbol{b}$, i and j are as in the convolution operator, and

$\hat{X}$ is a tensor of size (n, n, m) such that each vector $\hat{X}_{i,j,:}$ is given by $f(\boldsymbol{x}_i, \boldsymbol{x}_j)$,

$f(\boldsymbol{u}, \boldsymbol{v})$ is a binary operation on vectors, such as the Hadamard or element-wise product (i.e., $f(\boldsymbol{u}, \boldsymbol{v}) = \boldsymbol{u} \circ \boldsymbol{v}$), and

$\hat{X}_{i:j,i:j}$ is the sub-tensor formed by selecting indices i to j from the first two dimensions of tensor $\hat{X}$,

B is a learned convolutional kernel of dimension $(\ell + r, \ell + r, m)$.

Unlike convolution operations, which are linear, the auto-correlation operator introduces second-order interaction terms through the tensor $\hat{X}$ (since it multiplies the vector representations for each pair of input words). This naturally encodes the similarity between input words when applied at level $k = 1$ (or the co-activations of multiple CNN features, if applied at higher levels). As illustrated in Figure 1, blocks of similar words are indicative of "rough copies". We provide an illustration of the auto-correlation operation in Figure 2.

4 Experiments

4.1 Switchboard Dataset

We evaluate the proposed ACNN model for disfluency detection on the Switchboard corpus of conversational speech (Godfrey and Holliman, 1993). Switchboard is the largest available corpus (1.2×10^6 tokens) where disfluencies are annotated according to Shriberg's (1994) scheme:

[reparandum + {interregnum} repair]

where (+) is the interruption point marking the end of reparandum and {} indicate optional interregnum. We collapse this annotation to a binary classification scheme in which reparanda are labeled as disfluent and all other words as fluent. We disregard interregnum words as they are trivial to detect as discussed in Section 1.

Following Charniak and Johnson (2001), we split the Switchboard corpus into training, dev and test set as follows: training data consists of all sw[23]$*$.dff files, dev training consists of all sw4[5-9]$*$.dff files and test data consists of all sw4[0-1]$*$.dff files. We lower-case all text and remove all partial words and punctuations from the training data to make our evaluation both harder and more realistic (Johnson and Charniak, 2004). Partial words are strong indicators of disfluency; however, speech recognition models never generate them in their outputs.

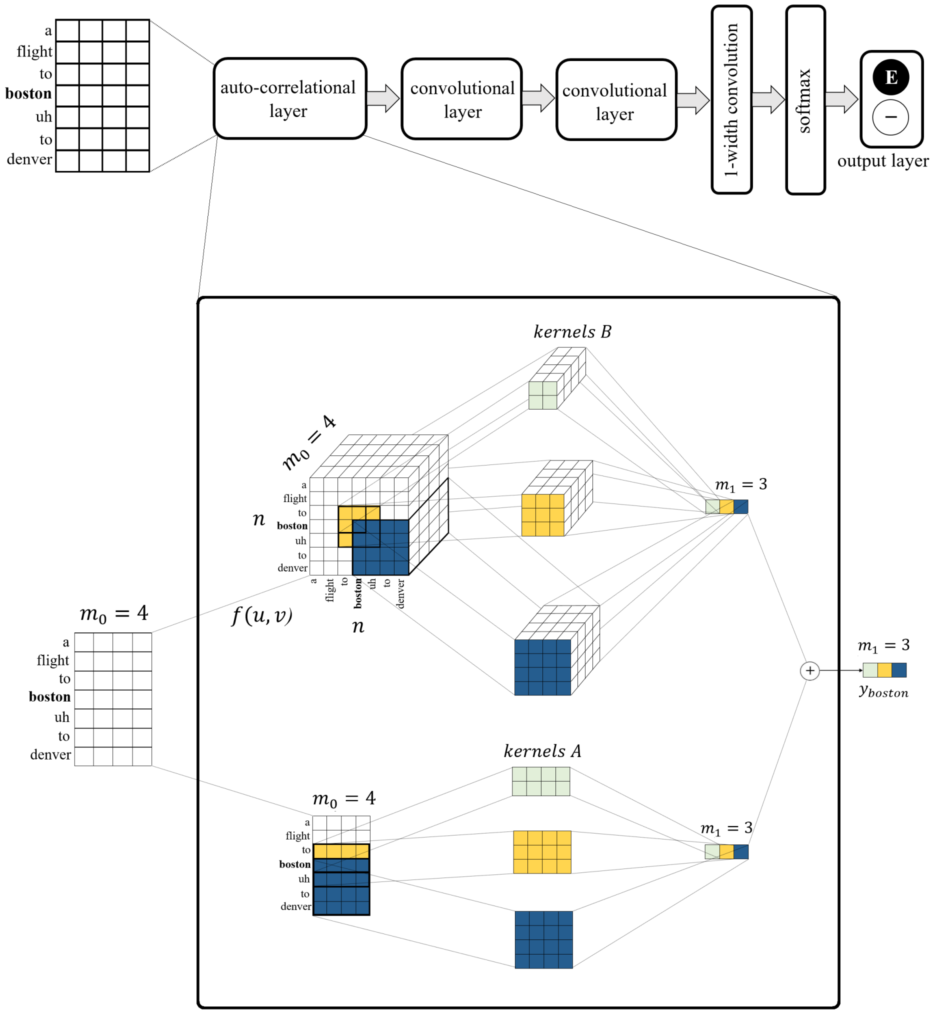

Figure 2: ACNN overview for labeling the target word "boston". A patch of words is fed into an auto-correlational layer. At inset bottom, the given patch of words is convolved with 2D kernels A of different sizes. At inset top, an auto-correlated tensor of size (n, n, m_0) is constructed by comparing each input vector $\boldsymbol{u} = \boldsymbol{x}_t$ with the input vector $\boldsymbol{v} = \boldsymbol{x}_{t'}$ using a binary function $f(\boldsymbol{u}, \boldsymbol{v})$. The auto-correlated tensor is convolved with 3D kernels B of different sizes. Each kernel group A and B outputs a matrix of size (n, m_1) (here, we depict only the row vector relating to the target word "boston"). These outputs are added element-wise to produce the feature representation that is passed to further convolutional layers, followed by a softmax layer. "E" = disfluent, "_" = fluent and m_0 = embedding size.

4.2 ACNN and CNN Baseline Models

We investigate two neural network models for disfluency detection; our proposed auto-correlational neural network (ACNN) and a convolutional neural network (CNN) baseline. The CNN baseline contains three convolutional operators (layers), followed by a width-1 convolution and a softmax output layer (to label each input word as either fluent or disfluent). The ACNN has the same general architecture as the baseline, except that we have replaced the first convolutional operator with an auto-correlation operator, as illustrated in Figure 2.

To ensure that equal effort was applied to the hyperparameter optimization of both models, we use randomized search (Bergstra and Bengio, 2012) to tune the optimization and architecture parameters separately for each model on the dev set, and to find an optimal stopping point for training. This results in different dimensions for each model. As indicated by Table 1, the resulting ACNN configuration has far fewer kernels at each layer than the CNN. However, as the auto-correlation kernels contain an additional dimension, both models have a similar number of parameters overall. Therefore, both models should have similar learning capacity except for their architectural differences (which is what we wish to investigate). Finally, we note that the resulting maximum right kernel width r_1 in the auto-correlational layer is 6. As illustrated in Figure 3, this is sufficient to capture almost all the "rough copies" in the Switchboard dataset (but could be increased for other datasets).

Configuration	CNN	ACNN
embedding dim	290	290
dropout rate	0.51	0.53
L_2 regularizer weight	0.13	0.23
#kernels at each layer	570	120
#kernel sizes at each layer	3	2
#words at left context ℓ_1	[0,1,4]	[5,3]
#words at left context ℓ_2	[1,2,3]	[4,2]
#words at left context ℓ_3	[0,1,2]	[3,2]
#words at right context r_1	[1,1,4]	[6,3]
#words at right context r_2	[1,2,4]	[5,3]
#words at right context r_3	[1,2,3]	[4,2]
#parameters	4.9M	4.9M

Table 1: Configuration of the CNN and ACNN models, where ℓ_k refers to the left kernel width at layer k, and r_k refers to the right kernel width at layer k. Both models have a similar total number of parameters.

For the ACNN, we considered a range of possible binary functions $f(\boldsymbol{u}, \boldsymbol{v})$ to compare the input vector $\boldsymbol{u} = \boldsymbol{x}_t$ with the input vector $\boldsymbol{v} = \boldsymbol{x}_{t'}$ in the auto-correlational layer. However, in initial experiments we found that the Hadamard or element-wise product (i.e. $f(\boldsymbol{u}, \boldsymbol{v}) = \boldsymbol{u} \circ \boldsymbol{v}$) achieved the best results. We also considered concatenating the outputs of kernels A and B in Equation 4, but we found that element-wise addition produced slightly better results on the dev set.

4.2.1 Implementation Details

In both models, we use $ReLU$ for the non-linear operation, all stride sizes are one word and there are no pooling operations. We randomly initialize the word embeddings and all weights of the model from a uniform distribution. The bias terms are initialized to be 1. To reduce overfitting, we apply dropout (Srivastava et al., 2014) to the input word embeddings and L_2 regularization to the weights of the width-1 convolutional layer. For parameter optimization, we use the Adam optimizer (Kingma and Ba, 2014) with a mini-batch size of 25 and an initial learning rate of 0.001.

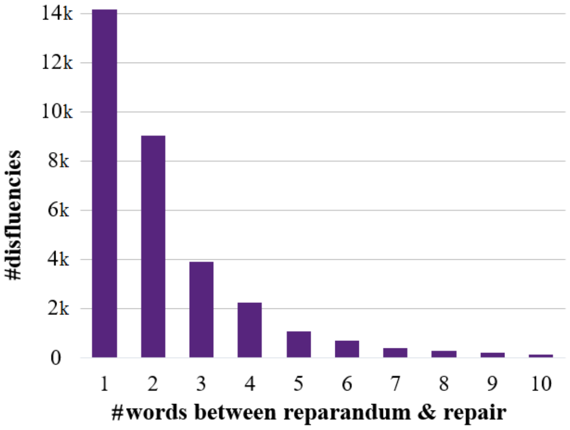

Figure 3: Distribution over the number of words in between the reparandum and the interregnum in the Switchboard training set (indicating the distance between "rough copies").

5 Results

As in previous work (Johnson and Charniak, 2004), we evaluate our model using precision, recall and f-score, where true positives are the words in the edit region (i.e., the reparandum words). As Charniak and Johnson (2001) observed, only 6% of words in the Switchboard corpus are disfluent, so accuracy is not a good measure of system performance. F-score, on the other hand, focuses more on detecting "edited" words, so it is more appropriate for highly skewed data.

Table 2 compares the dev set performance of the ACNN model against our baseline CNN, as well as the LSTM and BLSTM models proposed by Zayats et al. (2016) operating only on word inputs (i.e., without any disfluency pattern-match features). Our baseline CNN outperforms both the LSTM and the BLSTM, while the ACNN model clearly outperforms the baseline CNN, with a further 5% increase in f-score. In particular, the ACNN noticably improves recall without degrading precision.

model	P	R	F
BLSTM (words)*	87.8	71.1	78.6
LSTM (words)*	87.6	71.4	78.7
CNN	89.4	74.6	81.3
ACNN	**90.0**	**82.8**	**86.2**

Table 2: Precision (P), recall (R) and f-score (F) on the dev set for the BLSTM and LSTM models using words alone from *Zayats et al. (2016), as well as our baseline CNN and ACNN model.

To further investigate the differences between the two CNN-based models, we randomly select 100 sentences containing disfluencies from the Switchboard dev set and categorize them according to Shriberg's (1994) typology of speech repair disfluencies. *Repetitions* are repairs where the reparandum and repair portions of the disfluency are identical, while *corrections* are where the reparandum and repairs differ (so corrections are much harder to detect). *Restarts* are where the speaker abandons a sentence prefix, and starts a fresh sentence. As Table 3 shows, the ACNN model is better at detecting repetition and correction disfluencies than the CNN, especially for the more challenging correction disfluencies. On the other hand, the ACNN is no better than the baseline at detecting restarts, probably because the restart typically does not involve a rough copy dependency. Luckily restarts are much rarer than repetition and correction disfluencies.

model	**Rep.**	**Cor.**	**Res.**	**All**
CNN	93.3	66.0	57.1	80.4
ACNN	97.5	80.0	57.1	88.9

Table 3: F-scores for different types of disfluencies on a subset of the Switchboard dev set containing 140 disfluent structures — including 85 repetitions (Rep.), 51 corrections (Cor.) and 4 restarts (Res.).

We also repeated the analysis of (Zayats et al., 2014) on the dev data, so we can compare our models to their extended BLSTM model with a 17-state CRF output and hand-crafted features, including partial-word and POS tag features that enable it to capture some "rough copy" dependencies. As expected, the ACNN outperforms both the CNN and the extended BLSTM model, especially in the "Other" category that involve the non-repetition dependencies.

model	**Rep.**	**Other**	**Either**
CNN	92.2	66.7	81.3
BLSTM (17 states)*	94.1	66.7	85.8
ACNN	96.6	73.3	86.2

Table 4: F-scores for different types of disfluencies for the CNN, ACNN and BLSTM (17 states) *(Zayats et al., 2016) using the Switchboard dev set.

Finally, we compare the ACNN model to state-of-the-art methods from the literature, evaluated on the Switchboard test set. Table 5 shows that the ACNN model is competitive with recent models from the literature. The three models that score more highly than the ACNN all rely on hand-crafted features, additional information sources such as partial-word features (which would not be available in a realistic ASR application), or external resources such as dependency parsers and language models. The ACNN, on the other hand, only uses whole-word inputs and learns the "rough copy" dependencies between words without requiring any manual feature engineering.

5.1 Qualitative Analysis

We conduct an error analysis on the Switchboard dev set to characterize the disfluencies that the ACNN model can capture and those which are difficult for the model to detect. In the following examples, the highlighted words indicate ground truth disfluency labels and the underlined ones are the ACNN predictions.

1. But if you let them yeah if you let them in a million at a time it wouldn't make that you know it wouldn't make that big a bulge in the

population

2. They’re handy uh they they come in handy at the most unusual times
3. My mechanics loved it because it was an old it was a sixty-five buick
4. Well I I I think we did I think we did learn some lessons that we weren’t uh we weren’t prepared for
5. Uh I have never even I have never even looked at one closely
6. But uh when I was when my kids were young I was teaching at a university
7. She said she’ll never put her child in a in a in a in a in a preschool
8. Well I think they’re at they’re they’ve come a long way
9. I I like a I saw the the the the tapes that were that were run of marion berry’s drug bust
10. But I know that in some I know in a lot of rural areas they’re not that good

According to examples 1-10, the ACNN detects *repetition* (e.g. 1, 5) and *correction* disfluencies (e.g. 3, 6, 10). It also captures complex structures where there are multiple or nested disfluencies (e.g. 2, 8) or stutter-like repetitions (e.g. 4, 7, 9).

11. My point was that there is for people who don’t want to do the military service it would be neat if there were an alternative . . .
12. I believe from what I remember of the literature they gave uh if you fail I believe they give you one more chance
13. Kind of a coarse kind of test
14. So we could pour concrete and support it with a a nice firm four by four posts
15. But uh I’m afraid I’m I’m probably in the minority
16. Same thing same thing that the her kids had
17. Did you you framed it in uh on on you framed in new square footage
18. And and and there needs to be a line drawn somewhere at reasonable and proper
19. . . . I think there’s a couple of levels of tests in terms of of drugs
20. See they have uh we have two the both c spans here

In some cases where repetitions are fluent, the model has incorrectly detected the first occurence of the word as disfluency (e.g. 13, 14, 15, 19). Moreover, when there is a long distance between reparandum and repair words (e.g. 11, 12), the model usually fails to detect the reparanda. In some sentences, the model is also unable to detect the disfluent words which result in ungrammatical sentences (e.g. 16, 17, 18, 20). In these examples, the undetected disfluencies “the”, “did”, “at” and “two the” cause the residual sentence to be ungrammatical.

We also discuss the types of disfluency captured by the ACNN model, but not by the baseline CNN. In the following examples, the ACNN predictions (underlined words) are the same as the ground truth disfluency labels (highlighted words). The **bolded** words indicate the CNN prediction of disfluencies.

21. Uh well **I** actually my dad’s my dad’s almost ninety
22. Not a man not a repair man but just a friend
23. we**’re** from a county we’re from the county they marched in
24. Now let’s now we’re done
25. And they’ve most of them have been pretty good
26. I do as far as uh as far as uh as far as immigration as a whole goes
27. No need to use this to play around with this space stuff anymore
28. We couldn’t survive **in a** in a juror in a trial system without a jury
29. You stay within your uh within your means
30. So **we’re** we’re part we’re actually part of MIT

The ACNN model has a generally better performance in detecting "rough copies" which are important indicator of *repetition* (e.g. 21, 29), *correction* (e.g. 22, 23, 24, 25, 27), and *stutter-like* (e.g. 26, 28, 30) disfluencies.

6 Conclusion

This paper presents a simple new model for disfluency detection in spontaneous speech transcripts. It relies on a new auto-correlational kernel that is designed to detect the "rough copy" dependencies that are characteristic of speech disfluencies, and combines it with conventional convolutional kernels to form an auto-correlational neural network (ACNN). We show experimentally that using the ACNN model improves over a CNN baseline on disfluency detection task, indicating that the auto-correlational kernel can in fact detect the rough copy dependencies between words in disfluencies. The addition of the auto-correlational kernel permits a fairly conventional architecture to achieve near state-of-the-art results without complex hand-crafted features or external information sources.

We expect that the performance of the ACNN model can be further improved in future by using more complex similarity functions and by incorporating similar kinds of external information (e.g. prosody) used in other disfluency models. In future work, we also intend to investigate other applications of the auto-correlational kernel. The auto-correlational layer is a generic neural network layer, so it can be used as a component of other architectures, such as RNNs. It might also be useful in very different applications such as image processing.

Abstract

LSTMs are powerful tools for modeling contextual information, as evidenced by their success at the task of language modeling. However, modeling contexts in very high dimensional space can lead to poor generalizability. We introduce the Pyramidal Recurrent Unit (PRU), which enables learning representations in high dimensional space with more generalization power and fewer parameters. PRUs replace the linear transformation in LSTMs with more sophisticated interactions including pyramidal and grouped linear transformations. This architecture gives strong results on word-level language modeling while reducing the number of parameters significantly. In particular, PRU improves the perplexity of a recent state-of-the-art language model Merity et al. (2018) by up to 1.3 points while learning 15-20% fewer parameters. For similar number of model parameters, PRU outperforms all previous RNN models that exploit different gating mechanisms and transformations. We provide a detailed examination of the PRU and its behavior on the language modeling tasks. Our code is open-source and available at `https://sacmehta.github.io/PRU/`.

1 Introduction

Long short term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) are popular for many sequence modeling tasks and are used extensively in language modeling. A key to their success is their articulated gating structure, which allows for more control over the information passed along the recurrence. However, despite the sophistication of the gating mechanisms employed in LSTMs and similar recurrent units, the input and context vectors are treated with simple linear transformations prior to gating. Non-linear transformations such as convolutions (Kim et al., 2016) have been used, but these have not achieved the performance of well regularized LSTMs for language modeling (Melis et al., 2018).

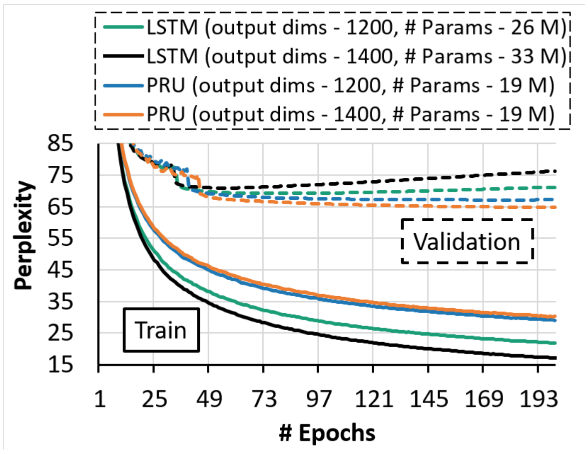

Figure 1: Comparison of training (solid lines) and validation (dashed lines) perplexities on the Penn Treebank with standard dropout for pyramidal recurrent units (PRU) and LSTM. PRUs learn latent representations in very high-dimensional space with good generalizability and fewer parameters. See Section 3 for more details about PRUs. Best viewed in color.

A natural way to improve the expressiveness of linear transformations is to increase the number of dimensions of the input and context vectors, but this comes with a significant increase in the number of parameters which may limit generalizability. An example is shown in Figure 1, where LSTMs performance decreases with the increase in dimensions of the input and context vectors. Moreover, the semantics of the input and context vectors are different, suggesting that each may benefit from specialized treatment.

Guided by these insights, we introduce a new recurrent unit, the Pyramidal Recurrent Unit (PRU), which is based on the LSTM gating structure. Figure 2 provides an overview of the PRU. At

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4620–4630
Brussels, Belgium, October 31 - November 4, 2018.

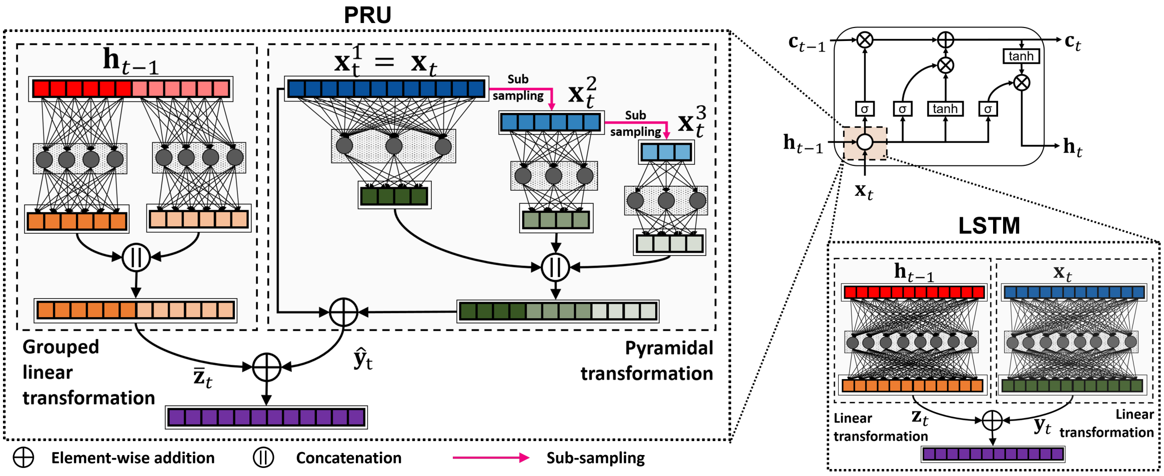

Figure 2: Block diagram visualizing the transformations in pyramidal recurrent unit (left) and the LSTM (bottom right) along with the LSTM gating architecture (top right). **Blue**, **red**, **green** (or **orange**), and **purple** signify the current input $\mathbf{x}_t$, output of the previous cell $\mathbf{h}_{t-1}$, the output of transformations, and the fused output, respectively. The color intensity is used to represent sub-sampling and grouping operations.

the heart of the PRU is the *pyramidal transformation* (PT), which uses subsampling to effect multiple views of the input vector. The subsampled representations are combined in a pyramidal fusion structure, resulting in richer interactions between the individual dimensions of the input vector than is possible with a linear transformation. Context vectors, which have already undergone this transformation in the previous cell, are modified with a *grouped linear transformation* (GLT) which allows the network to learn latent representations in high dimensional space with fewer parameters and better generalizability (see Figure 1).

We show that PRUs can better model contextual information and demonstrate performance gains on the task of language modeling. The PRU improves the perplexity of the current state-of-the-art language model (Merity et al., 2018) by up to 1.3 points, reaching perplexities of 56.56 and 64.53 on the Penn Treebank and WikiText2 datasets while learning 15-20% fewer parameters. Replacing an LSTM with a PRU results in improvements in perplexity across a variety of experimental settings. We provide detailed ablations which motivate the design of the PRU architecture, as well as detailed analysis of the effect of the PRU on other components of the language model.

2 Related work

Multiple methods, including a variety of gating structures and transformations, have been proposed to improve the performance of recurrent neural networks (RNNs). We first describe these approaches and then provide an overview of recent work in language modeling.

Gating-based mechanisms: The performance of RNNs have been greatly improved by gating mechanisms such as LSTMs (Hochreiter and Schmidhuber, 1997), GRUs (Chung et al., 2014), peep-hole connections (Gers and Schmidhuber, 2000), SRUs (Lei et al., 2018), and RANs (Lee et al., 2017). In this paper, we extend the gating architecture of LSTMs (Hochreiter and Schmidhuber, 1997), a widely used recurrent unit across different domains.

Transformations: Apart from the widely used linear transformation for modeling the temporal data, another transformation that has gained popularity is convolution (LeCun et al., 1995). Convolution-based methods have gained attention in computer vision tasks (Krizhevsky et al., 2012) as well as some of the natural language processing tasks including machine translation (Gehring et al., 2017). Convolution-based methods for language modeling, such as CharCNN (Kim et al., 2016), have not yet achieved the performance of well regularized LSTMs (Melis et al., 2018). We inherit ideas from convolution-based approaches, such as sub-sampling, to learn richer representations (Krizhevsky et al., 2012; Han et al., 2017).

Regularization: Methods such as dropout (Srivastava et al., 2014), variational dropout (Kingma et al., 2015), and weight dropout (Merity et al., 2018) have been proposed to regularize RNNs. These methods can be easily applied to PRUs.

Other efficient RNN networks: Recently, there has been an effort to improve the efficiency of RNNs. These approaches include quantization (Xu et al., 2018), skimming (Seo et al., 2018; Yu et al., 2017), skipping (Campos et al., 2018), and query reduction (Seo et al., 2017). These approaches extend standard RNNs and therefore, these approaches are complementary to our work.

Language modeling: Language modeling is a fundamental task for NLP and has garnered significant attention in recent years (see Table 1 for comparison with state-of-the-art methods). Merity et al. (2018) introduce regularization techniques such as weight dropping which, coupled with a non-monotonically triggered ASGD optimization, achieves strong performance improvements. Yang et al. (2018) extend Merity et al. (2018) with the mixture of softmaxes (MoS) technique, which increases the rank of the matrix used to compute next-token probabilities. Further, Merity et al. (2017) and Krause et al. (2018) propose methods to improve inference by adapting models to recent sequence history. Our work is complementary to these recent softmax layer and inference procedure improvements.

We extend state-of-the-art language model in Merity et al. (2018) by replacing the LSTM with the PRU. We show by experiments that the PRU improves the performance of Merity et al. (2018) while learning fewer parameters.

3 Pyramidal Recurrent Units

We introduce Pyramidal Recurrent Units (PRUs), a new RNN architecture which improves modeling of context by allowing for higher dimensional vector representations while learning fewer parameters. Figure 2 provides an overview of PRU. We first elaborate on the details of the pyramidal transformation and the grouped linear transformation. We then describe our recurrent unit, PRU.

3.1 Pyramidal transformation for input

The basic transformation in many recurrent units is a linear transformation $\mathcal{F}_L$ defined as:

$$\mathbf{y} = \mathcal{F}_L(\mathbf{x}) = \mathbf{W} \cdot \mathbf{x}, \qquad (1)$$

where $\mathbf{W} \in \mathbb{R}^{N \times M}$ are learned weights that linearly map $\mathbf{x} \in \mathbb{R}^N$ to $\mathbf{y} \in \mathbb{R}^M$. To simplify notation, we omit the biases.

Motivated by successful applications of sub-sampling in computer vision (e.g., (Burt and Adelson, 1987; Lowe, 1999; Krizhevsky et al., 2012; Mehta et al., 2018)), we subsample input vector $\mathbf{x}$ into K pyramidal levels to achieve representation of the input vector at multiple scales. This sub-sampling operation produces K vectors, represented as $\mathbf{x}^k \in \mathbb{R}^{\frac{N}{2^{k-1}}}$, where 2^{k-1} is the sampling rate and $k = \{1, \cdots, K\}$. We learn scale-specific transformations $\mathbf{W}^k \in \mathbb{R}^{\frac{N}{2^{k-1}} \times \frac{M}{K}}$ for each $k = \{1, \cdots K\}$. The transformed sub-samples are concatenated to produce the pyramidal analog to $\mathbf{y}$, here denoted as $\bar{\mathbf{y}} \in \mathbb{R}^M$:

$$\bar{\mathbf{y}} = \mathcal{F}_P(\mathbf{x}) = \left[\mathbf{W}^1 \cdot \mathbf{x}^1, \cdots, \mathbf{W}^K \cdot \mathbf{x}^K\right], \qquad (2)$$

where $[\cdot, \cdot]$ indicates concatenation. We note that pyramidal transformation with $K = 1$ is the same as the linear transformation.

To improve gradient flow inside the recurrent unit, we combine the input and output using an element-wise sum (when dimension matches) to produce residual analog of pyramidal transformation, as shown in Figure 2 (He et al., 2016).

Sub-sampling: We sub-sample the input vector $\mathbf{x}$ into K pyramidal levels using the kernel-based approach (LeCun et al., 1995; Krizhevsky et al., 2012). Let us assume that we have a kernel κ with $2e + 1$ elements. Then, the input vector $\mathbf{x}$ can be sub-sampled as:

$$\mathbf{x}^k = \sum_{i=1}^{N/s} \sum_{j=-e}^{e} \mathbf{x}^{k-1}[si]\kappa[j], \qquad (3)$$

where s represents the stride and $k = \{2, \cdots, K\}$.

Reduction in parameters: The number of parameters learned by the linear transformation and the pyramidal transformation with K pyramidal levels to map $\mathbf{x} \in \mathbb{R}^N$ to $\bar{\mathbf{y}} \in \mathbb{R}^M$ are NM and $\frac{NM}{K} \sum\limits_{k=1}^{K} 2^{(1-k)}$ respectively. Thus, pyramidal transformation reduces the parameters of a linear transformation by a factor of $K(\sum_{k=1}^{K} 2^{(1-k)})^{-1}$. For example, the pyramidal transformation (with $K = 4$ and $N = M = 600$) learns 53% fewer parameters than the linear transformation.

3.2 Grouped linear transformation for context

Many RNN architectures apply linear transformations to both the input and context vector. However, this may not be ideal due to the differing semantics of each vector. In many NLP applications including language modeling, the input vector is a dense word embedding which is shared across all contexts for a given word in a dataset. In contrast, the context vector is highly contextualized by the current sequence. The differences between the input and context vector motivate their separate treatment in the PRU architecture.

The weights learned using the linear transformation (Eq. 1) are reused over multiple time steps, which makes them prone to over-fitting (Gal and Ghahramani, 2016). To combat over-fitting, various methods, such as variational dropout (Gal and Ghahramani, 2016) and weight dropout (Merity et al., 2018), have been proposed to regularize these recurrent connections. To further improve generalization abilities while simultaneously enabling the recurrent unit to learn representations at very high dimensional space, we propose to use grouped linear transformation (GLT) instead of standard linear transformation for recurrent connections (Kuchaiev and Ginsburg, 2017). While pyramidal and linear transformations can be applied to transform context vectors, our experimental results in Section 4.4 suggests that GLTs are more effective.

The linear transformation $\mathcal{F}_L : \mathbb{R}^N \to \mathbb{R}^M$ maps $\mathbf{h} \in \mathbb{R}^N$ linearly to $\mathbf{z} \in \mathbb{R}^M$. Grouped linear transformations break the linear interactions by factoring the linear transformation into two steps. First, a GLT splits the input vector $\mathbf{h} \in \mathbb{R}^N$ into g smaller groups such that $\mathbf{h} = \{\mathbf{h}^1, \cdots, \mathbf{h}^g\}, \forall\, \mathbf{h}^i \in \mathbb{R}^{\frac{N}{g}}$. Second, a linear transformation $\mathcal{F}_L : \mathbb{R}^{\frac{N}{g}} \to \mathbb{R}^{\frac{M}{g}}$ is applied to map $\mathbf{h}^i$ linearly to $\mathbf{z}^i \in \mathbb{R}^{\frac{M}{g}}$, for each $i = \{1, \cdots, g\}$. The g resultant output vectors $\mathbf{z}^i$ are concatenated to produce the final output vector $\bar{\mathbf{z}} \in \mathbb{R}^M$.

$$\bar{\mathbf{z}} = \mathcal{F}_G(\mathbf{h}) = \left[\mathbf{W}^1 \cdot \mathbf{h}^1, \cdots, \mathbf{W}^g \cdot \mathbf{h}^g\right] \quad (4)$$

GLTs learn representations at low dimensionality. Therefore, a GLT requires g fewer parameters than the linear transformation. We note that GLTs are subset of linear transformations. In a linear transformation, each neuron receives an input from each element in the input vector while in a GLT, each neuron receives an input from a subset of the input vector. Therefore, GLT is the same as a linear transformation when $g = 1$.

3.3 Pyramidal Recurrent Unit

We extend the basic gating architecture of LSTM with the pyramidal and grouped linear transformations outlined above to produce the Pyramidal Recurrent Unit (PRU), whose improved sequence modeling capacity is evidenced in Section 4.

At time t, the PRU combines the input vector $\mathbf{x}_t$ and the previous context vector (or previous hidden state vector) $\mathbf{h}_{t-1}$ using the following transformation function as:

$$\hat{\mathcal{G}}_v(\mathbf{x}_t, \mathbf{h}_{t-1}) = \hat{\mathcal{F}}_P(\mathbf{x}_t) + \mathcal{F}_G(\mathbf{h}_{t-1}), \quad (5)$$

where $v \in \{f, i, c, o\}$ indexes the various gates in the LSTM model, and $\hat{\mathcal{F}}_P(\cdot)$ and $\mathcal{F}_G(\cdot)$ represents the pyramidal and grouped linear transformations defined in Eqns. 2 and 4, respectively.

We will now incorporate $\hat{\mathcal{G}}_v(\cdot, \cdot)$ into LSTM gating architecture to produce PRU. At time t, a PRU cell takes $\mathbf{x}_t \in \mathbb{R}^N$, $\mathbf{h}_{t-1} \in \mathbb{R}^M$, and $\mathbf{c}_{t-1} \in \mathbb{R}^M$ as inputs to produce forget $\mathbf{f}_t$, input $\mathbf{i}_t$, output $\mathbf{o}_t$, and content $\hat{\mathbf{c}}_t$ gate signals. The inputs are combined with these gate signals to produce context vector $\mathbf{h}_t \in \mathbb{R}^M$ and cell state $\mathbf{c}_t \in \mathbb{R}^M$. Mathematically, the PRU with the LSTM gating architecture can be defined as:

$$\begin{aligned}
\mathbf{f}_t &= \sigma\left(\hat{\mathcal{G}}_f(\mathbf{x}_t, \mathbf{h}_{t-1})\right) \\
\mathbf{i}_t &= \sigma\left(\hat{\mathcal{G}}_i(\mathbf{x}_t, \mathbf{h}_{t-1})\right) \\
\hat{\mathbf{c}}_t &= tanh\left(\hat{\mathcal{G}}_c(\mathbf{x}_t, \mathbf{h}_{t-1})\right) \\
\mathbf{o}_t &= \sigma\left(\hat{\mathcal{G}}_o(\mathbf{x}_t, \mathbf{h}_{t-1})\right) \\
\mathbf{c}_t &= \mathbf{f}_t \otimes \mathbf{c}_{t-1} + \mathbf{i}_t \otimes \hat{\mathbf{c}}_t \\
\mathbf{h}_t &= \mathbf{o}_t \otimes tanh(\mathbf{c}_t)
\end{aligned} \quad (6)$$

where $\otimes$ represents the element-wise multiplication operation, and σ and $tanh$ are the sigmoid and hyperbolic tangent activation functions. We note that LSTM is a special case of PRU when g=K=1.

4 Experiments

To showcase the effectiveness of the PRU, we evaluate the performance on two standard datasets for word-level language modeling and compare with state-of-the-art methods. Additionally, we provide a detailed examination of the PRU and its behavior on the language modeling tasks.

4.1 Set-up

Dataset: Following recent works, we compare on two widely used datasets, the Penn Treebank (PTB) (Marcus et al., 1993) as prepared by Mikolov et al. (2010) and WikiText2 (WT-2) (Merity et al., 2017). For both datasets, we follow the same training, validation, and test splits as in Merity et al. (2018).

Language Model: We extend the language model, AWD-LSTM (Merity et al., 2018), by replacing LSTM layers with PRU. Our model uses 3-layers of PRU with an embedding size of 400. The number of parameters learned by state-of-the-art methods vary from 18M to 66M with majority of the methods learning about 22M to 24M parameters on the PTB dataset. For a fair comparison with state-of-the-art methods, we fix the model size to 19M and vary the value of g and hidden layer sizes so that total number of learned parameters is similar across different configurations. We use 1000, 1200, and 1400 as hidden layer sizes for values of g=1,2, and 4, respectively. We use the same settings for the WT-2 dataset. We set the number of pyramidal levels K to two in our experiments and use average pooling for subsampling. These values are selected based on our ablation experiments on the validation set (Section 4.4). We measure the performance of our models in terms of word-level perplexity. We follow the same training strategy as in Merity et al. (2018).

To understand the effect of regularization methods on the performance of PRUs, we perform experiments under two different settings: (1) *Standard dropout*: We use a standard dropout (Srivastava et al., 2014) with probability of 0.5 after embedding layer, the output between LSTM layers, and the output of final LSTM layer. (2) *Advanced dropout:* We use the same dropout techniques with the same dropout values as in Merity et al. (2018). We call this model as AWD-PRU.

4.2 Results

Table 1 compares the performance of the PRU with state-of-the-art methods. We can see that the PRU achieves the best performance with fewer parameters.

Standard dropout: PRUs achieve either the same or better performance than LSTMs. In particular, the performance of PRUs improves with the increasing value of g. At $g = 4$, PRUs outperform LSTMs by about 4 points on the PTB dataset and by about 3 points on the WT-2 dataset. This is explained in part by the regularization effect of the grouped linear transformation (Figure 1). With grouped linear and pyramidal transformations, PRUs learn rich representations at very high dimensional space while learning fewer parameters. On the other hand, LSTMs overfit to the training data at such high dimensions and learn $1.4\times$ to $1.8\times$ more parameters than PRUs.

Advanced dropouts: With the advanced dropouts, the performance of PRUs improves by about 4 points on the PTB dataset and 7 points on the WT-2 dataset. This further improves with finetuning on the PTB (about 2 points) and WT-2 (about 1 point) datasets.

Comparison with state-of-the-art: For similar number of parameters, the PRU with standard dropout outperforms most of the state-of-the-art methods by large margin on the PTB dataset (e.g. RAN (Lee et al., 2017) by 16 points with 4M less parameters, QRNN (Bradbury et al., 2017) by 16 points with 1M more parameters, and NAS (Zoph and Le, 2017) by 1.58 points with 6M less parameters). With advanced dropouts, the PRU delivers the best performance. On both datasets, the PRU improves the perplexity by about 1 point while learning 15-20% fewer parameters.

Inference: PRU is a drop-in replacement for LSTM, therefore, it can improve language models with modern inference techniques such as dynamic evaluation (Krause et al., 2018). When we evaluate PRU-based language models (only with standard dropout) with dynamic evaluation on the PTB test set, the perplexity of PRU ($g = 4, k = 2, M = 1400$) improves from 62.42 to 55.23 while the perplexity of an LSTM ($M = 1000$) with similar settings improves from 66.29 to 58.79; suggesting that modern inference techniques are equally applicable to PRU-based language models.

4.3 Analysis

It is shown above that the PRU can learn representations at higher dimensionality with more generalization power, resulting in performance gains for language modeling. A closer analysis of the impact of the PRU in a language modeling system reveals several factors that help explain how the PRU achieves these gains.

Table 1: Comparison of single model word-level perplexity of our model with state-of-the-art on validation and test sets of Penn Treebank and Wikitext-2 dataset. For evaluation, we select the model with minimum validation loss. Lower perplexity value represents better performance.

Confidence: As exemplified in Table 2a, the PRU tends toward more confident decisions, placing more of the probability mass on the top next-word prediction than the LSTM. To quantify this effect, we calculate the entropy of the next-token distribution for both the PRU and the LSTM using 3687 contexts from the PTB validation set. Figure 3 shows a histogram of the entropies of the distribution, where bins of size 0.23 are used to effect categories. We see that the PRU more often produces lower entropy distributions corresponding to higher confidences for next-token choices. This is evidenced by the mass of the red PRU curve lying in the lower entropy ranges compared to the blue LSTM's curve. The PRU can produce confident decisions in part because more information is encoded in the higher dimensional context vectors.

Variance in word embeddings: The PRU has the ability to model individual words at different resolutions through the pyramidal transform; which provides multiple paths for the gradient to the embedding layer (similar to multi-task learning) and improves the flow of information. When considering the embeddings by part of speech, we find that the pyramid level 1 embeddings exhibit higher variance than the LSTM across all POS categories (Figure 4), and that pyramid level 2 embeddings show extremely low variance[1]. We hypothesize that the LSTM must encode both coarse group similarities and individual word differences into the same vector space, reducing the space between individual words of the same category. The PRU can rely on the subsampled embeddings to

---

[1] POS categories are computed using NLTK toolkit.

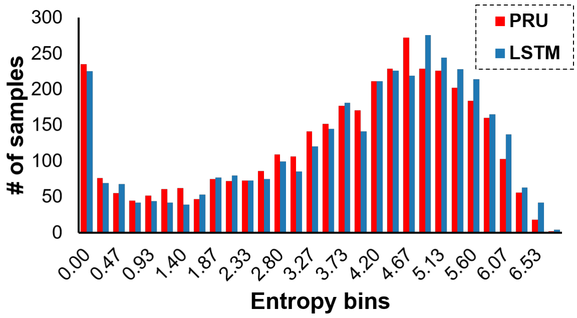

Figure 3: Histogram of the entropies of next-token distributions predicted by the PRU (mean 3.80) and the LSTM (mean 3.93) on the PTB validation set. Lower entropy values indicate higher confidence decisions, which is desirable if decisions are often correct.

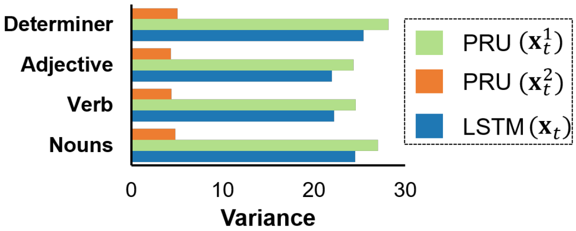

Figure 4: Variance of learned word embeddings for different categories of words on the PTB validation set. We compute the variance of a group of embeddings as the average squared euclidean distance to their mean. Higher variance may allow for better intra-category distinctions. The PRU with pyramid levels 1 and 2 is shown.

account for coarse-grained group similarities, allowing for finer individual word distinctions in the embedding layer. This hypothesis is strengthened by the entropy results described above: a model which can make finer distinctions between individual words can more confidently assign probability mass. A model that cannot make these distinctions, such as the LSTM, must spread its probability mass across a larger class of similar words.

Gradient-based analysis: Saliency analysis using gradients help identify relevant words in a test sequence that contribute to the prediction (Gevrey et al., 2003; Li et al., 2016; Arras et al., 2017). These approaches compute the relevance as the squared norm of the gradients obtained through back-propagation. Table 2a visualizes the heatmaps for different sequences. PRUs, in general, give more relevance to contextual words than LSTMs, such as southeast (sample 1), cost (sample 2), face (sample 4), and introduced (sample 5), which help in making more confident decisions. Furthermore, when gradients during back-propagation are visualized (Selvaraju et al., 2017) (Table 2b), we find that PRUs have better gradient coverage than LSTMs, suggesting PRUs use more features than LSTMs that contributes to the decision. This also suggests that PRUs update more parameters at each iteration which results in faster training. Language model in (Merity et al., 2018) takes 500 and 750 epochs to converge with PRU and LSTM as a recurrent unit, respectively.

4.4 Ablation studies

In this section, we provide a systematic analysis of our design choices. Our training methodology is the same as described in Section 4.1 with the standard dropouts. For a thorough understanding of our design choices, we use a language model with a single layer of PRU and fix the size of embedding and hidden layers to 600. The word-level perplexities are reported on the validation sets of the PTB and the WT-2 datasets.

Pyramidal levels K and groups g: The two hyper-parameters that control the trade-off between performance and number of parameters in PRUs are the number of pyramidal levels K and groups g. Figure 5 provides a trade-off between perplexity and recurrent unit (RU) parameters[2].

Variable K and fixed g: When we increase the number of pyramidal levels K at a fixed value of g, the performance of the PRU drops by about 1 to 4 points while reducing the total number of recurrent unit parameters by up to 15%. We note that the PRU with $K = 4$ at $g = 1$ delivers similar performance as the LSTM while learning about 15% fewer recurrent unit parameters.

Fixed K and variable g: When we vary the value of g at fixed number of pyramidal levels K, the total number of recurrent unit parameters decreases significantly with a minimal impact on the perplexity. For example, PRUs with $K = 2$ and $g = 4$ learns 77% fewer recurrent unit parameters while its perplexity (lower is better) increases by about 12% in comparison to LSTMs. Moreover, the decrease in number of parameters at higher value of g enables PRUs to learn the representations in high dimensional space with better generalizability (Table 1).

(a) PTB

(b) WT-2

Figure 5: Impact of number of groups g and pyramidal levels K on the perplexity. Reduction in recurrent unit (RU) parameters is computed with respect to LSTM. Lower perplexity value represents better performance.

Transformations: Table 3 shows the impact of different transformations of the input vector $\mathbf{x}_t$ and the context vector $\mathbf{h}_{t-1}$. We make following observations: (1) Using the pyramidal transformation for the input vectors improves the perplexity by about 1 point on both the PTB and WT-2 datasets while reducing the number of recurrent unit parameters by about 14% (see R1 and R4). We note that the performance of the PRU drops by up to 1 point when residual connections are not used (R4 and R6). (2) Using the grouped linear transformation for context vectors reduces the total number of recurrent unit parameters by about 75% while the performance drops by about 11% (see R3 and R4). When we use the pyramidal transformation instead of the linear transformation, the performance drops by up to 2% while there is no significant drop in the number of parameters (R4 and R5).

Subsampling: We set sub-sampling kernel κ (Eq. 3) with stride $s = 2$ and size of 3 ($e = 1$) in four different ways: (1) *Skip:* We skip every other element in the input vector. (2) *Convolution:* We initialize the elements of κ randomly from normal distribution and learn them during training the model. We limit the output values between -1 and 1 using $tanh$ activation function to make training stable. (3) *Avg. pool:* We initialize the elements of κ to $\frac{1}{3}$. (4) *Max pool:* We select the maximum value in the kernel window κ.

Table 4 compares the performance of the PRU with different sampling methods. Average pooling performs the best while skipping give comparable performance. Both of these methods enable the network to learn richer word representations while representing the input vector in different forms, thus delivering higher performance. Surprisingly, a convolution-based sub-sampling method does not perform as well as the averaging method. The $tanh$ function used after convolution limits the range of output values which are further limited by the LSTM gating structure, thereby impeding in the flow of information inside the cell. Max pooling forces the network to learn representations from high magnitude elements, thus distinguishing features between elements vanishes, resulting in poor performance.

PTB	75.12	87.6	**73.86**	81.56
WT-2	89.24	107.63	**88.88**	93.16

Table 4: Impact of different sub-sampling methods on the word-level perplexity (lower is better). We used g=1 and K=4 in our experiments.

5 Conclusion

We introduce the Pyramidal Recurrent Unit, which better model contextual information by admitting higher dimensional representations with good generalizability. When applied to the task of language modeling, PRUs improve perplexity across several settings, including recent state-of-the-art systems. Our analysis shows that the PRU improves the flow of gradient and expand the word embedding subspace, resulting in more confident decisions. Here we have shown improvements for language modeling. In future, we plan to study the performance of PRUs on different tasks, including machine translation and question answering. In addition, we will study the performance of the PRU on language modeling with more recent inference techniques, such as dynamic evaluation and mixture of softmax.

Abstract

Neural networks with tree-based sentence encoders have shown better results on many downstream tasks. Most of existing tree-based encoders adopt syntactic parsing trees as the explicit structure prior. To study the effectiveness of different tree structures, we replace the parsing trees with trivial trees (*i.e.*, binary balanced tree, left-branching tree and right-branching tree) in the encoders. Though trivial trees contain no syntactic information, those encoders get competitive or even better results on all of the ten downstream tasks we investigated. This surprising result indicates that explicit syntax guidance may not be the main contributor to the superior performances of tree-based neural sentence modeling. Further analysis show that tree modeling gives better results when crucial words are closer to the final representation. Additional experiments give more clues on how to design an effective tree-based encoder. Our code is open-source and available at `https://github.com/ExplorerFreda/TreeEnc`.

1 Introduction

Sentence modeling is a crucial problem in natural language processing (NLP). Recurrent neural networks with long short term memory (Hochreiter and Schmidhuber, 1997) or gated recurrent units (Cho et al., 2014) are commonly used sentence modeling approaches. These models embed sentences into a vector space and the resulting vectors can be used for classification or sequence generation in the downstream tasks.

In addition to the plain sequence of hidden units, recent work on sequence modeling proposes to impose tree structure in the encoder (Socher et al., 2013; Tai et al., 2015; Zhu et al., 2015). These tree-based LSTMs introduce syntax tree as an intuitive structure prior for sentence modeling. They have already obtained promising results in many NLP tasks, such as natural language inference (Bowman et al., 2016; Chen et al., 2017c) and machine translation (Eriguchi et al., 2016; Chen et al., 2017a,b; Zhou et al., 2017). Li et al. (2015) empirically concludes that syntax tree-based sentence modeling are effective for tasks requiring relative long-term context features.

On the other hand, some works propose to abandon the syntax tree but to adopt the latent tree for sentence modeling (Choi et al., 2018; Yogatama et al., 2017; Maillard et al., 2017; Williams et al., 2018). Such latent trees are directly learned from the downstream task with reinforcement learning (Williams, 1992) or Gumbel Softmax (Jang et al., 2017; Maddison et al., 2017). However, Williams et al. (2018) empirically show that, Gumbel softmax produces unstable latent trees with the same hyper-parameters but different initializations, while reinforcement learning (Williams et al., 2018) even tends to generate left-branching trees. Neither gives meaningful latent trees in syntax, but each method still obtains considerable improvements in performance. This indicates that syntax may not be the main contributor to the performance gains.

With the above observation, we bring up the following questions: What does matter in tree-based sentence modeling? If tree structures are necessary in encoding the sentences, what mostly contributes to the improvement in downstream tasks? We attempt to investigate the driving force of the improvement by latent trees without syntax.

In this paper, we empirically study the effectiveness of tree structures in sentence modeling. We compare the performance of bi-LSTM and five tree LSTM encoders with different tree layouts, including the syntax tree, latent tree (from Gum-

bel softmax) and three kinds of designed trivial trees (binary balance tree, left-branching tree and right-branching tree). Experiments are conducted on 10 different tasks, which are grouped into three categories, namely the single sentence classification (5 tasks), sentence relation classification (2 tasks), and sentence generation (3 tasks). These tasks depend on different granularities of features, and the comparison among them can help us learn more about the results. We repeat all the experiments 5 times and take the average to avoid the instability caused by random initialization of deep learning models.

We get the following conclusions:

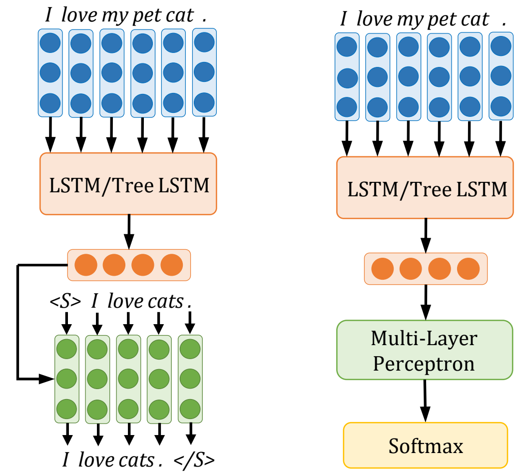
- Tree structures are helpful to sentence modeling on classification tasks, especially for tasks which need global (long-term) context features, which is consistent with previous findings (Li et al., 2015).
- Trivial trees outperform syntactic trees, indicating that syntax may not be the main contributor to the gains of tree encoding, at least on the ten tasks we investigate.
- Further experiments shows that, given strong priors, tree based methods give better results when crucial words are closer to the final representation. If structure priors are unavailable, balanced tree is a good choice, as it makes the path distances between word and sentence encoding to be roughly equal, and in such case, tree encoding can learn the crucial words itself more easily.

2 Experimental Framework

We show the applied encoder-classifier/decoder framework for each group of tasks in Figure 1. Our framework has two main components: the encoder part and the classifier/decoder part. In general, models encode a sentence to a length-fixed vector, and then applies the vector as the feature for classification and generation.

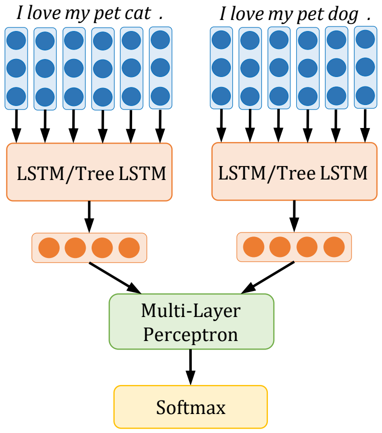
We fix the structure of the classifier/decoder, and propose to use five different types of tree structures for the encoder part including:

- Parsing tree. We apply binary constituency tree as the representative, which is widely used in natural language inference (Bowman et al., 2016) and machine translation (Eriguchi et al., 2016; Chen et al., 2017a). Dependency parsing trees (Zhou et al., 2015, 2016a) are not considered in this paper.



(a) Encoder-decoder framework for sentence generation.

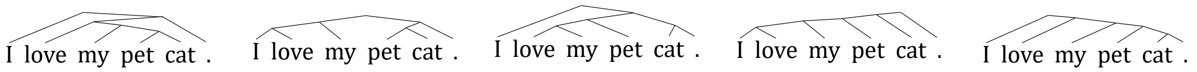
(b) Encoder-classifier framework for sentence classification.



(c) Siamese encoder-classifier framework for sentence relation classification.

Figure 1: The encoder-classifier/decoder framework for three different groups of tasks. We apply multi-layer perceptron (MLP) for classification, and left-to-right decoders for generation in all experiments.

- Binary balanced tree. To construct a binary balanced tree, we recursively divide a group of n leafs into two contiguous groups with the size of $\lceil \frac{n}{2} \rceil$ and $\lfloor \frac{n}{2} \rfloor$, until each group has only one leaf node left.
- Gumbel trees, which are produced by straight-forward Gumbel softmax models (Choi et al., 2018). Note that Gumbel trees are not stable to sentences (Williams et al., 2018), and we only draw a sample among all of them.
- Left-branching trees. We combine two nodes from left to right, to construct a left-branching tree, which is similar to those



(a) Parsing tree. (b) Balanced tree. (c) Gumbel tree. (d) Left-branching tree. (e) Right-branching tree.

Figure 2: Examples of different tree structures for the encoder part.

generated by the reinforce based RL-SPINN model (Williams et al., 2018).

- Right-branching trees. In contrast to left-branching ones, nodes are combined from right to left to form a right-branching tree.

We show an intuitive view of the five types of tree structures in Figure 2. In addition, existing works (Choi et al., 2018; Williams et al., 2018) show that using hidden states of bidirectional RNNs as leaf node representations (bi-leaf-RNN) instead of word embeddings may improve the performance of tree LSTMs, as leaf RNNs help encode context information more completely. Our framework also support leaf RNNs for tree LSTMs.

3 Description of Investigated Tasks

We conduct experiments on 10 different tasks, which are grouped into 3 categories, namely the single sentence classification (5 tasks), sentence relation classification (2 tasks), and sentence generation (3 tasks). Each of the tasks is compatible to the encoder-classifier/decoder framework shown in Figure 1. These tasks cover a wide range of NLP applications, and depend on different granularities of features.

Note that the datasets may use articles or paragraphs as instances, some of which consist of only one sentence. For each dataset, we only pick the subset of single-sentence instances for our experiments, and the detailed meta-data is in Table 1.

3.1 Sentence Classification

First, we introduce four text classification datasets from Zhang et al. (2015), including AG's News, Amazon Review Polarity , Amazon Review Full and DBpedia. Additionally, noticing that parsing tree was shown to be effective (Li et al., 2015) on the task of word-level semantic relation classification (Hendrickx et al., 2009), we also add this dataset to our selections.

AG's News (AGN). Each sample in this dataset is an article, associated with a label indicating its topic: world, sports, business or sci/tech.

Amazon Review Polarity (ARP). The Amazon Review dataset is obtained from the Stanford Network Analysis Project (SNAP; McAuley and Leskovec, 2013). It collects a large amount of product reviews as paragraphs, associated with a star rate from 1 (most negative) to 5 (most positive). In this dataset, 3-star reviews are dropped, while others are classified into two groups: positive (4 or 5 stars) and negative (1 or 2 stars).

Amazon Review Full (ARF). Similar to the ARP dataset, the ARF dataset is also collected from Amazon product reviews. Labels in this dataset are integers from 1 to 5.

DBpedia. DBpedia is a crowd-sourced community effort to extract structured information from Wikipedia (Lehmann et al., 2015). Zhang et al. (2015) select 14 non-overlapping classes from DBpedia 2014 to construct this dataset. Each sample is given by the title and abstract of the Wikipedia article, associated with the class label.

Word-Level Semantic Relation (WSR) SemEval-2010 Task 8 (Hendrickx et al., 2009) is to find semantic relationships between pairs of nominals. Each sample is given by a sentence, of which two nominals are explicitly indicated, associated with manually labeled semantic relation between the two nominals. For example, the sentence "*My [apartment]*$_{e_1}$ *has a pretty large [kitchen]*$_{e_2}$ *.*" has the label *component-whole*(e_2, e_1). Different from retrieving the path between two labels (Li et al., 2015; Socher et al., 2013), we feed the entire sentence together with the nominal indicators (*i.e.*, tags of e_1 and e_2) as words to the framework. We also ignore the order of e_1 and e_2 in the labels given by the dataset. Thus, this task turns to be a 10-way classification one.

3.2 Sentence Relation Classification

To evaluate how well a model can capture semantic relation between sentences, we introduce the second group of tasks: sentence relation classification.

Natural Language Inference (NLI). The Stanford Natural Language Inference (SNLI) Corpus (Bowman et al., 2015) is a challenging dataset for sentence-level textual entailment. It has 550K training sentence pairs, as well as 10K for development and 10K for test. Each pair consists of two relative sentences, associated with a label which is one of *entailment, contradiction* and *neutral*.

Conjunction Prediction (Conj). Information about the coherence relation between two sentences is sometimes apparent in the text explicitly (Miltsakaki et al., 2004): this is the case whenever the second sentence starts with a conjunction phrase. Jernite et al. (2017) propose a method to create *conjunction prediction* dataset from unlabeled corpus. They create a list of phrases, which can be classified into nine types, as conjunction indicators. The object of this task is to recover the conjunction type of given two sentences, which can be used to evaluate how well a model captures the semantic meaning of sentences. We apply the method proposed by Jernite et al. (2017) on the Wikipedia corpus to create our conj dataset.

3.3 Sentence Generation

We also include the sentence generation tasks in our experiments, to investigate the representation ability of different encoders over global (long-term) context features. Note that our framework is based on encoding, which is different from those attention based approaches.

Paraphrasing (Para). Quora Question Pair Dataset is a widely applied dataset to evaluate paraphrasing models (Wang et al., 2017; Li et al., 2017b). [1] In this work, we treat the paraphrasing task as a sequence-to-sequence one, and evaluate on it with our sentence generation framework.

Machine Translation (MT). Machine translation, especially cross-language-family machine translation, is a complex task, which requires models to capture the semantic meanings of sentences well. We apply a large challenging English-Chinese sentence translation task for this investigation, which is adopted by a variety of neural translation work (Tu et al., 2016; Li et al., 2017a; Chen et al., 2017a). We extract the parallel data from the LDC corpora,[2] selecting 1.2M from them as our training set, 20K and 80K of them as our development set and test set, respectively.

Dataset	**#Sentence** Train	 Dev	 Test	**#Cls**	**Avg. Len**
Sentence Classification					
News	60K	6.7K	4.3K	4	31.5
ARP	128K	14K	16K	2	33.7
ARF	110K	12K	27K	5	33.8
DBpedia	106K	11K	15K	14	20.1
WSR	7.1K	891	2.7K	10	23.1
Sentence Relation					
SNLI	550K	10K	10K	3	11.2
Conj	552K	10K	10K	9	23.3
Sentence Generation					
Para	98K	2K	3K	N/A	10.2
MT	1.2M	20K	80K	N/A	34.1
AE	1.2M	20K	80K	N/A	34.1

Table 1: Meta-data of the downstream tasks we investigated. For each task, we list the quantity of instances in train/dev/test set, the average length (by words) of sentences (source sentence only for generation task), as well as the number of classes if applicable.

Auto-Encoding (AE). We extract the English part of the machine translation dataset to form a auto-encoding task, which is also compatible with our encoder-decoder framework.

4 Experiments

In this section, we present our experimental results and analysis. Section 4.1 introduces our set-up for all the experiments. Section 4.2 shows the main results and analysis on ten downstream tasks grouped into three classes, which can cover a wide range of NLP applications. Regarding that trivial tree based LSTMs perform the best among all models, we draw two hypotheses, which are i) right-branching tree benefits a lot from strong structural priors; ii) balanced tree wins because it fairly treats all words so that crucial information could be more easily learned by the LSTM gates automatically. We test the hypotheses in

Table 2: Test results for different encoder architectures trained by a unified encoder-classifier/decoder framework. We report accuracy ($\times 100$) for classification tasks, and BLEU score (Papineni et al., 2002; word-level for English targets and char-level for Chinese targets) for generation tasks. Large is better for both of the metrics. The best number(s) for each task are in bold. In addition, average sentence length (in words) of each dataset is attached in the last row with underline.

Section 4.3. Finally, we compare the performance of linear and tree LSTMs with three widely applied pooling mechanisms in Section 4.4.

4.1 Set-up

In experiments, we fix the structure of the classifier as a two-layer MLP with ReLU activation, and the structure of decoder as GRU-based recurrent neural networks (Cho et al., 2014). [3] The hidden-layer size of MLP is fixed to 1024, while that of GRU is adapted from the size of sentence encoding. We initialize the word embeddings with 300-dimensional `GloVe` (Pennington et al., 2014) vectors.[4] We apply 300-dimensional bidirectional (600-dimensional in total) LSTM as leaf RNN when necessary. We use Adam (Kingma and Ba, 2015) optimizer to train all the models, with the learning rate of 1e-3 and batch size of 64. In the training stage, we drop the samples with the length of either source sentence or target sentence larger than 64. We do not apply any regularization or dropout term in all experiments except the task of WSR, on which we tune dropout term with respect to the development set. We generate the binary parsing tree for the datasets without parsing trees using ZPar (Zhang and Clark, 2011).[5] More details are summarized in supplementary materials.

4.2 Main Results

In this subsection, we aim to compare the results from different encoders. We do not include any attention (Wang et al., 2016; Lin et al., 2017) or pooling (Collobert and Weston, 2008; Socher et al., 2011; Zhou et al., 2016b) mechanism here, in order to avoid distractions and make the encoder structure affects the most. We will further analyze pooling mechanisms in Section 4.4.

Table 2 presents the performances of different

---

[3] We observe that ReLU can significantly boost the performance of Bi-LSTM on SNLI.

[4] `http://nlp.stanford.edu/data/glove.840B.300d.zip`

[5] `https://www.sutd.edu.sg/cmsresource/faculty/yuezhang/zpar.html`

encoders on a variety of downstream tasks, which lead to the following observations:

Tree encoders are useful on some tasks. We get the same conclusion with Li et al. (2015) that tree-based encoders perform better on tasks requiring long-term context features. Despiting the linear structured left-branching and right-branching tree encoders, we find that, tree-based encoders generally perform better than Bi-LSTMs on tasks of *sentence relation* and *sentence generation*, which may require relatively more long term context features for obtaining better performances. However, the improvements of tree encoders on **NLI** and **Para** are relatively small, which may be caused by that sentences of the two tasks are shorter than others, and the tree encoder does not get enough advantages to capture long-term context in short sentences.

Trivial tree encoders outperform other encoders. Surprisingly, binary balanced tree encoder gets the best results on most tasks of classification and right-branching tree encoder tends to be the best on sentence generation. Note that binary balanced tree and right-branching tree are only trivial tree structures, but outperform syntactic tree and latent tree encoders. The latent tree is really competitive on some tasks, as its structure is directly tuned by the corresponding tasks. However, it only beats the binary balanced tree by very small margins on NLI and ARP. We will give analysis about this in Section 4.3.

Larger quantity of parameters is not the only reason of the improvements. Table 2 shows that tree encoders benefit a lot from adding leaf-LSTM, which brings not only sentence level information to leaf nodes, but also more parameters than the bi-LSTM encoder. However, left-branching tree LSTM has a quite similar structure with linear LSTM, and it can be viewed as a linear LSTM-on-LSTM structure. It has the same amounts of parameters as other tree-based encoders, but still falls behind the balance tree encoder on most of the tasks. This indicates that larger quantity of parameters is at least not the only reason for binary balance tree LSTM encoders to gain improvements against bi-LSTMs.

4.3 Why Trivial Trees Work Better?

Binary balanced tree and right-branching are trivial ones, hardly containing syntax information. In this section, we analyze why these trees achieve high scores in deep.

4.3.1 Right Branching Tree Benefits from Strong Structural Prior

We argue that right-branching trees benefit from its strong structural prior. In sentence generation tasks, models generate sentences from left to right, which makes words in the left of the source sentence more important (Sutskever et al., 2014). If the encoder fails to memorize the left words, the information about right words would not help due to the error propagation. In right-branching trees, left words of the sentence are closer to the final representation, which makes the left words are more easy to be memorized, and we call this structure prior. Oppositely, in the case of left-branching trees, right words of the sentence are closer to the representation.

To validate our hypothesis, we propose to visualize the Jacobian as word-level saliency (Shi et al., 2018), which can be viewed as the contribution of each word to the sentence encoding:

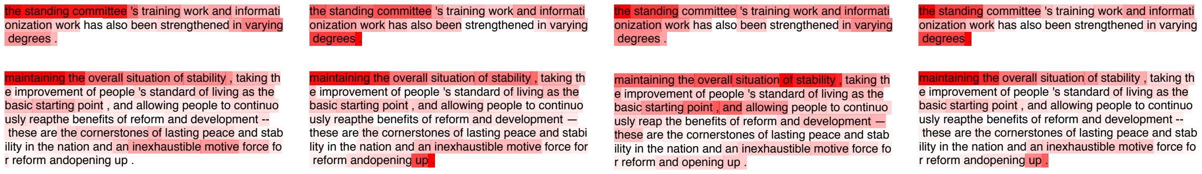
$$\mathrm{J}(\mathbf{s},\mathbf{w}) = \|\nabla \mathbf{s}(\mathbf{w})\|_1 = \sum_{i,j} |\frac{\partial s_i}{\partial w_j}|$$

where $\mathbf{s} = (s_1, s_2, \cdots, s_p)^T$ denotes the embedding of a sentence, and $\mathbf{w} = (w_1, w_2, \cdots, w_q)^T$ denotes embedding of a word. We can compute the saliency score using backward propagation. For a word in a sentence, higher saliency score means more contribution to sentence encoding.

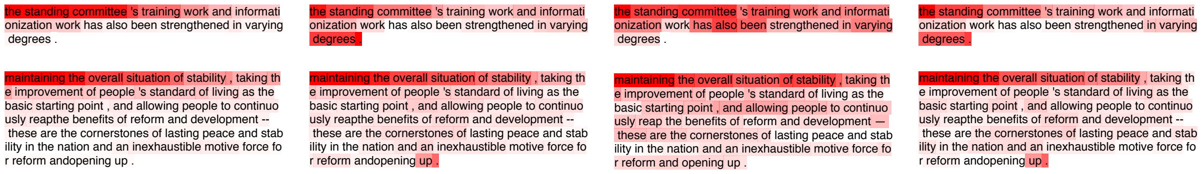
We present the visualization in Figure 3 using the visualization tool from Lin et al. (2017). It shows that right-branching tree LSTM encoders tend to look at the left part of the sentence, which is very helpful to the final generation performance, as left words are more crucial. Balanced trees also have this feature and we think it is because balance tree treats these words fairly, and crucial information could be more easily learned by the LSTM gates automatically.

However, bi-LSTM and left-branching tree LSTM also pay much attention to words in the right (especially the last two words), which maybe caused by the short path from the right words to the root representation, in the two corresponding tree structures.

Additionally, Table 3 shows that models trained with the same hyper-parameters but different initializations have strong agreement with each other.



(a) Balanced tree, MT. (b) Left-branching tree, MT. (c) Right-branching, MT. (d) Bi-LSTM, MT.



(e) Balanced tree, AE. (f) Left-branching tree, AE. (g) Right-branching, AE. (h) Bi-LSTM, AE.

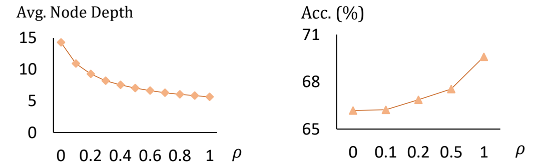
Figure 3: Saliency visualization of words in learned MT and AE models. Darker means more important to the sentence encoding.

Model	**MT**	**AE**
Balanced (BiLRNN)	93.1	96.9
Left-Branching (BiLRNN)	94.2	95.4
Right-Branching (BiLRNN)	92.3	95.1
Bi-LSTM	96.4	96.1

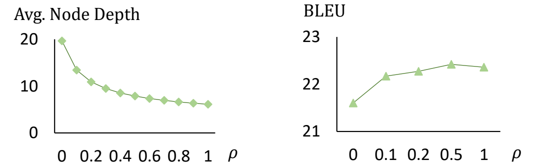
Table 3: Mean average Pearson correlation $(\times 100)$ across five models trained with same hyper-parameters. For each testing sentence, we compute the saliency scores of words. Cross-model Pearson correlation can show the agreement of two models on one sentence, and average Pearson correlation is computed through all sentences. We report mean average Pearson correlation of the 5×4 model pairs.

Thus, "looking at the first words" is a stable behavior of balanced and right-branching tree LSTM encoders in sentence generation tasks. So is "looking at the first and the last words" for Bi-LSTMs and left-branching tree LSTMs.

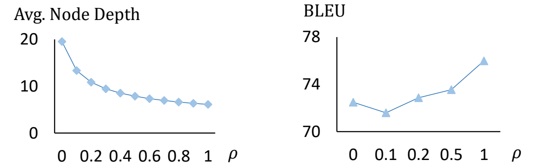
4.3.2 Binary Balanced Tree Benefits from Shallowness



(a) ρ-depth line for WSR. (b) ρ-Acc. line for WSR.



(c) ρ-depth line for MT. (d) ρ-BLEU line for MT.

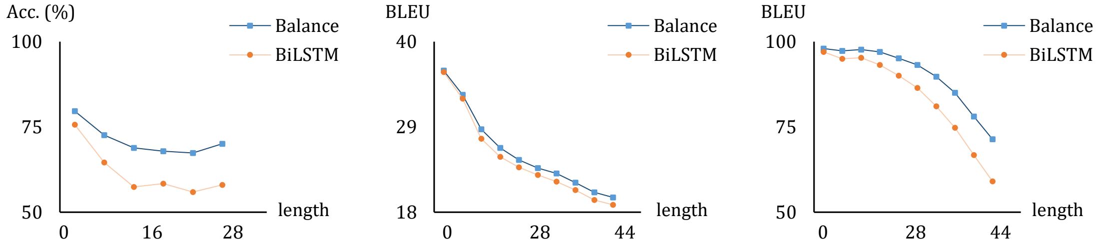


(e) ρ-depth line for AE. (f) ρ-BLEU line for AE.

Figure 4: ρ-depth and ρ-performance lines for three tasks. There is a trend that the depth drops and the performance raises with the growth of ρ.

Compared to syntactic and latent trees, the only advantage of balanced tree we can hypothesize is that, it is shallower and more balanced than others. Shallowness may lead to shorter path for information propagation from leafs to the root representation, and makes the representation learning more easy due to the reduction of errors in the propagation process. Balance makes the tree fairly treats all leaf nodes, which makes it more easily to automatically select the crucial information over all words in a sentence.

To test our hypothesis, we conduct the following experiments. We select three tasks, on which binary balanced tree encoder wins Bi-LSTMs with a large margin (WSR, MT and AE). We generate random binary trees for sentences, while con-



(a) Length-Accuracy lines for WSR. (b) Length-BLEU lines for MT. (c) Length-BLEU lines for AE.

Figure 5: Length-performance lines for the further investigated tasks. We divide test instances into several groups by length, and report the performance on each group respectively. Sentences with length in $[1, 8]$ are put to the first group, and the group $i (i \geq 2)$ covers the range of $[4i + 1, 4i + 4]$ in length.]

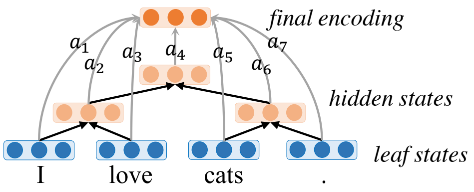
trolling the depth using a hyper-parameter ρ. We start by a group with all words (nodes) in the sentence. At each time, we separate n nodes to two continuous groups sized $(\lceil \frac{n}{2} \rceil, \lfloor \frac{n}{2} \rfloor)$ with probability ρ, while those sized $(n - 1, 1)$ with probability $1 - \rho$. Trees generated with $\rho = 0$ are exactly left-branching trees, and those generated with $\rho = 1$ are binary balanced trees. The expected node depth of the tree turns smaller with ρ varies from 0 to 1.

Figure 4 shows that, in general, trees with shallower node depth have better performance on all of the three tasks (for binary tree, shallower also means more balanced), which validates our above hypothesis that binary balanced tree gains the reward from its shallow and balanced structures.

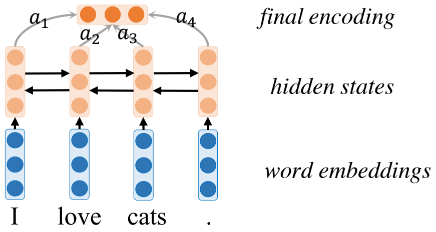
Additionally, Figure 5 demonstrates that binary balanced trees work especially better with relative long sentences. As desired, on short-sentence groups, the performance gap between Bi-LSTM and binary balanced tree LSTM is not obvious, while it grows with the test sentences turning longer. This explains why tree-based encoder gives small improvements on NLI and Para, because sentences on these two tasks are much shorter than others.

4.4 Can Pooling Replace Tree Encoder?

Max pooling (Collobert and Weston, 2008; Zhao et al., 2015), mean pooling (Conneau et al., 2017) and self-attentive pooling (also known as self-attention; Santos et al., 2016; Liu et al., 2016; Lin et al., 2017) are three popular and efficient choices to improve sentence encoding. In this part, we will compare the performance of tree LSTMs and bi-LSTM on the tasks of WSR, MT and AE, with each pooling mechanism respectively, aiming to demonstrate the role that pooling plays in sentence modeling, and validate whether tree encoders can be replaced by pooling.



(a) Balanced tree.



(b) Bi-LSTM.

Figure 6: An illustration of the investigated self-attentive pooling mechanism.

As shown in Figure 6, for linear LSTMs, we apply pooling mechanism to all hidden states; as for tree LSTMs, pooling is applied to all hidden states and leaf states of tree LSTMs. Implementation details are summarized in the supplementary materials.

Table 4 shows that max and attentive pooling improve all the structures on the task of WSR, but all the pooling mechanisms fail on MT and AE that require the encoding to capture complete information of sentences, while pooling mechanism may cause the loss of information through the procedure. The result indicates that, though pooling mechanism is efficient on some tasks, it cannot totally gain the advantages brought by tree structures. Additionally, we think the attention mech-

Model	WSR	MT	AE

+*self-attention*	72.4 ↑	21.6 ↓	68.9 ↓

Table 4: Performance of tree and linear-structured encoders with or without pooling, on the selected three tasks. We report accuracy ($\times 100$), char-level BLEU for MT and word-level BLEU for AE. All of the tree models have bidirectional leaf RNNs (BiLRNN). The best number(s) for each task are in bold. The top and down arrows indicate the increment or decrement of each pooling mechanism, against the baseline of pure tree based encoder with the same structure.

anism has the benefits of the balanced tree modeling, which also fairly treat all words and learn the crucial parts automatically. The path from representation to words in attention are even shorter than the balanced tree. Thus the fact that attentive pooling outperforms balanced trees on WSR is not surprising to us.

5 Discussions

Balanced tree for sentence modeling has been explored by Munkhdalai and Yu (2017) and Williams et al. (2018) in natural language inference (NLI). However, Munkhdalai and Yu (2017) focus on designing inter-attention on trees, instead of comparing balanced tree with other linguistic trees in the same setting. Williams et al. (2018) do compare balanced trees with latent trees, but balanced tree does not outperform the latent one in their experiments, which is consistent with ours. We analyze it in Section 4.2 that sentences in NLI are too short for the balanced tree to show the advantage.

Levy et al. (2018) argue that LSTM works for the gates ability to compute an element-wise weighted sum. In such case, tree LSTM can also be regarded as a special case of attention, especially for the balanced-tree modeling, which also automatically select the crucial information from all word representation. Kim et al. (2017) propose a tree structured attention networks, which combine the benefits of tree modeling and attention, and the tree structures in their model are also learned instead of the syntax trees.

Although binary parsing trees do not produce better numbers than trivial trees on many downstream tasks, it is still worth noting that we are not claiming the useless of parsing trees, which are intuitively reasonable for human language understanding. A recent work (Blevins et al., 2018) shows that RNN sentence encodings directly learned from downstream tasks can capture implicit syntax information. Their interesting result may explain why explicit syntactic guidance does not work for tree LSTMs. In summary, we still believe in the potential of linguistic features to improve neural sentence modeling, and we hope our investigation could give some sense to afterwards hypothetical exploring of designing more effective tree-based encoders.

6 Conclusions

In this work, we propose to empirically investigate what contributes mostly in the tree-based neural sentence encoding. We find that trivial trees without syntax surprisingly give better results, compared to the syntax tree and the latent tree. Further analysis indicates that the balanced tree gains from its shallow and balance properties compared to other trees, and right-branching tree benefits from its strong structural prior under the setting of left-to-right decoder.

Abstract

Most language modeling methods rely on large-scale data to statistically learn the sequential patterns of words. In this paper, we argue that words are atomic language units but not necessarily atomic semantic units. Inspired by HowNet, we use sememes, the minimum semantic units in human languages, to represent the implicit semantics behind words for language modeling, named Sememe-Driven Language Model (SDLM). More specifically, to predict the next word, SDLM first estimates the sememe distribution given textual context. Afterwards, it regards each sememe as a distinct semantic expert, and these experts jointly identify the most probable senses and the corresponding word. In this way, SDLM enables language models to work beyond word-level manipulation to fine-grained sememe-level semantics, and offers us more powerful tools to fine-tune language models and improve the interpretability as well as the robustness of language models. Experiments on language modeling and the downstream application of headline generation demonstrate the significant effectiveness of SDLM. Source code and data used in the experiments can be accessed at `https://github.com/thunlp/SDLM-pytorch`.

1 Introduction

Language Modeling (LM) aims to measure the probability of a word sequence, reflecting its fluency and likelihood as a feasible sentence in a human language. Language Modeling is an essential component in a wide range of natural language processing (NLP) tasks, such as Machine Translation (Brown et al., 1990; Brants et al., 2007), Speech Recognition (Katz, 1987), Information Retrieval (Berger and Lafferty, 1999; Ponte and Croft, 1998; Miller et al., 1999; Hiemstra, 1998) and Document Summarization (Rush et al., 2015; Banko et al., 2000).

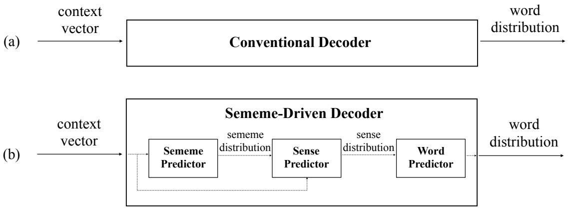

Figure 1: Decoder of (a) Conventional Language Model, (b) Sememe-Driven Language Model.

A probabilistic language model calculates the conditional probability of the next word given their contextual words, which are typically learned from large-scale text corpora. Taking the simplest language model for example, N-Gram estimates the conditional probabilities according to maximum likelihood over text corpora (Jurafsky, 2000). Recent years have also witnessed the advances of Recurrent Neural Networks (RNNs) as the state-of-the-art approach for language modeling (Mikolov et al., 2010), in which the context is represented as a low-dimensional hidden state to predict the next word.

Those conventional language models including neural models typically assume words as atomic symbols and model sequential patterns at word level. However, this assumption does not necessarily hold to some extent. Let us consider the following example sentence for which people want to predict the next word in the blank,

> *The U.S. trade deficit last year is initially estimated to be 40 billion* ______ .

People may first realize a *unit* should be filled in, then realize it should be a *currency unit*. Based on the country this sentence is talking about, the U.S., one may confirm it should be an *American cur-*

Brussels, Belgium, October 31 - November 4, 2018.

rency unit and predict the word *dollars*. Here, the *unit*, *currency*, and *American* can be regarded as basic semantic units of the word *dollars*. This process, however, has not been explicitly taken into consideration by conventional language models. That is, although in most cases words are atomic language units, words are not necessarily atomic semantic units for language modeling. We argue that explicitly modeling these atomic semantic units could improve both the performance and the interpretability of language models.

Linguists assume that there is a limited close set of atomic semantic units composing the semantic meanings of an open set of concepts (i.e. word senses). These atomic semantic units are named **sememes** (Dong and Dong, 2006).[i] Since sememes are naturally implicit in human languages, linguists have devoted much effort to explicitly annotate lexical sememes for words and build linguistic common-sense knowledge bases. HowNet (Dong and Dong, 2006) is one of the representative sememe knowledge bases, which annotates each Chinese word sense with its sememes. The philosophy of HowNet regards the parts and attributes of a concept can be well represented by sememes. HowNet has been widely utilized in many NLP tasks such as word similarity computation (Liu, 2002) and sentiment analysis (Fu et al., 2013). However, less effort has been devoted to exploring its effectiveness in language models, especially neural language models.

It is non-trivial for neural language models to incorporate discrete sememe knowledge, as it is not compatible with continuous representations in neural models. In this paper, we propose a Sememe-Driven Language Model (SDLM) to leverage lexical sememe knowledge. In order to predict the next word, we design a novel sememe-sense-word generation process: (1) We first estimate sememes' distribution according to the context. (2) Regarding these sememes as experts, we propose a sparse product of experts method to select the most probable senses. (3) Finally, the distribution of words could be easily calculated by marginalizing out the distribution of senses.

We evaluate the performance of SDLM on the language modeling task using a Chinese newspaper corpus People's Daily [ii] (Renmin Ribao), and also on the headline generation task using the Large Scale Chinese Short Text Summarization (LCSTS) dataset (Hu et al., 2015). Experimental results show that SDLM outperforms all those data-driven baseline models. We also conduct case studies to show that our model can effectively predict relevant sememes given context, which can improve the interpretability and robustness of language models.

2 Background

Language models target at learning the joint probability of a sequence of words $P(w^1, w^2, \cdots, w^n)$, which is usually factorized as $P(w^1, w^2, \cdots, w^n) = \prod_{t=1}^{n} P(w^t | w^{<t})$. Bengio et al. (2003) propose the first Neural Language Model as a feed-forward neural network. Mikolov et al. (2010) use RNN and a softmax layer to model the conditional probability. To be specific, it can be divided into two parts in series. First, a context vector $\mathbf{g}^t$ is derived from a deep recurrent neural network. Then, the probability $P(w^{t+1} | w^{\leq t}) = P(w^{t+1}; \mathbf{g}^t)$ is derived from a linear layer followed by a softmax layer based on $\mathbf{g}^t$. Let $\mathrm{RNN}(\cdot, \cdot; \boldsymbol{\theta}_{\mathrm{NN}})$ denote the deep recurrent neural network, where $\boldsymbol{\theta}_{\mathrm{NN}}$ denotes the parameters. The first part can be formulated as

$$\mathbf{g}^t = \mathrm{RNN}(\mathbf{x}_{w^t}, \{\mathbf{h}_l^{t-1}\}_{l=1}^{L}; \boldsymbol{\theta}_{\mathrm{NN}}). \qquad (1)$$

Here we use subscripts to denote layers and superscripts to denote timesteps. Thus $\mathbf{h}_l^t$ represents the hidden state of the L-th layer at timestep t. $\mathbf{x}_{w^t} \in \mathbb{R}^{H_0}$ is the input embedding of word w^t where H_0 is the input embedding size. We also have $\mathbf{g}^t \in \mathbb{R}^{H_1}$, where H_1 is the dimension of the context vector.

Supposing that there are N words in the language we want to model, the second part can be written as

$$P(w^{t+1}; \mathbf{g}^t) = \frac{\exp({\mathbf{g}^t}^{\mathrm{T}} \mathbf{w}_{w^{t+1}})}{\sum_{w'} \exp({\mathbf{g}^t}^{\mathrm{T}} \mathbf{w}_{w'})}, \qquad (2)$$

where $\mathbf{w}_w$ is the output embedding of word w and $\mathbf{w}_1, \mathbf{w}_2, \cdots \mathbf{w}_N \in \mathbb{R}^{H_2}$. Here H_2 is the output embedding size. For a conventional neural language model, H_2 always equals to H_1.

---

[i] Note that although sememes are defined as the minimum semantic units, there still exist several sememes for capturing syntactic information. For example, the word 和 "with" corresponds to one specific sememe 功能词 "FunctWord".

[ii] http://paper.people.com.cn/rmrb/

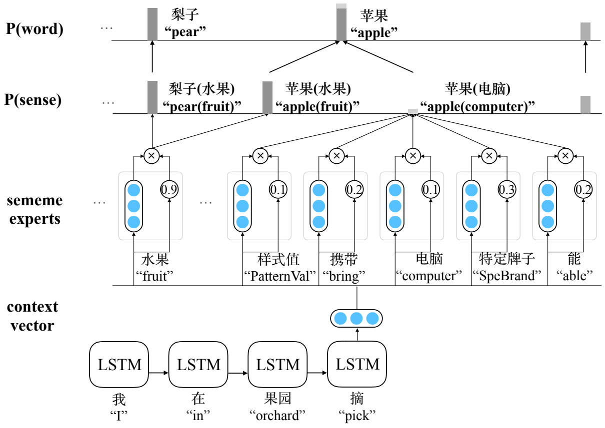

Figure 2: An example of the architecture of our model.

Given the corpus $\{w^t\}_{t=1}^{n}$, the loss function is defined by the negative log-likelihood:

$$\mathcal{L}(\boldsymbol{\theta}) = -\frac{1}{n}\sum_{t=1}^{n}\log P(w^t|w^{<t};\boldsymbol{\theta}), \qquad (3)$$

where $\boldsymbol{\theta} = \{\{\mathbf{x}_i\}_{i=1}^{N}, \{\mathbf{w}_i\}_{i=1}^{N}, \boldsymbol{\theta}_{\text{NN}}\}$ is the set of parameters that are needed to be trained.

3 Methodology

In this section, we present our SDLM which utilizes sememe information to predict the probability of the next word. SDLM is composed of three modules in series: Sememe Predictor, Sense Predictor and Word Predictor. The Sememe Predictor first takes the context vector as input and assigns a weight to each sememe. Then each sememe is regarded as an expert and makes predictions about the probability distribution over a set of senses in the Sense Predictor. Finally, the probability of each word is obtained in the Word Predictor.

Here we use an example shown in Figure 2 to illustrate our architecture. Given context 我在果园摘 “In the orchard, I pick”, the actual next word could be 苹果 “apples”. From the context, especially the word 果园 “orchard” and 摘 “pick”, we can infer that the next word probably represents a kind of fruit. So the Sememe Predictor assigns a higher weight to the sememe 水果 “fruit” (0.9) and lower weights to irrelevant sememes like 电脑 “computer” (0.1). Therefore in the Sense Predictor, the sense 苹果 (水果) “apple (fruit)” is assigned a much higher probability than the sense 苹果 (电脑) “apple (computer)”. Finally, the probability of the word 苹果 “apple” is calculated as the sum of the probabilities of its senses 苹果 (水果) “apple(fruit)” and 苹果 (电脑) “apple (computer)”.

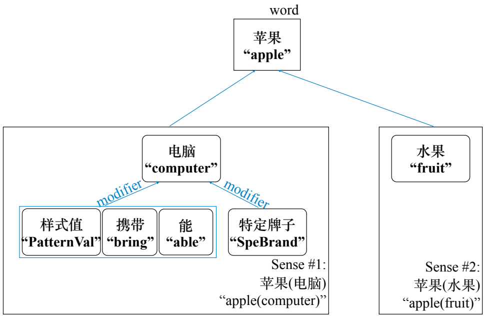

Figure 3: An example of the word-sense-sememe hierarchy.

In the following subsections, we first introduce the word-sense-sememe hierarchy in HowNet, and then give details about our SDLM.

3.1 Word-Sense-Sememe Hierarchy

We also use the example of “apple” to illustrate the word-sense-sememe hierarchy. As shown in Figure 3, the word 苹果 “apple” has two senses, one is the Apple brand, the other is a kind of fruit. Each sense is annotated with several sememes organized in a hierarchical structure. More specifically, in HowNet, sememes “PatternVal”, “bring”, “SpeBrand”, “computer” and “able” are annotated with the word “apple” and organized in a tree structure. In this paper, we ignore the structural relationship between sememes. For each word, we group all its sememes as an unordered set.

We present the notations that we use in the following subsections as follows. We define the overall sememe, sense, and word set as $\mathcal{E}$, $\mathcal{S}$ and $\mathcal{W}$. And we suppose the corpus contains $K = |\mathcal{E}|$ sememes, $M = |\mathcal{S}|$ senses and $N = |\mathcal{W}|$ words. For word $w \in \mathcal{W}$, we denote its corresponding sense set as $\mathcal{S}^{(w)}$. For sense $s \in \mathcal{S}^{(w)}$, we denote its corresponding sememes as an unordered set $\mathcal{E}^{(s)} = \{e_{n_1}, e_{n_2}, \cdots, e_{n_k}\} \subset \mathcal{E} = \{e_k\}_{k=1}^{K}$.

3.2 Sememe Predictor

The Sememe Predictor takes the context vector $\mathbf{g} \in \mathbb{R}^{H_1}$ as input and assigns a weight to each sememe. We assume that given the context $w^1, w^2, \cdots, w^{t-1}$, the events that word w^t contains sememe e_k ($k \in \{1, 2, \cdots, K\}$) are independent, since the sememe is the minimum semantic unit and there is no semantic overlap between any two different sememes. For simplicity, we ignore the superscript t. We design the Sememe Predictor as a linear decoder with the sigmoid activation function. Therefore, q_k, the probability that the next word contains sememe e_k, is formulated as

$$q_k = P(e_k|\mathbf{g}) = \sigma(\mathbf{g}^{\mathrm{T}}\mathbf{v}_k + b_k), \tag{4}$$

where $\mathbf{v}_k \in \mathbb{R}^{H_1}$, $b_k \in \mathbb{R}$ are trainable parameters, and $\sigma(\cdot)$ denotes the sigmoid activation function.

3.3 Sense Predictor and Word Predictor

The architecture of the Sense Predictor is motivated by Product of Experts (PoE) (Hinton, 1999). We regard each sememe as an expert that only makes predictions on the senses connected with it. Let $\mathcal{D}^{(e_k)}$ denote the set of senses that contain sememe e_k, the k-th expert. Different from conventional neural language models, which directly use the inner product of the context vector $\mathbf{g} \in \mathbb{R}^{H_1}$ and the output embedding $\mathbf{w}_w \in \mathbb{R}^{H_2}$ for word w to generate the score for each word, we use $\phi^{(k)}(\mathbf{g}, \mathbf{w})$ to calculate the score given by expert e_k. And we choose a bilinear function parameterized with a matrix $\mathbf{U}_k \in \mathbb{R}^{H_1 \times H_2}$ as a straight implementation of $\phi^{(k)}(\cdot, \cdot)$:

$$\phi^{(k)}(\mathbf{g}, \mathbf{w}) = \mathbf{g}^{\mathrm{T}}\mathbf{U}_k\mathbf{w}. \tag{5}$$

Let $\mathbf{w}_s$ denote the output embedding of sense s. The score of sense s provided by sememe expert e_k can be written as $\phi^{(k)}(\mathbf{g}, \mathbf{w}_s)$. Therefore, $P^{(e_k)}(s|\mathbf{g})$, the probability of sense s given by expert e_k, is formulated as

$$P^{(e_k)}(s|\mathbf{g}) = \frac{\exp(q_k C_{k,s}\phi^{(k)}(\mathbf{g}, \mathbf{w}_s))}{\sum_{s' \in \mathcal{D}^{(e_k)}} \exp(q_k C_{k,s'}\phi^{(k)}(\mathbf{g}, \mathbf{w}_{s'}))}, \tag{6}$$

where $C_{k,s}$ is a normalization constant because sense s is not connected to all experts (the connections are sparse with approximately λN edges, $\lambda < 5$). Here we can choose either $C_{k,s} = 1/|\mathcal{E}^{(s)}|$ (*left normalization*) or $C_{k,s} = 1/\sqrt{|\mathcal{E}^{(s)}||\mathcal{D}^{(e_k)}|}$ (*symmetric normalization*).

In the Sense Predictor, q_k can be viewed as a gate which controls the magnitude of the term $C_{k,s}\phi^{(k)}(\mathbf{g}, \mathbf{w}_{w_s})$, thus control the flatness of the sense distribution provided by sememe expert e_k. Consider the extreme case when $q_k \to 0$, the prediction will converge to the discrete uniform distribution. Intuitively, it means that the sememe expert will refuse to provide any useful information when it is not likely to be related to the next word.

Finally, we summarize the predictions on sense s by taking the product of the probabilities given by relevant experts and then normalize the result; that is to say, $P(s|\mathbf{g})$, the probability of sense s, satisfies

$$P(s|\mathbf{g}) \propto \prod_{e_k \in \mathcal{E}^{(s)}} P^{(e_k)}(s|\mathbf{g}). \tag{7}$$

Using Equation 5 and 6, we can formulate $P(s|\mathbf{g})$ as

$$P(s|\mathbf{g}) = \frac{\exp(\sum_{e_k \in \mathcal{E}^{(s)}} q_k C_{k,s}\mathbf{g}^{\mathrm{T}}\mathbf{U}_k\mathbf{w}_s)}{\sum_{s'} \exp(\sum_{e_k \in \mathcal{E}^{(s')}} q_k C_{k,s'}\mathbf{g}^{\mathrm{T}}\mathbf{U}_k\mathbf{w}_{s'})}. \tag{8}$$

It should be emphasized that all the supervision information provided by HowNet is embodied in the connections between the sememe experts and the senses. If the model wants to assign a high probability to sense s, it must assign a high probability to some of its relevant sememes. If the model wants to assign a low probability to sense s, it can assign a low probability to its relevant sememes. Moreover, the prediction made by sememe expert e_k has its own tendency because of its own $\phi^{(k)}(\cdot, \cdot)$. Besides, the sparsity of connections between experts and senses is also determined by HowNet itself. For our dataset, on average, a word is connected with 3.4 sememe experts and each sememe expert will make predictions about 22 senses.

As illustrated in Figure 2, in the Word Predictor, we get $P(w|\mathbf{g})$, the probability of word w, by summing up probabilities of corresponding s given by the Sense Predictor, that is

$$P(w|\mathbf{g}) = \sum_{s \in \mathcal{S}^{(w)}} P(s|\mathbf{g}). \tag{9}$$

3.4 Implementation Details

Basis Matrix Actually, HowNet contains $K \approx 2000$ sememes. In practice, we cannot directly introduce $K \times H_1 \times H_2$ parameters, which might be computationally infeasible and lead to overfitting. To address this problem, we apply a weight-sharing trick called the basis matrix. We use R basis matrices and their weighted sum to estimate $\mathbf{U}_k$:

$$\mathbf{U}_k = \sum_{r=1}^{R} \alpha_{k,r}\mathbf{Q}_r, \tag{10}$$

where $\mathbf{Q}_r \in \mathbb{R}^{H_1 \times H_2}$, $\alpha_{k,r} > 0$ are trainable parameters, and $\sum_{r=1}^{R} \alpha_{k,r} = 1$.

Weight Tying To incorporate the weight tying strategy (Inan et al., 2017; Press and Wolf, 2017), we use the same output embedding for multiple senses of a word. To be specific, the sense output embedding $\mathbf{w}_s$ for each $s \in S^{(w)}$ is the same as the word input embedding $\mathbf{x}_w$.

4 Experiments

We evaluate our SDLM on a Chinese language modeling dataset, namely People's Daily based on perplexity.[iii] Furthermore, to show that our SDLM structure can be a generic Chinese word-level decoder for sequence-to-sequence learning, we conduct a Chinese headline generation experiment on the LCSTS dataset. Finally, we explore the interpretability of our model with cases, showing the effectiveness of utilizing sememe knowledge.

4.1 Language Modeling

Dataset

We choose the People's Daily Corpus, which is widely used for Chinese NLP tasks, as the resource. It contains one month's news text from People's Daily (Renmin Ribao). Taking Penn Treebank (PTB) (Marcus et al., 1993) as a reference, we build a dataset for Chinese language modeling based on the People's Daily Corpus with 734k, 10k and 19k words in the training, validation and test set. After the preprocessing similar to (Mikolov et al., 2010) (see Appendix A), we get our dataset and the final vocabulary size is 13,476.

Baseline

As for baselines, we consider three kinds of neural language modeling architectures with LSTM cells: simple LSTM, Tied LSTM and AWD-LSTM.

LSTM and Tied LSTM Zaremba et al. (2014) use the dropout strategy to prevent overfitting for neural language models and adopt it to two-layer LSTMs with different embedding and hidden size: 650 for medium LSTM, and 1500 for large LSTM. Employing the weight tying strategy, we get Tied LSTM with better performance. We set LSTM and Tied LSTM of medium and large size as our baseline models and use the code from PyTorch examples[iv] as their implementations.

AWD-LSTM Based on several strategies for regularizing and optimizing LSTM-based language models, Merity et al. (2018) propose AWD-LSTM as a three-layer neural network, which serves as a very strong baseline for word-level language modeling. We build it with the code released by the authors[v].

Variants of Softmax Meanwhile, to compare our SDLM with other language modeling decoders, we set cHSM (Class-based Hierarchical Softmax) (Goodman, 2001), tHSM (Tree-based Hierarchical Softmax) (Mikolov et al., 2013) and MoS (Mixture of Softmaxes) (Yang et al., 2018) as the baseline add-on structures to the architectures above.

Experimental Settings

We apply our SDLM and other variants of softmax structures to the architectures mentioned above: LSTM (medium / large), Tied LSTM (medium / large) and AWD-LSTM. MoS and SDLM are only applied on the models that incorporate weight tying, while tHSM is only applied on the models without weight tying, since it is not compatible with this strategy.

For a fair comparison, we train these models with same experimental settings and conduct a hyper-parameter search for baselines as well as our models (the search setting and the optimal hyper-parameters can be found in Appendix C.1). We keep using these hyper-parameters in our SDLM for all architectures. It should be emphasized that we use the SGD optimizer for all architectures, and we decrease the learning rate by a factor of 2 if no improvement is observed on the validation set. We uniformly initialize the word embeddings, the class embeddings for cHSM and the non-leaf embeddings for tHSM in $[-0.1, 0.1]$. In addition, we set R, the number of basis matrices, to 5 in Tied LSTM architecture and to 10 in AWD-LSTM architecture. We choose the *left normalization* strategy because it performs better.

Experimental Results

Table 1 shows the perplexity on the validation and test set of our models and the baseline models. From Table 1, 2, and 3, we can observe that:

1. Our models outperform the corresponding baseline models of all structures, which indicates the effectiveness of our SDLM. Moreover, our SDLM not only consistently outperforms state-of-the-art MoS model, but also offers much better interpretability (as described in Sect. 4.3), which

---

[iii] Although we only conduct experiments on Chinese corpora, we argue that this model has the potential to be applied to other languages in the light of works on construction sememe knowledge bases for other languages, such as (Qi et al., 2018).

[iv] `https://github.com/pytorch/examples/tree/master/word_language_model`

[v] `https://github.com/salesforce/awd-lstm-lm`

makes it possible to interpret the prediction process of the language model. Note that under a fair comparison, we do not see MoS's improvement over AWD-LSTM while our SDLM outperforms it by 1.20 with respect to perplexity on the test set.

2. To further locate the performance improvement of our SDLM, we study the perplexity of the single-sense words and multi-sense words separately on Tied LSTM (medium) and Tied LSTM (medium) + SDLM. Improvements with respect to perplexity are presented in Table 2. The performance on both single-sense words and multi-sense words gets improved while multi-sense words benefit more from SDLM structure because they have richer sememe information.

3. In Table 3 we study the perplexity of words with different mean number of sememes. We can see that our model outperforms baselines in all cases and is expected to benefit more as the mean number of sememes increases.

Model	#Paras	Validation	Test
LSTM (medium)	24M	116.46	115.51
+ cHSM	24M	129.12	128.12
+ tHSM	24M	151.00	150.87
Tied LSTM (medium)	15M	105.35	104.67
+ cHSM	15M	116.78	115.66
+ MoS	17M	98.47	98.12
+ SDLM	17M	**97.75**	**97.32**
LSTM (large)	76M	112.39	111.66
+ cHSM	76M	120.07	119.45
+ tHSM	76M	140.41	139.61
Tied LSTM (large)	56M	101.46	100.71
+ cHSM	56M	108.28	107.52
+ MoS	67M	94.91	94.40
+ SDLM	67M	**94.24**	**93.60**
AWD-LSTM[iv]	26M	89.35	88.86
+ MoS	26M	92.98	92.76
+ SDLM	27M	**88.16**	**87.66**

Table 1: Single model perplexity on validation and test sets on the People's Daily dataset.

	#senses = 1	#senses > 1
Baseline ppl	93.21	121.18
SDLM ppl	87.22	111.88
Δppl	5.99	9.29
Δppl/Baseline ppl	6.4%	7.8%

Table 2: Perplexity of words with different number of senses on the test set.

We also test the robustness of our model by randomly removing 10% sememe-sense connections in HowNet. The test perplexity for Tied LSTM (medium) + SDLM slightly goes up to 97.67, compared to 97.32 with a complete HowNet, which shows that our model is robust to tiny incompleteness of annotations. However, the performance of out model is still largely dependent upon the accuracy of sememe annotations. As HowNet is continuously updated, we expect our model to perform better with sememe knowledge of higher quality.

	[1, 2)	[2, 4)	[4, 7)	[7, 14)
Baseline ppl	71.56	161.32	557.26	623.71
SDLM ppl	68.47	114.95	465.29	476.45
Δppl	3.09	16.36	91.98	147.25
Δppl/Baseline ppl	4.3%	10.1%	16.5%	23.61%

Table 3: Perplexity of words with different mean number of sememes on the test set.

4.2 Headline Generation

Dataset

We use the LCSTS dataset to evaluate our SDLM structure as the decoder of the sequence-to-sequence model. As its author suggests, we divide the dataset into the training set, the validation set and the test set, whose sizes are 2.4M, 8.7k and 725 respectively. Details can be found in Appendix B.

Models

For this task, we consider two models for comparison.

RNN-context As described in (Bahdanau et al., 2015), RNN-context is a basic sequence-to-sequence model with a bi-LSTM encoder, an LSTM decoder and attention mechanism adopted. The context vector is concatenated with the word embedding at each timestep when decoding. It's widely used for sequence-to-sequence learning, so we set it as the baseline model.

RNN-context-SDLM Based on RNN-context, we substitute the decoder with our proposed SDLM and name it RNN-context-SDLM.

Experimental Settings

We implement our models with PyTorch, on top of the OpenNMT libraries[v]. For both models, we set the word embedding size to 250, the hidden unit size to 250, the vocabulary size to 40000, and the beam size of the decoder to 5. For RNN-context-SDLM, we set the number of basis matrices to 3. We conduct a hyper-parameter search for both

---

[iv] We find that multi-layer AWD-LSTM has problems converging when adopting cHSM, so we skip that result.

[v] `http://opennmt.net`

models (see Appendix C.2 for settings and optimal hyper-parameters).

Experimental Results

Following previous works, we report the F1-score of ROUGE-1, ROUGE-2, and ROUGE-L on the test set. Table 4 shows that our model outperforms the baseline model on all metrics. We attribute the improvement to the use of SDLM structure.

Words in headlines do not always appear in the corresponding articles. However, words with the same sememes have a high probability to appear in the articles intuitively. Therefore, a probable reason for the improvement is that our model could predict sememes highly relevant to the article, thus generate more accurate headlines. This could be corroborated by our case study.

Model	Rouge-1	Rouge-2	Rouge-L
RNN-context	37.5	25.0	34.9
RNN-context-SDLM	**38.9**	**26.2**	**36.2**

Table 4: ROUGE scores of both models on the LCSTS test set.

4.3 Case Study

The above experiments demonstrate the effectiveness of our SDLM. Here we present some samples from the test set of the People's Daily Corpus in Table 5 as well as the LCSTS dataset in Table 6 and conduct further analysis.

For each example of language modeling, given the context of previous words, we list the Top 5 words and Top 5 sememes predicted by our SDLM. The target words and the sememes annotated with them in HowNet are blackened. Note that if the target word is an out-of-vocabulary (OOV) word, helpful sememes that are related to the target meaning are blackened.

Example (1)		
去年 美国 贸易逆差 初步 估计 为 <N> ______ 。		
The U.S. trade deficit last year is initially estimated to be <N> ______ .		
Top 5 word prediction		
美元 "dollar"	， ","	。 "."
日元 "yen"	和 "and"	
Top 5 sememe prediction		
商业 "commerce"	**金融 "finance"**	**单位 "unit"**
多少 "amount"	专 "proper name"	
Example (2)		
阿 总理 ______ 已 签署 了 一 项 命令 。		
Albanian Prime Minister ______ has signed an order.		
Top 5 word prediction		
内 "inside"	**<unk>**	在 "at"
塔 "tower"	和 "and"	
Top 5 sememe prediction		
政 "politics"	**人 "person"**	花草 "flowers"
担任 "undertake"	水域 "waters"	

Table 5: Some examples of word and sememe predictions on the test set of the People's Daily Corpus.

Sememes annotated with the corresponding sense of the target word 美元 "dollar" are 单位 "unit", 商业 "commerce", 金融 "finance", 货币 "money" and 美国 "US". In Example (1), the target word "dollar" is predicted correctly and most of its sememes are activated in the predicting process. It indicates that our SDLM has learned the word-sense-sememe hierarchy and used sememe knowledge to improve language modeling.

Example (2) shows that our SDLM can provide interpretable results on OOV word prediction with sememe information associated with it. The target word here should be the name of the Albanian prime minister, which is out of vocabulary. But with our model, one can still conclude that this word is probably relevant to the sememe "politics", "person", "flowers", "undertake" and "waters", most of which characterize the meaning of this OOV word – the name of a politician. This feature can be helpful when the vocabulary size is limited or there are many terminologies and names in the corpus.

For the example of headline generation, given the article and previous words, when generating the word 生 "student", except the sememe 预料 "predict", all other Top 5 predicted sememes have high relevance to either the predicted word or the context. To be specific, the sememe 学习 "study" is annotated with 生 "student" in HowNet. 考试 "exam" indicates "college entrance exam". 特定牌子 "brand" indicates "BMW". And 高等 "higher" indicates "higher education", which is the next step after this exam. We can conclude that with sememe knowledge, our SDLM structure can extract critical information from both the given article and generated words explicitly and produce better summarization based on it.

5 Related Work

Neural Language Modeling. RNNs have achieved state-of-the-art performance in the language modeling task since Mikolov et al. (2010) first apply RNNs for language modeling. Much work has been done to improve RNN-based language modeling. For example, a variety of work (Zaremba et al., 2014; Gal and Ghahramani, 2016; Merity et al., 2017, 2018) introduces many regularization and optimization methods for RNNs. Based on the observation that the word

Table 6: An example of generated headlines on the LCSTS test set.

appearing in the previous context is more likely to appear again, some work (Grave et al., 2017a,b) proposes to use cache for improvements. In this paper, we mainly focus on the output decoder, the module between the context vector and the predicted probability distribution. Similar to our SDLM, Yang et al. (2018) propose a high-rank model which adopts a Mixture of Softmaxes structure for the output decoder. However, our model is sememe-driven with each expert corresponding to an interpretable sememe.

Hierarchical Decoder Since softmax computation on large vocabulary is time-consuming, therefore being a dominant part of the model's complexity, various hierarchical softmax models have been proposed to address this issue. These models can be categorized to class-based models and tree-based models according to their hierarchical structure. Goodman (2001) first proposes the class-based model which divides the whole vocabulary into different classes and uses a hierarchical softmax decoder to model the probability as $\mathbb{P}(\text{word}) = \mathbb{P}(\text{word}|\text{class})\mathbb{P}(\text{class})$, which is similar to our model. For the tree-based models, all words are organized in a tree structure and the word probability is calculated as the probability of always choosing the correct child along the path from the root node to the word node. While Morin and Bengio (2005) utilize knowledge from WordNet to build the tree, Mnih and Hinton (2008) build it in a bootstrapping way and Mikolov et al. (2013) construct a Huffman Tree based on word frequencies. Recently, Jiang et al. (2017) reform the tree-based structure to make it more efficient on GPUs. The major differences between our model and theirs are the purpose and the motivation. Our model targets at improving the performance and interpretability of language modeling using external knowledge in HowNet. Therefore, we take its philosophy of the word-sense-sememe hierarchy to design our hierarchical decoder. Meanwhile, the class-based and tree-based models are mainly designed to speed up the softmax computation in the training process.

Sememe. Recently, there are a lot of works concentrating on utilizing sememe knowledge in traditional natural language processing tasks. For example, Niu et al. (2017) use sememe knowledge to improve the quality of word embeddings and cope with the problem of word sense disambiguation. Xie et al. (2017) apply matrix factorization to predict sememes for words. Jin et al. (2018) improve their work by incorporating character-level information. Our work extends the previous works and tries to combine word-sense-sememe hierarchy with the sequential model. To be specific, this is the first work to improve the performance and interpretability of Neural Language Modeling with sememe knowledge.

Product of Experts. As Hinton (1999, 2002) propose, the final probability can be calculated as the product of probabilities given by experts.Gales and Airey (2006) apply PoE to the speech recognition where each expert is a Gaussian mixture model. Unlike their work, in our SDLM, each expert is mapped to a sememe with better interpretability. Moreover, as the final distribution is a categorical distribution, each expert is only responsible for making predictions on a subset of the categories (usually less than 10), so we call it Sparse Product of Experts.

Headline Generation. Headline generation is a kind of text summarization tasks. In recent years, with the advances of RNNs, a lot of works have been done in this domain. The encoder-decoder models (Sutskever et al., 2014; Cho et al., 2014) have achieved great success in sequence-to-sequence learning. Rush et al. (2015) propose a local attention-based model for abstractive sentence summarization. Gu et al. (2016) introduce the copying mechanism which is close to the rote memorization of the human being. Ayana et al. (2016) employ the minimum risk training strategy to optimize model parameters. Different from these works, we focus on the decoder of the sequence-to-sequence model, and adopt SDLM to utilize sememe knowledge for sentence generation.

6 Conclusion and Further Work

In this paper, we propose an interpretable Sememe-Driven Language Model with a hierarchical sememe-sense-word decoder. Besides interpretability, our model also achieves state-of-the-art performance in the Chinese Language Modeling task and shows improvement in the Headline Generation task. These results indicate that SDLM can successfully take advantages of sememe knowledge.

As for future work, we plan the following research directions: (1) In language modeling, given a sequence of words, a sequence of corresponding sememes can also be obtained. We will utilize the context sememe information for better sememe and word prediction. (2) Structural information about sememes in HowNet is ignored in our work. We will extend our model with the hierarchical sememe tree for more accurate relations between words and their sememes. (3) It is imaginable that the performance of SDLM will be significantly influenced by the annotation quality of sememe knowledge. We will also devote to further enrich the sememe knowledge for new words and phrases, and investigate its effect on SDLM.

Abstract

Label-specific topics can be widely used for supporting personality psychology, aspect-level sentiment analysis, and cross-domain sentiment classification. To generate label-specific topics, several supervised topic models which adopt likelihood-driven objective functions have been proposed. However, it is hard for them to get a precise estimation on both topic discovery and supervised learning. In this study, we propose a supervised topic model based on the Siamese network, which can trade off label-specific word distributions with document-specific label distributions in a uniform framework. Experiments on real-world datasets validate that our model performs competitive in topic discovery quantitatively and qualitatively. Furthermore, the proposed model can effectively predict categorical or real-valued labels for new documents by generating word embeddings from a label-specific topical space.

1 Introduction

As one of the most widely used text mining techniques, topic modeling can extract meaningful descriptions (i.e., topics) from a corpus (Blei, 2012). Most previous topic models, such as probabilistic Latent Semantic Analysis (pLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2001) are unsupervised. In unsupervised topic models, each document is defined as a mixture distribution over topics and each topic is represented as a mixture distribution over words. Unsupervised topic models only exploit words in documents and do not incorporate the guidance of labels into learning processes. Therefore, these models fail to discover label-specific topics, which are important to support personality psychology (Weiner and Graham, 1990), aspect-level sentiment analysis (Liu, 2012), and cross-domain sentiment classification (He et al., 2011). For example, label-specific topics generated from sentimental texts can help to find attributions and causes for different sentiments by associating sentiments with real-world topics/events.

In light of this consideration, several supervised topic models are proposed to generate label-specific topics. One of the most representative models is the supervised Latent Dirichlet Allocation (sLDA) (Blei and McAuliffe, 2007), which restricts a document being associated with one real-valued response variable. To deal with categorical labels, multi-class sLDA (sLDAc) (Wang et al., 2009) and Labeled Latent Dirichlet Allocation (L-LDA) (Ramage et al., 2009) are proposed, but they are only applicable to classification. Recently, a supervised Neural Topic Model (sNTM) (Cao et al., 2015) is developed to tackle supervised tasks of both classification and regression. As a hybrid method, sNTM is in essence a neural network by following the document-topic distribution in topic models. Unfortunately, the label information has a little effect on topic generation since sNTM models documents and labels separately.

The above limitation motivates us to develop a supervised topic model which can jointly model documents and labels. Particularly, we propose a Siamese Labeled Topic Model (SLTM) to exploit the information of documents and labels based on the Siamese network (Bromley et al., 1993; Hu et al., 2014; Wang and Zhang, 2017), where weight matrices in SLTM represent conditional distributions. Therefore, by constraining weight matrices during the learning procedure, SLTM can follow probabilistic characteristics of topic models strictly. Compared to previous supervised topic models, the main advantages of our SLTM are summarized as follows. First, SLTM can gener-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4652–4662
Brussels, Belgium, October 31 - November 4, 2018.

ate more coherent label-specific topics than others. This is because the supervision of labels is incorporated into topic modeling for SLTM. On the other hand, the mapping of topics to labels is unconstrained for most existing supervised topic models, which renders many coherent topics being generated outside labels. Second, strengths of neural networks are incorporated into SLTM to bootstrap its inference power on label prediction. Third, each word can be mapped to a topical embedding space and represented by a word embedding after generating label-specific topics.

To validate the effectiveness of the proposed model, we evaluate it on two real-world datasets in text mining. Experimental results indicate that our method is able to discover more coherent and label-specific topics than baseline models. Moreover, word embeddings learned by the proposed model can be used to predict labels for new documents effectively.

The remainder of this paper is organized as follows. We summarize related studies on supervised topic modeling in Section 2. For convenience of describing our model, we present the neural network view of topic models in Section 3. Then, we detail the proposed SLTM in Section 4. Experimental design and analysis of results are shown in Section 5. Finally, we present conclusions and future work in Section 6.

2 Related Work

Topic models, which focus on discovering unobserved class variables named "topics" statistically, have been widely used in text mining. One of the early topic models is pLSA (Hofmann, 1999). In pLSA, a document's word vector was decomposed into a mixture of topics, and a topic was represented as a probability distribution over words. LDA (Blei et al., 2001) extended pLSA by adding Dirichlet priors for a document's multinomial distribution over topics and a topic's multinomial distribution over words, which makes it suitable to generate topics for unseen documents.

The aforementioned models are unsupervised, which may be computationally costly to do some task-specific transformation when there is extra labeling information (Cao et al., 2015). To address this issue, several supervised topic models have been proposed to introduce the label guidance in learning processes. One of the most widely used supervised topic models is sLDA (Blei and McAuliffe, 2007). In sLDA, each document was paired with a response variable which obeys the Gaussian distribution. By extending the sLDA, BP-sLDA (Chen et al., 2015) applied back propagation over a deep architecture in conjunction with stochastic gradient/mirror descent for model parameter estimation, leading to scalable and end-to-end discriminative learning characteristics. Based on sLDA, multi-class sLDA (sLDAc) (Wang et al., 2009) was proposed to model documents with categorical labels by adding a softmax classifier rather than a linear regression in sLDA to a standard LDA. Another method of tackling corpora with discrete labels is L-LDA (Ramage et al., 2009), which associated each label with only one topic. To improve the performance of L-LDA in the classification task, Dependency-LDA (Dep-LDA) (Rubin et al., 2012) incorporated an extra topic model to capture the dependencies between labels and took the label dependencies into consideration when estimating topic distributions. Recently, a nonparametric supervised topic model (Li et al., 2018) was proposed to predict the response of interest (e.g., product ratings and sales). The limitation of above models is that they are only applicable to either discrete or continuous data.

In this paper, we propose a Siamese network-based supervised topic model named SLTM. The most relevant work to SLTM is the supervised Neural Topic Model (sNTM) for both classification and regression tasks (Cao et al., 2015), which constructed two hidden layers to generate the n-gram topic and document-topic representations. However, different from our SLTM using bag-of-words methods, sNTM adopted fixed embeddings trained on external resources (Mikolov et al., 2013). Thus, sNTM can not learn data-specific topics. Furthermore, sNTM is hard to follow probabilistic characteristics of the topic-word distribution in topic models, because a topic generated by sNTM is composed of an infinite number of n-grams. Finally, sNTM modeled documents and labels separately rather than uniformly in our SLTM.

3 Preliminaries

For convenience of describing the proposed model, we use hollow uppercase letters (e.g., $\mathbb{D}$) to represent collections, bold uppercase letters (e.g., $\mathbf{W}_1$) to represent matrices, bold lowercase letters (e.g., $\mathbf{y}_i$) to represent vectors, regular uppercase letters (e.g., M) to represent scalar constants,

Table 1: Frequently used notations.

Notation	Description
M	Number of documents
K	Number of topics
N	Size of the vocabulary
L	Size of the label set
$\mathbb{D}$	Document collection
$d_i \in \mathbb{D}$	The i-th document
$\mathbb{V}$	Vocabulary
$v_j \in \mathbb{V}$	The j-th word
$\mathbb{Z}$	Topic collection
$z_k \in \mathbb{Z}$	The k-th topic
$\mathbb{Y}$	Label collection
$\mathbf{y}_i \in \mathbb{R}^L$	Labels for document d_i
$p(v_j\|d_i)$	The probability of v_j given d_i

and regular lowercase letters (e.g., v_j) to represent scalar variables. Based on the above convention, frequently used notations are shown in Table 1. Given a document d_i with labels $\mathbf{y}_i$, our goal is to discover topics with a neural network framework. Therefore, we first describe the neural network view of topic models briefly.

Topic modeling is a popular latent variable inference method for co-occurrence data which associates unobserved classes with observations d_i and v_j, where v_j is a word in d_i. The conditional probability $p(v_j|d_i)$ is defined as:

$$p(v_j|d_i) = \sum_{k=1}^{K} p(v_j|z_k)p(z_k|d_i). \tag{1}$$

Let $\phi(v_j) = [p(v_j|z_1), \ldots, p(v_j|z_K)]$ and $\theta(d_i) = [p(z_1|d_i), \ldots, p(z_K|d_i)]$, then $p(v_j|d_i)$ in Equation 1 can be represented as the following vector form:

$$p(v_j|d_i) = \phi(v_j) \cdot \theta(d_i). \tag{2}$$

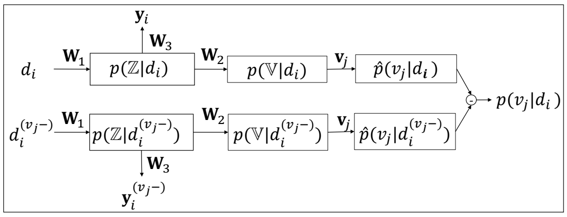

Figure 1: SLTM's word generation framework.

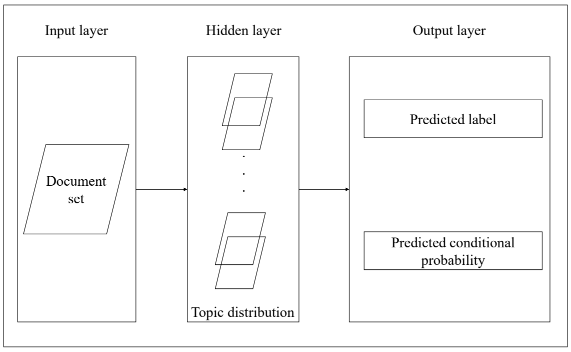

Figure 2: SLTM's architecture from the perspective of neural networks.

We represent horizontal stack by commas and vertical stack by semicolons, thus $\mathbf{W}_1 = [\theta(d_1)^T, \ldots, \theta(d_M)^T] \in \mathbb{R}^{K \times M}$ and $\mathbf{W}_2 = [\phi(v_1); \ldots; \phi(v_N)] \in \mathbb{R}^{N \times K}$, which are constrained by: $\mathbf{W}_1[k,m] \geq 0$, $\mathbf{W}_2[n,k] \geq 0$, $\sum_{k=1}^{K} \mathbf{W}_1[k,m] = 1$, and $\sum_{j=1}^{N} \mathbf{W}_2[j,k] = 1$, where $k \in [1,K]$, $m \in [1,M]$, and $n \in [1,N]$. Then, the vector form in Equation 2 can be extended to:

$$\begin{aligned} p(\mathbb{V}|\mathbb{D}) &= \begin{bmatrix} p(v_1|d_1) & \cdots & p(v_1|d_M) \\ \vdots & \ddots & \vdots \\ p(v_N|d_1) & \cdots & p(v_N|d_M) \end{bmatrix} \\ &= \begin{bmatrix} (\phi(v_1) \cdot \theta(d_1)) & \cdots & (\phi(v_1) \cdot \theta(d_M)) \\ \vdots & \ddots & \vdots \\ (\phi(v_N) \cdot \theta(d_1)) & \cdots & (\phi(v_N) \cdot \theta(d_M)) \end{bmatrix} \\ &= \mathbf{W}_2\mathbf{W}_1. \end{aligned} \tag{3}$$

With Equation 3, topic models can be viewed as neural networks, where $\mathbb{D}$ and $\mathbb{V}$ are input sets, $p(\mathbb{V}|\mathbb{D})$ is the output set, and $\mathbf{W}_1$ and $\mathbf{W}_2$ are parameter matrices of the neural network.

4 Siamese Labeled Topic Model

Similar to generative models such as pLSA, we propose a Siamese Labeled Topic Model (SLTM) based on the aforementioned neural network perspective of topic models. Figure 1 illustrates the framework of generating each word in SLTM, and the process is as follows. For a document d_i in $\mathbb{D}$, the topic distribution $p(\mathbb{Z}|d_i)$ is estimated by:

$$p(\mathbb{Z}|d_i) = \mathbf{W}_1\mathbf{d}_i, \tag{4}$$

where $\mathbf{d}_i$ is the indicator vector (Yang et al., 2013) of d_i, which means that the i-th entry of $\mathbf{d}_i$ is 1 and other entries are 0. Labels of d_i are $\mathbf{y}_i$, which are generated from the topic distribution of d_i as: $\mathbf{y}_i = \mathbf{W}_3 p(\mathbb{Z}|d_i)$. The above equation is constrained by $\mathbf{W}_3[l,k] \geq 0$, where $l \in [1, L]$, $k \in [1, K]$, and $\sum_{l=1}^{L} \mathbf{W}_3[l,k] = 1$ if $L > 1$. A topic z_k in $\mathbb{Z}$ has its word distribution $p(\mathbb{V}|z_k)$, which is computed by:

$$p(\mathbb{V}|z_k) = \mathbf{W}_2 \mathbf{z}_k, \tag{5}$$

where $\mathbf{z}_k$ is the indicator vector of z_k. Therefore, words can be generated from d_i as:

$$p(\mathbb{V}|d_i) = \mathbf{W}_2 \mathbf{W}_1 \mathbf{d}_i. \tag{6}$$

The architecture of SLTM from the perspective of neural networks is shown in Figure 2. With respect to the model optimization, we adopt the contrastive objective function used in previous works (Socher et al., 2014; Cui et al., 2014; Cao et al., 2015; He et al., 2017). For document d_i and every word v_j in d_i, we randomly sample a document from the document set $\mathbb{D}$ which does not contain v_j, as a negative sample document. The negative sample document is represented as $d_i^{(v_j-)}$ and has labels $\mathbf{y}_i^{(v_j-)}$. As shown in Figure 1, the lower sub-network, which takes $d_i^{(v_j-)}$ as input, has the same architecture as the the upper sub-network, which takes d_i as input. Because the document-topic distribution and the topic-word distribution of a corpus are fixed, $\mathbf{W}_1$, $\mathbf{W}_2$ and $\mathbf{W}_3$ are shared among two sub-networks of our model. These two sub-networks are twin networks and thus the proposed model is essentially the Siamese network. Our objective is to make word v_j be learned by topics in document d_i, while not be learned by topics in the negative sampled document $d_i^{(v_j-)}$. Therefore, we only take word v_j in $\mathbb{V}$ into consideration during the learning procedure, which can be implemented as dot-multiplying $p(\mathbb{V}|d_i)$ with the indicator vector of v_j (i.e., $\mathbf{v}_j$) as: $\hat{p}(v_j|d_i) = p(\mathbb{V}|d_i) \cdot \mathbf{v}_j$. Particularly, the objective is to make the predicted conditional probability $\hat{p}(v_j|d_i)$ approach the observed conditional probability $p(v_j|d_i)$ (i.e., term frequency of word v_j in document d_i), while make the conditional probability $\hat{p}(v_j|d_i^{(v_j-)})$ approach zero. Thus, the loss function of predicted conditional probabilities and the observed conditional probability can be defined as:

Algorithm 1 Training Algorithm for SLTM

Input: $\mathbb{S} = \{\mathbb{D}, \mathbb{Y}\}$;

```
repeat
    for all $(d_i, \mathbf{y}_i) \in \mathbb{S}$ do
        for each word $v_j$ in document $d_i$ do
            Sample a document $d_i^{(v_j-)}$ which does not contain $v_j$;
            Calculate $loss(SLTM)$;
            if $loss(SLTM)$ is reducing then
                Update $\mathbf{W}_1$, $\mathbf{W}_2$ and $\mathbf{W}_3$;
            end if
        end for
    end for
until convergence
```

$$\begin{aligned} &loss(d_i, d_i^{(v_j-)}) \\ &\quad = |p(v_j|d_i) - \hat{p}(v_j|d_i) + \hat{p}(v_j|d_i^{(v_j-)})|. \end{aligned} \tag{7}$$

We use another loss function $loss(\mathbf{y}_i, \mathbf{y}_i^{(v_j-)})$ to capture labels of d_i and $d_i^{(v_j-)}$, where $loss(\mathbf{y}_i, \mathbf{y}_i^{(v_j-)}) = loss(\mathbf{y}_i) + loss(\mathbf{y}_i^{(v_j-)})$. In the above, equations of $loss(\mathbf{y}_i)$ and $loss(\mathbf{y}_i^{(v_j-)})$ depend on the property of labels. For categorical and real-valued labels, the cross-entropy (Tang et al., 2014) and the mean absolute error (Willmott and Matsuura, 2005) are adopted, respectively.

The maximization of the weighted sum of conditional likelihoods is equivalent to minimize the losses of the weighted sum of loss functions, and these two loss functions are weighted by a hyperparameter α as in (Tang et al., 2014). Thus, the loss function of SLTM is:

$$\begin{aligned} loss(SLTM) &= \alpha \times loss(d_i, d_i^{(v_j-)}) \\ &\quad + (1-\alpha) \times loss(\mathbf{y}_i, \mathbf{y}_i^{(v_j-)}). \end{aligned} \tag{8}$$

The effect of α on predicting labels and discovering topics will be investigated in Section 5.6. Based on $loss(SLTM)$, three kinds of weights, i.e., $\mathbf{W}_1$, $\mathbf{W}_2$, and $\mathbf{W}_3$ can be updated together by a vanilla back propagation (BP) algorithm with the early stopping criteria (Bengio, 2012). The training algorithm is shown in Algorithm 1.

After training, we obtain both document-topic and topic-word distributions. Then, each word can be mapped to a topic-level embedding space and represented as a word embedding. For instance, the word embedding of v_j is generated from the topic-word distribution $\mathbf{W}_2$ as:

$$\mathbf{e}(v_j) = \mathbf{W}_2[j, :]. \tag{9}$$

The generated word embeddings can be used for specific applications, such as label prediction. Particularly, we firstly represent a new document d_n by its document embeddings $\mathbf{e}(d_n)$, where $\mathbf{e}(d_n)$ is the sum of word embeddings of all words in d_n. Then, the predicted labels $\hat{\mathbf{y}}_n$ of document d_n can be estimated by:

$$\hat{\mathbf{y}}_n = f(\mathbf{W}_4 \mathbf{e}(d_n)), \tag{10}$$

where $\mathbf{W}_4$ denotes weights of each topic contributing to labels, and $f(.)$ is the activation function which depends on the type of labels. For categorical and normalized real-valued labels, we respectively adopt softmax and sigmoid as activation functions. Note that we do not predict labels for new documents based on $\mathbf{W}_3$ directly, because topic distributions of these documents can only be learned without the supervision of labels, i.e., new documents' topic distributions may be inconsistent to $\mathbf{W}_3$. Finally, we update $\mathbf{W}_4$ and word embeddings by RMSprop (Tieleman and Hinton, 2012) for label prediction.

5 Experiments

In this section, we firstly describe datasets and the setting of experiments. Secondly, we investigate the quality of generated topics by the topic coherence score and qualitative analysis. Thirdly, the quality of generated word embeddings is evaluated by label prediction and word similarity. Finally, the effect of the hyper-parameter α is evaluated on coherence of topics and label prediction.

5.1 Datasets and Setting

To evaluate the effectiveness of our method comprehensively, we conduct experiments on two real-world datasets with categorical and real-valued labels, respectively. The first corpus named ISEAR contains a collection of 7,666 sentences and each item is manually tagged with a categorical label over 7 emotions (Scherer and Wallbott, 1994). The second dataset YouTube[1] is often used for sentiment strength detection, which contains 3,407 comments on videos and each item is labeled with a real value between 0.1 (i.e., very negative sentiment) and 0.9 (i.e., very positive sentiment). These two datasets are selected for their similar word numbers in average. After removing stop words, the mean numbers of words in each document are 8.53 and 8.56 for ISEAR and YouTube. Besides, it is appropriate to evaluate the model performance on predicting emotions and sentiment strengths, because topics play an important role in understanding sentences or user comments (Liu, 2012). Since the proposed SLTM is suitable to both topic discovery and classification/regression tasks, we employ five kinds of baselines for comparison.

The first kind are the support vector machine (SVM), an efficient deep learning model for classification (i.e., fastText) (Grave et al., 2017), and the following supervised topic models which are confined to categorical labels:

- sLDAc (Wang et al., 2009): it models documents with categorical labels by adding a softmax classifier to a standard LDA.
- L-LDA (Ramage et al., 2009): it is a supervised model which associates labels with topics by one-to-one correspondence. Accordingly, the number of topics in L-LDA must equal the size of the label set.
- Dep-LDA (Rubin et al., 2012): it extends L-LDA by introducing a multinomial distribution over labels and capturing the dependencies between labels. Then, the label dependencies are used to sample topic distributions in supervised learning.

The second kind are the support vector regression (SVR), a state-of-the-art deep learning model for sentiment strength detection (i.e., HCNN) (Chen et al., 2017), and the following supervised topic models which are developed for predicting real-valued labels only:

- sLDA (Blei and McAuliffe, 2007): it is a classical supervised topic model, in which, each document is paired with a response variable, and the variable is defined as a Gaussian distribution with a mean value that is computed by a linear regression of topics.
- BP-sLDA (Chen et al., 2015): it applies back propagation over a deep architecture together with stochastic gradient/mirror descent for

parameter estimation of sLDA. The number of hidden layers is set to 3.

The third kind is a supervised n-gram model named sNTM, which is applicable to predict both categorical and real-valued labels for new documents (Cao et al., 2015). In sNTM, each n-gram is represented by a 300-dimensional embedding vector using the available tool word2vec[2]. By following (Cao et al., 2015), a large-scale Google News dataset with around 100 billion words is adopted for training. For topic discovery, two unsupervised topic models, pLSA (Hofmann, 1999) and LDA (Blei et al., 2001), are used as the fourth kind of baselines. Finally, we adopt two hybrid methods by combining LDA and supervised learning algorithms as baselines. In particular, a softmax classifier and a liner regression (LR) are used to predict categorical and real-valued labels for documents, respectively. Unless otherwise specified, we set α to 0.5 and adopt the stochastic gradient descent with batch size of 100 for training SLTM.

5.2 Coherence Score of Topics

To investigate the quality of topics discovered by SLTM quantitatively, we use the topic coherence score based on the normalised pointwise mutual information (Lau et al., 2014) as the evaluation metric. Intuitively, a topic coherence score that is larger indicates that the quality of topics is better. All unsupervised topic models (i.e., pLSA and LDA) and supervised methods which associate one label with multiple topics (i.e., sLDAc, sLDA, BP-sLDA, and sNTM) are adopted for comparison. Although L-LDA and Dep-LDA can identify label-specific topics on ISEAR, these models' one-to-one mapping of labels and topics makes them unsuitable in this evaluation. Particularly, L-LDA and Dep-LDA constraint each topic to words in certain documents with the same label, which renders their coherence scores being estimated by a subset of the corpus only. On the other hand, the quality of topics is evaluated on the whole corpus for SLTM and other baseline models.

Table 4: Each label's top 5 words on ISEAR.

Labels	Models	Top 5 words of label-specific topics
fear	sLDAc	home night car **afraid fear**
	L-LDA/Dep-LDA	night **afraid** car home **fear** felt
	SLTM	night **afraid fear** car home dark
joy	sLDAc	year passed heard exam university
	L-LDA/Dep-LDA	friend got time passed felt
	SLTM	**happy joy** passed got university
guilt	sLDAc	did didn't asked **guilty** said
	L-LDA/Dep-LDA	felt **guilty** friend did mother
	SLTM	**guilty** felt mother did friend
disgust	sLDAc	saw man **disgusted disgust** woman
	L-LDA/Dep-LDA	**disgusted** saw felt people friend
	SLTM	**disgusted** saw people man **disgust**
shame	sLDAc	know **ashamed** teacher happened lot
	L-LDA/Dep-LDA	**ashamed** felt friend time did
	SLTM	**ashamed** felt **shame** class teacher
anger	sLDAc	**angry** called new **anger** expected
	L-LDA/Dep-LDA	friend **angry** did time told
	SLTM	**angry** friend **anger** brother told
sadness	sLDAc	father close died away years
	L-LDA/Dep-LDA	died friend **sad** felt time
	SLTM	died **sad** death away friend

The average coherence scores of topics generated by different models on ISEAR and YouTube are respectively shown in Table 2 and Table 3, where the number of topics is 20, the number of top words T is set to 5, 10, and 15, and the best scores are highlighted in boldface. The results indicate that SLTM can discover more coherent topics than both unsupervised topic models and supervised methods, except for $T = 5$ on YouTube. It is also interesting to observe that supervised baseline models (i.e., sLDAc, sLDA, BP-sLDA, and sNTM) perform worse than pLSA and LDA for most cases, which validates that it is challenging to trade off label-specific word distributions with document-specific label distributions (Ramage et al., 2009).

5.3 Qualitative Analysis on Topics

In this part, we conduct qualitative inspection of 20 topics generated by SLTM. The ISEAR dataset

---

[2] https://code.google.com/p/word2vec/

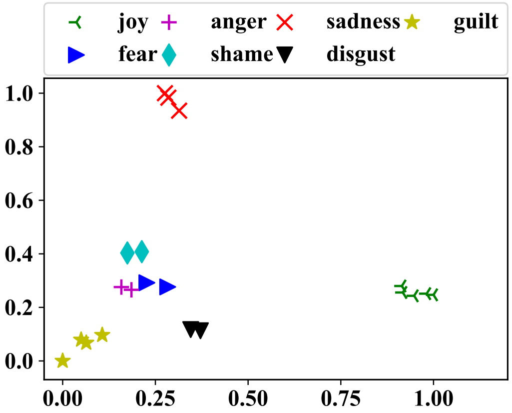

Figure 3: Scatter plot of topics identified by SLTM on ISEAR, where each point indicates a topic.

which contains multiple labels is used for illustration, since it is inappropriate to present the results on YouTube with a single real-valued label. For each model that is applicable to ISEAR, we show top 5 words of the generated label-specific topics in Table 4. It is worth to note that L-LDA and Dep-LDA achieve the same top words, since their difference only exists in the process of label prediction. The results indicate that although all models can learn meaningful topics, SLTM performs better than baseline models in label-specific topic discovery. For example, two words "happy" and "joy" which are strongly related to the label of "joy" are identified by SLTM with large probabilities. Similar results can be observed in other labels, thus topics discovered by our model are more convenient to be understood than others. Such a kind of performance enhancement is valuable to many real-world applications, e.g., personality education and psychotherapy, by producing human interpretable topics/events that evoke users' particular emotions.

For completeness, we also examine all topics generated by the baseline of sNTM. As mentioned earlier, sNTM is based on n-grams, instead of single words for SLTM and other baseline models. In the practical implementation, only unigrams and bigrams are considered since the embedding representation becomes less precise as n increases (Cao et al., 2015). The results indicate that sNTM can generate some topic bigrams such as "smelled disgusting" and "graduation exams", which are more appropriate to expressing a topic. However, only three topics are manually examined to be correlated with the seven emotions. This validates that sNTM is hard to introduce the guidance of labels in topic generation, because it models documents and labels separately.

Table 5: Classification performance on ISEAR.

	Accuracy	Cohen's kappa
SVM	0.5063	0.4240
fastText	0.5104	0.4298
LDA+softmax	0.1506	0.0089
sLDAc	0.1875	0.0540
L-LDA	0.4650	0.3758
Dep-LDA	0.4888	0.4036
sNTM	0.2478	0.1212
SLTM	**0.5213**	**0.4415**

To further evaluate the interpretability of topics extracted from SLTM, we firstly get topic embeddings by: $emb(z_k) = \mathbf{W}_1[k,:]$. Then, we map $emb(z_k)$ to a two-dimensional space via Principal Component Analysis (PCA). Figure 3 presents distributions of topics generated by SLTM over the ISEAR dataset. The scatter plot indicates that topics corresponding to the same label are closer than those of different labels. Furthermore, the distance between topics on correlated labels such as "fear" and "anger", is closer than that of topics on "joy" and other labels.

5.4 Evaluation on Label Prediction

We here evaluate the quality of word embeddings generated by SLTM on predicting categorical and real-valued labels based on ISEAR and YouTube, respectively. Since there are varied parameters for different models, we randomly select 60% of instances as the training set, 20% as the validation set, and the remaining 20% as the testing set. The values of parameters (e.g., the number of topics) for each model are all determined by the validation set. In label prediction, the main difference between SLTM and other supervised topic models is as follows. On one hand, a label-specific word embedding is introduced for predicting labels in SLTM according to Equation 10. On the other hand, other supervised topic models for both categorical and real-valued label prediction tasks infer labels for unlabeled documents by topic distributions directly, in which, topic distributions of unlabeled documents are learned without the supervision of labels.

For the task of categorical label prediction, the

Table 6: Regression performance on YouTube.

	MAE	pR^2
SVR	0.1424	-0.0591
HCNN	0.1112	0.3462
LDA+LR	0.1408	-0.0069
sLDA	0.1583	-0.2836
BP-sLDA	0.1394	-0.0208
sNTM	0.1342	0.0807
SLTM	**0.1005**	**0.4112**

accuracy and the Cohen's kappa score (Artstein and Poesio, 2008) are used as the evaluation metrics. Table 5 shows the classification performance of different models on ISEAR, where the best results are highlighted in boldface. For the prediction of real-valued labels on YouTube, we compare different models' regression performance by the mean absolute error (MAE) and the predictive R^2 (pR^2) (Blei and McAuliffe, 2007), as shown in Table 6. From the above results we can observe that SLTM achieves substantial performance improvement over baselines in predicting both categorical and real-valued labels, which indicates that word embeddings generated from labeled documents are more suitable for label prediction tasks than topic distributions generated from unlabeled documents without the guidance of labels.

5.5 Similarity of Word Embeddings

Word embeddings can reflect relations between words, and most methods of generating word embeddings are based on the local context information. This is because words with similar contexts may have similar semantics. However, a large-scale corpus is required to learn high quality word embeddings from the local context. Different from the previous word embedding generation methods, SLTM generates word embeddings based on the global label-specific topic information (i.e., the topical embedding space). Therefore, we further compare the quality of word embeddings learned by SLTM and three widely used methods: Word2Vec (W2V) (Mikolov et al., 2013), subword information Word2Vec (siW2V) (Joulin et al., 2017), and SSPMI (Levy and Goldberg, 2014). Among these baseline word embedding models, W2V and siW2V use the neural network framework, and SSPMI implicitly factorizes the pointwise mutual information (PMI) matrix of the local word co-occurrence patterns.

Table 7: Word similarity results on ISEAR.

	MEN	SimLex	Rare
W2V	0.002	-0.008	-0.119
siW2V	0.002	0.017	0.062
SSPMI	0.023	0.028	-0.004
SLTM	**0.169**	**0.037**	**0.089**

Table 8: Word similarity results on YouTube.

	MEN	SimLex	Rare
W2V	-0.018	0.004	-0.036
siW2V	-0.002	0.019	-0.051
SSPMI	-0.031	0.038	-0.026
SLTM	**0.048**	**0.040**	**0.068**

As our evaluation metric, the word similarity is estimated as follows. Firstly, we calculate cosine similarity scores for word pairs which occur in both the training set and the testing set. Secondly, word pairs are ranked according to their cosine similarities in the embedding space and human-assigned similarity scores, respectively. Finally, rankings of word similarity scores are evaluated by measuring the Spearman's rank correlation with rankings of human-assigned similarity scores. A higher correlation value indicates that it is more consistent to human judgements in word similarity. The following standard corpora which contain word pairs associated with human-assigned similarity scores are used for this evaluation: MEN (Bruni et al., 2014), SimLex-999 (SimLex) (Hill et al., 2015), and Rare (Luong et al., 2013).

We train W2V, siW2V, and SSPMI over each corpus by setting the number of context window size to 5. Furthermore, the dimension of word embeddings generated from all models is set to 50 according to (Lai et al., 2016). The values of word similarity on ISEAR and YouTube are respectively shown in Table 7 and Table 8, where the best results are highlighted in boldface. We can observe that SLTM outperforms baselines for all cases. The results indicate that word embeddings learned from the global label-specific topic information are better than those from the local context information without any external corpora.

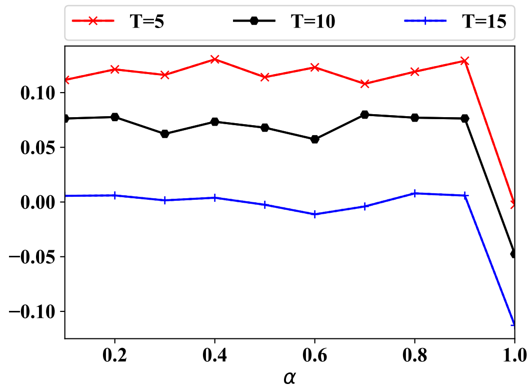

Figure 4: Topic coherence scores on ISEAR using different α values.

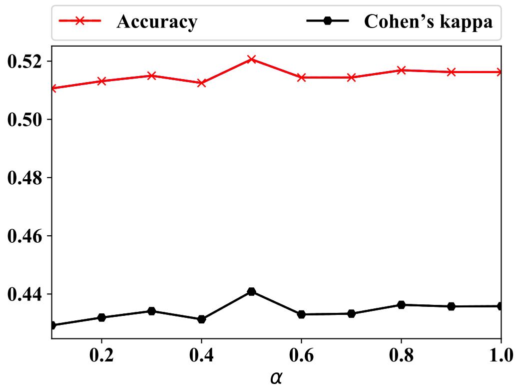

Figure 5: Label prediction performance on ISEAR using different α values.

5.6 Effect of the Hyper-parameter

After validating the effectiveness of SLTM on discovering topics and learning word embeddings, we now investigate the effect of the hyper-parameter in SLTM on these two aspects. According to Equation 8, the hyper-parameter α is used to weight two kinds of loss functions. Since $\mathbf{W}_2$ can be updated subject to $\alpha > 0$, we evaluate the performance of SLTM by varying α from 0.1 to 1 over the ISEAR dataset, as follows.

First, we evaluate the influence of hyper-parameter α on topic discovery by the coherence score of topics. To clearly illustrate the performance trend with different values of α, we set the number of top words T to 5, 10, and 15, and present topic coherence scores in Figure 4. The results indicate that SLTM performs stably under these α values on topic discovery, except for $\alpha = 1$ which ignores the label information totally. This validates the importance of label information in generating coherent topics.

Second, we use the learned word embeddings to predict document labels under different values of α. As shown in Figure 5, we can observe that when $\alpha = 0.5$, i.e., $loss(d_i, d_i^{(v_j-)})$ and $loss(\mathbf{y}_i, \mathbf{y}_i^{(v_j-)})$ are weighted equally, SLTM achieves the best performance in label prediction. The results indicate that the co-occurrence of documents and words as well as the label information are both important to generate good word embeddings. Furthermore, the label prediction performance of SLTM using any of these α values is better than that of most baselines (ref. Table 5). This validates the robustness of SLTM with different hyper-parameter values in supervised learning.

We also conduct experiments on YouTube using varied α values, which indicates that the hyper-parameter has a similar effect on both datasets.

6 Conclusion

In this paper, we proposed a supervised topic model named SLTM to discover label-specific topics by jointly modeling documents and labels. For the SLTM, weight matrices which represent document-topic and topic-word distributions can strictly follow probabilistic characteristics of topic models. Experiments were conducted on datasets with both categorical and real-valued labels, which validated that SLTM can not only discover more coherent topics, but also boost the performance of supervised learning tasks by learning high quality word embeddings. For future work, we plan to speed-up the training process of SLTM by GPUs and distributed algorithms. With the development of deep learning techniques, we also plan to de-emphasize irrelevant words with an attention mechanism.

University of Florida
{valder, fengzheng}@ufl.edu, andyli@ece.ufl.edu

Abstract

Discovering the latent topics within texts has been a fundamental task for many applications. However, conventional topic models suffer different problems in different settings. The Latent Dirichlet Allocation (LDA) may not work well for short texts due to the data sparsity (i.e., the sparse word co-occurrence patterns in short documents). The Biterm Topic Model (BTM) learns topics by modeling the word-pairs named biterms in the whole corpus. This assumption is very strong when documents are long with rich topic information and do not exhibit the transitivity of biterms. In this paper, we propose a novel way called GraphBTM to represent biterms as graphs and design Graph Convolutional Networks (GCNs) with residual connections to extract transitive features from biterms. To overcome the data sparsity of LDA and the strong assumption of BTM, we sample a fixed number of documents to form a mini-corpus as a training instance. We also propose a dataset called $All\ News$ extracted from (Thompson, 2017), in which documents are much longer than 20 Newsgroups. We present an amortized variational inference method for GraphBTM. Our method generates more coherent topics compared with previous approaches. Experiments show that the sampling strategy improves performance by a large margin.

1 Introduction

Topic model (Blei et al., 2003) is one of the most popular approaches to learn hidden representations of text. The broad applications of topic model range from recommender systems (Wang and Blei, 2011), computer vision (Fei-Fei and Perona, 2005), to bioinformatics (Rogers et al., 2005). Conventional topic models learning approaches are based on Gibbs Sampling (Griffiths and Steyvers, 2004) or Variational Expectation Maximization (VEM) algorithm (Blei et al., 2003). Both Gibbs Sampling and VEM are not directly applicable to new variations of the topic model. Specifically, the inference algorithm requires re-deriving for any minor changes to the model.

Recently, a neural network based topic model inference approach, the Autoencoded Variational Inference for Topic Model (AVITM), was proposed by (Srivastava and Sutton, 2017). This approach uses an inference network to directly map a document to its posterior distribution without any variational update steps. The proposed inference network is based on the Autoencoding Variational Bayes (AEVB) (Kingma and Welling, 2013), a stochastic variational inference algorithm over neural networks. Compared with the sampling based approaches, AVITM can scale to large datasets. Although it improves the model's robustness and reduces the computational cost, it still suffers from the data sparsity in short texts.

Biterm Topic Model (BTM) proposed by (Cheng et al., 2014) and (Yan et al., 2013) addresses the shortcoming of data sparsity for modeling the corpus of short texts. It explicitly models the patterns on top of word co-occurrence feature (Biterm, the unordered word-pair occurs in texts) from the corpus. It holds one topic distribution for the whole corpus rather than one document. BTM, therefore, is suitable for modeling short documents like tweets, and online QA texts. It also achieves better results than LDA in specific scenarios of the normal texts (Yan et al., 2013). However, using one topic distribution for all documents limits the model's expressiveness when the documents contain diverse topics.

To address the issue of data sparsity of LDA when modeling the short texts and the insufficient corpus-wise topic representation in BTM for normal texts, we strike a balance between these two approaches. Instead of modeling biterms in the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4663–4672
Brussels, Belgium, October 31 - November 4, 2018.

whole corpus, we extract biterms inside a fixed-length text window for every document and sample n documents to form an instance each time. As a result, we enhance the input feature with biterms that capture more word co-occurrence patterns than BOW and also avoid the insufficient corpus-wised topic representation in BTM. Another advantage of biterms is the transitivity. For example, we have two biterms (A, B) and (A, C). It is natural to think that B and C may share some similarities. This transitivity is similar to the graph structure data. So we model the biterms in a graph where the words are taken as nodes and the counts of biterms are the weight of edges. We extract the information from biterms explicitly by the graph convolutional network (Kipf and Welling, 2016).

In this paper, we propose a novel Graph-based inference network for the biterm topic model (GraphBTM). To the best of our knowledge, GraphBTM is the first AEVB inference approach for the biterm topic model with graph enhanced feature. Our model also strikes a good balance between LDA and BTM, leverages both advantages, and achieves better topics coherence scores than AVITM in two datasets. The main contributions of our work include:

- We are the first to apply the neural network based inference approach for the Biterm Topic Model, and achieve better results in *topic coherence* score than previous AEVB based inference method (AVITM) and online Variational Inference LDA.

- We propose a data argumentation method to enhance the input feature with word correlation from biterms in normal text and overcome the shortcoming of the data sparsity in LDA and the insufficient corpus-wise topic representation in BTM.

- We model the biterms as an undirected graph and adopt a novel graph convolutional network to encode word co-relationship in our inference network.

- We introduce a new dataset *All News* dataset containing 20,000 documents extracted from 15 news publishers (Thompson, 2017) for topic modeling. TThe documents are much longer compared with the 20 Newsgroups.

2 Background

2.1 Biterm Topic Model

BTM (Cheng et al., 2014) is proposed to solve the data sparsity problem in the scenario of short texts. Instead of modeling a single document, BTM considers the whole corpus as a mixture of topics. BTM collects all unordered word-pairs (biterms) from each short text or a fixed-length text window of normal texts. The generative progress of BTM can be described as follows, where α and β are two parameters of Dirichlet priors.

1. For each topic z
   (a) draw a topic-specific word distribution $\phi_z \sim Dir(\beta)$
2. Draw a topic distribution $\theta \sim Dir(\alpha)$ for the whole corpus
3. For each biterm b in the biterm set
   (a) draw a topic assignment $z \sim Multi(\theta)$
   (b) draw two words: $w_i, w_j \sim Multi(\phi_z)$

With the procedure above, the joint probability of a biterm $b = (w_i, w_j)$ can be written as:

$$P(b) = \sum_z P(z)P(w_i|z)P(w_j|z) \quad (1)$$

$$= \sum_z \theta_z \phi_{i|z} \phi_{j|z} \quad (2)$$

So the likelihood of the whole corpus B is:

$$P(B|\alpha, \beta) = \prod_{i,j} \sum_z \theta_z \phi_{i|z} \phi_{j|z} \quad (3)$$

2.2 Laplace Approximation of Dirichlet

Both LDA and BTM use the Dirichlet prior over the topic and word proportions. Wallach et al. (2009) showed that the Dirichlet prior is important to producing interpretable topics. However, it is hard to apply the Dirichlet prior to AEVB directly. AEVB uses the reparameterization trick (RT) to obtain a differentiable Monte Carlo estimator for the variational lower bound (details can be found in next section), and it is difficult to propose an effective RT for the Dirichlet prior.

Fortunately, we can approximate Dirichlet distribution with a logistic normal in the $softmax$ $basis$ by Laplace approximation (Hennig et al.,

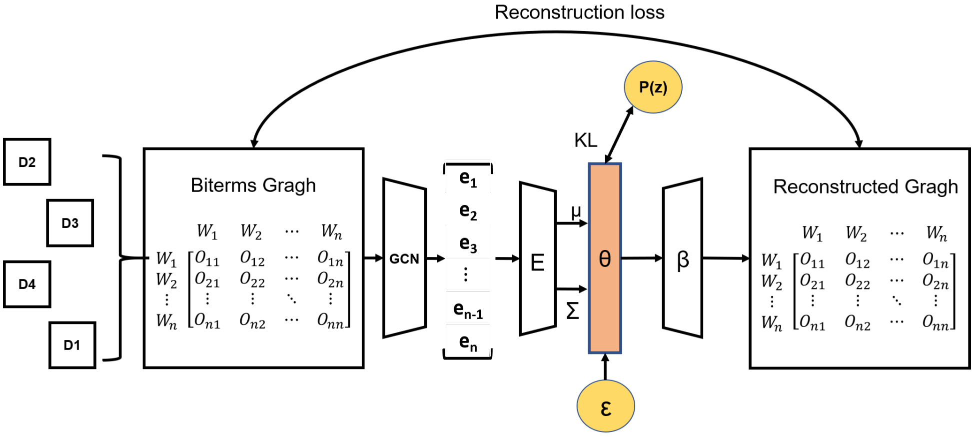

Figure 1: The overall structure of our proposed model GraphBTM. In this example, we sample 4 documents at a time and embed the aggregated biterm graph by GCNs. The graph embedding is sent to inference network E to produce the parameters for our variational distribution. We then use RT to generate the Monte Carlo samples. At last, we use the decoder network β to get the word probabilities and reconstruct the aggregated graph.

2012). MacKay (1998) gives the Dirichlet probability density function in the softmax basis over the variable x:

$$P(\pi|\alpha) = \frac{\Gamma(\sum_k^K(\alpha_k))}{\prod_k^K \Gamma(\alpha_k)} \prod_k \pi_k^{\alpha_k} g(1^T x) \tag{4}$$

where $\pi = \sigma(x)$ (softmax) and $g(1^T x)$ is an arbitrary density for integrability. Hennig et al. (2012) argued that the Eq. 4 could be approximately independent for large K (number of topics). So the covariance matrix of the Dirichlet prior becomes a diagonal matrix for large K. By this way, we can approximate the Dirichlet distribution with a multivariate normal with mean μ_k and covariance matrix Σ_{kk}:

$$\mu_k = log\alpha_k - \frac{1}{K}\sum_i^K log\alpha_i \tag{5}$$

$$\Sigma_{kk} = \frac{1}{\alpha_k}(1 - \frac{2}{K}) + \frac{1}{K^2}\sum_i^K \frac{1}{\alpha_i} \tag{6}$$

with this approximation in hand, we can easily apply RT by sampling from $\epsilon \sim \mathcal{N}(0, I)$ and compute probability $\pi_k = \sigma(\mu_k + \Sigma_{kk}^{1/2}\epsilon)$.

3 Graph Biterm Topic Model

Before getting into details of GraphBTM, we give an overall structure of GraphBTM, as shown in Fig. 1. We extract the biterms from a mini-corpus (aggregated sampled documents) and embed the whole biterm graph into a fixed length vector with the dimension of vocabulary size. Then we use this graph embedding as the input of our inference network and get the topic proportion. At last, we use the decoder network to get the word probabilities and reconstruct the biterm graph.

3.1 Model Biterms as Graphs

Commonly used input feature of topic models is bag-of-words (BOW) which implicitly capture the word co-occurrence patterns. BTM models the word co-occurrence explicitly by directly counting the word-pairs in a text window. However, using one-hot encoding for biterms may lose the transitive co-relations. We model collected biterms as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ (words as nodes and $|V|$ is the vocabulary size) and $\mathcal{E}$ (counts of corresponding biterms in the sample) are sets of nodes and edges, respectively. In this way, the adjacency matrix A ($A \in \mathbb{R}^{V \times V}$) denotes the counts of biterms in the sample. We also leverage the matrix A as the node feature matrix (A_i is the node feature for the word w_i).

We use GCNs proposed by (Kipf and Welling, 2016), which is a framework used for learning the graph structure data. Gilmer et al. (2017) presented a comprehensive overview. Consider an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and a matrix $X \in \mathbb{R}^{n \times m}$ in where each row is a node feature $x_v \in \mathbb{R}^m$ ($v \in \mathcal{V}$). One layer GCN encodes information of a node with its immediate neighbors, defined as

$$h^{l+1} = f\left(\tilde{D}^{-0.5}\tilde{A}\tilde{D}^{-0.5}(h^l W^l + b)\right) \tag{7}$$

where h^0 is the input features X, $\tilde{A} = A + I_N$

is the adjacency matrix of the graph with self-connections, I_N is the identity matrix, $\tilde{D}$ is the degree matrix of $\tilde{A}$, W^l is a trainable weight matrix in the layer and b is the bias. f denotes a non-linear activation function, such as ReLU. By stacking GCN layers, we can incorporate higher order neighborhoods. To represent the whole graph, we reduce the dimension of each node to one by using GCNs and concatenate them as the final representation of the biterm graph.

From another point of view, we can treat GCNs as a Laplacian smoothing. Repeatedly applying Laplacian smoothing may mix the features of vertices and make them indistinguishable (Li et al., 2018). On the other hand, the transitivity of words may not be meaningful when the number of hops (layers) of GCN increases. We solve this problem by adding shortcut connections between different layers inspired by Residual Networks (He et al., 2016). What's more, a recent study showed that adding the residual connection can help convergence (Li and Yuan, 2017).

3.2 AEVB for Biterm Graphs

Eq. 3 gives us the likelihood of the whole corpus based on $Multi(\phi_z)$. Here we rewrite the Eq. 3 with latent variables as

$$p(B|\alpha,\beta) = \int_\theta \left(\prod_{(i,j)} \sum_{z=1}^{k} \pi_i \pi_j p(z_n|\theta) \right) p(\theta|\alpha) d\theta \tag{8}$$

where $\pi_i = p(w_i|z_n,\beta)$. The inference of posterior $p(\theta, z|B,\alpha,\beta)$ over the hidden variables θ and z is intractable (Dickey, 1983). Many methods are proposed to solve this inference problem including Gibbs Sampling (Griffiths and Steyvers, 2004) and variational inference methods. Gibbs Sampling based approaches are computationally inefficient and varitional inference methods like mean field (Blei et al., 2003) scarify the topic quality for computational efficiency. Moreover, the major problem of these approximate inference algorithms is the inflexibility. Slight changes in model assumption may require designing a new inference algorithm. To alleviate this problem, we design an amortized approximate inference method similar to AVITM (Srivastava and Sutton, 2017). It is more flexible compared with other approximate inference methods and can be applied to any biterm graphs.

In Eq. 8, there are two latent variables θ and z, we introduce two free variational parameters γ over θ and ϕ over z. Our goal is to approximate the true posterior $p(\theta, z|B,\alpha,\beta)$ with variational distribution $q(\theta, z|\gamma,\phi) = q_\gamma(\theta)\prod_k q_\phi(z_k)$. Then we can transfer the inference problem as an optimization problem (Blei et al., 2003), which is to maximize

$$\begin{aligned} L(\gamma,\phi|\alpha,\beta) &= logp(B|\alpha,\beta) \\ &\quad - D_{KL}[q(\theta,z|\gamma,\phi)||p(\theta,z|B,\alpha,\beta)] \end{aligned} \tag{9}$$

L is a lower bound to the marginal log likelihood (ELBO). Following AEVB (Kingma and Welling, 2013), we rewrite the ELBO as

$$L(\gamma,\phi|\alpha,\beta) = -D_{KL} + R \tag{10}$$

where $R = E_q[logp(B|z,\theta,\alpha,\beta)]$. This form is intuitive. The first term is the KL divergence betweent the variational distribution and the prior on the latent variables, and the second term ensures that the latent variables are good at explaining and reconstructing the input data.

We use a neural network named $inference$ $network$ to compute the variational parameters. It takes the embedding of the biterm graph (sec. 3.1) as the input and outputs the parameters of the variational distribution. So the inference network can be defined as $(\mu_b, \Sigma_b) = f(b,\gamma)$, where μ_b and Σ_b are vectors of length k (topic numbers) and γ are the network parameters. In our setting, we use the logistic normal distribution which is an approximation of the Dirichlet prior to the variational distribution. We can choose the corresponding variational distribution $q_\gamma(\theta) = \mathcal{LN}(\theta|\mu_b, diag(\Sigma_b))$, where $diag(\cdot)$ converts a column vector to a diagonal matrix. One important advantage of using AEVB is that we couple the variational parameters for different inputs, unlike mean field variational inference, because they are computed from the same network.

Next is how to compute the expectations respect to q in R (Eq. 10). Kingma and Welling (2013) use a differential Monte Carlo estimator with the reparameterization trick. With RT, instead of sampling from the variational distribution directly, we sample from a simple distribution that is independent of all variational parameters. In this way, the gradient can be backpropagated through the variational parameters. For the logistic normal distribution, we can sample from a standard normal distribution $\epsilon \in \mathcal{N}(0, I)$.

Although the reparameterization trick helps us deal with θ, it is hard to deal with the discrete variable z. Fortunately, we can collapse the discrete variables z and only infer θ with collapsed inference method (Kurihara et al.) as

$$p(B|\alpha,\beta) = \int_{\theta}\left(\prod_{(i,j)}\pi_i\pi_j\right)p(\theta|\alpha)d\theta \qquad (11)$$

where $\pi_i = p(w_i|\beta,\theta)$, which is the probability of one word in the biterm. Now we only need to sampling from θ.

We can now get our final variational objective function as (to minimize the negative ELBO)

$$L = D_{KL} - E_{\epsilon}[\sum G_b \circ log(P^T P)] \qquad (12)$$

where G_b is the input biterm graph, $P = \sigma(\beta)\sigma(\mu + \Sigma^{1/2}\epsilon)$ is probabilities for all the words based on the input graph and $\circ$ denotes the element-wise production. The KL divergence between two logistic normal distritbutions are

$$\begin{aligned} D_{KL} =& \frac{1}{2}\{tr(\Sigma_1^{-1}\Sigma_0) + (\mu_1 - \mu_0)^T\Sigma_1^{-1}(\mu_1 - \mu_0) \\ & - K + log\frac{|\Sigma_1|}{|\Sigma_0|}\} \end{aligned} \qquad (13)$$

3.3 Sample Mini-corpus

To alleviate the data sparsity problem of LDA (Zhu and Xing, 2012; Lin et al., 2014), BTM learns topics from the aggregated patterns in the whole corpus. In our observation, this assumption is too strong for normal texts. Other than BTM, some approaches in the literature addressed this problem by aggregating documents into a mini-corpus before training the topic model. For example, in tweets analysis, Weng et al. (2010) aggregated the tweets from one user into a document. Hong and Davison (2010) combined the tweets containing the same word. Inspired by these strategies, we make the same assumption for normal text. We first extract all the biterms in each document and randomly select n documents in the dataset as a mini-corpus. The biterms of the mini-corpus simply merge all the biterms from the n documents. Experiments show that a proper sampling number achieves the best performance.

3.4 Unnormalize the β

The topic-word distribution β is a mixture of multinomials. One drawback of this formulation is that it cannot predict something that is sharper than the distributions being mixed (Hinton and Salakhutdinov, 2009). This problem may result in some poor quality topics. Previous research (Srivastava and Sutton, 2017) shows that unnormalizing the parameters β and changing the conditional distribution of w_n as $w_n|\beta,\theta \sim Multinomial(1, \sigma(\beta\theta))$ can solve this problem.

With the unnormalized β, we can model it as a *decoder network* whose weight matrix $M = (m_1, \ldots, m_K)$ denotes the weight for all words under K topics. Applying softmax to row m_i will give us the probabilities under topic i.

4 Experiments

4.1 Datasets and Settings

We demonstrate our model on two datasets: 20 Newsgroups and *All News*. For All News, we use the data from kaggle collection (Thompson, 2017) [1], which collects documents from 15 main news publishers between 2016 and July 2017. Among these, we randomly select 20,000 documents. In our preprocessing of the texts, we follow the steps of tokenization, filtering out stop words, and non-UTF-8 characters in (Srivastava and Sutton, 2017). From the statistics summarized in Table 1. We can know that the 20 Newsgroups dataset is relatively sparse and the All News has rich information. The ratio of text lengths less or equal to 30 of the 20 Newsgroups dataset is 28%, which only 2% in the All News dataset. The average size differs a lot between these two datasets: 302 for the All News and 88 for the 20 Newsgroups.

For the generation of the matrix W_g, the selection of the window size of words is critical, a small size of window leads to very sparse W_g. Here, we choose an experience value 30 for the window size follows the (Yan et al., 2013). For the logistic normal approximation, we use the Dirichlet distribution with parameter α as 0.02. Our GraphBTM approach, including the GCN layers and the inference network are implemented with Pytorch-v0.4.0 (Paszke et al.). Parameters in our implemented model are optimized by the stochastic optimizer Adadelta (Zeiler, 2012) with learning rate 1. To embed the biterm graph, we use a 3-layer GCNs with size 1995-100, 100-100 and 100-1 for 20 Newsgroups and 5000-1000, 1000-100, 100-1 for ALL News. We use the *edge dropout* in GCN: when computing h^l, we ignore each node with a probability of 0.6. We use batch normalization

(Ioffe and Szegedy, 2015) in $inference\ network$ with batch size 100 as same in (Srivastava and Sutton, 2017). We run each model 10 times and take the average results. Code is available at `https://github.com/valdersoul/GraphBTM`.

The perplexity has been used in the past works to measure the quality of the generated topics. However, the perplexity is not shown to be a good evaluation metric for the topics (Newman et al., 2010). What's more, our method models a mini-corpus instead of a real one and infer the topics through the pattern of biterms, so the perplexity is not suitable to measure the performance of our approach. To get a more objective measurement of the topics, we adopt "topic coherence" as our metric, proposed by (Mimno et al., 2011) to evaluate the quality of the topics. For a vector $V^{(z)} = (v_1^z, ..., v_T^z)$ as the top T words of the topic z, which ordered by the probability $p(w|z)$, the topic coherence is defined as:

$$C(z; V^{(z)}) = \sum_{t=2}^{T} \sum_{l=1}^{t} log \frac{D(v_m^{(z)}, v_l^{(z)}) + 1}{D(v_l^{(z)})}. \quad (14)$$

where $D(v)$ is the number of the documents that word v occurred, and $D(v, v')$ is the number of the documents that both the words v and v' occurred. The assumption of the topic coherence is the words with high frequency in a topic tend to appear in the same document. This measurement has been demonstrated to be highly consistent with the human evaluated quality of the topics.

4.2 Results and Discussions

Comparison with other approaches. We compare our GraphBTM approach with the AVITM (Srivastava and Sutton, 2017) and the LDA model (Blei et al., 2003). For AVITM, we use their results for 20 Newsgroups directly and run the model using the provided code[2]. We use the online variational inference for LDA (Hoffman et al., 2010) implementation by gensim library (Řehůřek and Sojka, 2010) as our LDA baseline. For both GraphBTM and AVITM, we run 200 iterations. Table 2 shows the average topic coherence for three models on the two datasets. The online VI LDA works worst in the three models and we find that on both datasets, the GraphBTM consistently outperforms other two models. We can verify the quality of the learned topics by displaying the topic examples in Table 4. The topics from GraphBTM are more coherent than the topics from both AVITM and LDA model.

---

Effect of the mini-corpus. To study the effect of our sampling strategy which has been discussed in section 3.3. Table 3 shows the performance of our model with different sample size for a mini-corpus. For the 20 Newsgroups dataset, the best performance is achieved when the sample size is 3. When we do not use our sample strategy (mini-corpus is 1), the performance drops by a large margin. From Table 1, we see that the average size of documents size in 20 Newsgroups is relatively short (88 compared with 302 in All News). Therefore, the 20 Newsgroups dataset may suffer from the sparsity problem. The experiment shows that our sampling strategy can help to overcome this problem. When sample size increases, the performance drops again. The biterm graph with large sample size may bring the same problem of the original BTM (insufficient topic representation). Compared to 20 Newsgroups dataset, documents in the All News dataset is longer and carried more topic information, so the best performance is achieved without sampling. We find that when the sample size is larger than an optimized value, the topic coherence starts to drop.

Effect of modeling biterms as graphs. To verify the effect of the graph modeling of biterms. We also do experiments on AVITM with the same sampling strategy. We use the sampling size 3 which achieves the best performance by GraphBTM in 20 Newsgroups to train AVITM model. The performance does not change a lot, with an average score of 0.25 which is the same as the score without sampling. It is not surprising to us because AVITM models the topic directly on the individual document with BOW feature. The BOW feature captures the word co-occurrence implicitly. So aggregating documents in AVITM can not enhance the input feature. However, our model uses GCN to capture the transitivity of biterms and can benefit from the sampling strategy a lot.

Residual connection. We add the residual connection between the first and second layer of GCN. On the other hand, it can also help convergence by adding residual connection (Li and Yuan, 2017). The residual can also help the network capture hierarchical information of the biterms. We remove the residual connection with the same setting which achieves the best performance in these two datasets and results in a **0.1** drop in performance.

5 Related Work

In this section, we briefly summarize the related work of the topic model into two categories: normal texts and short texts.

5.1 Normal Texts

The effort of uncovering the latent semantic representation of documents can be dated from the Latent Semantic Analysis (LSA) (Deerwester et al., 1990), which used the singular value decomposition of the document matrix to get the word patterns. The probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) improved the LSA model by adding a probabilistic model based on a mixture decomposition. It assumed that a document could be presented as a mixture of topics and a topic is a distribution over words. LDA added the Dirichlet priors on topic and word distributions and proposed a complete generative model.

With the rising of deep learning (LeCun et al., 2015), researchers achieve significant improvement in many areas including image classification (He et al., 2016), speech recognition (Hinton et al., 2012) and named entity recognition (Ma and Hovy, 2016; Zhu et al., 2018). Many attempts have been made for topic models based on neural networks (Hinton and Salakhutdinov, 2009; Cao et al., 2015; Miao et al., 2016; Srivastava and Sutton, 2017). Cao et al. (2015) embedded multinomial relationships between documents, topics, and words in differentiable functions. However, they lost the stochasticity and Bayesian inference of prior functions. Miao et al. (2016) introduced the Neural Variational Document Model (NVDM), which used Gaussian distribution over topics and averaged over topic-word distribution in the logit space. Although they used the black-box variational inference (VAE), they did not approximate the Dirichlet prior. Srivastava and Sutton (2017) approximated the Dirichlet prior with logistic Gaussian using the Laplace approximation of Hennig et al. (2012) and collapsed the hidden topic value z with a mixture of experts (Hinton, 2002). This model (AVITM) significantly improved the topic coherence compared with the NVDM model. However, same as the LDA, AVITM suffers from the data sparsity problem.

Table 4: Five selected topics from all models.

5.2 Short Texts

Early studies on short text topic model mainly focused on adding external knowledge to enrich the information of short texts. Phan et al. (2008) firstly learned hidden topics from substantial external resources to enrich the features in short text. Jin et al. (2011) leveraged the power of transfer learning to learn topics on short texts from auxiliary long text data. However, external knowledge in some domain may not be available.

Instead of adding external knowledge, one potential way is to add a sparse prior on the topic distribution. Chien and Chang (2014) used a spike model to control the sparsity of selected topics. Lin et al. (2014) used the same idea to add the sparsity on both topic and word distribution. Different from these approaches, some researchers tried to enhance data without external knowledge. Weng et al. (2010) aggregated the tweets from one user into a document. Hong and Davison (2010) combined the tweets containing the same words. Some other used non-probability topic model to solve this problem. Zhu and Xing (2012) proposed sparse topical coding, which relaxed the normalization constraint of admixture proportions and learned hierarchical latent representations.

6 Conclusion and Future Work

We proposed a Graph Enhanced Autoencoding Variational inference for Biterm Topic Model (GraphBTM). Our model used a black-box approximation inference approach to learn topics through the word co-occurrences (biterms). We modeled the biterms in the form of a graph where the nodes are the words and weighted edges are the counts of the corresponding biterms. On top of this graph representation, we designed a model by GCN layers with a residual connection to effectively extract node representations that preserve the missing connectivity. To overcome the problems of data sparsity in LDA and insufficient topic representation in BTM, we introduced a data argumentation approach by producing a mini-corpus with sampled documents. By setting a proper hyperparameter of sample size k, we achieved better topic coherence scores compared with previous works.

Our GCN model is based on spectral graph convolutions, which requires computing the graph Laplace for each sample. Compared to tasks with one graph input, we need to compute the graph Laplace for every input sample, causing substantial computational cost. It is critical to developing a memory efficient processing and storage strategy to handle the large-scale graph data when we generalize GraphBTM to complex tasks. Recently, fastGCN (Zhang et al., 2018) interpreted graph convolutions as integral transforms of functions under probability measures. Our following work will consider adopting fastGCN to speed up the process.

Abstract

In this paper, we propose a deep, globally normalized topic model that incorporates structural relationships connecting documents in socially generated corpora, such as online forums. Our model (1) captures discursive interactions along observed reply links in addition to traditional topic information, and (2) incorporates latent distributed representations arranged in a deep architecture, which enables a GPU-based mean-field inference procedure that scales efficiently to large data. We apply our model to a new social media dataset consisting of 13M comments mined from the popular internet forum Reddit, a domain that poses significant challenges to models that do not account for relationships connecting user comments. We evaluate against existing methods across multiple metrics including perplexity and metadata prediction, and qualitatively analyze the learned interaction patterns.

1 Introduction

Topic models have become one of the most common unsupervised methods for uncovering latent semantic information in natural language data, and have found a wide variety of applications across the sciences. However, many common models - such as Latent Dirichlet Allocation (Ng and Jordan, 2003) - make an explicit exchangeability assumption that treats documents as independent samples from a generative prior, thereby ignoring important aspects of text corpora which are generated by non-ergodic, interconnected social systems. While the direct application of such models to datasets such as transcripts of The French Revolution (Barron et al., 2017) and discussions on Twitter (Zhao et al., 2011) have yielded sensible topics and exciting insights, their exclusion of document-to-document interactions imposes limitations on the scope of their applicability and the analyses they support. For instance, on many social media platforms, comments are short (the average Reddit comment is 10 words long), making them difficult to treat as full documents, yet they do cohere as a collection, suggesting that contextual relationships should be considered. Moreover, analysis of social data is often principally concerned with understanding relationships between documents (such as question-asking and -answering), so a model able to capture such features is of direct scientific relevance.

To address these issues, we propose a design that models representations of comments jointly along observed reply links. Specifically, we attach a vector of latent binary variables to each comment in a collection of social data, which in turn connect to each other according to the observed reply-link structure of the dataset. The inferred representations can provide information about the rhetorical moves and linguistic elements that characterize an evolving discourse. An added benefit is that while previous work such as Sequential LDA (Du et al., 2012) has focused on modeling a linear progression, the model we present applies to a more general class of acyclic graphs such as tree-structured comment threads ubiquitous on the web.

Online data can be massive, which presents a scalability issue for traditional methods. Our approach uses latent binary variables similar to a Restricted Boltzmann Machine (RBM); related models such as Replicated Softmax (RS) (Salakhutdinov and Hinton, 2009) have previously seen success in capturing latent properties of language, and found substantial speedups over previous methods due to their GPU amenable training procedure. RS was also shown to deal well with documents of significantly different length, another key characteristic of online data. While RBMs permit exact inference, the additional coupling potentials present in our model make inference intractable. However, the choice of bilinear potentials and latent

Figure 1: DDTM factor graph for an example thread. Each comment is modeled as an observed bag-of-words x with topics represented by a latent binary vector h. Log-bilinear factors connect the latent and observed variables of each comment, and the latent variables of parent-child comment pairs along observed reply links. Biases are omitted for clarity.

features admits a mean-field inference procedure which takes the form of a series of dense matrix multiplications followed by nonlinearities, which is particularly amenable to GPU computation and lets us scale efficiently to large data.

Our model outperforms LDA and RS baselines on perplexity and downstream tasks including metadata prediction and document retrieval when evaluated on a new dataset mined from Reddit. We also qualitatively analyze the learned topics and discuss the social phenomena uncovered.

2 Model

We now present an overview of our model. Specifically, it will take the probabilistic form of an undirected graphical model whose architecture mirrors the tree structure of the threads in our data.

2.1 Motivating Dataset

We evaluate on a corpus mined from Reddit, an internet forum which ranks as the fourth most trafficked site in the US (Alexa, 2018) and sees millions of daily comments (Reddit, 2015). Discourse on Reddit follows a branching pattern, shown in Figure 1. The largest unit of discourse is a thread, beginning with a link to external content or a natural language prompt, posted to a relevant subreddit based on its subject matter. Users comment in response to the original post (OP), or to any other comment. The result is a structure which splits at many points into more specific or tangential discussions that while locally coherent may differ substantially from each other. The data reflect features of the underlying memory and network structure of the generating process; comments are serially correlated and highly cross-referential. We treat individual comments as "documents" under the standard topic modeling paradigm, but use observed reply structure to induce a tree of documents for every thread.

2.2 Description of Discursive Distributed Topic Model

We now introduce the Discursive Distributed Topic Model (DDTM) (illustrated in Figure 1). For each comment in the thread, DDTM assigns a latent vector of binary random variables (or *bits*) that collectively form a distributed embedding of the topical content of that comment; for instance, one bit might represent sarcastic language while another might track usage of specific acronyms - a given comment could have any combination of those features. These representations are tied to those of parent and child comments via coupling potentials (see Section 2.3), which allow them to learn discursive properties by inducing a deep undirected network over the thread. In order to encourage the model to use these *comment-level* representations to learn discursive and stylistic patterns as opposed to simply topics of discussion, we incorporate a single additional latent vector for the entire thread that interacts with each comment, explaining word choices that are mainly topical rather than discursive or stylistic. As we demonstrate in our experiments (see Section 6) the *thread-level* embedding learns distributions more reminiscent of what a traditional topic model would uncover, while the comment-level embeddings model styles of speaking and mannerisms that do not directly indicate specific subjects of conversation. The joint probability is defined in terms of an energy function that scores latent embeddings and observed word counts across the tree of comments within a thread using log-bilinear potentials, and is globally normalized over all word count and embedding combinations.

2.3 Probability Model

More formally, consider a thread containing N comments each of size D_n with a vocabulary of size K. As depicted in Figure 1, each comment is viewed as a bag-of-words, densely connected via a log-bilinear potential to a latent embedding of size F. Let each comment be represented as as an integer vector $x_n \in \mathbb{Z}^K$ where x_{nk} is number of times word k was observed in comment n, and let $h_n = \{0,1\}^F$ be the topic embedding for each comment, and let $h_0 = \{0,1\}^F$ be the embedding for the entire thread. To model topic transitions, we score the embeddings of parent-child pairs with a separate coupling potential as shown in Figure 1 (comments with no parents or children receive additional start/stop biases respectively). Let replies be represented with sets R, P_N, and C_N where $(n,m) \in R$ and $n \in P_m$ and $m \in C_n$ if comment m is a reply to comment n. DDTM assigns probability to a specific configuration of x, h with an energy function scored by the emission (π_e) and coupling (π_c) potentials.

$$\begin{aligned}
E(x,h;\theta) &= \underbrace{\sum_{n=1}^{N} \pi_\text{e}(h,x,n)}_{\text{Emission Potentials}} + \underbrace{\sum_{(n,m)\in R} \pi_\text{c}(h,n,m)}_{\text{Coupling Potentials}} \\
\pi_\text{e}(h,x,n) &= h_n^\intercal U x_n + x_n^\intercal a + D_n h_n^\intercal b \\
&\quad + h_0^\intercal V x_n + D_n h_0^\intercal c \\
\pi_\text{c}(h,n,m) &= h_n^\intercal W h_m
\end{aligned} \tag{1}$$

Note that the bias on embeddings is scaled by the number of words in the comment, which controls for their highly variable length. The joint probability is computed by exponentiating the energy and dividing by a normalizing constant.

$$\begin{aligned}
p(x,h;\theta) &= \frac{\exp(E(x,h;\theta))}{Z(\theta)} \\
Z(\theta) &= \sum_{x',h'} \exp(E(x',h';\theta))
\end{aligned} \tag{2}$$

This architecture encourages the model to learn discursive maneuvers via the coupling potentials while separating within-thread variance and across-thread variance through the comment-level and thread-level embeddings respectively. The coupling of latent variables makes factored inference impossible, meaning that even the exact computation of the partition function is no longer tractable. This necessitates approximating the gradients for learning which we will now address.

3 Learning and Inference

Inference in this model class in intractable, so as has been done in previous work on topic modeling (Ng and Jordan, 2003) we rely on variational methods to approximate the gradients needed during training as well as the posteriors over the topic bit vectors. Specifically, we will need the gradients of the normalizer and the sum of the energy function over the hidden variables

$$E(x;\theta) = \log \sum_h \exp(E(x,h;\theta)) \tag{3}$$

which we refer to as the *marginal energy*. Following the approach described for undirected models by Eisner (2011), we approximate these quantities and their gradients with respect to the model parameters θ as we will now describe (thread-level embeddings are omitted in this section for clarity).

3.1 Normalizer Approximation

We aim to train our model to maximize the marginal likelihood of the observed comment word counts, conditioned on the reply links. To do this we must compute the gradient of the normalizer $Z(\theta)$. However, this quantity is computationally intractable, as it contains a summation over all exponential choices for every word in the thread. Therefore, we must approximate $Z(\theta)$. Observe that under Jensen's Inequality, we can form the following lower bound on the normalizer using an approximate joint distribution $q^{(\text{Z})}$.

$$\begin{aligned}
&\log Z(\theta) = \log \sum_{x,h} \exp(E(x,h;\theta)) \\
&\geq \mathbb{E}_{q^{(\text{Z})}}[E(x,h;\theta)] - \mathbb{E}_{q^{(\text{Z})}}[\log q^{(\text{Z})}(x,h;\phi,\gamma)]
\end{aligned} \tag{4}$$

We now define $q^{(\text{Z})}$ as depicted in Figure 2 as a mean-field approximation that treats all variables as independent. We parameterize $q^{(\text{Z})}$ with

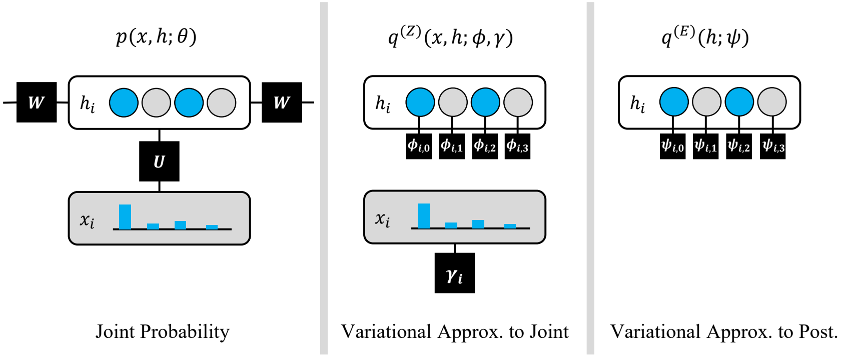

Figure 2: Factor graph of full joint compared to mean-field approximations to joint and posterior.

$\phi_{nf} \in [0,1]$, independent Bernoulli parameters representing the probability of h_{nf} being equal to 1, and γ_{nk} replicated softmaxes representing the probability of a word in x_n taking the value k. Note that all words in x_n are modeled as samples from this single distribution. The approximation then factors as follows:

$$
\begin{aligned}
q^{(\mathrm{Z})}(x,h;\phi,\gamma) &= q^{(\mathrm{Z})}(x;\gamma)\cdot q^{(\mathrm{Z})}(h;\phi)\\
q^{(\mathrm{Z})}(x;\gamma) &= \prod_{n=1}^{N}\prod_{k=1}^{K}(\gamma_{nk})^{x_{nk}}\\
q^{(\mathrm{Z})}(h;\phi) &= \prod_{n=1}^{N}\prod_{f=1}^{F}\left((\phi_{nf})^{h_{nf}}(1-\phi_{nf})^{(1-h_{nf})}\right)
\end{aligned}
\tag{5}
$$

We optimize the parameters of $q^{(\mathrm{Z})}$ to maximize its variational lower bound, via iterative mean-field updates, which allow us to perform coordinate ascent over the parameters of $q^{(\mathrm{Z})}$. Maximizing the lower bound with respect to particular ϕ_{nf} and γ_{nk} while holding all other parameters frozen, yields the following mean-field update equations (biases omitted for clarity):

$$
\begin{aligned}
\phi_{n\cdot} &= \sigma\left(U\gamma_n + \sum_{m\in C_n} W\phi_m + \phi_{P_n}^{\intercal}W\right)\\
\gamma_{n\cdot} &= \sigma\left(\phi_n^{\intercal}U\right)
\end{aligned}
\tag{6}
$$

We iterate over the parameters of $q^{(\mathrm{Z})}$ in an "upward-downward" manner; first updating ϕ for all comments with no children, then all comments whose children have been updated, and so on up to the root of the thread. Then we perform the same updates in reverse order. After updating all ϕ, we then update γ simultaneously (the components of γ are independent conditioned on ϕ). We iterate these upward-downward passes until convergence.

3.2 Marginal Energy Approximation

We can now approximate the normalizer, but still need the marginal data likelihood in order to take gradient steps on it and train our model. In order to recover the marginal likelihood, we must next approximate the marginal energy $E(x;\theta)$ as it too is intractable. This is due to the coupling potentials, which make the topics across comments dependent even when conditioned on the word counts. To do this, we form an additional variational approximation (see Figure 2) to the marginal energy, which we optimize similarly.

$$
\begin{aligned}
E(x;\theta) &= \log\sum_{h}\exp(E(x,h;\theta))\\
&\geq \mathbb{E}_{q^{(\mathrm{E})}}[E(x,h;\theta)] - \mathbb{E}_{q^{(\mathrm{E})}}[\log q^{(\mathrm{E})}(h;\psi)]
\end{aligned}
\tag{7}
$$

Since $q^{(\mathrm{E})}(h;\psi)$ need only model the hidden units h, we can parameterize it in the same manner as $q^{(\mathrm{Z})}(h;\phi)$. Note that while these distributions factor similarly, they do not share parameters, although we find that in practice, initializing $\phi \leftarrow \psi$ improves our approximation. We optimize the lower bound on $E(x;\theta)$ via a similar coordinate ascent strategy, where the mean-field updates take the following form (biases omitted for clarity):

$$
\psi_{n\cdot} = \sigma\left(Uh_n + \sum_{m\in C_n} W\psi_m + \psi_{P_n}^{\intercal}W\right) \tag{8}
$$

We can use $q^{(\mathrm{E})}$ to perform inference at test time in our model, as its parameters ψ directly correspond to the expected values of the hidden topic embeddings under our approximation.

3.3 Learning via Gradient Ascent

We train the parameters of our true model $p(x,h;\theta)$ via stochastic updates wherein we optimize both approximations on a single datum (i.e. thread) to compute the approximate gradient of its log-likelihood, and take a single gradient step on the model parameters (repeating on all training instances until convergence). That gradient is given by the difference in feature expectations under the approximations (entropy terms from the lower bounds are dropped as they do not depend on θ).

$$\begin{aligned}\nabla \log p(x;\theta) \approx\ & \mathbb{E}_{q^{(\mathrm{E})}(h;\psi)}\left[\nabla E(x,h;\theta)\right] \\ & - \mathbb{E}_{q^{(\mathrm{Z})}(x',h;\psi)}\left[\nabla E(x',h;\theta)\right]\end{aligned} \tag{9}$$

In summary, we use two separate mean-field approximations to compute lower bounds on the marginal energy $E(x,h;\theta)$, and its normalizer $Z(\theta)$, which lets us approximate the marginal likelihood $p(x;\theta)$. Note that as our estimate on the marginal likelihood is the difference between two lower bounds, it is not a lower bound itself, although in practice it works well for training.

3.4 Scalability and GPU Implementation

Given the magnitude of our dataset, it is essential to be able to train efficiently at scale. Many commonly used topic models such as LDA (Ng and Jordan, 2003) have difficulty scaling, particularly if trained via MCMC methods. Improvements have been shown from online training (Hoffman et al., 2010), but extending such techniques to model comment-to-comment connections and leverage GPU compute is nontrivial.

In contrast, our proposed model and mean-field procedure can be scaled efficiently to large data because they are amenable to GPU implementation. Specifically, the described inference procedure can be viewed as the output of a neural network. This is because DDTM is globally normalized with edges parameterized as log-bilinear weights, which results in the mean-field updates taking the form of matrix operations followed by nonlinearities. Therefore, a single iteration of mean-field is equivalent to a forward pass through a recursive neural network, whose architecture is defined by the tree structure of the thread. Multiple iterations are equivalent to feeding the output of the network back into itself in a recurrent manner, and optimizing for T iterations is achieved by unrolling the network over T timesteps. This property makes DDTM highly amenable to efficient training on a GPU, and allowed us to scale experiments to a dataset of over 13M total Reddit comments.

4 Experimental Setup

4.1 Data

We mined a corpus of Reddit threads pulled through the platform's API. Focusing on the twenty most popular subreddits (gifs, todayilearned, CFB, funny, aww, AskReddit, BlackPeopleTwitter, videos, pics, politics, The_Donald, soccer, leagueoflegends, nba, nfl, worldnews, movies, mildlyinteresting, news, gaming) over a one month period yielded $200,000$ threads consisting of $13,276,455$ comments total. The data was preprocessed by removing special characters, replacing URLs with a domain-specific token, stemming English words using a Snowball English Stemmer (Porter, 2001), removing stopwords, and truncating the vocabulary to only include the top $10,000$ most common words. OPs are modeled as a comment at the root of each thread to which all top-level comments respond. This dataset will be made available for public use after publication.

4.2 Baselines and Comparisons

We compare to baselines of Replicated Softmax (RS) (Salakhutdinov and Hinton, 2009) and Latent Dirichlet Allocation (LDA) (Ng and Jordan, 2003). RS is a distributed topic model similar to our own, albeit without any coupling potentials. LDA is a locally normalized topic model which defines topics as non-overlapping distributions over words. To ensure that DDTM does not gain an unfair advantage purely by having a larger embedding space, we divide the dimensions equally between comment- and thread-level. Unless specified 64 bits/topics were used. We experiment with RS and LDA treating either comments or full threads as documents.

4.3 Training and Initialization

SGD was performed using the Adam optimizer (Kingma and Ba, 2015). When running inference, we found convergence was reached in an average of 2 iterations of updates. Using a single NVIDIA Titan X (Pascal) card, we were able to train our model to convergence on the training set of 10M comments in less than 30 hours. It is worth noting that we found DDTM to be fairly sensitive to initialization. We found best results from Gaussian noise, with comment-level emissions at variance of 0.01, thread-level emissions at 0.0001, and transitions at 0. We initialized all biases to 0 except for the bias on word counts, which we set to the unigram log-probabilities from the train set.

	Perplexity (nats)			
Bits	32	64	96	128
RS (thr)	2240	2234	2233	2257
RS (cmt)	1675	1894	2245	2518
DDTM (-cpl)	2027	1704	1766	1953
DDTM	**1624**	**1590**	**1719**	**713**

Table 1: Perplexity of DDTM with and without coupling potentials (-cpl) vs. baselines trained at comment (cmt) or thread (thr) level across various numbers of topics and bits. For reference, a unigram model achieves 2644.

5 Results

5.1 Evaluating Perplexity

We compare models by perplexity on a held-out test set, a standard evaluation for generative and latent variables models.

Setup: Due to the use of mean-field approximations for both the marginal energy and normalizer we lose any guarantees regarding the accuracy of our likelihood estimate (both approximations are lower bounds, and therefore their difference is neither a strict lower bound nor guaranteed to be unbiased). To evaluate perplexity in a more principled way, we use Annealed Importance Sampling (AIS) to estimate the ratio between our model's normalizer and the tractable normalizer of a base model from which we can draw true independent samples as described by Salakhutdinov and Murray (2008). Note that since the marginal energy is intractable in our model, unlike a standard RBM, we must sample the joint - and not the marginal - intermediate distributions. This yields an unbiased estimate of the normalizer. The marginal energy must still be approximated via a lower bound, but given that AIS is unbiased and empirically low in variance, we can treat the overall estimate as a lower bound on likelihood for evaluation. Using 2000 intermediate distributions, and averaging over 20 runs, we evaluated per-word perplexity over a set of 50 unseen threads. Results are shown in Table 1.

Results: DDTM achieves the lowest perplexity at all dimensionalities. Note our ablation with the coupling potentials removed (-cpl), increases perplexity noticeably, indicating that modeling replies helps beyond simply modeling threads and comments jointly, particularly at larger embeddings. For reference, a unigram model achieves 2644. We find that LDA's approximate perplexity is even worse, likely due to slackness in its lower bound.

Task	**Upvote Regr.** (MSE)	**Deletion Pred.** (% acc.)
LDA (thr)	1.952	68.35
LDA (cmt)	2.047	59.26
RS (thr)	2.024	69.92
RS (cmt)	2.007	66.45
DDTM	**1.933**	**70.39**

Table 2: Performance of DDTM vs. Replicated Softmax (RS) and Latent Dirichlet Allocation (LDA) at predicting upvotes and child deletion.

5.2 Upvote Regression

To measure how well embeddings capture comment-level characteristics, we feed them into a linear regression model that predicts the number of upvotes the comment received. Upvotes provide a loose human-annotated measure of likability. We expect that context matters in determining how well received a comment is; the same comment posted in response to different parents may receive a very different number of upvotes. Hence, we expect comment-level embeddings to be more informative for this task when connected via our model's coupling potentials.

Setup: We trained a standard linear regressor for each model. The regressor was trained using ordinary least squares on the entire training set of comments using the model's computed topic embeddings as input, and the number of upvotes on the comment as the output to predict. As a preprocessing step, we took the log of the absolute number of votes before training. We compared models by mean squared error (MSE) on our test set. Results are shown in Table 2.

Results: DDTM achieves lowest MSE. To assess statistical significance, we performed a 500 sample bootstrap of our training set. The standard errors of these replications are small, and a two-sample t-test rejects the null hypothesis that DDTM has an average MSE equal to that of the next best method ($p < .001$). Note that our model outperforms both comment- and thread-level embeddings, suggesting that modeling these jointly, and modeling the effect of neighboring representations in the comment graph, more accurately learns information relevant to a comment's social impact.

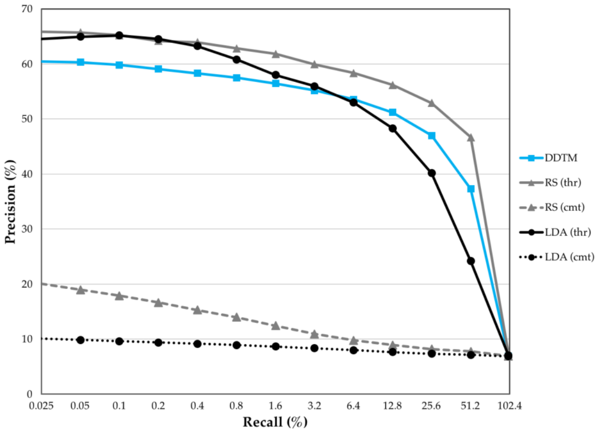

Figure 3: Precision vs. recall for document retrieval based on subreddit comparing various models for 1000 randomly selected held-out query comments.

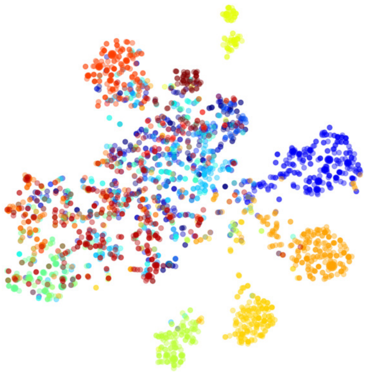

Figure 4: t-SNE visualization of a random sample of DDTM thread-level embeddings colored by subreddit (not observed in training)

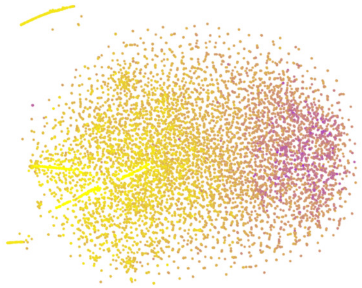

Figure 5: t-SNE visualization of a random sample of DDTM comment-level embeddings colored by log of comment length (darker is longer).

5.3 Deletion Prediction

Comments that are excessively provocative or in violation of site rules are often deleted, either by the author or a moderator. We can measure whether DDTM captures discursive interactions that lead to such intervention by training a logistic classifier that predicts whether any of a given comment's children have been deleted.

Setup: For each model, a logistic regression classifier was trained stochastically with the Adam optimizer on the entire training set of comments using the model's computed topic embeddings as input, and a binary label for whether the comment had any deleted children as the output to predict. We compared models by accuracy on our test set. Results are shown in Table 2.

Results: DDTM gets the highest accuracy. Interestingly, thread-level models do better than comment-level ones, which suggests that certain topics or even subreddits may correlate with comments being deleted. This makes sense given that subreddits vary in severity of moderation. DDTM's performance also demonstrates that modeling comment-to-comment interaction patterns is helpful in predicting when a comment will spawn a deleted future response, which strongly matches our intuition.

5.4 Document Retrieval

Finally, while DDTM is not designed to better capture topical structure, we evaluate the extent to which it can still capture this information by performing document retrieval, a standard evaluation, for which we treat the subreddit to which a thread was posted as a label for relevance. Note that every comment within the same thread belongs to the same subreddit, which gives thread-level models an inherent advantage at this task. We include this task purely for the purpose of demonstrating that by capturing discursive patterns, DDTM does not lose the ability to model thread-level topics as well.

Setup: Given a query comment from our held-out test set, we rank the training set by the Dice similarity of the hidden embeddings computed by the model. We consider a retrieved comment relevant to the query if they both originate from the same subreddit, which loosely categorizes the semantic content. Tuning the number of documents we return allows us to form precision recall curves, which we show in Figure 3.

Results: DDTM outperforms both comment-level baselines and is competitive with thread-level models, even beating LDA at high levels of recall. This indicates that despite using half of its dimensions to model comment-to-comment interactions DDTM can still do almost as good a job of modeling thread-level semantics as a model using its entire capacity

to do so. The gap between comment-level RS and LDA is also consistent with LDA's known issues dealing with sparse data (Sridhar, 2015), and lends credence to our theory that distributed topic representations are better suited to such domains.

6 Qualitative Analysis of Topics

We now offer qualitative analysis of the topic embeddings learned by our model. Note that since we use distributed embeddings, our bits are more akin to filters than complete distributions over words, and we typically observe as many as half of them active for a single comment. In a sense, we have an exponential number of topics, whose parameterization simply factors over the bits. Therefore, it can be difficult to interpret them as one would interpret topics learned by a model such as LDA. Furthermore, we find that in practice this effect is correlated with the topic embedding size; the more bits our model has, the less sparse and consequently less individually meaningful the bits become. Therefore for this analysis, we specifically focus on DDTM trained with 64 bits total.

6.1 Bits in Isolation

Directly inspecting the emission parameters, reveals that the comment-level and thread-level halves of our embeddings capture substantially different aspects of the data (shown in Table 3) akin to vertical, within-thread, and horizontal, across-thread sources of variance respectively. The comment-level topic bits tend to reflect styles of speaking, lingo, and memes that are not unique to a particular subject of discourse or even subreddit. For example, comment-level Bit 2 captures many words typical of taunting Reddit comments; replying with "/r/iamverysmart" (a subreddit dedicated to mocking people who make grandiose claims about their intellect) is a common way of jokingly implying that the author of the parent comment takes themselves too seriously — and thus corresponds to a certain kind of rhetorical move. Further, it is grouped with other words that indicate related rhetorical moves; calling a user "risky" or a "madman" is a common means of suggesting that they are engaging in a pointless act of rebellion. They also cluster at the coarsest level by length (see Figure 5) which we find to correlate with writing style.

By contrast, the thread-level bits are more indicative of specific topics of discussion, and unsurprisingly they cluster by subreddit (see Figure 4). For example, thread-level Bit 3 captures lexicon used almost exclusively by alt-right Donald Trump supporters as well as the names of various political figures. Bit 4 highlights words related to civil unrest in Spanish speaking parts of the world.

6.2 Bits in Combination

While these distributions over words (particularly for comment-level bits) can seem vague, when multiple bits are active, their effects compound to produce much more specific topics. One can think of the bits as defining soft filters over the space of words, that when stacked together carve out patterns not apparent in any of them individually. We now analyze a few sample topic embeddings. To do this, we perform inference as described on a held-out thread, and pass the comment-level topic embedding for a single sampled comment through our emission matrix and inspect the words with the highest corresponding weight (shown in Table 4). In generative terminology, these can be thought of as reconstructions of comments.

These topic embeddings capture more specific conversational and rhetorical moves. For example,

Sample #	**Associated Word Stems by Emission Weight (Higher Score → Lower Score)**
Comment-Level	
Sample 1	`grade grader math age 5th 9th 10th till mayb 7th`
2	`repost damn dope bamboozl shitload imagin cutest sad legendari awhil`
3	`heh dawg hmm spooki buddi aye m8 aww fam woah`
4	`hug merci bless tfw prayer pleas dear bear banana satan`
5	`chuckl cutest funniest yall bummer oooh mustv coolest ok oop`
6	`cutest heard coolest funniest havent seen ive craziest stupidest weirdest`
7	`reev keanu christoph murphi walken vincent chris til wick roger`
8	`moron douchebag stupid dipshit snitch jackass dickhead idioci hypocrit riddanc`
9	`technic actual realiz happen escal werent citat practic memo cba`
10	`reddit shill question background user subreddit answer relev discord guild`

Table 4: Words with the highest emission weight for sample held-out comment reconstructions.

Sample 6 displays supportive and interested reactionary language, which one might expect to see used in response to a post or comment linking to media or describing something intriguing. This is of note given that one of the primary aims of including coupling potentials was to encourage DDTM to learn "topics" that correspond to responses and interactive behavior, something existing methods are largely not designed for. By contrast, Sample 9 captures a variety of hostile language and insults, which unlike those discussed previously do not denote membership in a particular online community. As patterns of toxic and hateful behavior on Reddit are more well-studied (Chandrasekharan et al., 2017), it could be useful to have a tool to analyze precipitous contexts and parent comments, something which we hope systems based on coupling of comment embeddings have the capacity to provide. Sample 10 is of particular interest as it consists largely of Reddit terminology. Conversations about the meta of the site can manifest for example in users accusing each other of being "shills" (i.e. accounts paid to astroturf on behalf of external interests) or requesting/responding to "guilding", a feature which lets users purchase premium access for each other often in response to a particularly well made comment.

7 Related Work

Many topic models such as LDA (Ng and Jordan, 2003) treat documents as independent mixtures, yet this approach fails to model how comments interact with one another throughout a larger discourse if such connections exist in the data. Other work has considered modeling hierarchy in topics (Griffiths et al., 2004). These models form hierarchical representations of topics themselves, but still treat documents as independent. While this approach can succeed in learning topics of various granularities, it does not explicitly track how topics interact in the context of a nested conversation.

Some approaches such as Pairwise-Link-LDA and Link-PSLA-LDA (Nallapati et al., 2008) attempt to model interactions among documents in an arbitrary graph, albeit with important drawbacks. The former models every possible pairwise link between comments, and the latter models links as a bipartite graph, limiting its ability to scale to large tree-structured threads. Similar work on Topic-Link LDA (Liu et al., 2009) models link probabilities conditioned on both topic similarity and an authorship model, yet this approach is poorly suited to high volume, semi-anonymous online domains. Other studies have leveraged reply-structures on Reddit in the context of predicting persuasion (Hidey and McKeown), but DDTM differs in its generative, unsupervised approach.

DDTM's emission potentials are similar to those of Replicated Softmax (Salakhutdinov and Hinton, 2009), an undirected model based on a Restricted Boltzmann Machine. Unlike LDA-style models, RS does not assign a topic to each word, but instead builds a distributed representation. In this setting, a single word can be likely under two different topics, both of which are present, and lend probability mass to that word. LDA-style models by contrast would require the topics to compete for the word.

8 Conclusion

In this paper we introduce a novel way to learn topic interactions in observed discourse trees, and describe GPU-amenable learning techniques to train on large-scale data mined from Reddit. We demonstrate improvements over previous models on perplexity and downstream tasks, and offer qualitative analysis of learned discursive patterns. The dichotomy between the two levels of embeddings hints at applications in style-transfer.

Abstract

We propose a method for learning *disentangled* representations of texts that code for distinct and complementary aspects, with the aim of affording efficient model transfer and interpretability. To induce disentangled embeddings, we propose an adversarial objective based on the (dis)similarity between triplets of documents with respect to specific aspects. Our motivating application is embedding biomedical abstracts describing clinical trials in a manner that disentangles the *populations*, *interventions*, and *outcomes* in a given trial. We show that our method learns representations that encode these clinically salient aspects, and that these can be effectively used to perform aspect-specific retrieval. We demonstrate that the approach generalizes beyond our motivating application in experiments on two multi-aspect review corpora.

1 Introduction

A classic problem that arises in (distributed) representation learning is that it is difficult to determine what information individual dimensions in an embedding encode. When training a classifier to distinguish between images of people and landscapes, we do not know *a priori* whether the model is sensitive to differences in color, contrast, shapes or textures. Analogously, in the case of natural language, when we calculate similarities between document embeddings of user reviews, we cannot know if this similarity primarily reflects user sentiment, the product discussed, or syntactic patterns. This lack of interpretability makes it difficult to assess whether a learned representations is likely to generalize to a new task or domain, hindering model transferability. Disentangled representations with known semantics could allow more efficient training in settings in which supervision is expensive to obtain (e.g., biomedical NLP).

Thus far in NLP, learned distributed representations have, with few exceptions (Ruder et al., 2016; He et al., 2017; Zhang et al., 2017), been *entangled*: they indiscriminately encode all aspects of texts. Rather than representing text via a monolithic vector, we propose to estimate multiple embeddings that capture complementary aspects of texts, drawing inspiration from the ML in vision community (Whitney, 2016; Veit et al., 2017a).

As a motivating example we consider documents that describe clinical trials. Such publications constitute the evidence drawn upon to support *evidence-based medicine* (EBM), in which one formulates precise clinical questions with respect to the Populations, Interventions, Comparators and Outcomes (PICO elements) of interest (Sackett et al., 1996).[1] Ideally, learned representations of such articles would factorize into embeddings for the respective PICO elements. This would enable aspect-specific similarity measures, in turn facilitating retrieval of evidence concerning a given condition of interest (i.e., in a specific patient population), regardless of the interventions and outcomes considered. Better representations may reduce the amount of supervision needed, which is expensive in this domain.

Our work is one of the first efforts to induce disentangled representations of texts,[2] which we believe may be broadly useful in NLP. Concretely, our contributions in this paper are as follows:

- We formalize the problem of learning disentangled representations of texts, and develop a relatively general approach for learning these from aspect-specific similarity judgments expressed as triplets $(s, d, o)_a$, which indicate that document d is more similar to document s than to document o, with respect to aspect a.

---

[1] We collapse I and C because the distinction is arbitrary.

[2] We review the few recent related works that do exist in Section 5.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4683–4693
Brussels, Belgium, October 31 - November 4, 2018.

- We perform extensive experiments that provide evidence that our approach yields disentangled representations of texts, both for our motivating task of learning PICO-specific embeddings of biomedical abstracts, and, more generally, for multi-aspect sentiment corpora.

2 Framework and Models

Recent approaches in computer vision have emphasized unsupervised learning of disentangled representations by incorporating information-theoretic regularizers into the objective (Chen et al., 2016; Higgins et al., 2017). These approaches do not require explicit manual annotations, but consequently they require post-hoc manual assignment of meaningful interpretations to learned representations. We believe it is more natural to use weak supervision to induce meaningful aspect embeddings.

2.1 Learning from Aspect Triplets

As a general strategy for learning disentangled representations, we propose exploiting aspect-specific document triplets $(s, d, o)_a$: this signals that s and d are *more* similar than are d and o, with respect to aspect a (Karaletsos et al., 2015; Veit et al., 2017b), i.e., $\text{sim}_a(d, s) > \text{sim}_a(d, o)$, where sim_a quantifies similarity w.r.t. aspect a.

We associate with each aspect an encoder enc_a (encoders share low-level layer parameters; see Section 2.2 for architecture details). This is used to obtain text embeddings $(\mathbf{e}_s^a, \mathbf{e}_d^a, \mathbf{e}_o^a)$. To estimate the parameters of these encoders we adopt a simple objective that seeks to maximize the similarity between $(\mathbf{e}_d^a, \mathbf{e}_s^a)$ and minimize similarity between $(\mathbf{e}_d^a, \mathbf{e}_o^a)$, via the following maximum margin loss

$$\mathcal{L}(\mathbf{e}_s^a, \mathbf{e}_d^a, \mathbf{e}_o^a) = max\{0, 1 - sim(\mathbf{e}_d^a, \mathbf{e}_s^a) + sim(\mathbf{e}_d^a, \mathbf{e}_o^a)\} \quad (1)$$

Where similarity between documents i and j with respect to a particular aspect a, $sim_a(i, j)$, is simply the cosine similarity between the aspect embeddings $\mathbf{e}_i^a$ and $\mathbf{e}_j^a$. This allows for the same documents to be similar with respect to some aspects while dissimilar in terms of others.

The above setup depends on the correlation between aspects in the training data. At one extreme, when triplets enforce identical similarities for all aspects, the model cannot distinguish between aspects at all. At the other extreme, triplets are present for only one aspect a, and absent for all other aspects a': In this case the model will use only the embeddings for aspect a to represent similarities. In general, we expect a compromise between these extremes, and propose using negative sampling to enable the model to learn targeted aspect-specific encodings.

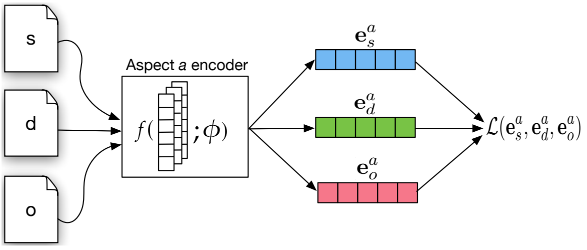

Figure 1: We propose associating aspects with encoders (low-level parameters are shared across aspects; this is not shown) and training these with triplets codifying aspect-wise relative similarities.

2.2 Encoder Architecture

Designing an aspect-based model requires specifying an encoder architecture. One consideration here is interpretability: a desirable property for aspect encoders is the ability to identify salient words for a given aspect. With this in mind, we propose using gated CNNs, which afford introspection via the token-wise gate activations.

Figure 2 schematizes our encoder architecture. The input is a sequence of word indices $d = (w_1, ..., w_N)$ which are mapped to m-dimensional word embeddings and stacked into a matrix $E = [\mathbf{e}_1, ..., \mathbf{e}_N]$. These are passed through sequential convolutional layers $C_1, ..., C_L$, which induce representations $H_l \in \mathbb{R}^{N \times k}$:

$$H_l = f_e(X * K_l + \mathbf{b}_l) \quad (2)$$

where $X \in \mathbb{R}^{N \times k}$ is the input to layer C_l (either a set of n-gram embeddings or H_{l-1}) and k is the number of feature maps. Kernel $K_l \in \mathbb{R}^{F \times k \times k}$ and $\mathbf{b}_l \in \mathbb{R}^k$ are parameters to be estimated, where F is the size of kernel window.[3] An activation function f_e is applied element-wise to the output of the convolution operations. We fix the size of $H_{l-1} \in \mathbb{R}^{N \times k}$ by zero-padding where necessary. Keeping the size of feature maps constant across layers allows us to introduce residual connections; the output of layer l is summed with the outputs of preceding layers before being passed forward.

We multiply the output of the last convolutional layer $H_L \in \mathbb{R}^{N \times k}$ with gates $\mathbf{g} \in \mathbb{R}^{N \times 1}$ to yield

---

[3] The input to C_1 is $E \in \mathbb{R}^{N \times m}$, thus $K_1 \in \mathbb{R}^{F \times m \times k}$.

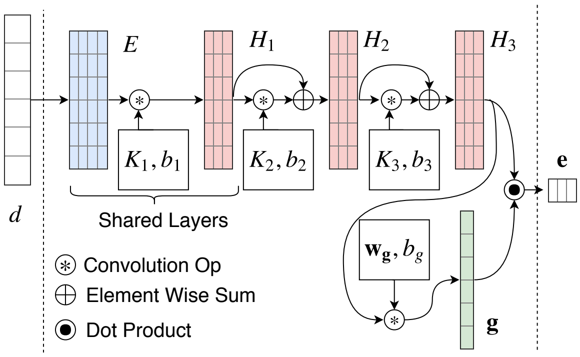

Figure 2: Schematic of our encoder architecture.

our final embedding $\mathbf{e}_d \in \mathbb{R}^{1\times k}$:

$$\begin{aligned} \mathbf{g} &= \sigma(H_L \cdot \mathbf{w}_g + b_g) \\ \mathbf{e}_d &= \mathbf{g}^T H_L \end{aligned} \tag{3}$$

where $\mathbf{w}_g \in \mathbb{R}^{k\times 1}$ and $b_g \in \mathbb{R}$ are learned parameters and σ is the sigmoid activation function. We impose a sparsity-inducing constraint on $\mathbf{g}$ via the ℓ_1 norm; this allows the gates to effectively serve as an attention mechanism over the input. Additionally, to capture potential cross-aspect correlation, weights in the embedding and first convolutional layers are shared between aspect encoders.

Alternative encoders. To assess the relative importance of the specific encoder model architecture used, we conduct experiments in which we fine-tune standard document representation models via triplet-based training. Specifically, we consider a single-layer MLP with BoW inputs, and a Neural Variational Document Model (NVDM) (Miao et al., 2016). For the NVDM we take a weighted sum of the original loss function and the triplet-loss over the learned embeddings, where the weight is a model hyperparameter.

3 Varieties of Supervision

Our approach entails learning from triplets that codify relative similarity judgments with respect to specific aspects. We consider two approaches to acquiring such triplets: the first exploits aspect-specific summaries written for texts, and the second assumes a more general scenario in which we solicit aspect-wise triplet judgments directly.

3.1 Deriving Triplets from Aspect Summaries

In the case of our motivating example – disentangled representations for articles describing clinical trials – we have obtained aspect-specific summaries from the *Cochrane Database of Systematic Reviews (CDSR)*. Cochrane is an international organization that creates and curates biomedical *systematic reviews*. Briefly, such reviews seek to formally synthesize all relevant articles to answer precise clinical questions, i.e., questions that specify a particular PICO frame. The CDSR consists of a set of reviews $\{R_i\}$. Reviews include multiple articles (studies) $\{S_{ij}\}$. Each study S consists of an abstract A and a set of free text summaries (s_P, s_I, s_O) written by reviewers describing the respective P, I and O elements in S.

Reviews implicitly specify PICO frames, and thus two studies in any given review may be viewed as equivalent with respect to their PICO aspects. We use this observation to derive document triplets. Recall that triplets for a given aspect include two comparatively similar texts (s, d) and one relatively dissimilar (o). Suppose the aspect of interest is the trial population. Here we match a given abstract (d) with its matched population summary from the CDSR (s); this encourages the encoder to yield similar embeddings for the abstract and the population description. The dissimilar o is constructed to distinguish the given abstract from (1) other aspect encodings (of interventions, outcomes), and, (2) abstracts for trials with different populations.

Concretely, to construct a triplet (s, d, o) for the PICO data, we draw two reviews R_1 and R_2 from the CDSR at random, and sample two studies from the first (s_1, s_1') and one from the second (s_2). Intuitively, s_2 will (very likely) comprise entirely different PICO elements than (s_1, s_1'), by virtue of belonging to a different review. To formalize the preceding description, our triplet is then: $(s = [s_1'^P], d = [s_1^{\text{abstract}}], o = [s_2^P | s_1'^I | s_1'^O])$, where s_1^{abstract} is the abstract for study s_1, and aspect summaries for studies are denoted by superscripts. We include a concrete example of triplet construction in the Appendix, Section D.

3.2 Learning Directly from Aspect-Wise Similarity Judgments

The preceding setup assumes a somewhat unique case in which we have access to aspect-specific summaries written for texts. As a more general setting, we also consider learning directly from triplet-wise supervision concerning relative similarity with respect to particular aspects (Amid and Ukkonen, 2015; Veit et al., 2017a; Wilber et al., 2014). The assumption is that such judgments can be solicited directly from annotators, and thus the approach may be applied to arbitrary domains, so long as meaningful aspects can be defined implicitly via pairwise similarities regarding them.

We do not currently have corpora with such judgments in NLP, so we constructed two datasets using aspect-specific sentiment ratings. Note that this highlights the flexibility of exploiting aspect-wise triplet supervision as a means of learning disentangled representations: existing annotations can often be repurposed into such triplets.

4 Datasets and Experiments

We present a series of experiments on three corpora to assess the degree to which the learned representations are disentangled, and to evaluate the utility of these embeddings in simple downstream retrieval tasks. We are particularly interested in the ability to identify documents similar w.r.t. a target aspect. All parameter settings for baselines are reported in the Appendix (along with additional experimental results). The code is available at `https://github.com/successar/neural-nlp`.

4.1 PICO (EBM) Domain

We first evaluate embeddings quantitatively with respect to retrieval performance. In particular, we assess whether the induced representations afford improved retrieval of abstracts relevant to a particular systematic review (Cohen et al., 2006; Wallace et al., 2010). We then perform two evaluations that explicitly assess the degree of disentanglement realized by the learned embeddings.

The PICO dataset comprises 41K abstracts of articles describing clinical trials extracted from the CDSR. Each abstract is associated with a review and three summaries, one per aspect (P/I/O). We keep all words that occur in ≥ 5 documents, converting all others to `unk`. We truncate documents to a fixed length (set to the 95th percentile).

4.1.1 Quantitative Evaluation

Baselines. We compare the proposed **P**, **I** and **O** embeddings and their concatenation $[\mathbf{P}|\mathbf{I}|\mathbf{O}]$ to the following. **TF-IDF**: standard TF-IDF representation of abstracts. **RR-TF**: concatenated TF-IDF vectors of sentences predicted to describe the respective PICO elements, i.e., sentence predictions made using the pre-trained model from (Wallace et al., 2016) — this model was trained using distant supervision derived from the CDSR. **doc2vec**: standard (entangled) distributed representations of abstracts (Le and Mikolov, 2014). **LDA**: Latent Dirichlet Allocation. **NVDM**: A generative model of text where the representation is a vector of log-frequencies that encode a topic (Miao et al., 2016). **ABAE**: An autoencoder model that discovers latent aspects in sentences (He et al., 2017). We obtain document embeddings by summing over constituent sentence embeddings. **DSSM**: A CNN based encoder trained with triplet loss over abstracts (Shen et al., 2014).

Hyperparameters and Settings. We use three layers for our CNN-based encoder (with 200 filters in each layer; window size of 5) and the PReLU activation function (He et al., 2015) as f_e. We use 200d word embeddings, initialized via pretraining over a corpus of PubMed abstracts (Pyysalo et al., 2013). We used the Adam optimization function with default parameters (Kingma and Ba, 2014). We imposed ℓ_2 regularization over all parameters, the value of which was selected from the range ($1e$-2, $1e$-6) as $1e$-5. The ℓ_1 regularization parameter for gates was chosen from the range ($1e$-2, $1e$-8) as $1e$-6. All model hyperparameters for our models and baselines were chosen via line search over a 10% validation set.

Metric. For this evaluation, we used a held out set of 15 systematic reviews (comprising 2,223 studies) compiled by Cohen et al. (2006). The idea is that good representations should map abstracts in the same review (which describe studies with the same PICO frame) relatively near to one another. To compute AUCs over reviews, we first calculate all pairwise study similarities (i.e., over all studies in the Cohen corpus). We can then construct an ROC for a given abstract a from a particular review to calculate its AUC: this measures the probability that a study drawn from the same review will be nearer to a than a study from a different review. A summary AUC for a review is taken as the mean of the study AUCs in that review.

Results. Table 1 reports the mean AUCs over individual reviews in the Cohen et al. (2006) corpus, and grand means over these (bottom row). In brief: The proposed PICO embeddings (concatenated) obtain an equivalent or higher AUC than baseline strategies on 12/14 reviews, and strictly higher AUCs in 11/14. It is unsurprising that we outperform unsupervised approaches, but we also best RR-TF, which was trained with the same CDSR corpus (Wallace et al., 2016), and DSSM (Shen et al., 2014), which exploits the same triplet loss

in a clinical trial mainly involving patients over qqq with coronary heart disease , ramipril reduced mortality while vitamin e had no preventive effect .

Table 2: Gate activations for each aspect in a PICO abstract. Note that because gates are calculated at the final convolution layer, activations are not in exact 1-1 correspondence with words.

as our model. We outperform the latter by an average performance gain of 4 points AUC (significant at 95% level using independent 2-sample t-test).

We now turn to the more important questions: are the learned representations actually disentangled, and do they encode the target aspects? Table 2 shows aspect-wise gate activations for PICO elements over a single abstract; this qualitatively suggests disentanglement, but we next investigate this in greater detail.

4.1.2 Qualitative Evaluation

To assess the degree to which our PICO embeddings are disentangled – i.e., capture complementary information relevant to the targeted aspects – we performed two qualitative studies.

First, we assembled 87 articles (not seen in training) describing clinical trials from a review on the effectiveness of decision aids (Stacey et al., 2014) for: women with, at risk for, and genetically at risk for, breast cancer (BCt, BCs and BCg, respectively); type II diabetes (D); menopausal women (MW); pregnant women generally (PW) and those who have undergone a C-section previously (PWc); people at risk for colon cancer (CC); men with and at risk of prostate cancer (PCt and PCs, respectively) and individuals with atrial fibrillation (AF). This review is unusual in that it *studies a single intervention (decision aids) across different populations*. Thus, if the model is successful in learning disentangled representations, the corresponding P vectors should roughly cluster, while the I/C should not.

Figure 3 shows a TSNE-reduced plot of the P, I/C and O embeddings induced by our model for these studies. Abstracts are color-coded to indicate the populations enumerated above. As hypothesized, P embeddings realize the clearest separation with respect to the populations, while the I and O embeddings of studies do not co-localize to the same degree. This is reflected quantitatively in the AUC values achieved using each aspect embedding (listed on the Figure). This result implies disentanglement along the desired axes.

Next we assembled 50 abstracts describing trials involving *hip replacement arthroplasty* (HipRepl). We selected this topic because HipRepl will either describe the trial population (i.e., patients who have received hip replacements) or it will be the intervention, but not both. Thus, we would expect that abstracts describing trials in which HipRepl describes the population cluster in the corresponding embedding space, but not in the intervention space (and vice-versa). To test this, we first manually annotated the 50 abstracts, associating HipRepl with either P or I. We used these labels to calculate pairwise AUCs, reported in Table 3. The results imply that the population embeddings discriminate between studies that

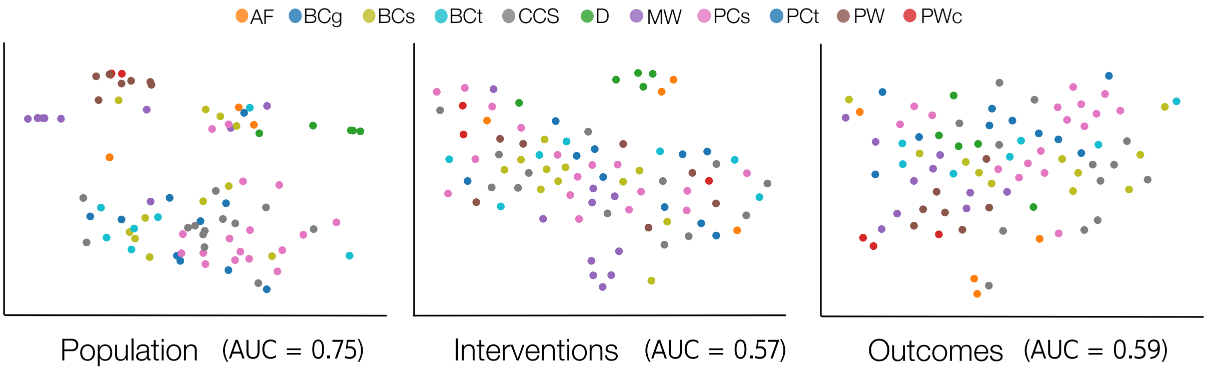

Figure 3: TSNE-reduced scatter of disentangled PICO embeddings of abstracts involving "decision aid" interventions. Abstracts are colored by known population group (see legend). Population embeddings for studies in the same group co-localize, more so than in the intervention and outcome space.

	HipRepl I	HipRepl P	Mean
Population	0.62	**0.68**	**0.66**
Intervention	**0.91**	0.46	0.57
Outcome	0.89	0.42	0.54

Table 3: AUCs realized over HipRepl studies using different embeddings. Column: Study label (HipRepl as P or I). Row: Aspect embedding used.

Population *american*, *area*, *breast*, *colorectal*, *diagnosis*, *inpatients*, *outpatients*, *stage*, *their*, *uk*

Intervention *adjunct*, *alone*, *an*, *discussion*, *intervention*, *methods*, *reduced*, *started*, *took*, *written*

Outcome *adults*, *area*, *either*, *eligible*, *importance*, *improve*, *mortality*, *pre*, *reduces*, *survival*

Table 4: Top ten most activated words, as determined by the gating mechanism.

Baseline	Look	Aroma	Palate	Taste
TF-IDF	0.63	0.62	0.62	0.61
LDA	0.73	0.73	0.73	0.73
Doc2Vec	0.61	0.61	0.61	0.61
NVDM	0.68	0.69	0.69	0.70
ABAE	0.50	0.50	0.50	0.50
BoW + Triplet	0.85	0.90	0.90	0.92
NVDM + Triplet	0.90	0.91	0.92	0.95
DSSM + Triplet	0.87	0.90	0.90	0.92
CNN + Triplet	**0.92**	**0.93**	**0.94**	**0.96**

Table 5: AUC results for different representations on the BeerAdvocate data. Models beneath the second line are supervised.

	Look	Aroma	Palate	Taste
Look	0.92	0.89	0.88	0.87
Aroma	0.90	0.93	0.91	0.92
Palate	0.89	0.92	0.94	0.95
Taste	0.90	0.94	0.95	0.96

Table 6: Cross AUC results for different representations on the BeerAdvocate data. Row: Embedding used. Column: Aspect evaluated against.

enrolled patients with HipRepl and other studies. Likewise, studies in which HipRepl was the intervention are grouped in the interventions embedding space, but not in the populations space.

Aspect words. In Table 4, we report the most activated unigrams for each aspect embedding on the decision aids corpus. To derive these we use the outputs of the gating mechanism (Eq. 3), which is applied to all words in the input text. For each word, we average the activations across all abstracts and find the top ten words for each aspect. The words align nicely with the PICO aspects, providing further evidence that our model learns to focus on aspect-specific information.

4.2 Multi-Aspect Reviews

We now turn from the specialized domain of biomedical abstracts to more general applications. In particular, we consider learning disentangled representations of beer, hotel and restaurant reviews. Learned embeddings should capture different aspects, e.g., taste or look in the case of beer.

4.2.1 Beer Reviews (BeerAdvocate)

We conducted experiments on the BeerAdvocate dataset (McAuley et al., 2012), which contains 1.5M reviews of beers that address four aspects: *appearance*, *aroma*, *palate*, and *taste*. Free-text reviews are associated with aspect-specific numerical ratings for each of these, ranging from 1 to 5. We consider ratings < 3 as negative, and > 3 as positive, and use these to generate triplets of reviews. For each aspect a, we construct triplets $(s, d, o)_a$ by first randomly sampling a review d. We then select s to be a review with the same sen-

	Look		Aroma		Palate		Taste	
Look	-	-	0.42	0.60	0.40	0.63	0.38	0.65
Aroma	0.33	0.69	-	-	0.41	0.59	0.41	0.60
Palate	0.32	0.70	0.46	0.54	-	-	0.49	0.52
Taste	0.23	0.80	0.35	0.66	0.33	0.67	-	-

Table 7: 'Decorrelated' cross-AUC results on the BeerAdvocate data, which attempt to mitigate confounding due to overall sentiment being correlated. Each cell reports metrics over subsets of reviews in which the sentiment differs between the row and column aspects. The numbers in each cell are the AUCs w.r.t. sentiment regarding the column aspect achieved using the row and column aspect representations, respectively.

timent with respect to a as d, and o to be a review with the opposite sentiment regarding a. We selected 90K reviews for experiments, such that we had an equal number of positive and negative reviews for each aspect. We only keep words appearing in at least 5 documents, converting all others to `unk`. We truncated reviews to 95 percentile length. We split our data into 80/10/10 ratio for training, validation and testing, respectively.

Baselines. We used the same baselines as for the PICO domain, save for *RR-TF*, which was domain-specific. Here we also evaluate the result of replacing the CNN-based encoder with NVDM, BoW and DSSM based encoders, respectively, each trained using triplet loss.

Hyperparameters and Settings. For the CNN-based encoder, we used settings and hyperparameters as described for the PICO domain. For the BoW encoder, we used 800d output embeddings and a PReLU activation function with ℓ_2 regularization set to $1e$-5. For the NVDM based encoder, we used 200d embeddings.

Metrics. We again performed an IR-type evaluation to assess the utility of representations. For each aspect k, we constructed an affinity matrix A^k such that $A^k_{ij} = sim_k(r_i, r_j)$ for beer reviews r_i and r_j. We consider two reviews similar under a given aspect k if they have the same (dichotomized) sentiment value for said aspect. We compute AUCs for each review and aspect using the affinity matrix A_k. The AUC values are averaged over reviews in the test set to obtain a final AUC metric for each aspect. We also report cross AUC measures in which we use embeddings for aspect k to distinguish reviews under aspect k'.

Results We report the AUC measures for each aspect on our test set using different representations in Table 5. Our model consistently outperforms baseline strategies over all aspects. Unsurprisingly, the model outperforms unsupervised approaches.[4] We realize consistent though modest improvement over triplet-supervised approaches that use alternative encoders.

In Table 6 we present cross AUC evaluations. Rows correspond to the embedding used and columns to the aspect evaluated against. As expected, aspect-embeddings perform better w.r.t. the aspects for which they code, suggesting some disentanglement. However, the reduction in performance when using one aspect representation to discriminate w.r.t. others is not as pronounced as above. This is because aspect ratings are highly correlated: if taste is positive, aroma is very likely to be as well. Effectively, here sentiment entangles all of these aspects.[5]

In Table 7, we evaluate cross AUC performance for beer by first 'decorrelating' the aspects. Specifically, for each cell (k, k') in the table, we first retrieve the subset of reviews in which the sentiment w.r.t. k differs from the sentiment w.r.t. k'. Then we evaluate the AUC similarity of these reviews on the basis of sentiment concerning k' using both k and k' embeddings, yielding a pair of AUCs (listed respectively). We observe that the using k' embeddings to evaluate aspect k' similarity yields better results than using k embeddings.

We present the most activated words for each aspect (as per the gating mechanism) in Table 8. And we present an illustrative review color-coded with aspect-wise gate activations in Table 9. For completeness, we reproduce the top words for aspects discovered using He et al. (2017) in the Appendix; these do not obviously align with the target aspects, which is unsurprising given that this is an unsupervised method.

4.2.2 Hotel & Restaurant Reviews

Finally, we attempt to learn embeddings that disentangle domain from sentiment in reviews. For this we use a combination of TripAdvisor and

---

[4] We are not sure why ABAE (He et al., 2017) performs so poorly on the review corpora. It may simply fail to prominently encode sentiment, which is important for these tasks. We note that this model performs reasonably well on the PICO data above, and qualitatively seems to recover reasonable aspects (though not specifically sentiment).

[5] Another view is that we are in fact inducing representations of <aspect, sentiment> pairs, and only the aspect varies across these; thus representations remain discriminative (w.r.t. sentiment) across aspects.

Look	*attractive*, *beautiful*, *fingers*, *pumpkin*, *quarter*, *received*, *retention*, *sheets*, *sipper*, *well-balanced*
Aroma	*beer*, *cardboard*, *cheap*, *down*, *follows*, *medium-light*, *rice*, *settled*, *skunked*, *skunky*
Palate	*bother*, *crafted*, *luscious*, *mellow*, *mint*, *range*, *recommended*, *roasted*, *tasting*, *weight*
Taste	*amazingly*, *down*, *highly*, *product*, *recommended*, *tasted*, *thoroughly*, *to*, *truly*, *wow*

Table 8: Most activated words for aspects on the beer corpus, as per the gating mechanism.

Yelp! ratings data. The former comprises reviews of hotels, the latter of restaurants; both use a scale of 1 to 5. We convert ratings into positive/negative labels as above. Here we consider aspects to be the domain (hotel or restaurant) and the sentiment (positive or negative). We aim to generate embeddings that capture information about only one of these aspects. We use 50K reviews from each dataset for training and 5K for testing.

Baselines. We use the same baselines as for the BeerAdvocate data, and similarly use different encoder models trained under triplet loss.

Evaluation Metrics. We perform AUC and cross-AUC evaluation as in the preceding section. For the domain aspect, we consider two reviews similar if they are from the same domain, irrespective of sentiment. Similarly, reviews are considered similar with respect to the sentiment aspect if they share a sentiment value, regardless of domain.

Results. In Table 10 we report the AUCs for each aspect on our test set using different representations. Baselines perform reasonably well on the domain aspect because reviews from different domains are quite dissimilar. Capturing sentiment information irrespective of domain is more difficult, and most unsupervised models fail in this respect. In Table 11, we observe that cross AUC results are much more pronounced than for the BeerAdvocate data, as the domain and sentiment are uncorrelated (i.e., sentiment is independent of domain).

5 Related Work

Work in representation learning for NLP has largely focused on improving word embeddings (Levy and Goldberg, 2014; Faruqui et al., 2015; Huang et al., 2012). But efforts have also been made to embed other textual units, e.g. characters (Kim et al., 2016), and lengthier texts including sentences, paragraphs, and documents (Le and Mikolov, 2014; Kiros et al., 2015).

Triplet-based judgments have been used in multiple domains, including vision and NLP, to estimate similarity information implicitly. For example, triplet-based similarity embeddings may be learned using 'crowdkernels' with applications to multi-view clustering (Amid and Ukkonen, 2015). Models combining similarity with neural networks mainly revolve around Siamese networks (Chopra et al., 2005) which use pairwise distances to learn embeddings (Schroff et al., 2015), a tactic we have followed here. Similarity judgments have also been used to generate document embeddings for IR tasks (Shen et al., 2014; Das et al., 2016).

Recently, He et al. (2017) introduced a neural model for aspect extraction that relies on an attention mechanism to identify aspect words. They proposed an autoencoder variant designed to tease apart aspects. In contrast to the method we propose, their approach is unsupervised; discovered aspects may thus not have a clear interpretation. Experiments reported here support this hypothesis, and we provide additional results using their model in the Appendix.

Other recent work has focused on text *generation* from factorized representations (Larsson et al., 2017). And Zhang et al. (2017) proposed a lightly supervised method for *domain adaptation* using aspect-augmented neural networks. They exploited *source* document labels to train a classifier for a *target* aspect. They leveraged sentence-level scores codifying sentence relevance w.r.t. individual aspects, which were derived from terms *a priori* associated with aspects. This supervision is used to construct a composite loss that captures both classification performance on the source task and a term that enforces *invariance* between source and target representations.

There is also a large body of work that uses probabilistic generative models to recover latent structure in texts. Many of these models derive from Latent Dirichlet Allocation (LDA) (Blei et al., 2003), and some variants have explicitly represented topics and aspects jointly for sentiment tasks (Brody and Elhadad, 2010; Sauper et al., 2010, 2011; Mukherjee and Liu, 2012; Sauper and Barzilay, 2013; Kim et al., 2013).

A bit more generally, *aspects* have also been interpreted as properties spanning entire texts, e.g., a perspective or theme which may then color the discussion of topics (Paul and Girju, 2010). This intuition led to the development of the *factorial LDA* family of topic models (Paul and Dredze, 2012; Wallace et al., 2014); these model individ-

ual word probability as a product of multiple latent factors characterizing a text. This is similar to the Sparse Additive Generative (SAGE) model of text proposed by Eisenstein et al. (2011).

6 Conclusions

We have proposed an approach for inducing disentangled representations of text. To learn such representations we have relied on supervision codified in aspect-wise similarity judgments expressed as document triplets. This provides a general supervision framework and objective. We evaluated this approach on three datasets, each with different aspects. Our experimental results demonstrate that this approach indeed induces aspect-specific embeddings that are qualitatively interpretable and achieve superior performance on information retrieval tasks.

Going forward, disentangled representations may afford additional advantages in NLP, e.g., by facilitating transfer (Zhang et al., 2017), or supporting aspect-focused summarization models.

Multi-Source Domain Adaptation with Mixture of Experts

Jiang Guo, Darsh J Shah and Regina Barzilay
Computer Science and Artificial Intelligence Laboratory

`{jiang_guo, darsh, regina}@csail.mit.edu`

Abstract

We propose a mixture-of-experts approach for unsupervised domain adaptation from multiple sources. The key idea is to explicitly capture the relationship between a target example and different source domains. This relationship, expressed by a *point-to-set* metric, determines how to combine predictors trained on various domains. The metric is learned in an unsupervised fashion using *meta-training*. Experimental results on sentiment analysis and part-of-speech tagging demonstrate that our approach consistently outperforms multiple baselines and can robustly handle negative transfer.[1]

1 Introduction

Typical domain adaptation methods are designed to transfer supervision from a single source domain. However, in many practical applications, we have access to multiple sources. For instance, in sentiment analysis of product reviews, we can often transfer from a wide range of product domains, rather than one. This can be particularly promising for target domains which do not match any one available source well. For example, the *Kitchen* product domain may include reviews on *pans*, *cookbooks* or *electronic devices*, which cannot be perfectly aligned to a single source such as *Cookware*, *Books* or *Electronics*. By intelligently aggregating distinct and complementary information from multiple sources, we may be able to better fit the target distribution.

A straightforward approach to utilizing data from multiple sources is to combine them into a single domain. This strategy, however, does not account for distinct relations between individual sources and the target example. Constructing a common feature space for this heterogeneous collection may wash out informative characteristics of individual domains and also lead to *negative transfer* (Rosenstein et al., 2005).

Therefore, we propose to explicitly model the relationship between different source domains and target examples. We hypothesize that different source domains are aligned to different sub-spaces of the target domain. Specifically, in this paper, we model the domain relationship with a mixture-of-experts (MoE) approach (Jacobs et al., 1991b). For each target example, the predicted posterior is a weighted combination of all the experts' predictions. The weights reflect the proximity of the example to each source domain. Our model learns this *point-to-set* metric automatically, without additional supervision.

We define the *point-to-set* metric using Mahalanobis distance (Weinberger and Saul, 2009) between individual examples and a set (i.e. domain), which are computed within the hidden representation space of our model. The main challenge is to learn this metric in an unsupervised setting. We address it through a *meta-training* procedure, in which we create multiple *meta*-tasks of domain adaptation from the source domains. In each *meta*-task, we pick one of the source domains as *meta-target*, and the rest source domains as *meta-sources*. By minimizing the loss using the MoE predictions on *meta-target*, we are able to learn both the model and the metric simultaneously. To further improve transfer quality, we align the encoding space of our target and source domains via adversarial learning.

We evaluate our approach on sentiment analysis using the benchmark multi-domain Amazon reviews dataset (Chen et al., 2012; Ziser and Reichart, 2017) as well as on part-of-speech (POS) tagging using the SANCL dataset (Petrov and McDonald, 2012). Experiments show that our ap-

Brussels, Belgium, October 31 - November 4, 2018.

proach consistently improves the adaptation results over the best single-source model and a unified multi-source model. On average, we achieve a 7% relative error reduction on the Amazon reviews dataset, and a 13% on the SANCL dataset. Importantly, the POS tagging experiments on the SANCL dataset demonstrate that our method is able to robustly handle negative transfer from unrelated sources (e.g., *Twitter*) and utilize it effectively to consistently improve performance.

2 Related Work

Unsupervised domain adaptation Most existing domain adaptation methods focus on aligning the feature space between source and target domains to reduce the domain shift (Ben-David et al., 2007; Blitzer et al., 2007, 2006; Pan et al., 2010). Our approach is close to the representation learning approaches, such as the denoising autoencoder (Glorot et al., 2011), the marginalized stacked denoising autoencoders (Chen et al., 2012), and domain adversarial networks (Tzeng et al., 2014; Ganin et al., 2016; Zhang et al., 2017; Shen et al., 2018).

In contrast to these previous approaches, however, our approach not only learns a shared representation space that generalizes well to the target domain, but also captures informative characteristics of individual source domains.

Multi-Source domain adaptation The main challenge in using multiple sources for domain adaptation is in learning domain relations. Some approaches assume that all source domains are equally important to the target domain (Li and Zong, 2008; Luo et al., 2008; Crammer et al., 2008). Others learn a global domain similarity metric using labeled data in a supervised fashion (Yang et al., 2007; Duan et al., 2009; Yu et al., 2018). Alternatively, Mansour et al. (2009) and Bhatt et al. (2016) utilize unlabeled data of the target domain to find a distribution weighted combination of the source domains or to construct an auxiliary training set of the source domain instances close to the target domain instances. Recent adversarial methods on multi-source domain adaptation (Zhao et al., 2018; Chen and Cardie, 2018) align source domains to the target domains globally, without accounting for the distinct importance of each source with respect to a specific target example.

The work most related to ours is by Kim et al. (2017). They also model the *example-to-domain* relations, but use an attention mechanism. The attention module is learned using limited training data from the target domain in a supervised fashion. Our method, however, works in an unsupervised setting without utilizing any labeled data from the target domain.

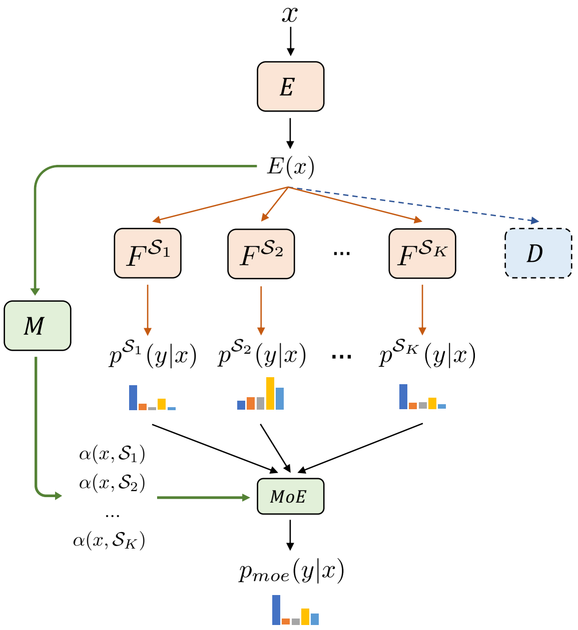

Figure 1: Architecture of the MoE model. E is the encoder which maps an input x to a hidden representation $E(x)$; $F^{\mathcal{S}_i}$ is the classifier on the i^{th} source domain; D is the critic that is only used during adversarial training. M is the metric learning component, which takes the encoding of x and source domains ($\mathcal{S}_{1:K}$) as input and computes α.

3 Methodology

Problem definition We follow the unsupervised multi-source domain adaptation setup, assuming access to labeled training data from K source domains: $\{\mathcal{S}_i\}_{i=1}^K$ where $\mathcal{S}_i \triangleq \{(x_t^{\mathcal{S}_i}, y_t^{\mathcal{S}_i})\}_{t=1}^{|\mathcal{S}_i|}$, and (optionally) unlabeled data from a target domain: $\mathcal{T} \triangleq \{x_t^{\mathcal{T}}\}_{t=1}^{|\mathcal{T}|}$. The goal is to learn a model using the source domain data, that generalizes well to the target domain.

Notations For the rest of the paper, we denote an individual example as x, and a batch of examples as $\mathbf{x}$. We use superscript to denote the domain from which an example is sampled, and use subscript to denote the index of an example.

3.1 Overview of Our Approach

We model the multiple source domains as a mixture of experts, and learn a *point-to-set* metric α to weight the experts for different target examples. The metric is learned in an unsupervised manner.

Our model consists of four key components as shown in Figure 1, namely the *encoder* (E), *classifier* (F), *metric* (M) and *adversary* (D). We use a typical neural multi-task learning architecture (Caruana, 1997), with a shared encoder across all sources, and domain-specific classifiers ($\{F^{\mathcal{S}_i}\}_{i=1}^{K}$). Each input is first encoded with E, and then fed to each classifier to obtain the domain-specific predictions (i.e. posteriors). The final predictions are then weighted based on the *metric* (see Equation 1).

We start by describing the representation learning component.

3.2 Representation

Our goal is to design an encoder that supports transfer, while maintaining source domain-specific information. Depending on different tasks and datasets, we select appropriate encoders — MLP, CNN or LSTM (see Section 4.3 for details).

We further add an adversarial module (D) on top of the encoder, in order to align the target domain with the sources. D is typically designed as a parameterized classifier in domain adversarial networks (Ganin et al., 2016; Zhang et al., 2017), which is trained jointly with the encoder and the classifiers through a minimax game. Here, we instead use Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) as our adversary. This distance metric measures the discrepancy between two distributions explicitly in a non-parametric manner, greatly simplifying the training procedure compared to domain adversarial networks which use an additional domain classifier module.

3.3 Mixture of Experts

Given an example x from the target domain, we model its posterior distribution as a mixture of posteriors produced by models trained on different source domain data:

$$\begin{aligned} p_{moe}(y|x) &= \sum_{i=1}^{K} \alpha(x, \mathcal{S}_i) \cdot p^{\mathcal{S}_i}(y|x) \\ &= \sum_{i=1}^{K} \alpha(x, \mathcal{S}_i) \cdot \texttt{softmax}\big(\mathbf{W}^{\mathcal{S}_i} E(x)\big) \end{aligned} \tag{1}$$

$p^{\mathcal{S}_i}$ is the posterior distribution produced by the i^{th} source classifier $F^{\mathcal{S}_i}$ (the i^{th} expert). $\mathbf{W}^{\mathcal{S}_i}$ is the output layer weights of $F^{\mathcal{S}_i}$, α is a parameterized metric function that measures how much confidence we put in the specific source expert for a given example x.[2] To derive α, we first define a *point-to-set* Mahalanobis distance metric between an example x and a set $\mathcal{S}$:

$$d(x, \mathcal{S}) = \Big(\big(E(x) - \mu^{\mathcal{S}}\big)^{\top} \mathbf{M}^{\mathcal{S}} \big(E(x) - \mu^{\mathcal{S}}\big)\Big)^{\frac{1}{2}}$$

where $\mu^{\mathcal{S}}$ is the mean encoding of $\mathcal{S}$. In its original form, the matrix $\mathbf{M}^{\mathcal{S}}$ played the role of the inverse covariance matrix. However, computing the inverse of the covariance matrix is both time consuming and numerically unstable in practice. Here we allow $\mathbf{M}$ to denote any positive semi-definite matrix which is to be estimated during training (Weinberger and Saul, 2009). To guarantee the positive semi-definiteness of $\mathbf{M}$, we approximate $\mathbf{M}$ with $\mathbf{M} = \mathbf{U}\mathbf{U}^{\top}$, where $\mathbf{U} \in \mathbb{R}^{h \times r}$, h is the dimension of hidden representations and r is a hyper-parameter controlling the rank of $\mathbf{M}$.

Based on the distance metric, we further derive a confidence score $e(x, \mathcal{S}_i) = f\big(d(x, \mathcal{S}_i)\big)$ for each specific expert. The final metric values $\alpha(x, \mathcal{S}_i)$ are then obtained by normalizing these confidence scores:

$$\alpha(x, \mathcal{S}_i) = \frac{\exp\big(e(x, \mathcal{S}_i)\big)}{\sum_{j=1}^{K} \exp\big(e(x, \mathcal{S}_j)\big)} \tag{2}$$

Here, we explain our design of $e(x, \mathcal{S})$ on two tasks, respectively *binary classification* and *sequence tagging*, which are also used for evaluation in this paper (Section 4).

Binary classification The *point-to-set* Mahalanobis distance metric measures the distance between an example x and the mean encoding of $\mathcal{S}$, i.e. $\mu^{\mathcal{S}}$, while taking into account the (pseudo) covariance of $\mathcal{S}$. In binary classification, however, the mean vector $\mu^{\mathcal{S}}$ is likely to be located near the decision boundary, particularly under a balanced

---

[2] In traditional MoE frameworks (Jacobs et al., 1991a,b; Shazeer et al., 2017), α is commonly realized as a "gating network", which produces a normalized weight vector that determines the combination of experts depending solely on the input example x. However, simple gating networks do not yield promising results in our scenario. We hypothesize that both the input instance and the underlying domain distribution should be captured for determining the credit assignment.

setting. Therefore, a small $d(x, \mathcal{S})$ actually implies lower confidence of the corresponding classifier, which is counter-intuitive. To this end, we instead define the confidence $e(x, \mathcal{S})$ as the difference between the distances from x to each category of $\mathcal{S}$:

$$e(x, \mathcal{S}) = \left| d(x, \mathcal{S}^+) - d(x, \mathcal{S}^-) \right|$$

Here $\mathcal{S}^+$ and $\mathcal{S}^-$ stand for the positive space and negative space of $\mathcal{S}$ respectively. Consequently, if x is either far away from $\mathcal{S}$ (i.e., x is not in the manifold of $\mathcal{S}$) or near the classification boundary, we will get a small $e(x, \mathcal{S})$ indicating a low confidence to the corresponding prediction. On the contrary, if x is much closer to a specific category of $\mathcal{S}$ than other categories, the classifier will get a higher confidence.

Sequence tagging For sequence tagging tasks (e.g., POS tagging), we compute the distance metric at the *token level*.[3] Unlike in *binary classification*, the decision boundary here is more complicated, and the label distribution is typically imbalanced. The mean vector $\mu^{\mathcal{S}}$ is unlikely to be located at the decision boundary. So we directly use the (reverse) distance as the confidence value for each token x:

$$e(x, \mathcal{S}) = -d(x, \mathcal{S})$$

3.4 Training

Since we do not have annotated data in the target domain, we have to learn our model in an unsupervised fashion. Inspired by the recent progress on few-shot learning with metric-based models such as matching network (Vinyals et al., 2016; Yu et al., 2018) and prototypical network (Snell et al., 2017), we propose the following *meta-training* approach. Given K source domains, each source domain will be considered as a target, referred to as ***meta-target***, with the rest of the source domains as ***meta-sources***. This way, we obtain K (*meta-sources*, *meta-target*) training pairs for domain adaptation. Then, we apply our MoE formulation over these *meta-training* pairs to learn the metric. At testing time, the metric will be applied to all the K source domains for each example in the target domain.

We optimize two main objectives: the MoE objective and the multi-task learning (MTL) objective.

MoE objective For each example in each *meta-target* domain, we compute its MoE posterior using the corresponding *meta-sources*. Therefore, we get the following MoE loss over the entire multi-source training data:

$$\begin{aligned}\mathcal{L}_{moe} &= -\sum_{i=1}^{K} \sum_{j=1}^{|\mathcal{S}_i|} \log p_{moe}(y_j^{\mathcal{S}_i} | x_j^{\mathcal{S}_i}) \\ &= -\sum_{i=1}^{K} \sum_{j=1}^{|\mathcal{S}_i|} \log \sum_{l=1, l \neq i}^{K} \alpha(x, \mathcal{S}_l) \cdot p^{\mathcal{S}_l}(y_j^{\mathcal{S}_i} | x_j^{\mathcal{S}_i})\end{aligned} \tag{3}$$

Note that α is normalized over the *meta-sources* for each *meta-target*, rather than over all the K sources.

MTL objective For each *meta-target*, we further optimize a supervised cross-entropy loss using the corresponding labels. All supervised objectives are optimized jointly with the encoder being shared, resulting in the following multi-task learning objective:

$$\mathcal{L}_{mtl} = -\sum_{i=1}^{K} \sum_{j=1}^{|\mathcal{S}_i|} \log p^{\mathcal{S}_i}(y_j^{\mathcal{S}_i} | x_j^{\mathcal{S}_i}) \tag{4}$$

Adversary-augmented MoE We use MMD (Gretton et al., 2012) as the adversary to minimize the divergence between the marginal distribution of target domain and source domains. Specifically, at each training epoch, given the K batches $\{\mathbf{x}^{\mathcal{S}_1}, \mathbf{x}^{\mathcal{S}_2}, ..., \mathbf{x}^{\mathcal{S}_K}\}$ from all the source domains, we sample a batch (unlabeled) $\mathbf{x}^{\mathcal{T}}$ from our target domain, and minimize the MMD:

$$\mathcal{L}_{adv} = \texttt{MMD}^2(\mathbf{x}^{\mathcal{S}_1} \cup ... \cup \mathbf{x}^{\mathcal{S}_K}, \mathbf{x}^{\mathcal{T}}) \tag{5}$$

where

$$\texttt{MMD}(\mathcal{D}^{\mathcal{S}}, \mathcal{D}^{\mathcal{T}}) = \left\| \frac{1}{|\mathcal{D}^{\mathcal{S}}|} \sum_{x_s \in \mathcal{D}^{\mathcal{S}}} \phi(E(x_s)) - \frac{1}{|\mathcal{D}^{\mathcal{T}}|} \sum_{x_t \in \mathcal{D}^{\mathcal{T}}} \phi(E(x_t)) \right\|_{\mathcal{H}}$$

measures the discrepancy between $\mathcal{D}^{\mathcal{S}}$ and $\mathcal{D}^{\mathcal{T}}$ based on Reproducing Kernel Hilbert Space (RKHS). $\phi(\cdot)$ is the feature map induced by a universal kernel. We follow Bousmalis et al. (2016) and use a linear combination of multiple RBF kernels: $\kappa(\boldsymbol{h}_i, \boldsymbol{h}_j) = \Sigma_n \exp(-\frac{1}{2\sigma_n} \|\boldsymbol{h}_i - \boldsymbol{h}_j\|^2)$.

---

[3] This actually makes it a multi-class classification problem with respect to every token of a sequence.

Algorithm 1 Training Procedure

```
**Input**: multi-source domain data $\mathcal{S} = \{\mathcal{S}_i\}_{i=1}^{K}$, target domain data $\mathcal{T}$
**Hyper-parameters**: mini-batch size $m$, coefficients for different losses: $\lambda$, $\gamma$ and $\eta$
**repeat**
    Sample $K$ source mini-batches $\{(\mathbf{x}^{\mathcal{S}_i}, \mathbf{y}^{\mathcal{S}_i})\}_{i=1}^{K}$ from $\mathcal{S}$ and a target mini-batch $\mathbf{x}^{\mathcal{T}}$ from $\mathcal{T}$
    $\mathcal{L}_{mtl}, \mathcal{L}_{moe}, \mathcal{L}_{adv}, \mathcal{R}_h \leftarrow 0$
    **for** $t = 1$ to $K$ **do**
        Set ***meta-target*** as $\mathcal{T}^{meta} \triangleq \tilde{\mathcal{S}}_t \triangleq (\mathbf{x}^{\mathcal{S}_t}, \mathbf{y}^{\mathcal{S}_t})$
        Set ***meta-sources*** as $\mathcal{S}^{meta} \triangleq \{\tilde{\mathcal{S}}_i\}_{i=1, i\neq t}^{K}$, where $\tilde{\mathcal{S}}_i \triangleq (\mathbf{x}^{\mathcal{S}_i}, \mathbf{y}^{\mathcal{S}_i})$
        Compute cross-entropy loss over $\mathcal{T}^{meta}$, and add to $\mathcal{L}_{mtl}$
        Compute Mahalanobis metric $\alpha(x, \mathcal{S}')$ for each $x \in \mathcal{T}^{meta}$ and $\mathcal{S}' \in \mathcal{S}^{meta}$        ▷ Eq. (2)
        Compute MoE loss over $(\mathcal{S}^{meta}, \mathcal{T}^{meta})$ using $\boldsymbol{\alpha}$, and add to $\mathcal{L}_{moe}$
        Compute entropy of $\boldsymbol{\alpha}$ over $\mathcal{S}$, and add to $\mathcal{R}_h$
    **end for**
    Compute MMD between $\mathbf{x}^{\mathcal{T}}$ and $\cup_{i=1}^{K} \mathbf{x}^{\mathcal{S}_i}$, and add to $\mathcal{L}_{adv}$        ▷ Eq. (5)
    Update parameters via backpropagating gradients of the total loss $\mathcal{L}$        ▷ Eq. (7)
**until** converge
```

Entropy regularization In the *meta-training* process, for each example x in *meta-target*, we know exactly from which source x is sampled. This provides additional insight that the α distribution is skewed, which can be utilized as a soft constraint. Therefore, we propose to regularize the entropy of the α distribution over all the sources, rather than *meta-sources*:[4]

$$H\big(\boldsymbol{\alpha}(x, \cdot)\big) = -\sum_{l=1}^{K} \alpha(x, \mathcal{S}_l) \cdot \log \alpha(x, \mathcal{S}_l)$$

$$\mathcal{R}_h = \sum_{i=1}^{K} \sum_{j=1}^{|\mathcal{S}_i|} H\big(\boldsymbol{\alpha}(x_j^{\mathcal{S}_i}, \cdot)\big) \qquad (6)$$

Joint learning Our final objective is the weighted combination of each individual component loss:

$$\begin{aligned} \mathcal{L} = \lambda \cdot \mathcal{L}_{moe} &+ (1-\lambda) \cdot \mathcal{L}_{mtl} \\ &+ \gamma \cdot \mathcal{L}_{adv} \\ &+ \eta \cdot \mathcal{R}_h \end{aligned} \qquad (7)$$

where λ controls the balance of the MoE loss and MTL loss. γ is set to 0 in *non-adversarial* setting when unlabeled data from the target domain is not provided. Additionally, it would be straightforward to add an MoE loss for labeled data in the target domain if they are available, thus extending our framework to a setting where we have few-shot target annotations. The training process is shown in Algorithm 1.

4 Experimental Setup

4.1 Task and Dataset

Sentiment classification We use the multi-domain Amazon reviews dataset (Blitzer et al., 2007), one of the standard benchmark datasets for domain adaptation. It contains reviews on four domains: *Books* (B), *DVDs* (D), *Electronics* (E), and *Kitchen appliances* (K).

We follow the specific experiment settings proposed by Chen et al. (2012) (CHEN12) and Ziser and Reichart (2017) (ZISER17).

1. In CHEN12, each domain has 2,000 labeled examples for training (1,000 positive and 1,000 negative), and the target test set has 3,000 to 6,000 examples.[5]
2. In ZISER17, each domain also has 2,000 labeled examples (1,000 positive and 1,000 negative), sampled differently from CHEN12.

For each dataset, we conduct experiments by selecting the target domain in a round-robin fash-

---

[4] Alternatively, we can directly exploit this supervision and minimize the KL divergence of the α distribution and its ground truth one-hot distribution. In practice, however, we found it beneficial to allow examples from one domain to be attended to different sources. This observation may be attributed to the fact that each domain indeed consists of multiple latent sub-domains.

[5] This dataset has been processed by the author to TF-IDF representations, using the 5,000 most frequent unigram and bigram features, thus word order information is not available.

ion. Following the protocol in previous work, we use cross-validation over source domains for hyper-parameters selection for each adaptation task (Zhao et al., 2018). When training with an adversary, we use the 2,000 examples training set of the target domain as the unlabeled data in both the settings. In ZISER17, the same data is also used for test, resulting in a transductive setting.

Part-of-Speech tagging We further consider a sequence tagging task, where the metric is computed over the token-level encodings and multi-class predictions are made at the token (word) level. We use the SANCL dataset (Petrov and McDonald, 2012) which contains part-of-speech (POS) tagging annotations in 5 web domains: *Emails*, *Weblogs*, *Answers*, *Newsgroups*, and *Reviews*. Among these, *Newsgroups*, *Reviews*, and *Answers* have both a validation and a test set, and are used as target domains. The test set from *Weblogs* and *Emails* are used as individual source domains. The tagging is performed using the Universal POS tagset (Petrov et al., 2012). We also use *Twitter* (Liu et al., 2018) as an additional training source. Since it differs substantially from other sources and the target domain, we can assess our model's ability to handle negative transfer. We consider 750 sentences from each SANCL source domain for training, and up to 2,250 sentences from the *Twitter* dataset to magnify the negative transfer. The validation set in the standard split of each target domain is used for hyper-parameters selection and early-stopping in our experiments.

4.2 Baselines

We verify the efficacy of our approach (MoE) in *non-adversarial* and *adversarial* settings respectively. In both settings, we compare our approach against the following two baselines:

- **best-SS**: the best single-source adaptation model among all the sources.
- **uni-MS**: the unified multi-source adaptation model, which is trained using the combination of all the source domain data with single-source transfer methods. uni-MS is a common and strong baseline for multi-source domain adaptation (Zhao et al., 2018).

For the rest of the paper, we name the adversarial counterpart of the models as $*$**-A**.

In the adversarial setting on CHEN12, in addition to best-SS and uni-MS with adversarial loss, we further compare with the following two systems that also utilize unlabeled data from target domain.

- **mSDA**: the marginalized stacked denoising autoencoder (Chen et al., 2012). mSDA outperforms prior deep learning and shallow learning approaches such as structural correspondence learning (Blitzer et al., 2007) and denoising autoencoder (Glorot et al., 2011).
- **MDAN**: the multi-source domain adversarial network (Zhao et al., 2018). MDAN gives the state-of-the-art performance for multi-source domain adaptation on CHEN12. It generalizes the domain adversarial network to multiple source domain adaptation by selectively backpropagating the domain discrimination loss according to domain classification error.

4.3 Implementation Details

For CHEN12, since the dataset is in TF-IDF format and the word ordering information is not available, we use a multilayer perceptron (MLP) with an input layer of 5,000 dimensions and one hidden layer of 500 dimensions as our encoder. For ZISER17, we instead use a convolutional neural network (CNN) encoder with a combination of kernel widths 3 and 5 (Kim, 2014), each with one hidden layer of size 150, which are then concatenated to a 300 dimension representation.[6]

For the POS tagging encoder, we use a hierarchical bidirectional LSTM (BiLSTM) network, which contains a character-level BiLSTM for generating individual word representations, followed by a word-level BiLSTM that generates contextualized word representations.

For MMD, we follow Bousmalis et al. (2016) and use 19 RBF kernels with the standard deviation parameters ranging from 10^{-6} to 10^{6}.[7]

All the models were trained using Adam with weight decay. Learning rate is set to 10^{-4} for CHEN12 and 10^{-3} for ZISER17 and POS tagging. We use mini-batches of 32 samples from each domain. We tune the coefficients λ, η for each adaptation task. γ is set to 1 for all experiments.

---

[6] Note that with a more extensive architecture search, we are likely to achieve better results. This, however, is not the main focus of this work.

[7] Detailed values are presented in the supplementary material in Bousmalis et al. (2016).

5 Results

5.1 Sentiment Analysis on Amazon Reviews

We report our results on the Amazon reviews datasets in Table 1 (CHEN12) and Table 2 (ZISER17). Our approach (MoE) consistently achieves the best performance across different settings and tasks.

The results clearly demonstrate the value of using multiple sources. In most cases, even a unified model performs better than the oracle best single source. By smartly combining all the sources, our model outperforms the unified model significantly. One exception is the task of "B,D,K-E" in CHEN12, where the unified multi-source model doesn't improve over the best single source model, constituting a *negative transfer* scenario. However, even in this scenario, our approach still performs significantly better, demonstrating its robustness in handling *negative transfer*.

Impact of adversarial adaptation We achieve consistent improvements over the baseline systems with the addition of the adversarial loss. In most cases, MoE also achieves additional improvement (e.g., 79.42% *vs.* 80.87% in "D,E,K-B"). We notice that in some cases, e.g., "B,D,K-E" in CHEN12 and "B,E,K-D" in ZISER17, the adversarial loss doesn't help MoE. This might be attributed to the fact that by aligning the target distribution with the source domains, the representation space becomes more compact, thus making it more difficult to capture source domain-specific characteristics and increasing the difficulty of metric learning in MoE.

Analysis on the metric (α) Figure 2 visualizes the distribution of α values, learned by our model in different tasks, across the source domains. The visualization is based on 200 examples for each domain randomly sampled from the corresponding test set. From the heatmap we can see that for a specific target domain, different examples may have different α distributions. Moreover, for most examples, the α distribution is skewed, indicating that our model draws on a few most informative source domains.

Figure 3 exemplifies the above point. For instance, the first review about "charger" and "battery" is closer to the *Electronics* source domain. This relation is successfully captured by the α distribution produced by our model.

We further investigate the impact of entropy regularization over α. Table 3 summarizes the ablation test results of entropy regularization ($\eta = 0$)

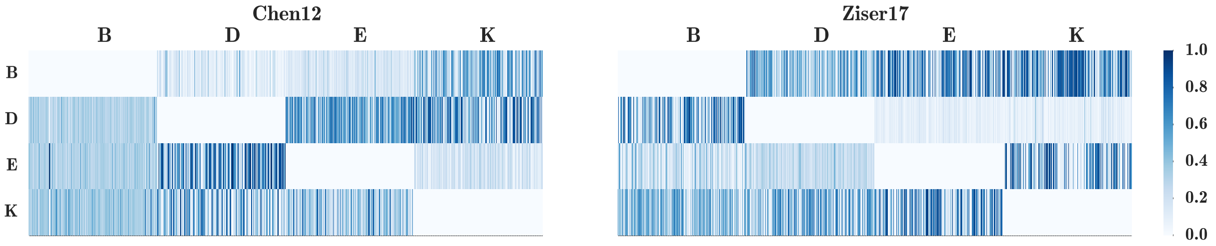

Figure 2: α distributions across source domains for randomly selected 200 examples in each target domain of Chen12 (left) and Ziser17 (right). Columns represent target domains and rows represent sources.

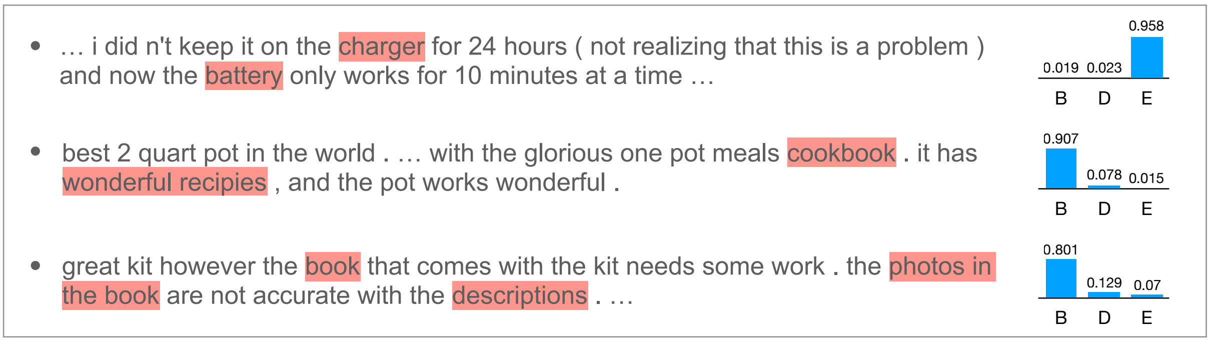

- … i did n't keep it on the charger for 24 hours (not realizing that this is a problem) and now the battery only works for 10 minutes at a time …
- best 2 quart pot in the world . … with the glorious one pot meals cookbook . it has wonderful recipies , and the pot works wonderful .
- great kit however the book that comes with the kit needs some work . the photos in the book are not accurate with the descriptions . …

Figure 3: Examples of *Kitchen* (K) reviews in Ziser17 and their α distribution over *Books* (B), *DVDs* (D) and *Electronics* (E). The manually highlighted words indicate the specific Kitchen products described in the reviews.

Setting	Chen12 (w/o $\mathcal{R}_h$)		Ziser17 (w/o $\mathcal{R}_h$)	
	MoE	MoE-A	MoE	MoE-A
D,E,K–B	*-0.70*	*-0.51*	*-0.75*	*-0.60*
B,E,K–D	*-0.67*	*-0.41*	*-0.05*	*-1.20*
B,D,K–E	*-1.93*	*-0.44*	*-0.70*	*-0.60*
B,D,E–K	*-0.49*	*-0.09*	*-0.50*	*+0.30*

Table 3: Ablation test of entropy regularizer on Chen12 and Ziser17 (decrease in accuracy).

on Chen12 and Ziser17. It shows that entropy regularization benefits our model under both non-adversarial and adversarial settings.

5.2 Part-of-Speech Tagging

Table 4 summarizes our results on POS tagging. Again, our approach consistently achieves the best performance across different settings and tasks. Adding *Twitter* as a source leads to a drop in performance for the unified model, as a result of negative transfer. Our method, however, robustly handles negative transfer and manages to even benefit from this additional source.

Impact of negative transfer Table 5 presents the α distribution learned by the metric, on average for all tokens of the target domain. As we can see, our model (MoE-A) effectively learns to decrease the weights on *Twitter*, demonstrating again its ability to alleviate negative transfer.

We further study the impact of this outlier source by varying the amount of *Twitter* data used during training. We gradually increase the number of *Twitter* instances by 750. As shown in Table 6, the increase of the *Twitter* data does not benefit the unified multi-source model (uni-MS-A), and even amplifies negative transfer for the *Answers* and *Reviews* domains. However, the performance of our MoE (MoE-A) model stays stable, consistently increasing with more *Twitter*, showing robustness in handling negative transfer.

6 Conclusion

In this paper, we propose a novel mixture-of-experts (MoE) approach for unsupervised domain adaptation from multiple diverse source domains. We model the domain relations through a *point-to-set* distance metric, and introduce a *meta-training* mechanism to learn this metric. Experimental results on sentiment classification and part-of-speech tagging demonstrate that our approach consistently outperforms various baselines and can robustly handle negative transfer. The effectiveness of our approach suggests its potential application to a broader range of domain adaptation tasks in NLP and other areas.

Abstract

It has been argued that humans rapidly adapt their lexical and syntactic expectations to match the statistics of the current linguistic context. We provide further support to this claim by showing that the addition of a simple adaptation mechanism to a neural language model improves our predictions of human reading times compared to a non-adaptive model. We analyze the performance of the model on controlled materials from psycholinguistic experiments and show that it adapts not only to lexical items but also to abstract syntactic structures.

1 Introduction

Reading involves the integration of noisy perceptual evidence with probabilistic expectations about the likely contents of the text. Words that are consistent with these expectations are identified more quickly (Ehrlich and Rayner, 1981; Smith and Levy, 2013). For the reader's expectations to be maximally effective, they should not only reflect the reader's past experience with the language (Hale, 2001; MacDonald and Christiansen, 2002), but should also be *adapted* to the current context. Optimal adaptation would reflect properties of the text being read, such as genre, topic and writer identity, as well as the general tendency for recently used words and syntactic structures to be reused with higher probability (Bock, 1986; Church, 2000; Dubey et al., 2006).

Several studies have suggested that readers do in fact adapt their lexical and syntactic predictions to the current context (Otten and Van Berkum, 2008; Fine et al., 2013; Fine and Jaeger, 2016).[1] For example, Fine and Jaeger investigated the processing of "garden path" sentences such as (1):

(1) The experienced soldiers warned about the dangers conducted the midnight raid.

The word *warned* in (1) is initially ambiguous between a main verb interpretation (the soldiers were doing the warning) and a reduced relative clause interpretation (the soldiers were being warned). When the word *conducted* is reached, this ambiguity is resolved in favor of the reduced relative parse. Reduced relatives are infrequent constructions. This makes the disambiguating word *conducted* unexpected, causing it to be read more slowly than it would be in a context such as (2), in which the words *who were* indicate early on that only the relative clause parse is possible:

(2) The experienced soldiers who were warned about the dangers conducted the midnight raid.

Fine and Jaeger included a large proportion of reduced relatives in their experiment. As the experiment progressed, the cost of disambiguation in favor of the reduced relative interpretation decreased, suggesting that readers had come to expect a construction that is normally infrequent.

Human syntactic expectations have been successfully modeled with syntax-based language models (Hale, 2001; Levy, 2008; Roark et al., 2009). Recently, language models (LMs) based on recurrent neural networks (RNNs) have been shown to make adequate syntactic predictions (Linzen et al., 2016; Gulordava et al., 2018), and to make comparable reading time predictions to syntax-based LMs (van Schijndel and Linzen, 2018). In this paper, we propose a simple way to continuously adapt a neural LM, and test the method's psycholinguistic plausibility. We show that LM adaptation significantly improves our ability to predict human reading times using the LM. Follow-up experiments with controlled materials show that the LM adapts not only to specific

---

[1] Recently, Harrington Stack et al. (2018) questioned the robustness of the results of Fine et al. (2013).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4704–4710
Brussels, Belgium, October 31 - November 4, 2018.

vocabulary items but also to abstract syntactic constructions, as humans do.

2 Method

We use a simple method to adapt our LM: at the end of each new test sentence, we update the parameters of the LM based on its cross-entropy loss when predicting that sentence; the new weights are then used to predict the next test sentence.[2] Our baseline LM is a long short-term memory (LSTM; Hochreiter and Schmidhuber, 1997) language model trained on 90 million words of English Wikipedia by Gulordava et al. (2018) (see Supplementary Materials for details). For adaptation, we keep the learning rate of 20 used by Gulordava et al. (the gradient is multiplied by this learning rate during weight updates). We examine the effect of this parameter in Section 5.2.

We tested the model on the Natural Stories Corpus (Futrell et al., 2018), which has 10 narratives with self-paced reading times from 181 native English speakers. There are two narrative genres in the corpus: fairy tales (seven texts) and documentary accounts (three texts).

3 Linguistic accuracy

We first measured how well the adaptive model predicted upcoming words. We report the model's perplexity, a quantity which is lower when the LM assigns higher probabilities to the words that in fact occurred. We adapted the model to the first k sentences of each text, then tested it on sentence $k+1$, for all k. Adaptation dramatically improved test perplexity compared to the non-adaptive version of the model (86.99 vs. 141.49).

We next adapted the model to each genre separately. If the model adapts to stylistic or syntactic patterns, we might expect adaptation to be more helpful in the fairy tale than the documentary genre: the Wikipedia corpus that the LM was originally trained on is likely to be more similar in style to the documentary genre. Consistent with this hypothesis, the documentary texts benefited less from adaptation (99.33 to 73.20) than the fairy tales (160.05 to 86.47), though the fact that both saw improvement from adaptation suggests that text-specific adaptation is beneficial even if the genre is similar to the training genre.

	$\hat{\beta}$	$\hat{\sigma}$	t
WITHOUT ADAPTIVE SURPRISAL:			
Sentence position	0.55	0.53	1.03
Word length	7.29	1.00	7.26
Non-adaptive surprisal	6.64	0.68	9.79
WITH ADAPTIVE SURPRISAL:			
Sentence position	0.29	0.53	0.55
Word length	6.42	1.00	6.40
Non-adaptive surprisal	-0.89	0.68	-1.31
Adaptive surprisal	8.45	0.63	13.42

Table 1: Fixed effect regression coefficients from fitting self-paced reading times. The top model lacks fixed and random effects of adaptive surprisal. In general, a coefficient is significant when $|t| > 2$.

Each genre consists of multiple texts. Does adaptation to a particular text lead to catastrophic forgetting (McCloskey and Cohen, 1989), such that the LM overfits to the text and forgets its more general knowledge acquired from the Wikipedia training corpus? This was not the case; in fact, adapting to the entirety of each genre without reverting to the baseline model after each text led to a very slightly *better* perplexity (fairytales: 86.47, documentaries: 73.20) compared with a setting in which the LM was reverted after each text (fairytales: 86.61, documentaries: 73.63).

4 Modeling human expectations

We next tested whether our adaptive LM matches human expectations better than a non-adaptive model. Since each reader saw the texts in a different order, we adapted the LM to each text separately: after each story, we reverted to the initial Wikipedia-trained LM and restarted adaptation on the next text. If anything, this likely resulted in a conservative estimate of the benefit of adaptation compared to a model that adapts continuously across multiple stories from the same genre, as humans might do.[3]

We used surprisal as a linking function between the LM's predictions and human reading times

---

[2] Our code is publicly available at: `https://github.com/vansky/neural-complexity.git`

[3] We do not distinguish between *priming* and *adaptation* in this paper. While it may be tempting to think of the LSTM memory cell as a model of priming and of the weight updates as a model of adaptation, Bock and Griffin (2000) provide evidence that priming cannot simply be a function of residual activation and that priming can be driven by longer-term learning (see Tooley and Traxler (2010) for more discussion on priming vs. adaptation).

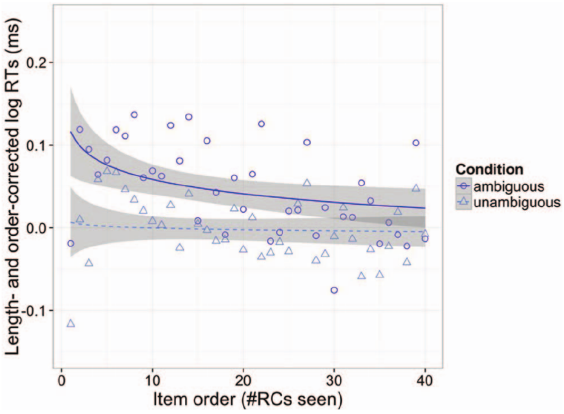

Figure 1: Mean length- and order-corrected reading times over the disambiguating region of the critical items in Fine and Jaeger (2016). Figure adopted from that paper.

(Hale, 2001; Smith and Levy, 2013). Surprisal quantifies how unpredictable each word (w_i) is given the preceding words:

$$\text{surprisal}(w_i) = -\log \text{P}(w_i \mid w_1 ... w_{i-1}) \quad (1)$$

We fit the self-paced reading times in the Natural Stories Corpus with linear mixed effects models (LMEMs), a generalization of linear regression (see Supplementary Materials for details).

In line with previous work, non-adaptive surprisal was a significant predictor of reading times ($p < 0.001$) when the model only included other baseline factors (Table 1, Top). Adaptive surprisal was a significant predictor of reading times ($p < 0.001$) over non-adaptive surprisal and all baseline factors (Table 1, Bottom). Crucially, non-adaptive surprisal was no longer a significant predictor of reading times once adaptive surprisal was included. This indicates that the predictions of the adaptive model subsume the predictions of the non-adaptive one.

5 Does the model adapt to syntax?

We have shown that LM adaptation improves our ability to model human expectations as reflected in a self-paced reading time corpus. How much of this improvement is due to adaptation of the model's syntactic representations (Bacchiani et al., 2006; Dubey et al., 2006) and how much is simply due to the model assigning a higher probability to words that have recently occurred (Kuhn and de Mori, 1990; Church, 2000)? We address this question using two syntactic phenomena: reduced relative clauses and the dative alternation.

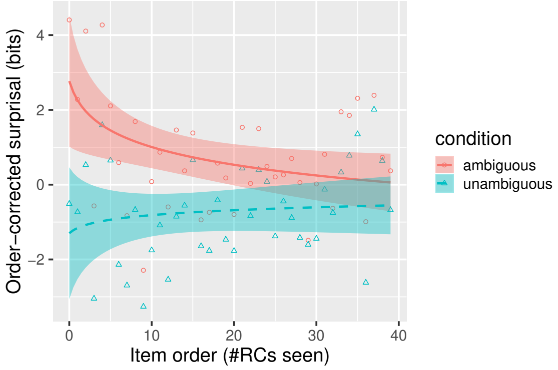

Figure 2: Mean order-corrected model surprisal over the disambiguating region of the critical items in Fine and Jaeger (2016).

5.1 Reduced relative clauses

We adapted the model independently to random orderings of the critical and filler stimuli used in Experiment 3 of Fine and Jaeger (2016);[4] this experiment (described in the Introduction) contained a much higher proportion of reduced relative clauses than their general distribution in English. We used surprisal as our proxy for reading times. Following Fine and Jaeger, we took the mean surprisal over three words in each ambiguous sentence: the disambiguating word and the following two words (e.g., *conducted the midnight* in example (1)). To estimate the magnitude of the syntactic disambiguation penalty while also controlling for lexical content, we subtracted this quantity from the mean surprisal over the exact same words in the paired unambiguous sentence (2). Linear regression showed that the disambiguation penalty decreased as the model was exposed to more critical items (item order coefficient: $\hat{\beta} = -0.0804$, $p < 0.001$), indicating that the LM was adapting to reduced relatives, a syntactic construction without any lexical content.

In order to compare our findings more directly with the results given by Fine and Jaeger (2016) (shown in Figure 1), we mimicked their method of plotting reading times. First, we fit a linear model of the mean surprisal of each disambiguating region with the number of trials the model had seen in the experiment thus far to account for a general trend of subjects speeding up over the course

---

[4] See details in the Supplementary Materials.

of the experiment. Then, we plotted the mean residual model surprisal that was left in the disambiguating region in both the ambiguous and unambiguous conditions as the experiment progressed. The shape of our model's adaptation to the reduced relative construction (upper curve in Figure 2) matched the human results reported by Fine and Jaeger. Like humans, the model showed an initially large adaptation effect, followed by more gradual adaptation thereafter. Both humans and our model continued to adapt over all the items rather than just at the beginning of the experiment. Also like humans, the model's response to unambiguous items did not change significantly over the course of the experiment ($p = 0.91$).

5.2 The dative alternation

Dative events can be expressed using two roughly equivalent English constructions:

(3) a. *Prepositional object (PO)*:
The boy threw the ball to the dog.
b. *Double object (DO)*:
The boy threw the dog the ball.

Work in psycholinguistics has shown that recent experience with one of these variants increases the probability of producing that variant (Bock, 1986; Kaschak et al., 2006) as well as the likelihood of predicting it in reading (Tooley and Bock, 2014). To test whether our adaptation method can reproduce this behavior, we generated 200 pairs of dative sentences similar to (3). We shuffled 100 DO sentences into 1000 filler sentences sampled from the Wikitext-2 training corpus (Merity et al., 2016) and adapted the model to these 1100 sentences. We then froze the weights of the adapted model and tested its predictions for two types of sentences: the PO counterparts of the DO sentences in the adaptation set, which shared the vocabulary of the adaptation set but differed in syntax; and 100 new DO sentences, which shared syntax but no content words with the adaptation set.[5]

An additional goal of this experiment was to examine the effect of learning rate on adaptation. During adaptation the model performs a single parameter update after each sentence and does not train until convergence with gradual reduction of the learning rate as would normally be the case during LM training. Consequently, the learning rate parameter crucially determines the amount of adaptation the model can undertake after each sentence. If the learning rate is very low, adaptation will not have any effect; if it is too high, either the model will overfit after each update and will not generalize well, or the model will forget its trained representation as it overshoots the targeted minima. The optimal rate may differ between lexical and syntactic adaptation. Our experiments thus far all used the same learning rate as our original model (20); here, we varied the learning rate on a logarithmic scale between 0.002 and 200.

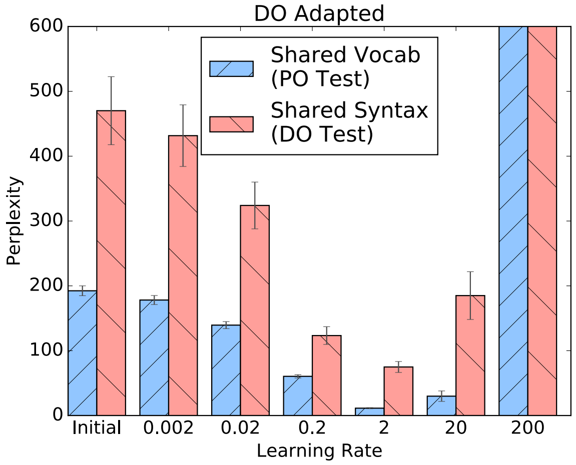

Figure 3: Learning rate influence over syntactic and lexical adaptation. The initial non-adaptive model performance is equivalent to the performance when using a learning rate of 0; the learning rate of 200 resulted in perplexity in the billions.

The results of this experiment are shown in Figure 3. The model successfully adapted to the DO construction as well as to the vocabulary of the adaptation sentences. This was the case for all of the learning rates except for 200, which resulted in enormous perplexity on both sentence types. Both lexical and syntactic adaptation were most successful when the learning rate was around 2, with perplexity reductions of 94% for lexical adaptation and 84% for syntactic adaptation.

Syntactic adaption was penalized at higher learning rates more than lexical adaptation (compare learning rates of 2 and 20). This fragility of syntactic adaptation likely stems from the fact that the model can directly observe the relevant vocabulary but syntax is latent and must be inferred from multiple similar sentences, a generalization which is impeded by overfitting at higher learning rates.

---

[5] For additional details as well as the reverse setting (adaptation to PO), see Supplementary Materials.

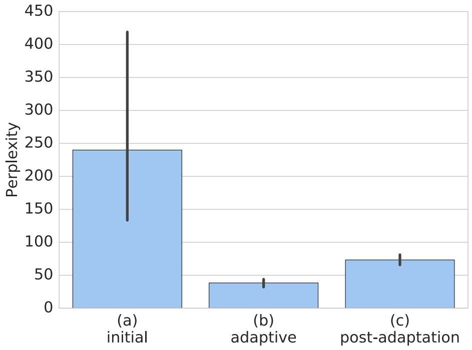

Figure 4: Perplexity on the held-out set of G_1 (a) before adaptation, (b) after adaptation to G_1, (c) after adapting to G_1 then adapting to G_2.

6 Testing for catastrophic forgetting

Our analysis of the Natural Stories corpus did not indicate that the model suffered from catastrophic forgetting. Yet the Natural Stories corpus contained only two genres; to address the issue of catastrophic forgetting more systematically, we used the premise sentences from the MultiNLI corpus (Williams et al., 2018) — a total of 2000 sentences for each of 10 genres.

For each genre pair G_1 and G_2 (omitting cases where $G_1 = G_2$), we first adapted the baseline Wikipedia model to 1000 sentences of G_1 using a learning rate of 2 (shown to be optimal in Section 5.2). We then adapted the model to 1000 sentences of G_2. Finally, we froze the model's weights and tested its perplexity on the 1000 held-out sentences from G_1.

The results averaged across all pairs of genres are plotted in Figure 4. Unsurprisingly, the model performed best on G_1 immediately after adapting to it (middle bar). Crucially, even after adapting to 1000 sentences of G_2 after its last exposure to G_1 (right bar), it still modeled G_1 much better than the non-adapted model (left bar). These results suggest that catastrophic forgetting is not a concern even with a relatively large amount of data.

7 Discussion

Adaptation greatly improved an RNN LM's word prediction accuracy, in line with other work on LM adaptation (Kneser and Steinbiss, 1993). We showed that the adapted model was psycholinguistically plausible, in two senses. First, it improved the correlation between surprisal derived from the model and human reading times, suggesting that the model generated more human-like expectations. Second, using materials that teased apart lexical content from syntax, we showed that the model adapted both its lexical and its syntactic predictions, in line with findings from human experiments. Finally, as in other neural-network based models in psychology (Chang et al., 2006), our gradient-based updates naturally incorporate the error-driven nature of syntactic adaptation; while we did not demonstrate this in the current paper, we hypothesize that our model will reproduce the finding that more surprising words lead to greater adaptation (Jaeger and Snider, 2013).

The simplicity of our adaptation method makes it attractive for use in modeling human expectations. Since adaptive surprisal is strictly superior to non-adaptive surprisal in modeling reading times, it would be a stronger baseline in analyses that aim to demonstrate the contribution of factors other than predictability.

We used a simple neural adaptation approach, where we performed continuous gradient updates based on the prediction error on the adaptation sentences (see also Krause et al., 2017). An alternative approach to neural LM adaptation uses recent RNN states in conjunction with the current state to make word predictions (Grave et al., 2017; Merity et al., 2017); a comparison of the two methods using our paradigms may provide insight into their relative strengths and weaknesses.

Finally, we reverted to the base model after the end of each text in our experiments, forgetting any text-specific adaptation. This mimics the effect of a participant leaving an experiment that had an unusual distribution of syntactic constructions and reverting to their standard expectations. In practice, however, humans are able to generalize from prior experience when they begin adapting to a new speaker or text if it is similar in some way to their previous experiences. For example, the model of Jaech and Ostendorf (2018) adapts to environmental factors, so it could potentially draw on independent experiences with female speakers and with lawyer speech in order to initialize a model of adaptation to a new female lawyer (see also Mikolov and Zweig, 2012; Kleinschmidt, 2018). The psycholinguistic plausibility of these models can be tested in future work.

Abstract

Interpreting the performance of deep learning models beyond test set accuracy is challenging. Characteristics of individual data points are often not considered during evaluation, and each data point is treated equally. We examine the impact of a test set question's difficulty to determine if there is a relationship between difficulty and performance. We model difficulty using well-studied psychometric methods on human response patterns. Experiments on Natural Language Inference (NLI) and Sentiment Analysis (SA) show that the likelihood of answering a question correctly is impacted by the question's difficulty. As DNNs are trained with more data, easy examples are learned more quickly than hard examples.

1 Introduction

One method for interpreting deep neural networks (DNNs) is to examine model predictions for specific input examples, e.g. testing for shape bias as in Ritter et al. (2017). In the traditional classification task, the difficulty of the test set examples is not taken into account. The number of correctly-labeled examples is tallied up and reported. However, we hypothesize that it may be worthwhile to use difficulty when evaluating DNNs. For example, what does it mean if a trained model answers the more difficult examples correctly, but cannot correctly classify what are seemingly simple cases? Recent work has shown that for NLP tasks such as Natural Language Inference (NLI), models can achieve strong results by simply using the hypothesis of a premise-hypothesis pair and ignoring the premise entirely (Gururangan et al., 2016; Tsuchiya, 2018; Poliak et al., 2018).

In this work we consider understanding DNNs by looking at the difficulty of specific test set examples and comparing DNN performance under different training scenarios. Do DNN models learn examples of varying difficulty at different rates? If a model does well on hard examples and poor on easy examples, then can we say that it has really learned anything? In contrast, if a model does well on easy items, because a dataset is all easy, have we really "solved" anything?

To model difficulty we use Item Response Theory (IRT) from psychometrics (Baker and Kim, 2004). IRT models characteristics such as difficulty and discrimination ability of specific examples (called "items"[1]) in order to estimate a latent ability trait of test-takers. Here we use IRT to model the difficulty of test items to determine how DNNs learn items of varying difficulty. IRT provides a well-studied methodology for modeling item difficulty as opposed to more heuristic-based difficulty estimates such as sentence length. IRT was previously used to build a new test set for the NLI task (Lalor et al., 2016) and show that model performance is dependent on test set difficulty. In this work we use IRT to probe specific items to try to analyze model performance at a more fine-grained level, and expand the analysis to include the task of SA.

We train three DNNs models with varying training set sizes to compare performance on two NLP tasks: NLI and Sentiment Analysis (SA). Our experiments show that a DNN model's likelihood of classifying an item correctly is dependent on the item's difficulty. In addition, as the models are trained with more data, the odds of answering easy examples correctly increases at a faster rate than the odds of answering a difficult example correctly. That is, performance starts to look more human, in the sense that humans learn easy items faster than they learn hard items.

That the DNNs are better at easy items than hard items seems intuitive but is a surprising and interesting result since the item difficulties are modeled *from human data*. There is no underlying reason

---

[1] For the remainder of the paper we will refer to a single test set example as an "item" for consistency.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4711–4716
Brussels, Belgium, October 31 - November 4, 2018.

that the DNNs would find items that are easy for humans inherently easy. To our knowledge this is the first work to use a grounded measure of difficulty learned from human responses to understand DNN performance. Our contributions are as follows: (i) we use a well-studied methodology, IRT, to estimate item difficulty in two NLP tasks and show that this human-estimated difficulty is a useful predictor of DNN model performance, (ii) we show that as training size increases DNN performance trends towards expected human performance.[2]

2 Methods

2.1 Estimating Item Difficulty

To model item difficulty we use the Three Parameter Logistic (3PL) model from IRT (Baker, 2001; Baker and Kim, 2004; Lalor et al., 2016). The 3PL model in IRT models an individual's latent ability (θ) on a task as a function of three item characteristics: discrimination ability (a), difficulty (b), and guessing (c). For a particular item i, the probability that an individual j will answer item i correctly is a function of the individual's ability and the three item characteristics:

$$p_{ij}(\theta_j) = c_i + \frac{1 - c_i}{1 + e^{-a_i(\theta_j - b_i)}} \tag{1}$$

where a_i is the discrimination parameter (the value of the function slope at it's steepest point), b_i is the difficulty parameter (the value where $p_{ij}(\theta_j) = 0.5$), and c_i is the guessing parameter (the lower asymptote of the function). For a set of items I and a set of individuals J, the likelihood of each individual in J's responses to the items in I is:

$$L = \prod_{j=1}^{J} \prod_{i=1}^{I} p_{ij}(\theta_j)^{y_{ij}} q_{ij}(\theta_j)^{(1-y_{ij})} \tag{2}$$

where $q_{ij}(\theta_j) = 1 - p_{ij}(\theta_j)$ and $y_{ij} = 1$ if individual j answered item i correctly and $y_{ij} = 0$ otherwise. Item parameters and individual ability are jointly estimated from a set of individuals' response patterns using an Expectation-Maximization algorithm (Bock and Aitkin, 1981).

In this work we focus on the difficulty parameter b_i, which represents the latent ability level at which an individual has a 50% chance of answering item i correctly. Low values of b_i are associated with easier items (since an individual with low ability has a 50% chance of answering correctly), and higher values of b_i represent more difficult items.

2.2 Data

To estimate item difficulties for NLI, we used the pre-trained IRT models of Lalor et al. (2016) and extracted the difficulty item parameters. The data consists of approximately 1000 human annotator responses from Amazon Mechanical Turk (AMT) for a selection of 180 premise-hypothesis pairs from the SNLI data set (Bowman et al., 2015). Each AMT worker (Turker) was shown the premise-hypothesis pairs and was asked to indicate whether, if the premise was taken to be true, the hypothesis was (a) definitely true (*entailment*), (b) maybe true (*neutral*), or (c) definitely not true (*contradiction*).

For SA, we collected a new data set of labels for 134 examples randomly selected from the Stanford Sentiment Treebank (SSTB) (Socher et al., 2013), using a similar AMT setup as Lalor et al. (2016). For each randomly selected example, we had 1000 Turkers label the sentence as very negative, negative, neutral, positive, or very positive. We converted these responses to binary positive/negative labels and fit a new IRT 3PL model (§2.1) using the *mirt* R package (Chalmers et al., 2015). Very negative and negative labels were binned together, and neutral, positive, and very positive were binned together.

Tables 1 and 2 show examples of the items in our data sets, and the difficulty values estimated from the IRT models. The first example in Table 1 is a clear case of *entailment*, where if we assume that the premise is true, we can infer that the hypothesis is also true. The label of the second example in SNLI is *contradiction*, but in this case the result is not as clear. There are sports stadiums that offer lawn seating, and therefore this could potentially be a case of entailment (or neutral). Either way, one could argue that the second example here is more difficult than the first. Similarly, the first two examples of Table 2 are interesting. Both of these items are labeled as *negative* examples in the data set. The first example is clear, but the second one is more ambiguous. It could be considered a mild complement, since the author still endorses renting the movie. Therefore you could argue again that the second example is more difficult than the first. The learned difficulty parameters reflect this difference

Dataset	Fleiss' κ
SNLI 4GS Contradiction	0.37
SNLI 4GS Entailment	0.48
SNLI 4GS Neutral	0.41
SNLI 5GS Contradiction	0.59
SNLI 5GS Entailment	0.63
SNLI 5GS Neutral	0.54
Sentiment Analysis	0.52

Table 3: Fleiss' κ scores for the NLI and SA annotations collected from AMT.

in difficulty in both cases.

Inter-rater reliability scores for the collected annotations are showin in Table 3. Scores for the NLI annotations were calculated when the original dataset was collected and are reproduced here (Lalor et al., 2016). Human annotations for the SA annotations were converted to binary before calculating the agreement. We see that the agreement scores are in the range of 0.4 to 0.6 which is considered moderate agreement (Landis and Koch, 1977). With the large number of annotators it is to be expected that there is some disagreement in the labels. However this disagreement can be interpreted as varying difficulty of the items, which is what we expect when we fit the IRT models.

2.3 Experiments

Our goal in this work is to understand how DNN performance on items of varying difficulty changes under different training scenarios. To test this, we trained three DNN models using subsets of the original SNLI and SSTB training data sets: (i) Long Short Term Memory Network (LSTM) (Bowman et al., 2015), (ii) Convolutional Neural Network (CNN) (Kim, 2014), and (iii) Neural Semantic Encoder (NSE), a type of memory-augmented RNN (Munkhdalai and Yu, 2017).[3] For each task (NLI and SA), we randomly sampled subsets of training data, from 100 examples up to and including the full training data sets.[4] We trained each model on the training data subsets, using the original development sets for early stopping to prevent overfitting. The IRT data with difficulty estimates were used as test sets for the trained models.

Once the models were trained and had classified the IRT data sets, we fit logistic regression models to predict whether a DNN model would label an item correctly, using the training set size and item difficulty as the dependent parameters.

3 Results

Figure 1 plots the contour plots of our learned regression models. The top row plots results for the NLI task, and the bottom row plots results for the SA task. From left to right in both rows, the plots show results for the LSTM, CNN, and NSE models. In each plot, the x-axis is the training set size, the y-axis is the item difficulty, and the contour lines represent the log-odds that the DNN model would classify an item correctly. As the plots show, item difficulty has a clear effect on classification. Easier items have higher odds of being classified correctly

---

[3] Please refer to the appendix for model details.

[4] We sampled 100, 1000, 2000, 5000, 10000, 50000, 100000, 200000, and 500000 examples for NLI, and sampled 100, 1000, 5000, 10000, 50000, and 75000 examples for SA.

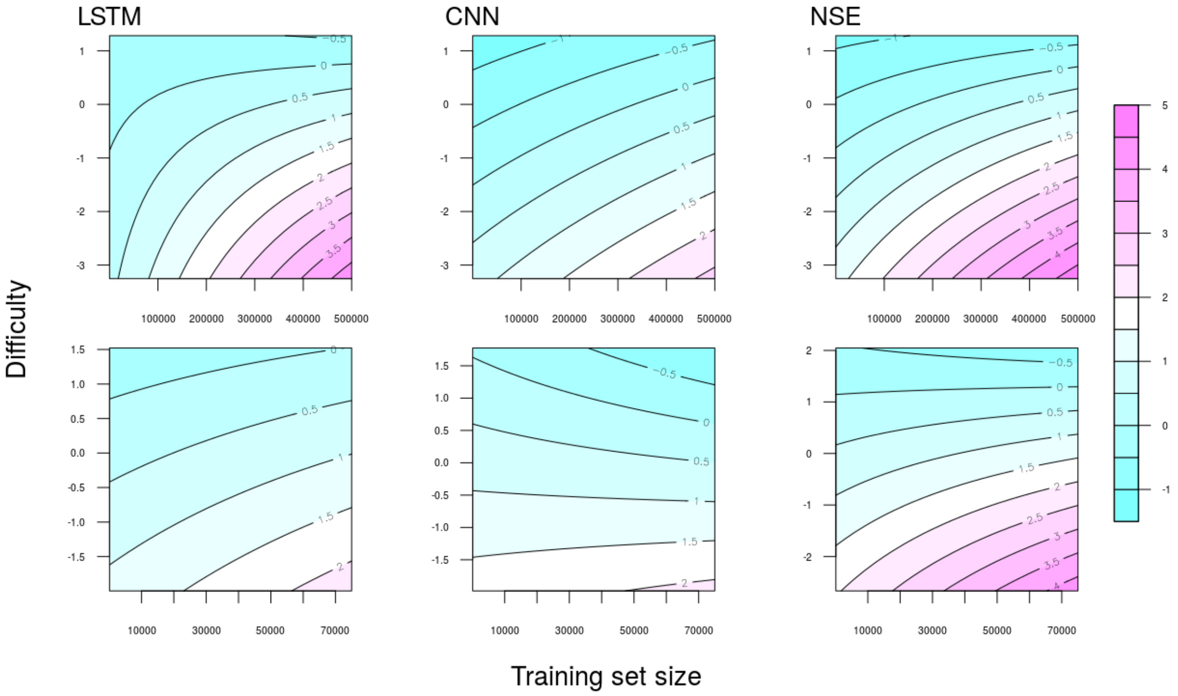

Figure 1: Contour plots showing log-odds of labeling an item correctly for NLI (top row) and SA (bottom row) as a function of training set size (x-axis) and item difficulty (y-axis). Each line in the plots represents a single log-odds value for labeling an item correctly. Blue indicates low log-odds of labeling an item correctly, and pink indicates high log-odds of labeling an item correctly. The contour colors are consistent across plots and log-odds values are shown in the legend on the right.

across all of the training set sizes. In addition, the slopes of the contour lines are steeper at lower levels of difficulty. This indicates that, moving left to right along the x-axis, a model's odds of answering an easy item correctly increase more quickly than the odds of answering a harder item correctly.

The contour plots for the CNN and NSE models on the SA task (Figure 1, second row middle and right plots) show that the easier items have higher likelihood of being classified correctly, but the odds for the most difficult items decrease as training size increases. This suggests that these models are learning in such a way that improves performance on easy items but has a negative effect on hard items. This result is important for interpretability, as it could inform stakeholder decisions if they need to have difficult examples classified.

The idea that easy items should be easier than hard items is consistent with learning strategies in humans. For example, when teaching new concepts to students, easier concepts are presented first so that the students can learn patterns and core information before moving to more difficult concepts (Collins et al., 1988; Arroyo et al., 2010). As students do more examples, all questions get easier, but easy questions get easier at a faster rate. Our result is also consistent with the key assumptions of curriculum learning (Bengio et al., 2009).

4 Related Work

Lalor et al. (2016) introduced the idea of applying IRT evaluation to NLP tasks. They built a set of scales using IRT for NLI and evaluated a single LSTM neural network to demonstrate the effectiveness of the evaluation, but did not evaluate other NLP models or tasks. Martínez-Plumed et al. (2016) consider IRT in the context of evaluating ML models, but they do not use a human population to calibrate the models, and obtain results that are difficult to interpret under IRT assumptions.

There has been work in the NLP community around modeling latent characteristics of data (Bruce and Wiebe, 1999) and annotators (Hovy et al., 2013), but none that apply the resulting metrics to interpret DNN models. Passonneau and Carpenter (2014) model the probability a label is correct with the probability of an annotator to label an item correctly according to the Dawid and Skene (1979) model, but do not consider difficulty or discriminatory ability of the data points.

One-shot learning is an attempt to build ML models that can generalize after being trained on one or a few examples of a class as opposed to a large training set (Lake et al., 2013). One-shot learning attempts to mimic human *learning behaviors* (i.e., generalization after being exposed to a small number of training examples) (Lake et al., 2016). Our work instead looks at comparisons to human *performance*, where any learning (on the part of models) has been completed beforehand. Our goal is to analyze DNN models and training set variations as they affect ability in the context of IRT.

5 Discussion

In this work we have shown that DNN model performance is affected by item difficulty as well as training set size. This is the first work that has used a well-established method for estimating difficulty to analyze DNN model performance as opposed to heuristics. DNN models perform better on easy items, and as more data is introduced in training, easy items are learned more quickly than hard items. Learning easy examples faster than harder examples is what would be expected when examining human response patterns as they learn more about a subject. However this has not previously been shown to be true in DNN models.

That the results are consistent across NLI and SA shows that the methods can be applied to a number of NLP tasks. The SA results do show that the odds of labeling a difficult item correctly decrease with more training data 1. It could be the case that these difficult items in the SA task are more subjective than the easier items, for example a review that is fairly neutral and is split between positive and negative annotations. These cases would be more difficult for a model to label, and are worth examining in more detail. By identifying items such as these as difficult makes it easier to see where the model is going wrong and allows for research on better way to represent these cases.

This result has implications for how machine learning models are evaluated across tasks. The traditional assumption that the test data is drawn from the same distribution as the training data, makes it difficult to understand how a model will perform in settings where that assumption does not hold. However, if the difficulty of test set data is known, we can better understand what kind of examples a given model performs well on, and specific instances where a model underperforms (e.g. the most difficult examples). In addition, researhers can build test sets that consist of a specific type of data (very easy, very hard, or a mix) to evaluate a trained model under specific assumptions to test generalization ability in a controlled way. This could allow for more confidence in model performance in more varied deployment settings, since there would be a set of tests a model would have to pass before being deployed.

It is important to note that the difficulty parameters were estimated *from a human population*, meaning that those items that are difficult for humans are in fact more difficult for the DNN models as well. This does not need to be the case given that DNNs learn very different patterns, etc. than humans. In fact there were exceptions in our results which shows that these models should be carefully examined using techniques like those described here. Future work can investigate why this is the case and how we can leverage this information to improve model performance and interpretability.

Abstract

We investigate neural models' ability to capture *lexicosyntactic inferences*: inferences triggered by the interaction of lexical and syntactic information. We take the task of event factuality prediction as a case study and build a factuality judgment dataset for all English clause-embedding verbs in various syntactic contexts. We use this dataset, which we make publicly available, to probe the behavior of current state-of-the-art neural systems, showing that these systems make certain systematic errors that are clearly visible through the lens of factuality prediction.

1 Introduction

The formal semantics literature has long been concerned with the complex array of inferences that different open class lexical items trigger (Kiparsky and Kiparsky, 1970; Karttunen, 1971a,b; Horn, 1972; Karttunen and Peters, 1979; Heim, 1992; Simons, 2001, 2007; Simons et al., 2010; Abusch, 2002, 2010; Gajewski, 2007; Anand and Hacquard, 2013, 2014). For example, why does (1a) give rise to the inference (2a), while the structurally identical (1b) triggers the inference (2b)?

(1) a. Jo doesn't believe that Bo left.
b. Jo doesn't know that Bo left.

(2) a. Jo believes that Bo didn't leave.
b. Bo left.
c. Bo didn't leave.

A major finding of this literature is that lexically triggered inferences are conditioned by surprising aspects of the syntactic context that a word occurs in. For example, while (3a), (3b), and (4a) trigger the inference (2b), (4b) triggers the inference (2c).

(3) a. Jo remembered that Bo left.
b. Jo didn't remember that Bo left.

(4) a. Bo remembered to leave.
b. Bo didn't remember to leave.

Accurately capturing such interactions – e.g. between clause-embedding verbs, negation, and embedded clause type – is important for any system that aims to do general natural language inference (MacCartney et al. 2008 *et seq*; cf. Dagan et al. 2006) or event extraction (see Grishman and Sundheim 1996 *et seq*), and it seems unlikely to be a trivial phenomenon to capture, given the complexity and variability of the inferences involved (see, e.g., Karttunen, 2012, 2013; Karttunen et al., 2014; van Leusen, 2012; White, 2014; Baglini and Francez, 2016; Nadathur, 2016, on implicatives).

In this paper, we investigate how well current state-of-the-art neural systems for a subtask of general event extraction – event factuality prediction (EFP; Nairn et al., 2006; Saurí and Pustejovsky, 2009, 2012; de Marneffe et al., 2012; Lee et al., 2015; Stanovsky et al., 2017; Rudinger et al., 2018) – capture inferential interactions between lexical items and syntactic context – *lexicosyntactic inferences* – when trained on current event factuality datasets. Probing these particular systems is useful for understanding neural systems' behavior more generally because (i) the best performing neural models for EFP (Rudinger et al., 2018) are simple instances of common baseline models; and (ii) the task itself is relatively constrained.

To do this, we substantially extend the MegaVeridicality1 dataset (White and Rawlins, 2018) to cover all English clause-embedding verbs in a variety of the syntactic contexts covered by recent psycholinguistic work (White and Rawlins, 2016), and we use the resulting dataset – MegaVeridicality2 – to probe these models' behavior. We focus on clause-embedding verbs because they show effectively every possible patterning of lexicosyntactic inference (Karttunen, 2012).

We discuss three findings: (i) Tree biLSTMs (T-biLSTMs) are better able to correctly predict lexicosyntactic inferences than linear-chain biLSTMs

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4717–4724
Brussels, Belgium, October 31 - November 4, 2018.

(L-biLSTMs); (ii) L-biLSTMs and T-biLSTMs capture different lexicosyntactic inferences, and thus ensembling their predictions can reliably improve performance; and (iii) even when ensembled, these models show systematic errors – e.g. performing well when the polarity of the matrix clause matches the polarity of the true inference, but poorly when these polarities mismatch.

We furthermore release MegaVeridicality2 at MegaAttitude.io as a benchmark for probing the ability of neural systems – whether for factuality prediction or for general natural language inference – to capture lexicosyntactic inference.

2 Data collection

We substantially extend the MegaVeridicality1 dataset (White and Rawlins, 2018), which contains factuality judgments for all English clause-embedding verbs that take tensed subordinate clauses. In White and Rawlins's annotation protocol, all verbs that are grammatical with such subordinate clauses – based on the MegaAttitude dataset (White and Rawlins, 2016) – are slotted into contexts either like (5a) or (5b), depending on whether they take a direct object or not.

(5) a. Someone {knew, didn't know} that a particular thing happened.
b. Someone {was, wasn't} told that a particular thing happened.

For each sentence generated in this way, 10 different annotators are asked to answer the question *did that thing happen?*: *yes*, *maybe or maybe not*, *no*.

There are two important aspects of these contexts to note. First, all lexical items besides the embedding verbs are semantically bleached to ensure that the measured lexicosyntactic inferences are only due to interactions between the embedding predicate – e.g. *know* or *tell* – and the syntactic context. Second, the matrix polarity – i.e. the presence or absence of *not* as a direct dependent of the embedding verb – is manipulated to create two sentences for each verb-context pair.

Our extension, MegaVeridicality2, includes judgments for a variety of infinitival subordinate clause types, exemplified in (6).[1] We investigate infinitival clauses because they can give rise to different lexicosyntactic inferences than finite subordinate clauses – e.g. compare (3) and (4).

Syntactic context	**# verbs**	**# sents**	**Ex.**
NP _ed that S	375	750	(5a)
NP was _ed that S	169	338	(5b)
NP _ed for NP to VP	184	368	(6a)
NP _ed NP to VP[+ev]	197	394	(6b)
NP _ed NP to VP[-ev]	128	256	(6c)
NP was _ed to VP[+ev]	278	556	(6d)
NP was _ed to VP[-ev]	256	512	(6e)
NP _ed to VP[+ev]	217	434	(6f)
NP _ed to VP[-ev]	165	330	(6g)
Total	1,969	3,938	

Table 1: Contexts and number of verbs for which annotations were collected: S = *something happened*, NP = *someone*, VP = *happen*, VP[+ev] = *do something*, VP[-ev] = *have something*. First two rows: MegaVeridicality1. All rows: MegaVeridicality2. The number of sentences is always twice the number of verbs, since matrix polarity is manipulated.

(6) a. Someone {needed, didn't need} for a particular thing to happen.
b. Someone {wanted, didn't want} a particular person to do, have a particular thing.
c. Someone {wanted, didn't want} a particular person to have a particular thing.
d. A particular person {was, wasn't} overjoyed to do a particular thing.
e. A particular person {was, wasn't} overjoyed to have a particular thing.
f. A particular person {managed, didn't manage} to do a particular thing.
g. A particular person {managed, didn't manage} to have a particular thing.

For each sentence, we also collect judgments from 10 different annotators, using the same question as White and Rawlins for context (6a) and modified questions for contexts (6b)-(6g): *did that person do that thing?* for (6b), (6d), and (6f); and *did that person have that thing?* for for (6c), (6e), and (6g). Table 1 shows the number of verb types for each syntactic context. With the polarity manipulation, this yields a total of 3,938 sentences.

To build a factuality prediction test set from these sentences, we combine MegaVeridicality1 with our dataset and replace each instance of *a particular person* or *a particular thing* with *someone* or *something* (respectively). Then, following White and Rawlins, we normalize the 10 responses for each sentence to a single real value using an ordinal mixed model-based procedure. We refer to the resulting dataset as MegaVeridicality2.

3 Model and evaluation

We use MegaVeridicality2 to evaluate the performance of three state-of-the-art neural models of

---

[1] We also explicitly manipulate two aspects of the subordinate clause in our extension of the MegaVeridicality dataset: (i) how NP embedded subjects are introduced; and (ii) whether the embedded clause contains an eventive predicate (*do*, *happen*) or a stative predicate (*have*). See Appendix A for details on the reasoning behind these manipulations.

event factuality (Rudinger et al., 2018): a linear-chain biLSTM (L-biLSTM), a dependency tree biLSTM (T-biLSTM), and a hybrid biLSTM (H-biLSTM) that ensembles the two. To predict the factuality of the event referred to by a particular predicate, these models pass the output state of the biLSTM at that predicate through a two-layer regression. In the case of the H-biLSTM, the output state of both the L- and T-biLSTMs are simply concatenated and passed through the regression.[2]

Following the multi-task training regime described by Rudinger et al. (2018), we train these models on four standard factuality datasets – FactBank (Saurí and Pustejovsky, 2009, 2012), UW (Lee et al., 2015), MEANTIME (Minard et al., 2016), and UDS (White et al., 2016; Rudinger et al., 2018) – with tied biLSTM weights but regression parameters specific to each dataset. We then use these trained models to predict the factuality of the embedded predicate in our dataset.

To understand how much of these models' performance on our dataset is really due to a correct computation of lexicosyntactic inferences, we also generate predictions for the sentences in our dataset with the embedding verbs UNKed. In this case, the model can rely only on the syntactic context surrounding the predicate to make its inferences. We refer to the models with lexical information as the LEX models and the ones without lexical information as the UNK models.

Each model produces four predictions, corresponding to the four different datasets it was trained on. We consider three different ways of ensembling these predictions using a cross-validated ridge regression: (i) ensembling the four predictions for each specific model (LEX or UNK); (ii) ensembling the predictions for the LEX version of a particular model with the UNK version of that same model (LEX+UNK); and (iii) ensembling the predictions across all models (LEX, UNK, or LEX+UNK). Each ensemble is evaluated in a 10-fold/10-fold nested cross-validation (see Cawley and Talbot, 2010). In each iteration of the outer cross-validation, a 10% test set is split off, and a 10-fold cross-validation to tune the regularization is conducted on the remaining 90%.

4 Results

Figure 1 shows the mean correlation between model predictions and true factuality on the outer fold test sets of the nested cross-validation described in §3. We note three aspects of this plot.

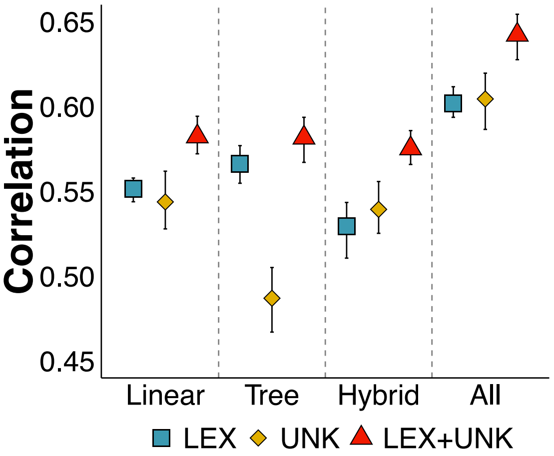

Figure 1: Mean correlation between model predictions and true factuality in nested cross-validation. Error bars show bootstrapped (iter=1,000) 95% confidence intervals for mean correlation across 10 outer folds.

First, among the LEX models, the T-biLSTM performs best, followed by the L-biLSTM, then the H-biLSTM. This is somewhat surprising, since Rudinger et al. find the opposite pattern of performance: the L- and H-biLSTMs vie for dominance, both outperforming the T-biLSTM. This indicates that T-biLSTMs are better able to represent the lexicosyntactic inferences relevant to this dataset, even though they underperform on more general datasets. This possibility is bolstered by the fact that, in contrast to the L- and H-biLSTMs, the LEX version of the T-biLSTMs performs significantly better than the UNK version, suggesting that the T-biLSTM is potentially more reliant on the lexical information than the other two.

Second, when the LEX and UNK version of each model is ensembled (LEX+UNK), we find comparable performance for all three biLSTMs – each outperforming the LEX version of the T-biLSTM. This indicates that each model captures similar amounts of information about lexicosyntactic inference, but this information is captured in the models' parameterizations in different ways.

Finally, when all three models are ensembled, we find that both the LEX and UNK version perform significantly better than any specific LEX+UNK model. This may indicate two things: (i) the models that only have access to syntax can perform just as well as ones that have access to both lexical information and syntax; but (ii) these models appear to capture different aspects of inference, since an ensemble of all models (All-LEX+UNK) performs significantly better than ei-

Table 2: Sentences with the highest prediction errors.

ther the All-LEX or All-UNK ensembles alone.

Interestingly, however, even this ensemble performs more than 10 points worse than each model alone on FactBank, UW, and UDS. This raises the question of which lexicosyntactic inferences these models are missing – investigated below.

5 Analysis

We investigate two questions: (i) which inferences do all models do poorly on?; and (ii) what drives the differing strengths of each model?

Where do all models fail? Table 2 shows the 20 sentences with the highest prediction errors under the All-LEX+UNK ensemble. There are two interesting things to note about these sentences. First, most of them involve negative lexicosyntactic inferences that the model predicts to be either positive or near zero. Second, when the true inference is not positive, the matrix polarity of the original sentence is negative. This suggests that the models are not able to capture inferences whose polarity mismatches the matrix clause polarity.

One question that arises here is whether this inability affects all contexts equally. To answer this, we regress the absolute error of the predictions from this same ensemble (logged and standardized) against true factuality, matrix polarity, and context (as well as all of their two- and three-way interactions).[3] We find that the three-way interactions in this regression are reliable ($\chi^2(8)$=27.97, p < 0.001) – suggesting that there are nontrivial differences in these state-of-the-art factuality systems' ability to capture inferential interactions across verbs and syntactic contexts. The differences can be verified visually in Figure 2, which plots the factuality predicted by this ensemble against the true factuality from MegaVeridicality2.

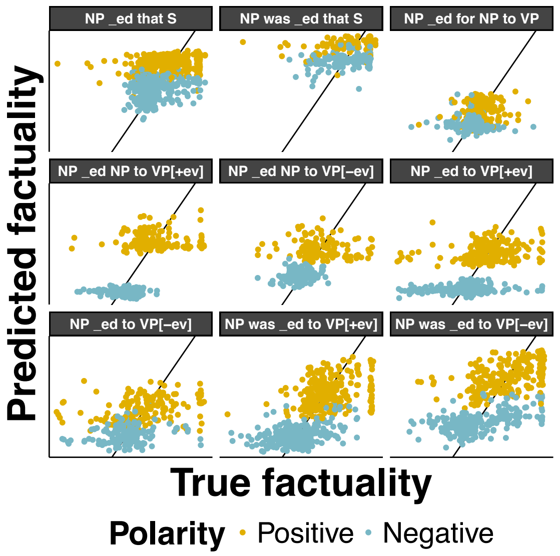

Figure 2: Factuality by syntactic context and polarity, each point a verb. Diagonals show perfect prediction.

To elaborate, the ensemble does best overall on contexts like (7a) and (7b), and worst overall on contexts like (7c). The contrast between (7b) and (7c) is particularly interesting because (i) (7c) is just the passivized form of (7b); and (ii) we do not observe similar behavior for contexts (7d) and (7e), which are analogous to (7b) and (7c), but replace the stative *have* with the eventive *do*.

(7) Someone...
  a. {_ed, didn't _} for something to happen.
  b. {_ed, didn't _} someone to have something.
  c. {was _ed, wasn't _ed} to have something.
  d. {_ed, didn't _} someone to do something.
  e. {was _ed, wasn't _ed} to do something.
  f. {_ed, didn't _} that something happened.

An additional nuance is that the ensemble does reliably better on the negative matrix polarity version of (7b) than on the positive, with the opposite true for (7e). This suggests these models do not capture an important inferential interaction between passivization and eventivity.

This suggestion is further bolstered by the fact that the ensemble's ability to predict cases where the matrix polarity mismatches the true factuality are reliably poorer in context (7c) but not in its minimal pairs (7e) and (7b), where the ensemble performs reliably poorer when the two match. Indeed, it is contexts (7c) and (7f) that drive the polarity mismatch effect evident in Table 2.

What drives differences between models? In §4, we noted two ways that the biLSTMs we in-

---

[3] See Appendix C for further details, including a summary of the regression on which the above discussion is based.

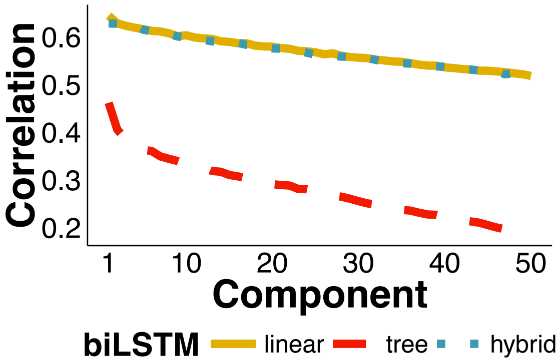

Figure 3: Canonical correlations between embedding verb embeddings and embedded verb hidden states.

vestigate differ: (i) the T-biLSTM appears to be more reliant on lexical information than L- and H-biLSTMs; and (ii) each model appears to encode information about lexicosyntactic inference in its parameterizations in different ways. We hypothesize that these two differences are related – specifically, that the T-biLSTM's heavier reliance on lexical information comes about as a consequence of stronger entanglement between lexical and syntactic information in its hidden states.

To probe this, we ask to what extent the embedding verb's embedding can be recovered from the embedded verb's hidden state using linear functions. If the lexical information is more strongly entangled with the syntactic information, it should be more difficult to construct a homomorphic (linear) function to decode the embedding verb's embedding from the embedded verb's hidden state. To measure this, we conduct a Canonical Correlation Analysis (CCA; Hotelling, 1936) between these two vector space representations for every sentence in our dataset. Given two matrices $\mathbf{X}$ (the embedding verb embeddings column stacked) and $\mathbf{Y}$ (the embedded verb hidden states column stacked), CCA constructs matrices $\mathbf{A}$ and $\mathbf{B}$, such that $\mathbf{a}_i, \mathbf{b}_i = \text{arg}_{\mathbf{a}', \mathbf{b}'}\text{max} \;\; \text{corr}(\mathbf{a}'\mathbf{X}, \mathbf{b}'\mathbf{Y})$ and $\text{corr}(\mathbf{a}_i\mathbf{X}, \mathbf{a}_j\mathbf{X}) = \text{corr}(\mathbf{b}_i\mathbf{Y}, \mathbf{b}_j\mathbf{Y}) = 0, \forall i < j$. This guarantees that the canonical correlation at component i, $\text{corr}(\mathbf{a}_i\mathbf{X}, \mathbf{b}_i\mathbf{Y})$, is nonincreasing in i, and thus the linearly decodable information about $\mathbf{Y}$ in $\mathbf{X}$ can be assessed using this function.

Figure 3 plots the canonical correlations for the first 50 components for each of the biLSTMs we investigated. We find that the canonical correlations associated with the T-biLSTM are substantially lower than those associated with the L- and H-biLSTMs across these first 50 components. This suggests that the T-biLSTM more strongly entangles lexical and syntactic information, perhaps explaining its apparently heavier reliance on lexical information, observed in §4.

Of note here is that the pattern seen in Figure 3 is probably at least partly a consequence of the different nonlinearities used for the L-biLSTM (tanh) and T-biLSTM (ReLU), and not the architectures themselves. But whether or not this pattern is due to the architectures, nonlinearities, or both, the entanglement hypothesis may still help explain the pattern of results discussed in §4.

6 Related work

This work is inspired by recent work in *recasting* various semantic annotations into natural language inference (NLI) datasets (White et al., 2017; Poliak et al., 2018a,b; Wang et al., 2018) to gain a better understanding of which phenomena standard neural NLI models (Bowman et al., 2015; Conneau et al., 2017) can capture – a line of work with deep roots (Cooper et al., 1996). The experimental setup – specifically, the idea of UNKing the embedding verb – was inspired by recent work that uses hypothesis-only baselines for a similar purpose (Gururangan et al., 2018; Poliak et al., 2018c; Tsuchiya, 2018). This work is also related to the broader investigation of sentence representations – particularly, tasks aimed at probing these representations' content (Pavlick and Callison-Burch, 2016; Adi et al., 2016; Conneau et al., 2018; Conneau and Kiela, 2018; Dasgupta et al., 2018).

7 Conclusion

We investigated neural models' ability to capture lexicosyntactic inference, taking the task of event factuality prediction (EFP) as a case study. We built a factuality judgment dataset for all English clause-embedding verbs in various syntactic contexts and used this dataset to probe current state-of-the-art EFP systems. We showed that these systems make certain systematic errors that are clearly visible through the lens of factuality.

Abstract

In this paper, we propose a new approach to employ the fixed-size ordinally-forgetting encoding (FOFE) (Zhang et al., 2015b) in neural languages modelling, called *dual-FOFE*. The main idea behind dual-FOFE is that it allows to use two different forgetting factors so that it can avoid the trade-off in choosing either small or large values for the single forgetting factor in the original FOFE. In our experiments, we have compared the dual-FOFE based neural network language models (NNLM) against the original FOFE counterparts and various traditional NNLMs. Our results on the challenging Google Billion Words corpus show that both FOFE and dual FOFE yield very strong performance while significantly reducing the computational complexity over other NNLMs. Furthermore, the proposed dual-FOFE method further gives over 10% relative improvement in perplexity over the original FOFE model.

1 Introduction

Language modelling is an essential task for many natural language processing (NLP) applications including speech recognition, machine translation and text summarization. The goal of language modelling is to learn the distribution over a sequence of characters or words; this distribution may be utilized for encoding the language structure (e.g. the grammatical structure) as well as extracting information from the corpora (Jozefowicz et al., 2016). In the recent years, the popularity of neural networks (NN) has been a significant driving force for language modelling (LM) research; the well-known NN-LM models includes the feedforward NN-LMs (FNN-LMs) (Bengio et al., 2001, 2003), recurrent NN-LMs (RNN-LMs) (Mikolov et al., 2010; Mikolov and Zweig, 2012) and the long short-term memory (LSTM-LMs) (Hochreiter and Schmidhuber, 1997). Among all, FNN-LMs often have a simpler and more efficient learning process, but they tend to underperform the other NN-LMs due to the limited capability to memorize the long term dependency in natural languages (Zhang et al., 2015b). However this drawback could be addressed by applying the fixed-size ordinally-forgetting encoding (FOFE) to FNN's inputs. FOFE is an encoding method, which relies on the ordinally-forgetting mechanism to encode any word sequence based on the positions of words; this also allows the FOFE code to capture the long-term dependency (Zhang et al., 2015b). As shown in Zhang (2015b), FNN-LMs with FOFE can easily yield comparable performance as other NN-LMs. The key parameter in the FOFE method is the forgetting factor, which is responsible for determining the degree of sensitivity of the encoding with respect to the past context. However, the choice of a good value for the forgetting factor could be tricky since both small and large forgetting factors are offering different benefits.

In this paper, we propose a simple alteration to FOFE method, which allows to incorporate two forgetting factors into the fixed-size encoding of the variable-length word sequences. We name this approach as *dual-FOFE*. Our hypothesis is that by incorporating both the small and large forgetting factors in the FOFE encoding, the dual-FOFE is able to simultaneously optimize the abilities to capture the positional information as well as to model long term dependency. In our experiments, we have evaluated the proposed dual FOFE models on two large scale language modeling tasks, namely *enwiki9* and *Google Billion Words (GBW)* corpora. Experimental results have shown that both FOFE models yield very competitive performance on these tasks, comparable with the state-

Brussels, Belgium, October 31 - November 4, 2018.

of-the-art systems but with significantly reduced learning complexity. Furthermore, the proposed dual-FOFE method further gives over 10% relative improvement in perplexity over the original FOFE model.

2 Related Work

In this section, we will briefly review the NN-LMs and the original FOFE method. The general idea behind NN-LM is to project the discrete words onto a continuous space, then learn to estimate the conditional probabilities of each known word within the projected space. The training of NN-LMs are often incredibly slow due to the inefficiency of softmax normalization when applied to the extremely large output layer. The solution currently used by many NN-LMs (including our models in this work) is to use noise contrastive estimation (NCE) (Gutmann and Hyvrinen, 2010). The basic idea of NCE is to reduce the probability estimation problem into a probabilistic binary classification problem (Mnih and Teh, 2012; Mnih and Kavukcuoglu, 2013).

2.1 Fixed-Size Ordinally Forgetting Encoding

Fixed-size ordinally-forgetting Encoding (FOFE) is an encoding method which generates a fixed-size representation, namely the FOFE code, for any variable-length word sequence (Zhang et al., 2015b). For a given word sequence $S = \{w_1, w_2, ..., w_T\}$, let e_t denote the one-hot representation of the word w_t, z_t for the FOFE code of the partial word sequence up to word w_t, z_t is computed as follows:

$$z_t = \alpha \cdot z_{t-1} + e_t \quad (1 \leq t \leq T) \tag{1}$$

where α ($0 < \alpha < 1$) denotes the forgetting factor, a parameter responsible for determining the degree of influence each time step of the past context has on the FOFE code. Obviously, FOFE can convert any variable-length sequence into a fixed-size code with length equal to the size of vocabulary.

In regard to uniqueness of FOFE code, the code is said to be (almost) unique under the two theorems (proven in Zhang (2015a)):

Theorem 1 *If $0 < \alpha \leq 0.5$, then FOFE code is guarantee uniqueness for any values of vocabulary's size and sequence's length.*

Theorem 2 *If $0.5 < \alpha < 1$, then FOFE code is guarantee almost uniqueness for any finite values of vocabulary's size and sequence's length, except for a finite set of countable choices of α.*

Furthermore, the chance of actually having any collisions for α between 0.5 and 1 is nearly impossible in practice, due to quantization errors in real computer systems. Hence in practice, it is safe to argue that FOFE is able to uniquely encodes any variable-length sequence into a fixed-size representation.

2.2 FOFE for FNN-LMs

The idea of FOFE based NN-LMs is to use FOFE to encode the partial history sequence of past words in a sentence, then feed this fixed-size FOFE code to a feedforward neural network as an input to predict next word. As shown in Figure 1, the FOFE code could be efficiently computed via time-delayed recursive structure, where the symbol z^{-1} in the figure represents a unit time delay (or equivalently a memory unit) from z_t to z_{t-1}.

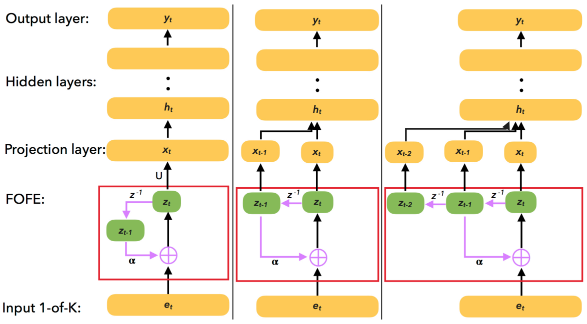

Figure 1: (Left) 1st-order FOFE FNN-LM; (Center) 2nd-order FOFE FNN-LM; (Right) 3rd-order FOFE FNN-LM.

The basic architecture for FOFE based FNN-LMs (called 1st-order) is the standard FNN architecture with an additional layer for encoding the input into FOFE code. However, in this work, we use the 2nd-order and 3rd-order FOFE FNN-LMs, which are shown to produce slightly better results (Zhang et al., 2015b). In a 2nd-order FOFE model, both the current partial sequences FOFE code (denoted as z_t) and the previous partial sequences FOFE code (denoted as z_{t-1}) are utilized to predict next word. In a 3rd-order FOFE model, all z_t, z_{t-1} and z_{t-2} are used as inputs to neural networks.

More recently, the FOFE methods have been successfully applied to many NLP tasks, including word embedding (Sanu et al., 2017), named entity recognition (Xu et al., 2017a), entity discovery and linking (Xu et al., 2016, 2017b).

3 Dual-FOFE

The main idea of dual-FOFE is to generate augmented FOFE encoding codes by concatenating two FOFE codes using two different forgetting factors. Each of these FOFE codes is still computed in the same way as the mathematical formulation shown in Equation (1). The difference between them is that we may select to use two different values for the forgetting factor (denoted as α) for additional modeling benefits.

3.1 Intuition behind Dual-FOFE

As mentioned in the subsection 2.1, the values in a FOFE code are used to encode both the content and the order information in a sequence. This is achieved by a recursive encoding method where at each recursive step the code will be multiplied by the forgetting factor (α) whose value is bounded by $0 < \alpha < 1$. In a practical computer with finite precision, this has an impact on the FOFE's abilities to precisely memorize the long-term dependency of past context as well as to properly represent the positional information.

The FOFE's ability to represent the positional information would improve with smaller forgetting factors. The reason is that that when α is small, the FOFE code (z_t) for each word vastly differs from its neighbour in magnitude. If α is too large (close to 1), the contribution of a word may not change too much no matter where it is. This may hamper the following neural networks to model the positional information. Conversely, the FOFE's ability to model the long-term dependency of the older context would improve with larger forgetting factors. This is because when α is small, the contribution of a word from the older history may quickly underflow to become irrelevant (i.e. forgotten) when computing the current word.

In the original FOFE with just a single forgetting factor, we would have to determine the best trade-off between these two benefits. On the other hand, the dual-FOFE does not face such issues since it is composed of two FOFE codes: the half of the dual-FOFE code using a smaller forgetting factor is solely optimized and responsible for representing the positional information of all words in the sequence; meanwhile the other half of the dual-FOFE code using a larger forgetting factor is optimized and responsible for maintaining the long-term dependency of past context.

3.2 Dual-FOFE based FNN-LM

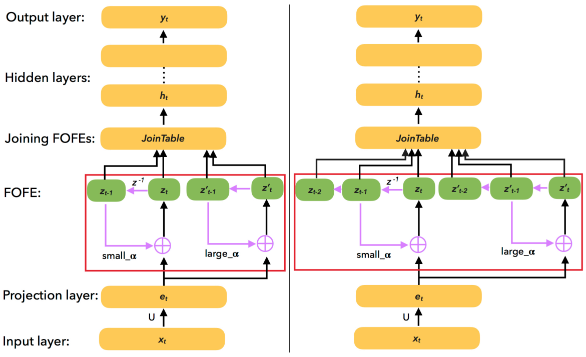

Figure 2: (Left) 2nd-order Dual-FOFE FNN-LM; (Right) 3rd-order Dual-FOFE FNN-LM.

As shown in Figure 2, the architecture of dual-FOFE based FNN-LMs is very similar to the original FOFE FNN-LMs.[1] In the Dual-FOFE FNN-LMs, the input word sequence would have to pass through two branches of the FOFE layers (using two different forgetting factors) and each encoding branch will produce a FOFE code representing the input sequence. These two FOFE codes are then joined to produce the dual-FOFE code, which would be fed to FNNs to predict the next word.

It might also be worth noting that in our implementation we do not explicitly reset FOFE codes, i.e. z_t value, at sentence boundaries. However, far-away histories will be gradually forgotten by the recursive calculation in FOFE due to $0 < \alpha < 1$ and finite precision in computers.

3.3 Dual-FOFE vs. Higher Order FOFE

As mentioned previously in the subsection 2.2, the higer order FOFE codes would utilize both the current and the previous sequence FOFE codes for prediction. Hence similar to dual-FOFE, the higher order FOFE could also maintain the sensitivity to both nearby and faraway context. Obviously a much higher order FOFE code may be required in order to achieve the same effect as dual-FOFE in terms of modelling long-term dependency. In this case, the higher order FOFE may also significantly increase the number of parameters in the input layer. At last, the dual FOFE

---

[1] The difference in the location of the projection layer between Figure 1 and 2 simply indicates two equivalent ways to do word projection. Figure 1 was originally from Zhang (2015b), but they mentioned in text (without a figure) that it is more efficient to do projection as in Figure 2 and both methods are mathematically equivalent since both projection and FOFE steps are linear.

and the higher order FOFE are largely complementary since we have observed consistent performance gains when combining dual FOFE with either 2nd-order or 3rd-order FOFE in our experiments.

4 Experiments

In this work, we have evaluated the proposed dual-FOFE based FNN-LMs against various traditional neural language models on two corpora: i) *enwik9* corpus: it consists of the first 1 billion bytes of English wikipedia dump, having total size of 170.8 million words; the corpus was divided into three parts: the training set (153M words), the test set (8.9M words), and the validation set (8.9M words); the vocabulary size is limited to 80k words (Zhang et al., 2015b). ii) Google Billion Words (GBW) corpus: it contains about 800 million words and the corpus is divided into two parts: the training set (792M words) and the test set (8M words); the vocabulary size for this corpus is limited to 800k words (Chelba et al., 2013).

4.1 Results on enwiki9

In the experiments on the enwiki9 corpus, we have trained three dual-FOFE FNN-LMs with different forgetting factor pairs, one FOFE FNN-LM, and one tri-FOFE FNN-LM. All five models adopt a 2nd-order FOFE structure, employing a word embeddings of 256 dimensions, three hidden layers of $400, 600, 600$ neurons and an output layer of 80k words (reflecting the vocabulary). [2] Note that the dual-FOFE FNN-LMs have to double the size of input context windows since dual-FOFE essentially contain two FOFE codes. But this increase only accounts for a negligible faction of total model parameters.

As shown in Table 1, all three dual-FOFE FNN-LMs, using three pairs of forgetting factors as (0.5, 0.7) and (0.7, 0.9) and (0.5, 0.9), can significantly outperform other traditional models previously reported on this corpus. We also note that it is beneficial to include a relatively large forgetting factor, such as 0.9, in the dual FOFE models since such a large alpha may help to memorize much longer context in the inputs. When compared with the original FOFE counterpart, the best dual-FOFE model using forgetting factors (0.5, 0.9) offers a relative gain of around 8% in test PPL.

It is worth noting that our dual-FOFE models can be extended to incorporate more than two alpha values. In fact after we have obtained a strong result supporting our dual-FOFE hypothesis, we have performed additional experiments using three alpha values, the so-called tri-FOFE model. The result on Table 1 has shown that the tri-FOFE FNN-LMs still slightly outperforms the dual-FOFE models. However, the gain is marginal. This leads us to believing that further extension of more alpha values in FOFE would be of limited use.

4.2 Results on Google Billion Words (GBW)

In the experiments on the GBW corpus, we have trained one dual-FOFE FNN-LM and one FOFE FNN-LM. Following the best dual-FOFE model configuration on the previous corpus, this dual-FOFE FNN-LM uses the same pair of dual forgetting factors $(0.5, 0.9)$. Both models adopt a 3rd-order structure, employing word embeddings of 256 dimensions, three hidden layers each of 4096 neurons, a compression layer with 720 neurons, and an output layer of 800k words (reflecting the vocabulary). Although dual-FOFE FNN-LM has doubled the size of input context windows of FOFE FNN-LM, the total number of model parameters in both models are almost equal, roughly 0.82 billion parameters.

As shown in Table 2, the dual-FOFE FNN-LM is able to produce a very competitive performance, comparable with the best previously reported results on this task, such as GCNN-13 (Dauphin et al., 2016) and LSTM-LM (Jozefowicz et al., 2016). The dual-FOFE FNN-LM are among the few single-model systems that are able to achieve test PPL below 40 on this task. Furthermore, our proposed dual FOFE model can significantly reduce the computational complexity, e.g., our model has a relatively smaller number of parameter (0.82B parameters) and it requires much less hardware resource to train (using only 1 GPU in our experiments). When compared with the original FOFE counterpart, the dual-FOFE FNN-LM is able to provide approximately 11% relative improvement in PPL.

5 Conclusions

In this paper, we have proposed a new approach of utilizing the fixed-size ordinally-forgetting encoding (FOFE) method for neural network lan-

---

[2] Comparing with Zhang (2015b), our single FOFE FNN-LM baseline use a slightly larger model, which lead to slightly better perplexity.

Table 1: Test PPL of various LMs on *enwiki9*.

Model	Architecture	PPL
KN 3-gram (Zhang et al., 2015b)	-	156

guage models (NN-LMs), known as dual-FOFE. As the name implies, this approach involves to produce a new fixed-sized representation for any variable-length sequence from a concatenation of two FOFE codes. This would have allowed us to select two values for the forgetting factors. One FOFE code with a smaller forgetting factor is responsible for representing the positional information of all words in the sequence while the other using a larger forgetting factor is responsible for modelling the even longer term dependency in far away history. Our experiments on both *enwiki9* and Google Billion Words (GBW) tasks have both demonstrated the effectiveness of the dual-FOFE modeling approach. Experimental results on the challenging GBW corpus have shown that the dual-FOFE FNN-LM has achieved over 10% improvement in perplexity over the original FOFE FNN-LM, without any significant drawback in model and learning complexity. When compared with other traditional neural language models, the dual-FOFE FNN-LM has achieved competitive performance with significantly lower computational complexity.

Abstract

Recent work has shown that recurrent neural networks (RNNs) can implicitly capture and exploit hierarchical information when trained to solve common natural language processing tasks (Blevins et al., 2018) such as language modeling (Linzen et al., 2016; Gulordava et al., 2018) and neural machine translation (Shi et al., 2016). In contrast, the ability to model structured data with non-recurrent neural networks has received little attention despite their success in many NLP tasks (Gehring et al., 2017; Vaswani et al., 2017). In this work, we compare the two architectures—*recurrent* versus *non-recurrent*—with respect to their ability to model hierarchical structure and find that recurrency is indeed important for this purpose. The code and data used in our experiments is available at `https://github.com/ketranm/fan_vs_rnn`

1 Introduction

Recurrent neural networks (RNNs), in particular Long Short-Term Memory networks (LSTMs), have become a dominant tool in natural language processing. While LSTMs appear to be a natural choice for modeling sequential data, recently a class of non-recurrent models (Gehring et al., 2017; Vaswani et al., 2017) have shown competitive performance on sequence modeling. Gehring et al. (2017) propose a fully convolutional sequence-to-sequence model that achieves state-of-the-art performance in machine translation. Vaswani et al. (2017) introduce Transformer networks that do not use any convolution or recurrent connections while obtaining the best translation performance. These non-recurrent models are appealing due to their highly parallelizable computations on modern GPUs. But do they have the same ability to exploit hierarchical structures *implicitly* in comparison to RNNs? In this work, we provide a first answer to this question.

Our interest here is the ability of capturing hierarchical structure without being equipped with explicit structural representations (Bowman et al., 2015b; Tran et al., 2016; Linzen et al., 2016). We choose Transformer as a non-recurrent model to study in this paper. We refer to Transformer as Fully Attentional Network (FAN) to emphasize this characteristic. Our motivation to favor FANs over convolutional neural networks (CNNs) is that FANs always have full access to the sequence history, making them more suited for modeling long distance dependencies than CNNs. Additionally, FANs promise to be more interpretable than LSTMs by visualizing attention weights.

The rest of the paper is organized as follows: We first highlight the differences between the two architectures (§2) and introduce the two tasks (§3). Then we provide setup and results for each task (§4 and §5) and discuss our findings (§6).

2 FAN versus LSTM

Conceptually, FANs differ from LSTMs in the way they utilize the previous input to predict the next output. Figure 1 depicts the main difference in terms of computation when each model is making predictions. At time step t, a FAN can access information from all previous time steps *directly* with $\mathcal{O}(1)$ computational operations. FANs do so by employing a self-attention mechanism to compute the weighted average of all previous input representations. In contrast, LSTMs compress at each time step all previous information into a single vector *recursively* based on the current input and the previous compressed vector. By their definition, LSTMs require $\mathcal{O}(d)$ computational operations to access the information at time step $t - d$.

For the details of self-attention mechanics in FANs, we refer to the work of Vaswani et al. (2017). We now proceed to measure both models' ability to

learn hierarchical structure with a set of controlled experiments.

3 Tasks

We choose two tasks to study in this work: (1) subject-verb agreement, and (2) logical inference. The first task was proposed by Linzen et al. (2016) to test the ability of recurrent neural networks to capture syntactic dependencies in natural language. The second task was introduced by Bowman et al. (2015b) to compare tree-based recursive neural networks against sequence-based recurrent networks with respect to their ability to exploit hierarchical structures to make accurate inferences. The choice of tasks here is important to ensure that both models have to exploit hierarchical structural features (Jia and Liang, 2017).

4 Subject-Verb Agreement

Linzen et al. (2016) propose the task of predicting number agreement between subject and verb in naturally occurring English sentences as a proxy for the ability of LSTMs to capture hierarchical structure in natural language. We use the dataset provided by Linzen et al. (2016) and follow their experimental protocol of training each model using either (a) a general language model, i.e., next word prediction objective, and (b) an explicit supervision objective, i.e., predicting the number of the verb given its sentence history. Table 1 illustrates the training and testing conditions of the task.

Data: Following the original setting, we take 10% of the data for training, 1% for validation, and the rest for testing. The vocabulary consists of the 10k most frequent words, while the remaining words are replaced by their part-of-speech.

Table 1: Examples of training and test conditions for the two subject-verb agreement subtasks. The full input sentence is "The **keys** to the cabinet **are** on the table" where verb and subject are bold and intervening nouns are underlined.

	Input	Train	Test
(a)	the keys to the cabinet	are	$p(\text{are}) > p(\text{is})$?
(b)	the keys to the cabinet	plural	plural/singular?

Hyperparameters: To allow for a fair comparison, we find the best configuration for each model by running a grid search over the following hyperparameters: number of layers in $\{2, 3, 4\}$, dropout rate in $\{0.2, 0.3, 0.5\}$, embedding size and number of hidden units in $\{128, 256, 512\}$, number of heads (for FAN) in $\{2, 4\}$, and learning rate in $\{0.00001, 0.0001, 0.001\}$. The weights of the word embeddings and output layer are shared (Inan et al., 2017; Press and Wolf, 2017). Models are optimized by Adam (Kingma and Ba, 2015).

We first assess whether the LSTM and FAN models trained with respect to the language model objective assign higher probabilities to the correctly inflected verbs. As shown in Figures 2a and 2b, both models achieve high accuracies for this task, but LSTMs consistently outperform FANs. Moreover, LSTMs are clearly more robust than FANs with respect to task difficulty, measured both in terms of word distance and number of agreement attractors[1] between subject and verb. Christiansen and Chater (2016); Cornish et al. (2017) have argued that human memory limitations give rise to important characteristics of natural language, including its hierarchical structure. Similarly, our experiments suggest that, by compressing the history into a single vector before making predictions, LSTMs are forced to better learn the input structure. On the other hand, despite having direct access to all words in their history, FANs are less capable of detecting the verb's subject. We note that the validation perplexities of the LSTM and FAN are 67.06 and 69.14, respectively.

Secondly, we evaluate FAN and LSTM models explicitly trained to predict the verb number (Figures 2c and 2d). Again, we observe that LSTMs consistently outperform FANs. This is a particularly interesting result since the self-attention mechanism in FANs connects two words in any po-

---

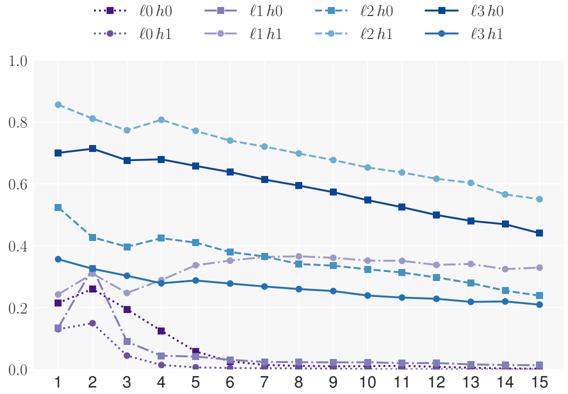

Figure 3: Proportion of times the subject is the most attended word by different heads at different layers ($\ell 3$ is the highest layer). Only cases where the model made a correct prediction are shown.

sition with a $\mathcal{O}(1)$ number of executed operations, whereas RNNs require more recurrent operations. Despite this apparent advantage of FANs, the performance gap between FANs and LSTMs increases with the distance and number of attractors.[2]

To gain further insights into our results, we examine the attention weights computed by FANs during verb-number prediction (supervised objective). Specifically, for each attention head at each layer of the FAN, we compute the percentage of times the subject is the most attended word among all words in the history. Figure 3 shows the results for all cases where the model made the correct prediction. While it is hard to interpret the exact role of attention for different heads and at different layers, we find that some of the attention heads at the higher layers ($\ell 2\ h1$, $\ell 3\ h0$) frequently point to the subject with an accuracy that decreases linearly with the distance between subject and verb.

5 Logical inference

In this task, we choose the artificial language introduced by Bowman et al. (2015b). The vocabulary of this language includes six word types {*a, b, c, d, e, f*} and three logical operators {*or*, *and*, *not*}. The task consists of predicting one of seven mutually exclusive logical relations that describe the relationship between a pair of sentences: entailment ($\sqsubset$, $\sqsupset$), equivalence ($\equiv$), exhaustive and non-exhaustive contradiction ($^\wedge$, $|$), and two types of semantic independence ($\#$, $\smile$). We generate 60,000 samples[3] with the number of logical operations ranging from 1 to 12. The train/dev/test dataset ratios are set to 0.8/0.1/0.1. Here are some samples of the training data:

(d (or f)) $\sqsupset$ (f (and a))
(d (and (c (or d)))) $\#$ (not f)
(not (d (or (f (or c))))) $\sqsubset$ (not (c (and (not d))))

Why artificial data? Despite the simplicity of the

---

[2] We note that our LSTM results are better than those in Linzen et al. (2016). Also surprising is that the language model objective yields higher accuracies than the number prediction objective. We believe this may be due to better model optimization and to the embedding-output layer weight sharing, but we leave a thorough investigation to future work.

[3] `https://github.com/sleepinyourhat/vector-entailment`

language, this task is not trivial. To correctly classify logical relations, the model must learn nested structures as well as the scope of logical operators. We verify the difficulty of the task by training three bag-of-words models followed by sum/average/max-pooling. The best of the three models achieve less than 59% accuracy on the logical inference versus 77% on the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015a). This shows that the SNLI task can be largely solved by exploiting shallow features without understanding the underlying linguistic structures, which has also been pointed out by recent work (Glockner et al., 2018; Gururangan et al., 2018).

Concurrently to our work Evans et al. (2018) proposed an alternative data set for logical inference and also found that a FAN model underperformed various other architectures including LSTMs.

5.1 Models

We follow the general architecture proposed in (Bowman et al., 2015b): Premise and hypothesis sentences are encoded by fixed-size vectors. These two vectors are then concatenated and fed to a 3-layer feed-forward neural network with ReLU non-linearities to perform 7-way classification of the logical relation.

The LSTM architecture used in this experiment is similar to that of Bowman et al. (2015b). We simply take the last hidden state of the top LSTM layer as a fixed-size vector representation of the sentence. Here, we use a 2-layer LSTM with skip connections. The FAN maps a sentence x of length n to $\mathbf{H} = [\mathbf{h}_1, \ldots, \mathbf{h}_n] \in \mathbb{R}^{d \times n}$. To obtain a fixed-size representation $\mathbf{z}$, we use a self-attention layer with two trainable queries $\mathbf{q}_1, \mathbf{q}_2 \in \mathbb{R}^{1 \times d}$:

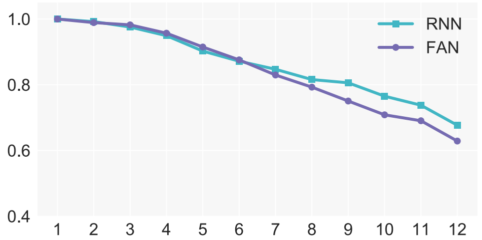
$$\mathbf{z}_i = \text{softmax}\left(\frac{\mathbf{q}_i \mathbf{H}}{\sqrt{d}}\right) \mathbf{H}^\top \quad i \in \{1, 2\}$$

$$\mathbf{z} = [\mathbf{z}_1, \mathbf{z}_2]$$

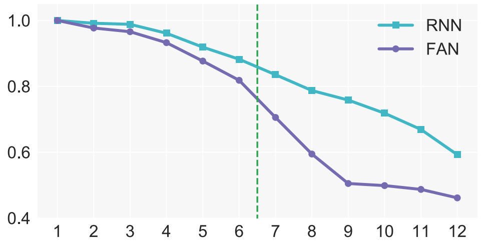
We find the best hyperparameters for each model by running a grid search as explained in §4.

5.2 Results

Following the experimental protocol of Bowman et al. (2015b), the data is divided into 13 bins based on the number of logical operators. Both FANs and LSTMs are trained on samples with at most n logical operators and tested on all bins. Figure 4 shows the result of the experiments with $n \leq 6$ and $n \leq 12$. We see that FANs and LSTMs perform similarly when trained on the whole dataset (Figure 4a). However when trained on a subset of the data (Figure 4b), LSTMs obtain better accuracies on similar examples ($n \leq 6$) and generalize better on longer examples ($6 < n \leq 12$).



(a) $n \leq 12$



(b) $n \leq 6$

Figure 4: Results of logical inference when training on all data (a) or only on samples with at most n logical operators (b).

6 Discussion and Conclusion

We have compared a recurrent architecture (LSTM) to a non-recurrent one (FAN) with respect to the ability of capturing the underlying hierarchical structure of sequential data. Our experiments show that LSTMs slightly but consistently outperform FANs. We found that LSTMs are notably more robust with respect to the presence of misleading features in the agreement task, whether trained with explicit supervision or with a general language model objective. Secondly, we found that LSTMs generalize better than FANs to longer sequences in a logical inference task. These findings suggest that recurrency is a key model property which should not be sacrificed for efficiency when hierarchical structure matters for the task.

This does not imply that LSTMs should always be preferred over non-recurrent architectures. In fact, both FAN- and CNN-based networks have proved to perform comparably or better than LSTM-based ones on a very complex task like machine translation (Gehring et al., 2017; Vaswani et al., 2017). Nevertheless, we believe that the ability of capturing hierarchical information in sequential data remains a fundamental need for building intelligent systems that can understand and process language. Thus we hope that our insights will be useful towards building the next generation of neural networks.

Abstract

Targeted sentiment analysis (TSA) aims at extracting targets and classifying their sentiment classes. Previous works only exploit word embeddings as features and do not explore more potentials of neural networks when jointly learning the two tasks. In this paper, we carefully design the hierarchical multi-layer bidirectional gated recurrent units (HMBi-GRU) model to learn abstract features for both tasks, and we propose a HMBi-GRU based joint model which allows the target label of word to have influence on its sentiment label. Experimental results on two datasets show that our joint learning model can outperform other baselines and demonstrate the effectiveness of HMBi-GRU in learning abstract features.

1 Introduction

Targeted sentiment analysis (TSA) aims to extract targets in a text and simultaneously predict their sentiment classes (Hu and Liu, 2004; Jin et al., 2009; Li et al., 2010; Yang and Cardie, 2013). For example, given a sentence *"ESPN poll says Michael Jordan is the greatest basketball athlete"*, the targets are *ESPN* and *Michael Jordan* and their sentiment classes are *Neutral* and *Positive* respectively.

Targeted sentiment analysis can be seen as two tasks: target extraction and sentiment classification. Some researchers have tackled two tasks separately, e.g., target extraction (Liu et al., 2013; Wang et al., 2016a; Yin et al., 2016) and sentiment classification (Tang et al., 2016; Wang et al., 2016b; Ruder et al., 2016). Recently, some researches have attempted to conduct the two tasks jointly and generally see them as sequence labeling problems, where the *B/I/O* labels indicate target boundaries and the *Positive/Neutral/Negative* labels denote sentiment classes (Klinger and Cimiano, 2013; Yang and Cardie, 2013). Mitchell et al. (2013) explore labeling targets and their sentiment classes simultaneously by using the Conditional Random Fields (CRF) approach with traditional manual discrete features, and present three models: pipeline, joint and collapsed, according to different labeling processes of the two tasks. They find that the pipeline method outperforms the joint model on tweet dataset. Further, Zhang et al. (2015) introduce word embedding representations into the CRF framework and find that it is beneficial to integrate word embeddings into handcraft features in TSA regardless of pipeline, joint or collapsed methods.

With the success of deep learning techniques, neural networks have demonstrated their capability of sequence labeling (Collobert et al., 2011; Pei et al., 2014; Chen et al., 2015). However, Zhang et al. (2015) only use word embeddings to enrich features without taking full advantages of neural networks' potential in automatically capturing important sequence labeling features like long distance dependencies and character-level features.

To make better use of neural networks to explore appropriate character-level features and high-level semantic features for the two tasks, we design a hierarchical multi-layer bidirectional gated recurrent units networks (HMBi-GRU) which uses a multi-layer Bi-GRU to automatically learn character features (e.g. capitalization, noun suffix, etc) on letter sequence and model long distance dependencies between words on the concatenation of word embedding and its character features. The learned character features can also address out-of-vocabulary word problems.

In above example, the target label and sentiment label for *Michael Jordon* are "B-Person, I-Person" and "B-Positive, I-Positive", we can see that the boundary information (B, I) of target label and sentiment label is consistent. From the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4737–4742
Brussels, Belgium, October 31 - November 4, 2018.

view of human, we should first predict the target label and give corresponding sentiment label afterwards. Therefore, we introduce target label information into predicting sentiment label. In this way, our model can know about the target boundary information when predicting the sentiment label. Meanwhile, we also introduce transition matrix (Collobert et al., 2011) to model the dependencies between labels.

We conduct experiments on two datasets, and the performances show that our models outperform other baselines. This verifies the effectiveness of neural networks in TSA. In the experiments, we find that the target label information is important for predicting sentiment label. We also analyze the performance of multi-layer Bi-GRU and hierarchical architecture in learning character features and dependencies between words.

2 Model

We will detailedly introduce our model in this section, and our model is shown in Figure 1. Supposing that a sentence is composed of n words $[w_1, w_2, ..., w_n]$. For each word w_i consists of l_i characters $[c_1, c_2, ..., c_{l_i}]$ and l_i is the length of w_i. We embed all words and characters into low-dimensional real-value vectors which can be learned by language model (Bengio et al., 2003; Mikolov et al., 2013). We represent sentence as a matrix of word embeddings $W = [E_1, E_2, ..., E_n] \in R^{n \times d_w}$. Similarly, word w_i is denoted as a matrix of character embeddings $C_i \in R^{l_i \times d_c}$, and d_w and d_c are the size of word embedding and character embedding respectively.

First, we design a hierarchical two-layer architecture where each layer includes a multi-layer bidirectional Gated Recurrent Units (MBi-GRU). GRU is good at modeling a sequence with the benefits of avoiding the gradient vanishing and exploding problems. For a MBi-GRU, supposing that it has M layers of Bi-GRU, the hidden state on layer $m \in \{1, 2, ..., m\}$ at time $t \in \{1, 2, ..., n\}$ is recursively computed by:

$$h_t^m = \text{BiGRU}(h_t^{m-1}, h_{t-1}^m). \tag{1}$$

where the superscript of h denotes the corresponding layer of a MBi-GRU, and h^0 means the original inputs. BiGRU is bidirectional GRU which is defined as:

$$\text{BiGRU}(x_t, h_{t-1}) = \overrightarrow{h_t} \oplus \overleftarrow{h_t}; \tag{2}$$

$$\overrightarrow{h_t} = \text{GRU}(x_t, \overrightarrow{h_{t-1}}); \tag{3}$$

$$\overleftarrow{h_t} = \text{GRU}(x_t, \overleftarrow{h_{t-1}}). \tag{4}$$

where x_t is inputs which can be word embeddings or the hidden states of other BiGRU. $\oplus$ indicates the operation of concatenating two vectors.

With the matrix of character embeddings C_i as inputs, we utilize a MBi-GRU to learn character-level abstract features for word w_i based on its character embeddings. Through MBi-GRU, we can obtain the hidden states $[h_1^M, h_2^M, ..., h_{l_i}^M]$ on which a max-pooling operation is applied to output the character-level features $r_i \in R^{2d_c}$ for word w_i. The character features of all words in a sentence form a new matrix $C \in R^{n \times 2d_c}$. Next, We concatenate C with the matrix of word embeddings W and denote the concatenation as $F \in R^{n \times (d_w + 2d_c)}$. With F as input, We utilize another MBi-GRU to learn the hidden states $H = [h'^M_1, h'^M_2, ..., h'^M_n]$ as the final representations of the sentence. Therefore, the hierarchical two-layer MBi-GRU architecture can learn high-level abstract features with consideration of both character-level and word-level information.

After learning the final representations for sentence, we first project the features: $tf_i = h'^M_i$ of each word into target label space by:

$$y_t^i = f(tf_i \cdot W_p^t + b_p^t) \tag{5}$$

where W_p^t and b_p^t are weight matrix and bias.

As we know, the boundary of a target should be the same as that of its sentiment in sequence label. As the example in Section 1, the target label and sentiment label of *Michael Jordan* are "**B**-Person, **I**-Person" and "**B**-Positive, **I**-Positive" respectively. To learn this kind of consistency, we introduce the target label information into predicting sentiment label by:

$$y_s^i = f(sf_i \cdot W_p^s + b_p^s) \tag{6}$$

where $sf_i = h'^M_i \oplus y_t^i$, W_s^t and b_s^t are weight matrix and bias respectively. This makes our model know the target label information when predicting their sentiment.

For sequence labeling, there usually exist dependencies between labels. Take the target labeling task for example, label *I* will never follow label

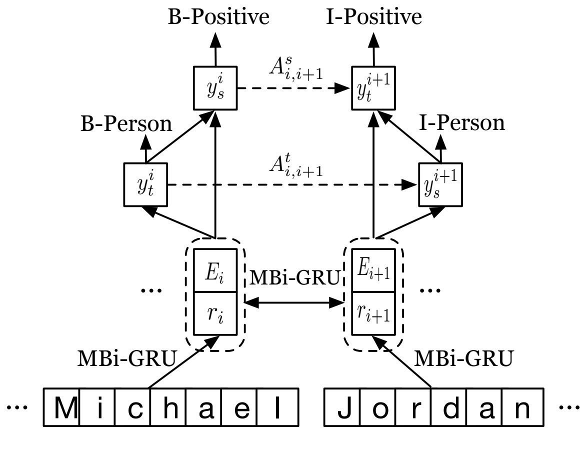

Figure 1: The overall architecture of our model.

O. To consider the influence of label dependencies, we introduce the transition matrix $A_{i,j}$ proposed by Collobert et al. (2011) which measures the probability of jumping from label i to label j.

Given the sentence $x = [w_1, w_2, ..., w_n]$ and the scores $y_t = [y_t^1, y_t^2, ..., y_t^n]$ and $y_s = [y_s^1, y_s^2, ..., y_s^n]$ computed by Eq. 5 and Eq. 6, we get the target labeling scores by summing up transition scores and the scores y_t^i:

$$s(y_t, x, \theta_t) = \sum\nolimits_{i=1}^{n} (A^t_{i-1,i} + y_t^i); \qquad (7)$$

where A^t is label transition matrix for target labeling. $\theta_t = \theta \cup \{A^t_{i,j}\}$, and θ denotes parameters of HMBi-GRUs.

Next, we normalize the target label scores over all possible labeling paths of target (i.e., Y_t) by a softmax function:

$$p_t(y_t|x) = \frac{e^{s(y_t,x,\theta_t)}}{\sum_{\hat{y}_t \in Y_t} e^{s(\hat{y}_t,x,\theta_t)}}; \qquad (8)$$

We can also use Eq. 7 and Eq. 8 to get the normalized sentiment label scores $p_s(y_s|x)$. To train our model, we define the loss function by:

$$\text{loss} = -\log(p_t(y_t|x)) - \log(p_s(y_s|x)). \qquad (9)$$

Finally, we obtain targets label sequence y_t^* and their sentiment label sequence y_s^* which have maximal score $y_t^* = \arg\max_{\hat{y} \in Y_t}(s(x, \hat{y}, \theta_t))$ $y_s^* = \arg\max_{\hat{y} \in Y_s}(s(x, \hat{y}, \theta_s))$. y_t^* and y_s^* can be computed by *Viterbi* algorithm.

3 Experiments

3.1 Setup

To validate the effectiveness of our model, we conduct experiments on two datasets, consisting of English tweets and Spanish tweets, which are constructed by Mitchell et al. (2013)[1]. Table 2 depicts the statistics of data, which contains sentence number, target number and the number of positive target, negative target and neutral target. To evaluate the system performance, we adopt *Precision*, *Recall* and *F-measure*. In our experiments, we evaluate the performance of detecting targets (DT) and targeted sentiment analysis (TSA) which a target is taken as correct only when the boundary and the sentiment are both correctly recognized. We also adopt *Precision*, *Recall* and *F-measure* used in Zhang et al. (2015) to evaluate our model. The reason why we don't compare with Mitchell et al. (2013) is that they only evaluate the beginning of targets along with the sentiment expressed towards it.

Datasets	#Sent	#Target	#Pos	#Neg	#Neu
English	2350	3288	707	275	2306
Spanish	5145	6658	1555	1007	4096

Table 1: Statistics of Datasets.

In our experiments, we use embeddings from Pennington et al. (2014)[2] and Cieliebak et al. (2017)[3] for English words and Spanish words respectively. The character embeddings are initialized by Xavier (Glorot and Bengio, 2010) and their dimension is 50. In our model, all unknown words, weight matrices and biases are initialized by Xavier Glorot and Bengio (2010). The dimensions of the character-level and word-level hidden states in MBi-GRU are set to 300 and 600 respectively. The layer number of multi-layer bidirectional GRU is set to 2. To avoid overfitting, we adopt dropout on embeddings, sf_i and tf_i, and the dropout rate is set to 0.5. The word embeddings and character embeddings will be tuned during training. Finally, we utilize Adam (Kingma and Ba, 2014) to optimize all parameters of our model.

3.2 Baselines

To investigate the performance of our joint model, we compare it with several baselines as follows:

- **Discrete** uses traditional discrete features as

Table 2: Performance comparison of our models with the baselines.

inputs and multi-label CRF which contains two separate output clique potentials and two separate edge clique potentials for target extraction and sentiment classification respectively. There also exist links between target labels and sentiment labels for each word (Zhang et al., 2015).

- **Neural** uses word embeddings transformed with non-linear function as inputs, and others are the same as *Discrete* model (Zhang et al., 2015).

- **Integrated** integrates both discrete features and word embeddings into the same CRF framework and other settings are the same as *Discrete* (Zhang et al., 2015).

- **Bi-GRU** only uses word embeddings as inputs, and Bi-GRU is employed to learn representations for sentence.

- **MBi-GRU** also uses word embeddings as inputs, but MBi-GRU is utilized to model sentence.

- **HBi-GRU** first uses Bi-GRU to learn character level features for each word. Then, character level features and word embeddings are concatenated as inputs for another Bi-GRU to learn final representations for sentence.

- **No-Target** uses HMBi-GRU to learn representations for sentence, but h'^{M}_{i} (depicted in Section 2) are used to predict target label and sentiment label separately. *No-Target* doesn't let target label information to affect sentiment label. This is the biggest difference between *No-Target* and ours.

It is noticed that all of *Bi-GRU*, *MBi-GRU* and *HBi-GRU* use transition matrix to model the dependencies between labels and introduce target label information into predicting sentiment label.

3.3 Analysis

Table 2 displays the performance comparison of our models with the baselines. We can see that *Discrete* gets the worst results on English dataset, and *Neural* gets the worst results on Spanish dataset. The *Integrate* greatly improves the performances on both datasets because discrete features and word embeddings can complement each other.

Bi-GRU greatly improves the performance compared with *Discrete* and *Neural* but gets worse performance than *Integrate*. This verifies the effectiveness of neural networks in TAS. However, simple neural networks are not enough to acquire better results. *MBi-GRU* learns high-level features via multi-layer bidirectional GRU and achieves comparable results compared with *Integrate*.

Nevertheless, *Bi-GRU* and *MBi-GRU* do not make full use of character-level features. *HBi-GRU* incorporates character-level features by Bi-GRU on letter sequence of word. We can see that *HBi-GRU* improves about 1.85% and 1.16% in TSA on both datasets compared with *Integrate*. The performance of *HBi-GRU* demonstrates the importance of character-level features in TSA, and the hierarchical architecture is good at leaning multi-level (character-level, word-level) features.

Our model improves 3.20%, 2.59% in TSA and 2.39%, 0.27% in DT on both datasets compared with the existing best system: *Integrate*. Compared with *No-Target*, our model introduces target label information into predicting sentiment label and improves about 0.66%, 1.44% in TSA and 0.59%, 0.91% in DT on both datasets. The improvements demonstrate that target label information plays important roles in predicting sentiment label. It is noticed that the results of our model in

DT are also improved compared with *No-Target*. The reason may be that the gradients from sentiment loss have positive effects on detecting targets.

In a word, our model achieves state-of-the-art in DT and TSA on both datasets. Character-level features play great roles in DT and TSA, and HMBi-GRU is good at learning multi-level features. It is useful to learn boundary consistence by introducing target label information into predicting sentiment label.

3.4 Case Study

Here, we use a tweet from English Dataset as a case study, and the tweet is "Congratulations to our Champ Roger Federer ...". We apply *No-Target* and our model on the tweet. *No-Target* and our model get the same target labels: [O,O,O,O,B-Person,I-Person,...], and we can see that both models correctly extract the target: *Roger Federer*, and this results show the effectiveness of both models in detecting targets. Our model successfully obtains the correct sentiment labels: [O,O,O,O,B-Positive,I-Positive,...]. However, *No-Target* predicts a wrong sentiment label sequence: [O,O,O,B-Positive,I-Positive,O,...]. We can see that *No-Target* wrongly regard *Champ* as the beginning position and ignore *Federer*. The reasons are that the first letter of Champ is capitalized, which may mislead No-Target and there is no correlation between target and sentiment label. In our model, we incorporate target label information into predicting sentiment label. Therefore, our model tends to force target and sentiment label to have same boundary information.

This case study shows that the target label information plays important roles in predicting sentiment label because they share the same boundary information.

4 Related Work

Early works on target sentiment analysis were based on subjects and features. For example, Yi et al. (2003) extracted all references to the given subject and determined the sentiment of each reference. Hu and Liu (2004) first proposed several techniques to mine the product features that customers have expressed their opinions and determined their sentiment, and Popescu and Etzioni (2007) utilized unsupervised methods to identify opinions with respect to features and determine the polarity of opinions. Jin et al. (2009) proposed a novel lexicalized HMMs model to mine customer reviews of a product and extract highly specific product related entities which reviewers expressed their opinion, and they also identified the sentiment of opinion entities. The works of (Yang and Cardie, 2013) and (Li et al., 2010) are similar to (Jin et al., 2009). However, these works only take pre-defined features into account and can not find new features. To automatically extract targets and predict their sentiment, Mitchell et al. (2013) first proposed a conditional random fields (CRF) framework to jointly detect entities and identify their sentiment. Based on the work of (Mitchell et al., 2013), Zhang et al. (2015) explored the effect of word embeddings and automatic feature combinations by extending a CRF baseline using neural networks.

We propose a neural networks based joint model which extracts targets and their sentiments simultaneously. Our model takes full advantages of neural networks' potential in capturing sequence labeling features such as long distance dependencies and character-level features. Furthermore, Our model allows the target label to have positive effects on their sentiment label because target label shares boundary information with sentiment label.

5 Conclusion

In this paper, we propose a HMBi-GRU based joint model for targeted sentiment analysis. Our model will simultaneously extract targets and predict their sentiment. Furthermore, our model introduces target information into predicting corresponding sentiment label. Experiments show that the well-designed neural networks can greatly improve the result for targeted sentiment analysis, and target label information plays great roles in predicting sentiment label.

Abstract

We analyze the performance of different sentiment classification models on syntactically-complex inputs like *A-but-B* sentences. The first contribution of this analysis addresses reproducible research: to meaningfully compare different models, their accuracies must be averaged over far more random seeds than what has traditionally been reported. With proper averaging in place, we notice that the distillation model described in Hu et al. (2016), which incorporates explicit logic rules for sentiment classification, is ineffective. In contrast, using contextualized ELMo embeddings (Peters et al., 2018a) instead of logic rules yields significantly better performance. Additionally, we provide analysis and visualizations that demonstrate ELMo's ability to implicitly learn logic rules. Finally, a crowdsourced analysis reveals how ELMo outperforms baseline models even on sentences with ambiguous sentiment labels.

1 Introduction

In this paper, we explore the effectiveness of methods designed to improve sentiment classification (positive vs. negative) of sentences that contain complex syntactic structures. While simple bag-of-words or lexicon-based methods (Pang and Lee, 2005; Wang and Manning, 2012; Iyyer et al., 2015) achieve good performance on this task, they are unequipped to deal with syntactic structures that affect sentiment, such as contrastive conjunctions (i.e., sentences of the form *"A-but-B"*) or negations. Neural models that explicitly encode word order (Kim, 2014), syntax (Socher et al., 2013; Tai et al., 2015) and semantic features (Li et al., 2017) have been proposed with the aim of improving performance on these more complicated sentences. Recently, Hu et al. (2016) incorporate logical rules into a neural model and show that these rules increase the model's accuracy on sentences containing contrastive conjunctions, while Peters et al. (2018a) demonstrate increased overall accuracy on sentiment analysis by initializing a model with representations from a language model trained on millions of sentences.

In this work, we carry out an in-depth study of the effectiveness of the techniques in Hu et al. (2016) and Peters et al. (2018a) for sentiment classification of complex sentences. Part of our contribution is to identify an important gap in the methodology used in Hu et al. (2016) for performance measurement, which is addressed by averaging the experiments over several executions. With the averaging in place, we obtain three key findings: (1) the improvements in Hu et al. (2016) can almost entirely be attributed to just one of their two proposed mechanisms and are also less pronounced than previously reported; (2) contextualized word embeddings (Peters et al., 2018a) incorporate the "A-but-B" rules more effectively without explicitly programming for them; and (3) an analysis using crowdsourcing reveals a bigger picture where the errors in the automated systems have a striking correlation with the inherent sentiment-ambiguity in the data.

2 Logic Rules in Sentiment Classification

Here we briefly review background from Hu et al. (2016) to provide a foundation for our reanalysis in the next section. We focus on a logic rule for sentences containing an *"A-but-B"* structure (the only rule for which Hu et al. (2016) provide experimental results). Intuitively, the logic rule for such sentences is that the sentiment associated with the whole sentence should be the same as the sentiment associated with phrase *"B"*.[1]

---

[1] The rule is vacuously true if the sentence does not have this structure.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4743–4751
Brussels, Belgium, October 31 - November 4, 2018.

More formally, let $p_\theta(y|x)$ denote the probability assigned to the label $y \in \{+,-\}$ for an input x by the baseline model using parameters θ. A logic rule is (softly) encoded as a variable $r_\theta(x,y) \in [0,1]$ indicating how well labeling x with y satisfies the rule. For the case of *A-but-B* sentences, $r_\theta(x,y) = p_\theta(y|B)$ if x has the structure *A-but-B* (and 1 otherwise). Next, we discuss the two techniques from Hu et al. (2016) for incorporating rules into models: *projection*, which directly alters a trained model, and *distillation*, which progressively adjusts the loss function during training.

Projection. The first technique is to *project a trained model into a rule-regularized subspace*, in a fashion similar to Ganchev et al. (2010). More precisely, a given model p_θ is projected to a model q_θ defined by the optimum value of q in the following optimization problem:[2]

$$\min_{q,\xi\geq 0} \mathrm{KL}(q(X,Y)||p_\theta(X,Y)) + C\sum_{x\in X}\xi_x$$
$$\text{s.t. } \left(1 - \mathbb{E}_{y\leftarrow q(\cdot|x)}[r_\theta(x,y)]\right) \leq \xi_x$$

Here $q(X,Y)$ denotes the distribution of (x,y) when x is drawn uniformly from the set X and y is drawn according to $q(\cdot|x)$.

Iterative Rule Knowledge Distillation. The second technique is to transfer the domain knowledge encoded in the logic rules into a neural network's parameters. Following Hinton et al. (2015), a "student" model p_θ can learn from the "teacher" model q_θ, by using a loss function $\pi H(p_\theta, P_{\text{true}}) + (1-\pi)H(p_\theta, q_\theta)$ during training, where P_{true} denotes the distribution implied by the ground truth, $H(\cdot,\cdot)$ denotes the cross-entropy function, and π is a hyperparameter. Hu et al. (2016) computes q_θ after every gradient update by projecting the current p_θ, as described above. Note that both mechanisms can be combined: After fully training p_θ using the iterative distillation process above, the projection step can be applied one more time to obtain q_θ which is then used as the trained model.

Dataset. All of our experiments (as well as those in Hu et al. (2016)) use the SST2 dataset, a binarized subset of the popular Stanford Sentiment Treebank (SST) (Socher et al., 2013). The dataset includes phrase-level labels in addition to sentence-level labels (see Table 1 for detailed statistics); following Hu et al. (2016), we use both types of labels for the comparisons in Section 3.2. In all other experiments, we use only sentence-level labels, and our baseline model for all experiments is the CNN architecture from Kim (2014).

3 A Reanalysis

In this section we reanalyze the effectiveness of the techniques of Hu et al. (2016) and find that most of the performance gain is due to projection and not knowledge distillation. The discrepancy with the original analysis can be attributed to the relatively small dataset and the resulting variance across random initializations. We start by analyzing the baseline CNN by Kim (2014) to point out the need for an averaged analysis.

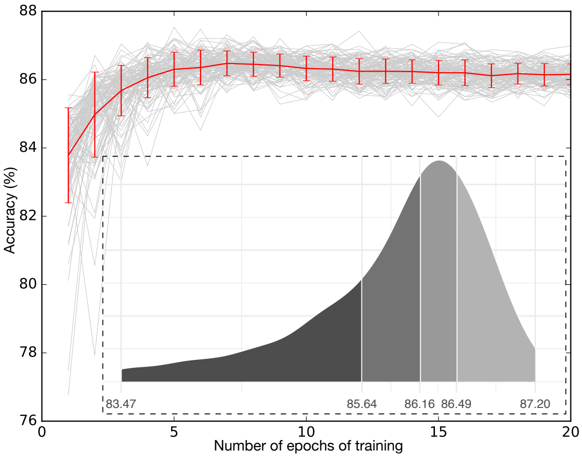

Figure 1: Variation in models trained on SST-2 (sentence-only). Accuracies of 100 randomly initialized models are plotted against the number of epochs of training (in gray), along with their average accuracies (in red, with 95% confidence interval error bars). The inset density plot shows the distribution of accuracies when trained with early stopping.

3.1 Importance of Averaging

We run the baseline CNN by Kim (2014) across 100 random seeds, training on sentence-level la-

Number of	Phrases	Train	Dev	Test
Instances	76961	6920	872	1821
A-but-B	3.5%	11.1%	11.5%	11.5%
Negations	2.0%	17.5%	18.3%	17.2%
Discourse	5.0%	24.6%	26.0%	24.5%

Table 1: Statistics of SST2 dataset. Here "Discourse" includes both *A-but-B* and negation sentences. The mean length of sentences is in terms of the word count.

---

[2] The formulation in Hu et al. (2016) includes another hyperparameter λ per rule, to control its relative importance; when there is only one rule, as in our case, this parameter can be absorbed into C.

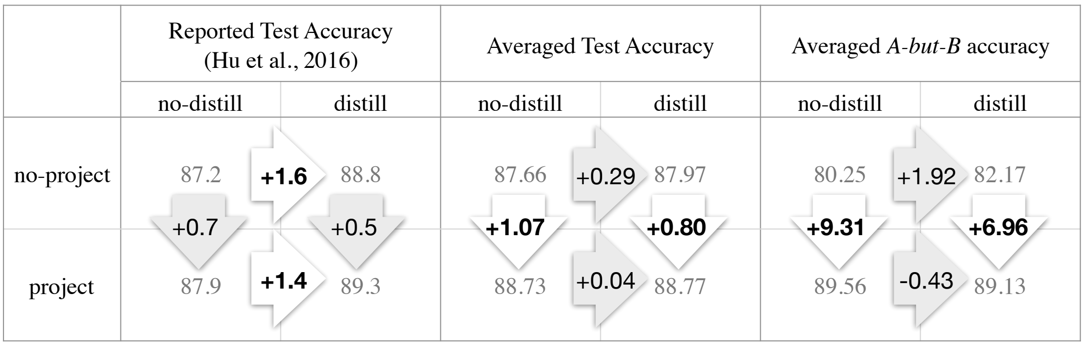

Figure 2: Comparison of the accuracy improvements reported in Hu et al. (2016) and those obtained by averaging over 100 random seeds. The last two columns show the (averaged) accuracy improvements for *A-but-B* style sentences. All models use the publicly available implementation of Hu et al. (2016) trained on phrase-level SST2 data.

bels. We observe a large amount of variation from run-to-run, which is unsurprising given the small dataset size. The inset density plot in Figure 1 shows the range of accuracies (83.47 to 87.20) along with 25, 50 and 75 percentiles.[3] The figure also shows how the variance persists even after the average converges: the accuracies of 100 models trained for 20 epochs each are plotted in gray, and their average is shown in red.

We conclude that, to be reproducible, only averaged accuracies should be reported in this task and dataset. This mirrors the conclusion from a detailed analysis by Reimers and Gurevych (2017) in the context of named entity recognition.

3.2 Performance of Hu et al. (2016)

We carry out an averaged analysis of the publicly available implementation[4] of Hu et al. (2016). Our analysis reveals that the reported performance of their two mechanisms (projection and distillation) is in fact affected by the high variability across random seeds. Our more robust averaged analysis yields a somewhat different conclusion of their effectiveness.

In Figure 2, the first two columns show the reported accuracies in Hu et al. (2016) for models trained with and without distillation (corresponding to using values $\pi = 1$ and $\pi = 0.95^t$ in the t^{th} epoch, respectively). The two rows show the results for models with and without a final projection into the rule-regularized space. We keep our hyper-parameters identical to Hu et al. (2016).[5]

The baseline system (no-project, no-distill) is identical to the system of Kim (2014). All the systems are trained on the phrase-level SST2 dataset with early stopping on the development set. The number inside each arrow indicates the improvement in accuracy by adding either the projection or the distillation component to the training algorithm. Note that the reported figures suggest that while both components help in improving accuracy, the distillation component is much *more* helpful than the projection component.

The next two columns, which show the results of repeating the above analysis after averaging over 100 random seeds, contradict this claim. The averaged figures show lower overall accuracy increases, and, more importantly, they attribute these improvements almost entirely to the projection component rather than the distillation component. To confirm this result, we repeat our averaged analysis restricted to only *"A-but-B"* sentences targeted by the rule (shown in the last two columns). We again observe that the effect of projection is pronounced, while distillation offers little or no advantage in comparison.

4 Contextualized Word Embeddings

Traditional context-independent word embeddings like `word2vec` (Mikolov et al., 2013) or `GloVe` (Pennington et al., 2014) are fixed vectors for every word in the vocabulary. In contrast, contextualized embeddings are dynamic representations, dependent on the current context of the word. We hypothesize that contextualized word embeddings might inherently capture these logic rules due to increasing the effective context size for the CNN layer in Kim (2014). Following the recent success of ELMo (Peters et al., 2018a) in sentiment analysis, we utilize the TensorFlow Hub implementation of ELMo[6] and feed these contextualized embeddings into our CNN model. We

---

[3] We use early stopping based on validation performance for all models in the density plot.

[4] `https://github.com/ZhitingHu/logicnn/`

[5] In particular, $C = 6$ for projection.

[6] `https://tfhub.dev/google/elmo/1`

fine-tune the ELMo LSTM weights along with the CNN weights on the downstream CNN task. As in Section 3, we check performance with and without the final projection into the rule-regularized space. We present our results in Table 2.

Switching to ELMo word embeddings improves performance by 2.9 percentage points on an average, corresponding to about 53 test sentences. Of these, about 32 sentences (60% of the improvement) correspond to *A-but-B* and negation style sentences, which is substantial when considering that only 24.5% of test sentences include these discourse relations (Table 1). As further evidence that ELMo helps on these specific constructions, the non-ELMo baseline model (no-project, no-distill) gets 255 sentences wrong in the test corpus on average, only 89 (34.8%) of which are *A-but-B* style or negations.

Statistical Significance: Using a two-sided Kolmogorov-Smirnov statistic (Massey Jr, 1951) with $\alpha = 0.001$ for the results in Table 2, we find that ELMo and projection each yield statistically significant improvements, but distillation does not. Also, with ELMo, projection is not significant. Specific comparisons have been added in the Appendix, in Table A3.

KL Divergence Analysis: We observe no significant gains by projecting a trained ELMo model into an *A-but-B* rule-regularized space, unlike the other models. We confirm that ELMo's predictions are much closer to the *A-but-B* rule's manifold than those of the other models by computing $\mathrm{KL}(q_\theta || p_\theta)$ where p_θ and q_θ are the original and projected distributions: Averaged across all *A-but-B* sentences and 100 seeds, this gives $0.27, 0.26$ and 0.13 for the Kim (2014), Hu et al. (2016) with distillation and ELMo systems respectively.

Intra-sentence Similarity: To understand the information captured by ELMo embeddings for *A-but-B* sentences, we measure the cosine similarity between the word vectors of every pair of words within the *A-but-B* sentence (Peters et al., 2018b). We compare the intra-sentence similarity for fine-tuned `word2vec` embeddings (baseline), ELMo embeddings without fine-tuning and finally fine-tuned ELMo embeddings in Figure 3. In the fine-tuned ELMo embeddings, we notice the words within the *A* and within the *B* part of the *A-but-B* sentence share the same part of the vector space. This pattern is less visible in the ELMo embeddings without fine-tuning and absent in the `word2vec` embeddings. This observation is indicative of ELMo's ability to learn specific rules for *A-but-B* sentences in sentiment classification. More intra-sentence similarity heatmaps for *A-but-B* sentences are in Figure A1.

Model		Test	*but*	*but* or *neg*
no-distill	no-project	85.98	78.69	80.13
no-distill	project	86.54	83.40	-
distill [7]	no-project	86.11	79.04	-

ELMo	no-project	88.89	86.51	87.24
ELMo	project	88.96	87.20	-

Table 2: Average performance (across 100 seeds) of ELMo on the SST2 task. We show performance on *A-but-B* sentences ("*but*"), negations ("*neg*").

5 Crowdsourced Experiments

We conduct a crowdsourced analysis that reveals that SST2 data has significant levels of ambiguity even for human labelers. We discover that ELMo's performance improvements over the baseline are robust across varying levels of ambiguity, whereas the advantage of Hu et al. (2016) is reversed in sentences of low ambiguity (restricting to *A-but-B* style sentences).

Our crowdsourced experiment was conducted on Figure Eight.[8] *Nine* workers scored the sentiment of each *A-but-B* and negation sentence in the test SST2 split as 0 (negative), 0.5 (neutral) or 1 (positive). (SST originally had *three* crowdworkers choose a sentiment rating from 1 to 25 for every phrase.) More details regarding the crowd experiment's parameters have been provided in Appendix A.

We average the scores across all users for each sentence. Sentences with a score in the range $(x, 1]$ are marked as positive (where $x \in [0.5, 1)$), sentences in $[0, 1-x)$ marked as negative, and sentences in $[1-x, x]$ are marked as neutral. For instance, "*flat , but with a revelatory performance by michelle williams*" (score=0.56) is neutral when $x = 0.6$.[9] We present statistics of our dataset[10] in Table 3. Inter-annotator agree-

---

[7] Trained on sentences and not phrase-level labels for a fair comparison with baseline and ELMo, unlike Section 3.2.

[8] `https://www.figure-eight.com/`

[9] More examples of neutral sentences have been provided in the Appendix in Table A1, as well as a few "flipped" sentences receiving an average score opposite to their SST2 label (Table A2).

[10] The dataset along with source code can be found in

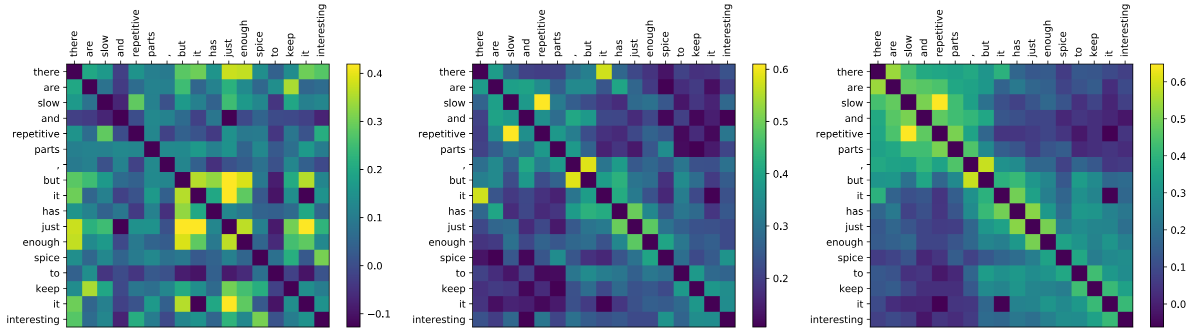

Figure 3: Heat map showing the cosine similarity between pairs of word vectors within a single sentence. The left figure has fine-tuned `word2vec` embeddings. The middle figure contains the original ELMo embeddings without any fine-tuning. The right figure contains fine-tuned ELMo embeddings. For better visualization, the cosine similarity between identical words has been set equal to the minimum value in the heat map.

ment was computed using Fleiss' Kappa (κ). As expected, inter-annotator agreement is higher for higher thresholds (less ambiguous sentences). According to Landis and Koch (1977), $\kappa \in (0.2, 0.4]$ corresponds to "fair agreement", whereas $\kappa \in (0.4, 0.6]$ corresponds to "moderate agreement".

We next compute the accuracy of our model for each threshold by removing the corresponding neutral sentences. Higher thresholds correspond to sets of less ambiguous sentences. Table 3 shows that ELMo's performance gains in Table 2 extends across all thresholds. In Figure 4 we compare all the models on the *A-but-B* sentences in this set. Across all thresholds, we notice trends similar to previous sections: 1) ELMo performs the best among all models on *A-but-B* style sentences, and projection results in only a slight improvement; 2) models in Hu et al. (2016) (with and without distillation) benefit considerably from projection; but 3) distillation offers little improvement (with or without projection). Also, as the ambiguity threshold increases, we see decreasing gains from projection on all models. In fact, beyond the 0.85 threshold, projection degrades the average performance, indicating that projection is useful for more ambiguous sentences.

Threshold	0.50	0.66	0.75	0.90
Neutral Sentiment	10	70	95	234
Flipped Sentiment	15	4	2	0
Fleiss' Kappa (κ)	0.38	0.42	0.44	0.58
no-distill, no-project	81.32	83.54	84.54	87.55
ELMo, no-project	87.56	90.00	91.31	93.14

Table 3: Number of sentences in the crowdsourced study (447 sentences) which got marked as neutral and which got the opposite of their labels in the SST2 dataset, using various thresholds. Inter-annotator agreement is computed using Fleiss' Kappa. Average accuracies of the baseline and ELMo (over 100 seeds) on non-neutral sentences are also shown.

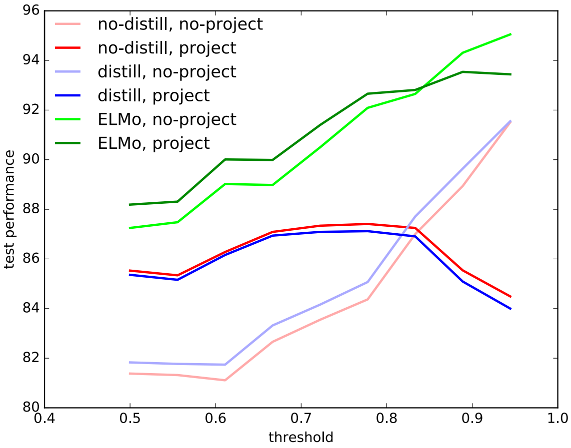

Figure 4: Average performance on the *A-but-B* part of the crowd-sourced dataset (210 sentences, 100 seeds)). For each threshold, only non-neutral sentences are used for evaluation.

6 Conclusion

We present an analysis comparing techniques for incorporating logic rules into sentiment classification systems. Our analysis included a meta-study highlighting the issue of stochasticity in performance across runs and the inherent ambiguity in the sentiment classification task itself, which was tackled using an averaged analysis and a crowdsourced experiment identifying ambiguous sentences. We present evidence that a recently proposed contextualized word embedding model (ELMo) (Peters et al., 2018a) implicitly learns logic rules for sentiment classification of complex sentences like *A-but-B* sentences. Future work includes a fine-grained quantitative study of ELMo word vectors for logically complex sentences along the lines of Peters et al. (2018b).

Appendix

A Crowdsourcing Details

Crowd workers residing in five English-speaking countries (United States, United Kingdom, New Zealand, Australia and Canada) were hired. Each crowd worker had a Level 2 or higher rating on Figure Eight, which corresponds to a “group of more experienced, higher accuracy contributors”. Each contributor had to pass a test questionnaire to be eligible to take part in the experiment. Test questions were also hidden throughout the task and untrusted contributions were removed from the final dataset. For greater quality control, an upper limit of 75 judgments per contributor was enforced.

Crowd workers were paid a total of $1 for 50 judgments. An internal unpaid workforce (including the first and second author of the paper) of 7 contributors was used to speed up data collection.

# Judgments			Average	Sentence
Positive	Negative	Neutral		
1	1	7	0.50	the fight scenes are fun , but it grows tedious
3	2	4	0.56	it 's not exactly a gourmet meal but the fare is fair , even coming from the drive thru
2	3	4	0.44	propelled not by characters but by caricatures
4	2	3	0.61	not everything works , but the average is higher than in mary and most other recent comedies

Table A1: Examples of neutral sentences for a threshold of 0.66

# Judgments			Average	Original	Sentence
Positive	Negative	Neutral			
1	5	3	0.28	Positive	de niro and mcdormand give solid performances , but their screen time is sabotaged by the story 's inability to create interest
6	0	3	0.83	Negative	son of the bride may be a good half hour too long but comes replete with a flattering sense of mystery and quietness
0	5	4	0.22	Positive	wasabi is slight fare indeed , with the entire project having the feel of something tossed off quickly (like one of hubert 's punches) , but it should go down smoothly enough with popcorn

Table A2: Examples of flipped sentiment sentences, for a threshold of 0.66

Model 1		vs	Model 2		Significant
distill	no-project		distill	project	Yes
no-distill	no-project		no-distill	project	Yes
ELMo	no-project		ELMo	project	No
no-distill	no-project		distill	no-project	No
no-distill	project		distill	project	No
no-distill	no-project		ELMo	no-project	Yes
distill	no-project		ELMo	no-project	Yes
no-distill	project		ELMo	project	Yes
distill	project		ELMo	project	Yes

Table A3: Statistical significance using a two-sided Kolmogorov-Smirnov statistic (Massey Jr, 1951) with $\alpha = 0.001$.

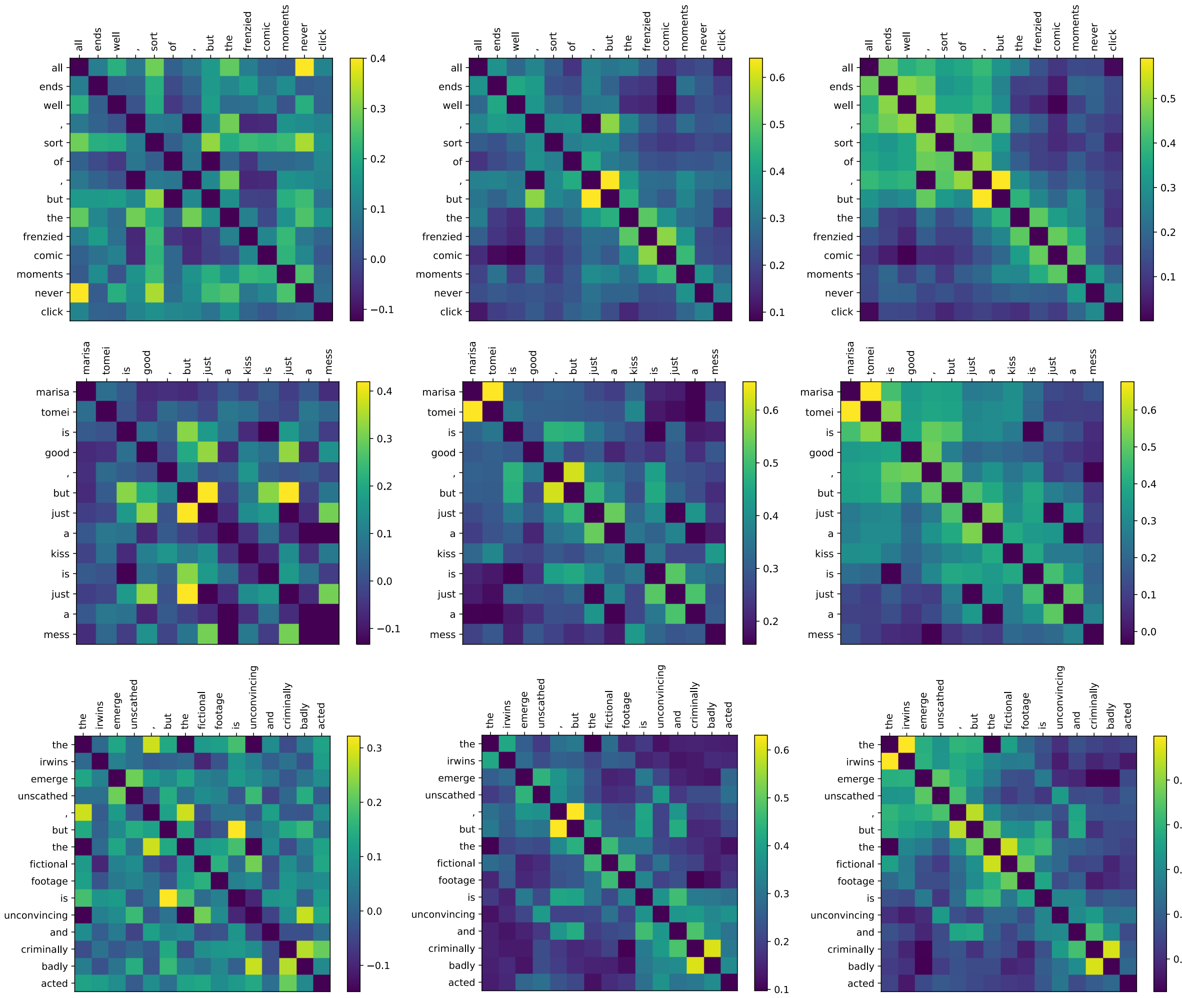

Figure A1: Heat map showing the cosine similarity between pairs of word vectors within a single sentence. The leftmost column has `word2vec` (Mikolov et al., 2013) embeddings, fine-tuned on the downstream task (SST2). The middle column contains the original ELMo embeddings (Peters et al., 2018a) without any fine-tuning. The representations from the three layers (token layer and two LSTM layers) have been averaged. The rightmost column contains ELMo embeddings fine-tuned on the downstream task. For better visualization, the cosine similarity between identical words has been set equal to the minimum value in the map.

A Co-Attention Neural Network Model for Emotion Cause Analysis with Emotional Context Awareness

Xiangju Li[1] **, Kaisong Song**[2] **, Shi Feng**[1] **, Daling Wang**[1] **, Yifei Zhang**[1]

Abstract

Emotion cause analysis has been a key topic in natural language processing. Existing methods ignore the contexts around the emotion word which can provide an emotion cause clue. Meanwhile, the clauses in a document play different roles on stimulating a certain emotion, depending on their content relevance. Therefore, we propose a co-attention neural network model for emotion cause analysis with emotional context awareness. The method encodes the clauses with a co-attention based bi-directional long short-term memory into high-level input representations, which are further fed into a convolutional layer for emotion cause analysis. Experimental results show that our approach outperforms the state-of-the-art baseline methods.

1 Introduction

Emotion cause analysis (ECA) aims to identify the reasons behind a certain emotion expressed in text. Compared with emotion classification (Gao et al., 2013; Song et al., 2016, 2017; Feng et al., 2018), ECA is more challenging because it requires deep comprehension of text semantics and then extracts the cause of emotions accurately. Recently, Gui et al. (2017) considered ECA as a question answer problem and proposed a method which took a query (i.e., a single emotion word) as the input of a QA system. However, their method ignores an important fact that the context around the emotion word details the emotions and serves as an emotion cause clue. Therefore, the emotion clause consisting of the emotion word and its context should be treated as a whole unit for query.

Example 1 *In 2016* (c_1)*, Lakers' Kobe announced his retirement* (c_2)*. In the same year* (c_3)*, Spurs' Duncan also retired* (c_4)*. The Spurs' athletes and Duncan's fans are frustrated* (c_5)*.*

For example, a microblog user published a post in Twitter (see Example 1). From Example 1, we can find that the clause c_5 is the emotion clause which contains the emotion word "*frustrated*" and the clause c_4 is the cause clause of the emotion. However, it is difficult for previous works (Gui et al., 2017) to extract the expected emotion causes by only taking the emotion word "*frustrated*" as a query. In other words, the retirement of Kobe can also stimulate "*frustrated*" emotion, but it is not the cause of the clause c_5. Therefore, the context around the emotion word in the same emotion clause can serve as a useful emotion cause clue for the ECA task. In addition, the words shared by the emotion cause clause and the emotion clause (e.g., "*Spurs*" and "*Duncan*") usually reflect stronger emotion-cause associations and should be paid more attention when modeling.

In this paper, we propose a novel, extensive and effective Co-Attention Neural Network method (CANN) for this ECA task. The method incorporates the contextual information by a bi-directional long short-term memory encoder. Then, an attention matrix is constructed to model the mutual impacts of each candidate cause clause and the whole emotion clause. Meanwhile, the above clauses are paid different attention based on the transformed attention matrix. Finally, a convolutional neural network is utilized for classification. To sum up, the main contributions of our paper are three-fold: (1) We present a novel Co-Attention Neural Network model (CANN), which identifies the emotion cause from subjective texts by combining a co-attention mechanism, bi-directional long short-term memory units and convolutional neural network into a unified framework. (2) A co-attention mechanism is designed to capture the mutual impacts between each candidate cause clause and the emotion clause for enhancing the input representations of a neural network model. (3) Our

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4752–4757
Brussels, Belgium, October 31 - November 4, 2018.

comparative results on a public benchmark dataset show that CANN outperforms several state-of-the-art methods, which verifies the effectiveness of our proposed method.

2 Related Work

A variety of learning methods have been applied to emotion cause analysis and achieved plausible improvements since Lee et al. (2010) first gave the formal definition of this task and constructed a public available Chinese emotion cause annotated corpus based on manual annotation scheme. Chen et al. (2010) developed two sets of linguistic features based on linguistic cues and proposed a rule-based approach. Similarly, Gui et al. (2014) also proposed a rule based emotion cause detection method by designing 25 manually complied rules for this task and Gao et al. (2015) extended this method to deal with informal text such as microblog. Ghazi et al. (2015) built a Conditional Random Fields (CRF) learner to detect the emotion stimulus. However, this model is based on a simplistic assumption that emotion cause and emotion word co-exist in the same sentence, which limits its application scenario. More recently, Gui et al. (2016b) proposed a multi-kernel based method trained from a public SINA city news ECA Corpora. However, this method is still heavily dependent on the design of effective features.

With the apparent success of neural network methods and attention mechanisms, Gui et al. (2017) proposed a novel deep neural networks model which considers emotion cause identification as a question answering task. However, their method only takes a single emotion word as the query, which ignores important emotion-cause clues. Meanwhile, their method fails to utilize the mutual influences between each candidate cause clause and the emotion clause, which will depress the model performance. To address these issues, we propose a novel CANN model which not only considers the whole emotion clause as a query but also models the mutual influences between the candidate cause clause and the whole emotion clause via co-attention mechanism.

3 Methodology

In this section, we will first give the formal definition of the emotion cause analysis task. Then, we introduce our proposed method in detail.

3.1 The Definition of Emotion Cause Analysis

Given a document $D = \{c_1, c_2, \cdots, c_n\}$ about an emotion cause event, the goal of this ECA task is to identify which clause stimulates the emotion expression. For convenience, we suppose each document has a unique emotion clause (containing a single emotion word) and at least a corresponding emotion cause clause. Previous work considers emotion cause analysis as a question answering task by taking a single emotion word as a query to retrieve the emotion cause (Gui et al., 2017). This is not applicable to our observation that context around the emotion word in the same clause can serve as an important emotion-cause clue. Here, we are intended to take the whole emotion clause (i.e., the emotion word and its context words) as a query. Therefore, the emotion cause analysis task can be formulated as below:

$$P_x = \text{emotion-cause}\left(c^q, c^a\right)$$

where c^q is an emotion clause (i.e., query) and c^a is a candidate emotion cause clause (i.e., candidate answer)[1]. The probability P_x of identifying the clause c^a as the emotion cause of the emotion clause c^q is computed by the emotion-cause function ($x = 1$ if c^a stimulates the emotion expressed in the c^q, or $x = 0$ otherwise).

3.2 Co-Attention Neural Network for Emotion Cause Analysis

In this section, we propose a Co-Attention Neural Network (CANN) method, which contains four different layers: (1) an embedding layer for the input words; (2) a bi-directional long short-term memory (Bi-LSTM) layer; (3) a co-attention layer for generating the attention maps of the emotion clause and the candidate cause clause; and (4) a convolutional neural network layer to generate a probability distribution over the output classes. Figure 1 illustrates the details of our CANN.

(1) The embedding layer maps each word w_i into a d-dimensional vector $v_i \in \mathbb{R}^d$. Then, the clause c^q can be represented as a feature map $E^q = [v_1^q, v_2^q, ..., v_n^q]$. Symmetrically, we can also produce E^a for the emotion cause clause c^a.

(2) Bi-LSTM layer aims to encode contextual information with a Bi-LSTM (Wang et al., 2016). Let v_t^q be the t-th word vectors of the clause c^q. Each contextual embedding at time-step t of c^q can be formulated as $h_t^q = concat(\overrightarrow{h}_t^q, \overleftarrow{h}_t^q)$, where

---

[1] Note that the emotion clause c^q and the emotion cause clause c^a can be the same clause.

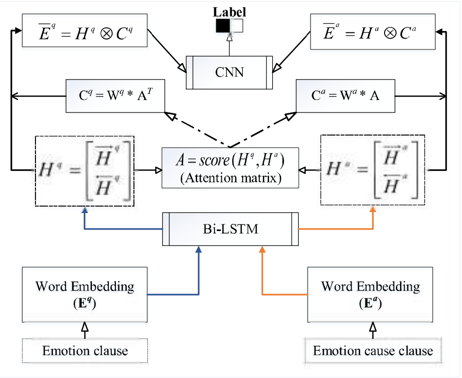

Figure 1: CANN architecture for ECA task.

$concat(\cdot,\cdot)$ is a concatenation operation, $\overrightarrow{h}_t^q = \overrightarrow{LSTM}(\overrightarrow{h}_{t-1}^q, v_t^q)$ and $\overleftarrow{h}_t^q = \overleftarrow{LSTM}(\overleftarrow{h}_{t+1}^q, v_t^q)$ are hidden states produced by a forward LSTM and a backward LSTM, respectively. Finally, a context embedding matrix $H^q \in \mathbb{R}^{n\times 2h}$ of the clause c^q can be obtained by concatenating all the context embeddings, where h is the number of hidden units. Similarly, we can also generate H^a for the emotion cause clause c^a.

(3) Co-attention layer contains three steps: construction of attention matrix, construction of attention feature maps and input transformation.

Firstly, we construct an attention matrix $A \in \mathbb{R}^{n\times n}$ which models mutual influences between the c^q and c^a via a measurement function: $A = score\big(H^q, H^a\big)$. Element $A_{i,j}$ represents the semantic similarity between the i-th word of the clause c^q and the j-th word of the c^a clause[2].

Next, two attention feature maps $C^q \in \mathbb{R}^{2h\times n}$ and $C^a \in \mathbb{R}^{2h\times n}$ can be derived from linearly transformed attention matrix A: $C^q = W^q \cdot A^\top$ and $C^a = W^a \cdot A$, where $W^q \in \mathbb{R}^{2h\times n}$ and $W^a \in \mathbb{R}^{2h\times n}$ are weight matrices.

Finally, we apply the attention feature maps to the original representations of c^q and c^a respectively: $\bar{E}^q = H^q \otimes C^q$, $\bar{E}^a = H^a \otimes C^a$.[3] They will be fed into CNN layer for future operations.

(4) In CNN layer, we applied three convolution filters with lengths 2, 3 and 4, each of which is followed by a max pooling operation to select most informative features. Two high-level feature vectors z^q and z^a are generated and then concatenated as the inputs of a fully interconnected softmax layer before classification.

Model Training: We use cross-entropy error between gold distribution and predicted distribution as the loss function. We use back-propagation to calculate the gradients of all the trainable parameters and update them with Adam (Kingma and Ba, 2015).

4 Experiments and Results

4.1 Dataset and Setup

Our experiments are conducted based on a Chinese emotion cause dataset[4]. The statistics are presented in Table 1. We evaluate the performance by precision (*P*), recall (*R*), and F-measure (*F*), which are commonly used evaluation metrics (Gui et al., 2016a). We set the number hidden units $h = 50$, the number of filters as $N = 100$, the dimension of word embedding $d = 30$, the initial learning rate $lr = 10^{-4}$, the dropout rate $p = 0.5$ and the batch size as 50 according to the best F value on the development set which is set aside 10% from the training set.

Item	Number	Item	Number
#Documents	2,105	#Cause$_1$	2,046
#Causes	2,167	#Cause$_2$	56
#Clauses	11,799	#Cause$_3$	3

Table 1: Statistics of the experimental dataset we used. Cause$_1$, Cause$_2$ and Cause$_3$ represent the documents with 1, 2 and 3 cause clauses, respectively.

4.2 Comparison of Different Methods

We compare CANN with some traditional and advanced baselines in Table 2, and separate results into three groups: (1) rule based or common-sense based methods; (2) machine learning methods; (3) deep neural network methods.

(1) **RB** is a rule based method, which generalizes two sets of linguistic rules for emotion cause analysis (Lee et al., 2010). **CB** is a knowledge based method (Russo et al., 2011), which uses the Chinese Emotion Cognition Lexicon (Xu et al., 2013) as the common-sense knowledge base.

(2) **RB+CB+ML** is a support vector machine (SVM) classifier trained on features including rules (Lee et al., 2010) and the Chinese Emotion Cognition Lexicon (Xu et al., 2013). **SVM** is a SVM classifier trained on unigrams, bigrams and

---

[2] function *score* is the cosine distance

[3] $\otimes$ denotes element-wise product.

[4] Dataset: http://hlt.hitsz.edu.cn/?page%20id=694

Methods	*P*	*R*	*F*
RB$^\diamond$	**0.6747**	0.4287	0.5243
CB$^\diamond$	0.2672	**0.7130**	0.3887
RB + CB$^\diamond$	0.5435	0.5307	**0.5370**
RB + CB + ML$^\diamond$	0.5921	0.5307	0.5597
SVM$^\diamond$	0.4200	0.4375	0.4285
Word2vec$^\diamond$	0.4301	0.4233	0.4136
Multi-kernel$^\diamond$	**0.6588**	**0.6927**	**0.6752**
CNN	0.5307	0.6427	0.5807
ConvMS-Memnet$^\diamond$	0.7076	0.6838	0.6955
CANN	**0.7721**	**0.6891**	**0.7266**

Table 2: Comparison among different methods. The results with superscript $\diamond$ are reported in (Gui et al., 2017). The best results in each group are highlighted.

trigrams features. **Word2vec** uses word representations obtained by Word2vec (Mikolov et al., 2013b) as features and then trains a SVM classifier. **Multi-kernel** (Gui et al., 2016a) uses the multi-kernel method to identify the emotion cause.

(3) **ConvMS-Memnet** is the current state-of-the-art method using the convolutional multiple-slot deep memory network to identify the emotion causes (Gui et al., 2017). **CNN** is the basic convolutional neural network proposed by (Kim, 2014). **CANN** is our co-attention neural network method.

From Group 1 in Table 2, we can observe that RB+CB outperforms RB and CB methods in F, which verifies that RB and CB are complementary to improve the model performance. In Group 2, Multi-kernel performs the best among the machine learning methods because it considers the structured context information, which plays an important role in this task. In Group 3, the best F value is achieved by our proposed CANN, which outperforms the state-of-the-art method ConvMS-Memnet by 3.11%. Meanwhile, the optimal values on P and R are also generated by CANN method. The results imply that considering context around the emotion word is helpful to capture useful emotion clues and detail context information. We can also find that CANN outperforms CNN method by 14.33% in F, which indicates that our co-attention mechanism has a significant positive effect for emotion cause identification by capturing the mutual impacts between the emotion clause (i.e., query) and each candidate cause clause (i.e., candidate answer).

4.3 Effects of Different CANN Components

We further validate the different roles of model components by comparing several sub-networks based on our proposed architectures: **Full** is our proposed CANN method which considers the whole emotion clause as a query unit. **Full-BCA** does not contain the Bi-LSTM encoder and the co-attention mechanism. **Full-CA** does not consider the co-attention mechanism. **Full-EA** only pays attention to the candidate cause clause.

Methods	*P*	*R*	*F*
Full-BCA	0.5307	0.6427	0.5807
Full-CA	0.7209	0.5405	0.6147
Full-EA	0.7714	0.6596	0.7100
Full	**0.7721**	**0.6891**	**0.7266**

Table 3: Effects of different CANN components.

From Table 3, we can find that all the partial configured models cannot compete with the **Full** model indicating that the co-attention mechanism is effective for the emotion cause analysis task. Meanwhile, the F value is improved remarkably when co-attention mechanism is considered. **Full-CA** performs better than **Full-BCA**, which verifies the effectiveness of Bi-LSTM in clause presentation. We also notice that **Full** gains nearly 12% improvements in F compared with **Full-CA** , which indicates that both emotion clause and emotion contribute to acquiring better performance.

4.4 Effects of Emotion Word and Context Words around Emotion Word

In this section, we further study the effects of context words around emotion word in the same emotion clause on the classification performance. **Full** is our proposed CANN method which considers the whole emotion clause as a query unit. **Full-emotion** does not consider the emotion word. **Full-context** only considers emotion word but ignores its context words. We compare above three different configurations of CANN in Table 4.

Methods	*P*	*R*	*F*
Full-emotion	0.6514	0.7203	0.6827
Full-context	0.5534	0.6815	0.6095
Full	**0.6939**	**0.7601**	**0.7240**

Table 4: Effects of emotion word and context words around emotion word.

As shown in Table 4, it is clear that the partial configurations cannot compete with the **Full** model indicating both emotion word and its context words are helpful. Specifically, emotion word can provide emotion clues directly and its context words can provide richer emotional details, both of which contribute to capturing intrinsic emotion causes. **Full-context** performs slightly better than **Full-emotion** because context words reflect the "skeleton" of emotion expression directly, such as "I feel so much _" where the whitespace "_" can be any emotion word (e.g., happy or sad). This verifies the advantages of context words.

4.5 Effects of Initialization Methods

We further study the influences of different initialization ways by applying different word embeddings into the input layer of our CANN method. **Random** initializes word embeddings randomly from a truncated standard normal distribution. **CBOW** and **Skip** represent the word embeddings which are pre-trained respectively by CBOW and Skip-Gram models (Mikolov et al., 2013a) based on the training set and then applied to parameter initialization.

Methods	*P*	*R*	*F*
Random	0.6519	0.5650	0.6022
CBOW	0.7207	**0.7245**	0.7226
Skip	**0.7721**	0.6891	**0.7266**

Table 5: Effects of different initialization methods.

As shown in Table 5, pre-trained initialization methods perform better than random initialization, which indicates that CANN is sensitive to the initial settings of the parameters. Meanwhile, **Skip** method performs slightly better than **CBOW** method by achieving best results in metrics P and F. Therefore, we adopt the pre-trained word embeddings generated by **Skip** method to initialize all the word vectors of our CANN in this work.

4.6 Case Study

In order to validate whether our CANN can focus on the words which describe the emotion causes. We select two clauses ($\mathbf{c_2}$ and $\mathbf{c_4}$) from Example 1 and visualize the attention feature map C^a in Figure 2. The horizontal coordinate represents the different dimensions of each word representation obtained by Bi-LSTM. The vertical coordinate represents the words of the clause. And the color depth represents different degrees of the attention weights of each word in emotion cause clause.

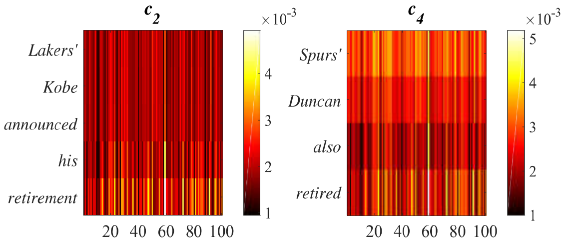

Figure 2: Visualization of Attention.

From Figure 2, we can easily find the word "*retirement*" in the clause $\mathbf{c_2}$ has much higher attention weights than other words in this emotion cause clause, which indicates that the cause is closely related to the word "*retirement*". In the clause $\mathbf{c_4}$, the words "*Spurs'*" and "*Duncan*" also have high attention weights expect "*retired*", which shows that the emotion cause is not only related to "*retirement*" and "*retired*" but also "*Spurs'*" and "*Duncan*". Above all, clause $\mathbf{c_4}$ is more likely to be identified as the emotion cause clause according to our method, which is consistent with our observation. We observe that words like *"Lakers'"*, *"his"* and *"also"* have low attention weights and they are irrelevant to the emotion word *"frustrated"*. These again verify the effectiveness of our proposed attention mechanism on the emotion cause analysis task.

5 Conclusions

This paper proposes an effective Co-Attention Neural Network to identify the emotion causes. The mutual impacts between the emotion clause and each candidate clause are modeled as an attention matrix which further transforms original inputs into high-level input features of a constitutional neural network for classification. Experimental results conducted on a real-word dataset shows that our method achieves substantial improvements against "state-of-the-art" baselines.

Abstract

Computational detection and understanding of empathy is an important factor in advancing human-computer interaction. Yet to date, text-based empathy prediction has the following major limitations: It underestimates the psychological complexity of the phenomenon, adheres to a weak notion of ground truth where empathic states are ascribed by third parties, and lacks a shared corpus. In contrast, this contribution presents the first publicly available gold standard for empathy prediction. It is constructed using a novel annotation methodology which reliably captures empathy assessments by the writer of a statement using multi-item scales. This is also the first computational work distinguishing between multiple forms of empathy, empathic concern, and personal distress, as recognized throughout psychology. Finally, we present experimental results for three different predictive models, of which a CNN performs the best.

1 Introduction

Over two decades after the seminal work by Picard (1997) the quest of *Affective Computing*, to ease the interaction with computers by giving them a sense of how emotions shape our perception and behavior, is still far from being fulfilled. Undoubtedly, major progress has been made in NLP, with sentiment analysis being one of the most vivid and productive areas in recent years (Liu, 2015).

However, the vast majority of contributions has focused on *polarity prediction*, typically only distinguishing between positive and negative feeling or evaluation, usually in social media postings or product reviews (Rosenthal et al., 2017; Socher et al., 2013). Only very recently, researchers started exploring more sophisticated models of human emotion on a larger scale (Wang et al., 2016; Abdul-Mageed and Ungar, 2017; Mohammad and Bravo-Marquez, 2017a; Buechel and Hahn, 2017, 2018a,b). Yet such approaches, often rooted in psychological theory, also turned out to be more challenging in respect to annotation and modeling (Strapparava and Mihalcea, 2007).

Surprisingly, one of the most valuable affective phenomena for improving human-machine interaction has received surprisingly little attention: *Empathy*. Prior work focused mostly on *spoken dialogue*, commonly addressing conversational agents, psychological interventions, or call center applications (McQuiggan and Lester, 2007; Fung et al., 2016; Pérez-Rosas et al., 2017; Alam et al., 2017).

In contrast, to the best of our knowledge, only three contributions (Xiao et al., 2012; Gibson et al., 2015; Khanpour et al., 2017) previously addressed *text-based* empathy prediction[1] (see Section 4 for details). Yet, all of them are limited in three ways: (a) neither of their corpora are available leaving the NLP community without shared data, (b) empathy ratings were provided by others than the one actually experiencing it which qualifies only as a weak form of ground truth, and (c) their notion of empathy is quite basic, falling short of current and past theory.

---

* These authors contributed equally to this work. Anneke Buffone designed and supervised the crowdsourcing task and the survey described in Section 2, and provided psychological background knowledge. Sven Buechel was responsible for corpus creation, data analysis, and modeling. The technical set-up of the crowdsourcing task and the survey was done jointly by both first authors.

†Work conducted while being at the University of Pennsylvania.

[1] Psychological studies commonly distinguish between *state* and *trait* empathy. While the former construct describes the amount of empathy a person experiences as a direct result of encountering a given stimulus, the latter refers to how empathetic one is on average and across situations. This studies exclusively addresses *state empathy*. For a contribution addressing *trait empathy* from an NLP perspective, see Abdul-Mageed et al. (2017).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4758–4765
Brussels, Belgium, October 31 - November 4, 2018.

In this contribution we present the first publicly available gold standard for text-based empathy prediction. It is constructed using a novel annotation methodology which reliably captures empathy assessments via multi-item scales. The corpus as well as our work as a whole is also unique in being—to the best of our knowledge—the first computational approach differentiating *multiple types of empathy*, empathic concern and personal distress, a distinction well recognized throughout psychology and other disciplines.[2]

2 Corpus Design and Methodology

Background. Most psychological theories of empathic states are focused on reactions to negative rather than positive events. Empathy for positive events remains less well understood and is thought to be regulated differently (Morelli et al., 2015). Thus we focus on empathetic reactions to need or suffering. Despite the fact that everyone has an immediate, implicit understanding of empathy, research has been vastly inconsistent in its definition and operationalization (Cuff et al., 2016). There is agreement, however, that there are multiple forms of empathy (see below). The by far most widely cited state empathy scale is Batson's Empathic Concern – Personal Distress Scale (Batson et al., 1987), henceforth *empathy* and *distress*.

Distress is a self-focused, negative affective state that occurs when one feels upset due to witnessing an entity's suffering or need, potentially via "catching" the suffering target's negative emotions. Empathy is a warm, tender, and compassionate feeling for a suffering target. It is other-focused, retains self-other separation, and is marked by relatively more positive affect (Batson and Shaw, 1991; Goetz et al., 2010; Mikulincer and Shaver, 2010; Sober and Wilson, 1997).

Selection of News Stories. Two research interns (psychology undergraduates) collected a total of 418 articles from popular online news platforms, selected to likely evoke empathic reactions, after being briefed on the goal and background of this study. These articles were then used to elicit empathic responses in participants.

Acquiring Text and Ratings. The corpus acquisition was set up as a crowdsourcing task on `MTurk.com` pointing to a `Qualtrics.com` questionnaire. The participants completed background measures on demographics and personality, and then proceeded to the main part of the survey where they read a random selection of five of the news articles. After reading each of the articles, participants were asked to rate their level of empathy and distress before describing their thoughts and feelings about it in writing.

In contrast to previous work, this set-up allowed us to acquire empathy scores of the actual *writer* of a text, instead of having to rely on an external evaluation by third parties (often student assistants with background in computer science). Arguably, our proposed annotation methodology yields more appropriate gold data, yet also leads to more variance in the relationship between linguistic features and empathic state ratings. That is because each rating reflects a single individual's feelings rather than a more stable average assessment by multiple raters. To account for this, we use *multi-item scales* as is common practice in psychology. I.e., participants give ratings for multiple items measuring the same construct (e.g., empathy) which are then averaged to obtain more reliable results. As far as we know, this is the first time that multi-item scales are used in sentiment analysis.[3]

In our case, participants used Batson's Empathic Concern – Personal Distress Scale (see above), i.e, rating 6 items for empathy (e.g., *warm, tender, moved*) and 8 items for distress (e.g., *troubled, disturbed, alarmed*) using a 7-point scale for each of those (see Appendix for details). After rating their empathy, participants were asked to share their feelings about the article as they would with a friend in a private message or with a group of friends as a social media post in 300 to 800 characters. Our final gold standard consists of these *messages* combined with the numeric ratings for empathy and distress.

In sum, 403 participants completed the survey. Median completion time was 32 minutes and each participant received 4 USD as compensation.

Post-Processing. Each message was manually reviewed by the authors. Responses which deviated from the task description (e.g., mere copying from the articles at display) were removed (31 responses, 155 messages), leading to a total 1860 messages in our final corpus. Gold ratings for empathy and distress were derived by averaging the respective items of the two multi-item scales.

---

[2] Data and code are available at: `https://github.com/wwbp/empathic_reactions`

[3] Here, we use *sentiment* as an umbrella term subsuming semantic orientation, emotion, as well as highly related concepts such as empathy.

	E	**D**	**Message**
(1)	4.8	3.1	*I'm sorry to hear that about Dakota's parents. Even when you are adult it must be hard to see your parents splitting up. No one wants that to happen and it's unfortunate that her parents couldn't work it out. I hope they are able to still remain civil around the kids and family. Just because it didn't work romantically doesn't mean it won't work at all.*
(2)	4.0	5.5	*Here's an article about crazed person who murdered two unfortunate women overseas. Life is crazy. I can't imagine what the families are going through. Having to go to or being forced into sex work is bad enough, but for it to end like this is just sad. It feels like there's no place safe in this world to be a woman sometimes.*
(3)	1.0	1.3	*I just read an article about some chowder-head who used a hammer and a pick ax to destroy Donald Trump's star on the Hollywood walk of fame. Wow, what a great protest. You sure showed him. Good job. Lol, can you believe this garbage? Who has such a hollow and pathetic life that they don't have anything better to do with their time than commit petty vandalism because they dislike some politician? What a dingus.*

Table 1: Illustrative examples from our newly created gold standard with ratings for empathy (**E**) and distress (**D**).

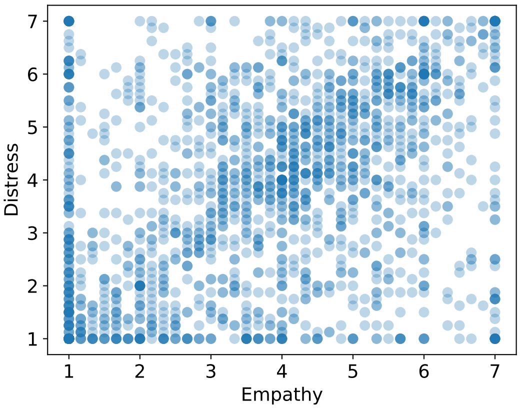

Figure 1: Scatter plot of the bivariate distribution of empathy and distress ratings.

3 Corpus Analysis

For a first impression of the language of our new gold standard, we provide illustrative examples in Table 1. The participant in Example (1) displays higher empathy than distress, (2) displays higher distress than empathy, and (3) shows neither empathic state, but employs sarcasm, colloquialisms and social-media-style acronyms to express lack of emotional response to the article. As can be seen, the language of our corpus is diverse and authentic, featuring many phenomena of natural language which render its computational understanding difficult, thus constituting a sound but challenging gold standard for empathy prediction.

Token Counts. We tokenized the 1860 messages using NLTK tools (Bird, 2006). In total, our corpus amounts to $173,686$ tokens. Individual message length varies between 52 and 198 tokens, the median being 84. See Appendix for details.

Rating Distribution. Figure 1 displays the bivariate distribution of empathy and distress ratings. As can be seen both target variables have a clear linear dependence, yet show only a moderate Pearson correlation of $r{=}.451$, similar to what was found in prior research (Batson et al., 1987, 1997). This finding supports that the two scales capture distinct affective phenomena and underscores the importance of our decision to describe empathic states in terms of *multiple* target variables, constituting a clear advancement over previous work. Both kinds of ratings show good coverage over the full range of the scales.

Reliability of Ratings. Since each message is annotated by only one rater, its author, typical measures of inter-rater agreement are not applicable. Instead, we compute *split-half reliability* (SHR), a standard approach in psychology (Cronbach, 1947) which also becomes increasingly popular in sentiment analysis (Mohammad and Bravo-Marquez, 2017a; Buechel and Hahn, 2018a). SHR is computed by splitting the ratings for the individual scale items (e.g., *warm*, *tender*, etc. for empathy) of all participants randomly into two groups, averaging the individual item ratings for each group and participant, and then measuring the correlation between both groups. This process is repeated 100 times with random splits, before again averaging the results. Doing so for empathy and distress, we find very high[4] SHR values of $r{=}.875$ and .924, respectively.

4 Modeling Empathy and Distress

In this section, we provide experimental results for modeling empathy and distress ratings based on the participants' messages (see Section 2). We examine three different types of models, varying in

---

[4] For a comparison against previously reported SHR values for different emotional categories, see Mohammad and Bravo-Marquez (2017b).

design complexity. Distinct models were trained for empathy and distress prediction.

First, ten percent of our newly created gold standard were randomly sampled to be used in development experiments. Then, the main experiment was conducted using 10-fold cross-validation (CV), providing each model with identical train-test splits to increase reliability. The dev set was excluded for the CV experiment.

Model performance is measured in terms of Pearson correlation r between predicted values and the human gold ratings. Thus, we phrase the prediction of empathy and distress as regression problems.

The input to our models is based on word embeddings, namely the publicly available FastText embeddings which were trained on Common Crawl ($\approx$600B tokens) (Bojanowski et al., 2017; Mikolov et al., 2018).

Ridge. Our first approach is Ridge regression, an ℓ^2-regularized version of linear regression. The centroid of the word embeddings of the words in a message is used as features (embedding centroid). The regularization coefficient α is automatically chosen from $\{1, .5, .1, ..., .0001\}$ during training.

FFN. Our second approach is a Feed-Forward Net with two hidden layers (256 and 128 units, respectively) with ReLU activation. Again, the embedding centroid is used as features.

CNN. The last approach is a Convolutional Neural Net.[5] We use a single convolutional layer with filter sizes 1 to 3, each with 100 output channels, followed by an average pooling layer and a dense layer of 128 units. ReLUs were used for the convolutional and again for the dense layer.

Both deep learning models were trained using the Adam optimizer (Kingma and Ba, 2015) with a fixed learning rate of 10^{-3} and a batch size of 32. We trained for a maximum of 200 epochs yet applied early stopping if the performance on the validation set did not improve for 20 consecutive epochs. We applied dropout with probabilities of .2, .5 and .5 on input, dense and pooling layers, respectively. Moreover ℓ^2 regularization of .001 was applied to the weights of conv and dense layers. Word embeddings were not updated.

The results are provided in Table 2. As can be seen, all of our models achieve satisfying performance figures ranging between r=.379 and .444, given the assumed difficulty of the task (see Section 3). On average over the two target variables, the CNN performs best, followed by Ridge and the FFN. While the CNN significantly outperforms the other models in every case, the differences between Ridge and the FFN are not statistically significant for either empathy or distress.[6] The improvements of the CNN over the other two approaches are much more pronounced for distress than for empathy. Since only the CNN is able to capture semantic effects from composition and word order, our data suggest that these phenomena are more important for predicting distress, whereas lexical features alone already perform quite well for empathy.

	Empathy	**Distress**	**Mean**
Ridge	.385	.410	.398
FFN	.379	.401	.390
CNN	**.404***	**.444***	**.424***

Table 2: Model performance for predicting empathy and distress in Pearson's r; with row-wise mean; best result per column in bold, significant ($p < .05$) improvement over other models marked with '*'.

Discussion. In comparison to closely related tasks such as emotion prediction (Mohammad and Bravo-Marquez, 2017a) our performance figures for empathy and distress prediction are generally lower. However, given the small amount of previous work for the problem at hand, we argue that our results are actually quite strong. This becomes obvious, again, in comparison with emotion analysis where early work achieved correlation values around r=.3 at most (Strapparava and Mihalcea, 2007). Yet state-of-the-art performance literally doubled over the last decade (Beck, 2017), in part due to much larger training sets.

Comparison to the limited body of previous work in text-based empathy prediction is difficult for a number of reasons, e.g., differences in domain, evaluation metric, as well as methodology and linguistic level of annotation. Khanpour et al. (2017) annotate and model empathy in online health communities on the *sentence*-level, whereas the instances in our corpus are much longer and comprise multiple sentences. In contrast to our work, they treat empathy prediction as a classification problem. Their best performing model, a CNN-LSTM, achieves an F-score of .78. Gibson

---

[5] Recurrent models did not perform well during development due to high sequence length.

[6] We use a two-tailed t-test for paired samples based on the results of the individual CV runs; $p < .05$.

et al. (2015) predict therapists' empathy in motivational interviews. Each therapy session transcript received one numeric score. Thus, each prediction is based on much more language data than our individual messages comprise. Their best model achieves a Spearman rank correlation of .61 using n-gram and psycholinguistic features.

Our contribution goes beyond both of these studies by, first, enriching empathy prediction with personal distress and, second, by annotating and modeling the empathic state actually felt by the writer, instead of relying on external assessments.

5 Conclusion

This contribution was the first to attempt empathy prediction in terms of *multiple* target variables, empathic concern and personal distress. We proposed a novel annotation methodology capturing empathic states actually felt by the author of a statement, instead of relying on third-party assessments. To ensure high reliability in this single-rating setting, we employ multi-item scales in line with best practices in psychology. Hereby we create the first publicly available gold standard for empathy prediction in written language, our survey being set-up and supervised by an expert psychologist. Our analysis shows that the data set excels with high rating reliability and an authentic and diverse language, rich of challenging phenomena such as sarcasm. We provide experimental results for three different predictive models, our CNN turning out superior.

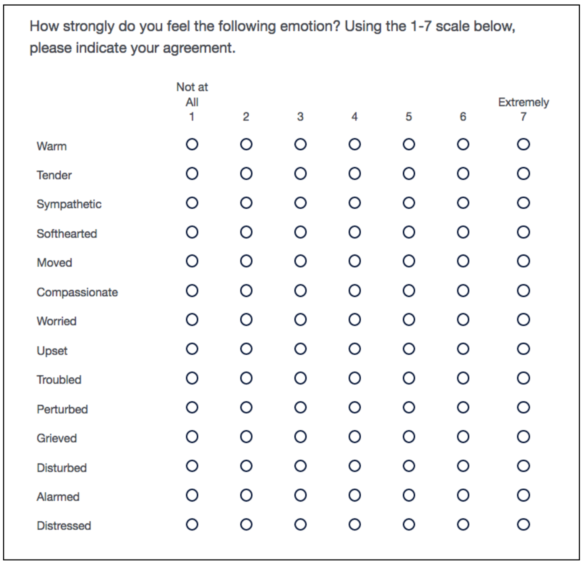
A Supplemental Material

Details on Stimulus and Instructions

Before being used in our survey, the selected news articles were categorized by the research interns who gathered them in terms of their intensity of suffering (major or minor), cause of suffering (political, human, nature or other), patient of suffering (humans, animals, environment, or other) and scale of suffering (individual or mass). Research interns also provided a short list of key words for each article. This additional information was gathered to examine the influence of these factors on empathy elicitation and modeling performance in later studies.

At the beginning of the survey participants completed background items covering general demographics (including age, gender, and ethnicity), the most commonly used *trait* empathy scale, the Interpersonal Reactivity Index (Davis, 1980), a brief assessment of the Big 5 personality traits (Gosling et al., 2003), life satisfaction (Diener et al., 1985), as well as a brief measure of generalized trust.

After reading each of the articles, participants rated their level of empathic concern and personal distress using multi-item scales. **Figure 2** shows a cropped screenshot of the survey hosted on `Qualtrics.com`. The first six items (*warm, tender, sympathetic, softhearted, moved*, and *compassionate*) refer to empathy. The last eight items (*worried, upset, troubled, perturbed, grieved, disturbed, alarmed*, and *distressed*) refer to distress.



How strongly do you feel the following emotion? Using the 1-7 scale below, please indicate your agreement.

	Not at All 1	2	3	4	5	6	Extremely 7
Warm	○	○	○	○	○	○	○
Tender	○	○	○	○	○	○	○
Sympathetic	○	○	○	○	○	○	○
Softhearted	○	○	○	○	○	○	○
Moved	○	○	○	○	○	○	○
Compassionate	○	○	○	○	○	○	○
Worried	○	○	○	○	○	○	○
Upset	○	○	○	○	○	○	○
Troubled	○	○	○	○	○	○	○
Perturbed	○	○	○	○	○	○	○
Grieved	○	○	○	○	○	○	○
Disturbed	○	○	○	○	○	○	○
Alarmed	○	○	○	○	○	○	○
Distressed	○	○	○	○	○	○	○

Figure 2: Multi-item scales for empathic concern and personal distress.

After completing the rating items, participants were instructed to describe their reactions in writing as follows: *Now that you have read this article, please write a message to a friend or friends about your feelings and thoughts regarding the article you just read. This could be a private message to a friend or something you would post on social media. Please do not identify your intended friend(s) — just write your thoughts about the article as if you were communicating with them. Please use between 300 and 800 characters.*

Further Corpus Analyses

The word clouds in **Figure 3** and **Figure 4** show 1-grams of our corpus which correlate significantly (Benjamini-Hochberg corrected $p < .05$) with high empathy and high distress ratings, respectively. In the word clouds, larger size indicates higher correlation and the color scale, gray-blue-red, indicates word frequency, dark red being most prevalent. The Differential Language Analysis Toolkit (Schwartz et al., 2017) was utilized for this analysis. As can be seen, the word clouds display high face-validity, giving further evidence for the soundness of our acquisition methodology.

Figure 3: Word cloud of high empathy 1-grams.

Figure 4: Word cloud of high distress 1-grams.

Figure 5 displays the distribution of the message length of our corpus in tokens. As can be seen the majority of messages contain between 60 and 100 tokens. Yet outliers go up to almost 200. The introduction of a character cap for the writing task proved successful in comparison to a pilot study where this measure has not been in place. In the latter case, the maximum number of tokens was nearly twice as high due to even stronger outliers.

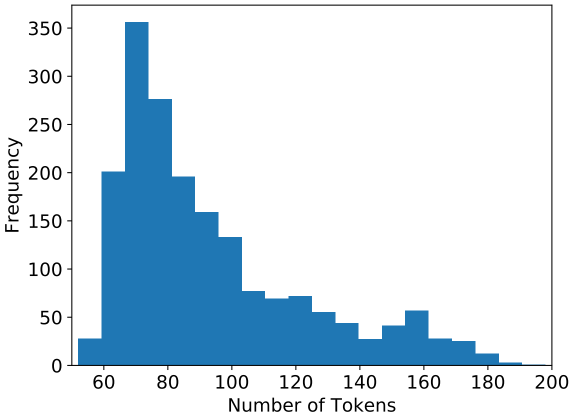


Figure 5: Histogram of message length in our corpus.

Interpretable Emoji Prediction via Label-Wise Attention LSTMs

Abstract

Human language has evolved towards newer forms of communication such as social media, where emojis (i.e., ideograms bearing a visual meaning) play a key role. While there is an increasing body of work aimed at the computational modeling of emoji semantics, there is currently little understanding about what makes a computational model represent or predict a given emoji in a certain way. In this paper we propose a label-wise attention mechanism with which we attempt to better understand the nuances underlying emoji prediction. In addition to advantages in terms of interpretability, we show that our proposed architecture improves over standard baselines in emoji prediction, and does particularly well when predicting infrequent emojis.

1 Introduction

Communication in social media differs from more standard linguistic interactions across a wide range of dimensions. Immediacy, short text length, the use of pseudowords like *#hashtags* or *@mentions*, and even metadata such as user information or geolocalization are essential components of social media messages. In addition, the use of *emojis*, small ideograms depicting objects, people and scenes (Cappallo et al., 2015), are becoming increasingly important for fully modeling the underlying semantics of a social media message, be it a product review, a *tweet* or an *Instagram* post. Emojis are the evolution of character-based emoticons (Pavalanathan and Eisenstein, 2015), and are extensively used, not only as sentiment carriers or boosters, but more importantly, to express ideas about a myriad of topics, e.g., mood (😘), food (🍲), sports (🏃) or scenery (🏝).

Emoji modeling and prediction is, therefore, an important problem towards the end goal of properly capturing the intended meaning of a social media message. In fact, emoji prediction, i.e., given a (usually short) message, predict its most likely associated emoji(s), may help to improve different NLP tasks (Novak et al., 2015), such as information retrieval, generation of emoji-enriched social media content or suggestion of emojis when writing text messages or sharing pictures online. It has furthermore proven to be useful for sentiment analysis, emotion recognition and irony detection (Felbo et al., 2017). The problem of emoji prediction, albeit recent, has already seen important developments. For example, Barbieri et al. (2017) describe an LSTM model which outperforms a logistic regression baseline based on word vector averaging, and even human judgement in some scenarios.

The above contributions, in addition to emoji similarity datasets (Barbieri et al., 2016; Wijeratne et al., 2017) or emoji sentiment lexicons (Novak et al., 2015; Wijeratne et al., 2016; Kimura and Katsurai, 2017; Rodrigues et al., 2018), have paved the way for better understanding the semantics of emojis. However, our understanding of what exactly the neural models for emoji prediction are capturing is currently very limited. What is a model prioritizing when associating a message with, for example, positive (😁), negative (😠) or patriotic (🇺🇸) intents? A natural way of assessing this would be to implement an attention mechanism over the hidden states of LSTM layers. Attentive architectures in NLP, in fact, have recently received substantial interest, mostly for sequence-to-sequence models (which are useful for machine translation, summarization or language modeling), and a myriad of modifications have been proposed, including additive (Bahdanau et al., 2015), multiplicative (Luong et al., 2015) or self (Lin et al., 2017) attention mechanisms.

However, standard attention mechanisms only tell us which text fragments are considered impor-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4766–4771
Brussels, Belgium, October 31 - November 4, 2018.

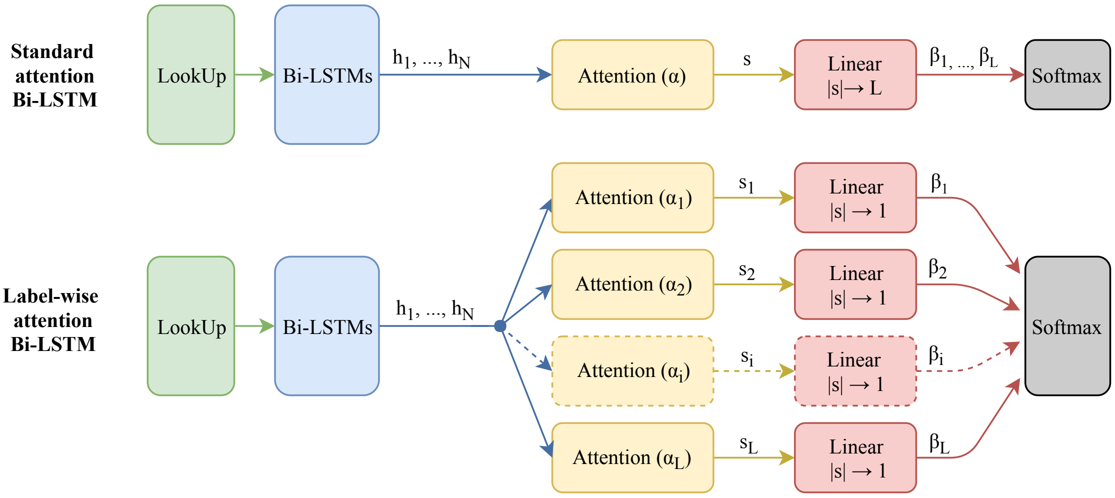

Figure 1: A classic attention network (top), and our attentive label-wise network (bottom), with a specific attention module for each label.

tant for the overall prediction distribution. While emoji prediction has predominantly been treated as a multi-class classification problem in the literature, it would be more informative to analyze which text fragments are considered important *for each individual emoji*. With this motivation in mind, in this paper we put forward a *label-wise* mechanism that operates over each label during training. The resulting architecture intuitively behaves like a batch of binary mini-classifiers, which make decisions over one single emoji at a time, but without the computational burden and risk of overfitting associated with learning separate LSTM-based classifiers for each emoji.

Our contribution in this paper is twofold. First, we use the proposed label-wise mechanism to analyze the behavior of neural emoji classifiers, exploiting the attention weights to uncover and interpret emoji usages. Second, we experimentally compare the effect of the label-wise mechanism on the performance of an emoji classifier. We observed a performance improvement over competitive baselines such as `FastText` (`FT`) (Joulin et al., 2017) and `Deepmoji` (Felbo et al., 2017), which is most noticeable in the case of infrequent emojis. This suggests that an attentive mechanism can be leveraged to make neural architectures more sensitive to instances of underrepresented classes.

2 Methodology

Our base architecture is the Deepmoji model (Felbo et al., 2017), which is based on two stacked word-based bi-directional LSTM recurrent neural networks with skip connections between the first and the second LSTM. The model also includes an attention module to increase its sensitivity to individual words during prediction. In general, attention mechanisms allow the model to focus on specific words of the input (Yang et al., 2016), instead of having to memorize all the important features in a fixed-length vector. The main architectural difference with respect to the typical attention is illustrated in Figure 1.

In Felbo et al. (2017), attention is computed as follows:

$$z_i = w_a h_i + b_a$$
$$\alpha_i = \frac{e^{z_i}}{\sum_{j=1}^{N} e^{z_j}}$$
$$s = \sum_{j=1}^{N} \alpha_j h_j$$

Here $h_i \in \mathbb{R}^d$ is the hidden representation of the LSTM corresponding to the i^{th} word, with N the total number of words in the sentence. The weight vector $w_a \in \mathbb{R}^d$ and bias term $b_a \in \mathbb{R}$ map this hidden representation to a value that reflects the importance of this state for the considered classification problem. The values $z_1, ..., z_n$ are then normalized using a softmax function, yielding the attention weights α_i. The sentence representation s is defined as a weighted average of the vectors h_i. The final prediction distribution is then defined as follows:

$$\beta_l = w_{f,l} s + b_{f,l}$$

$$p_l = \frac{e^{\beta_l}}{\sum_{r=1}^{L} e^{\beta_r}}$$

where $w_{f,l} \in \mathbb{R}^d$ and $b_{f,l}$ define a label-specific linear transformation, with β_l reflecting our confidence in the l^{th} label and L is the total number of labels. The confidence scores β_l are then normalized to probabilities using another softmax operation. However, while the above design has contributed to better emoji prediction, in our case we are interested in understanding the contribution of the words of a sentence for each label (i.e., emoji), and not in the whole distribution of the target labels. To this end, we propose a label-wise attention mechanism. Specifically, we apply the same type of attention, but repeating it $|L|$ (number of labels) times, where each attention module is reserved for a specific label l:

$$\begin{aligned} z_{i,l} &= w_{a,l} h_i + b_{a,l} \\ \alpha_{i,l} &= \frac{e^{z_{i,l}}}{\sum_{j=1}^{N} e^{z_{j,l}}} \\ s_l &= \sum_{j=1}^{N} \alpha_{j,l} h_j \\ \beta_l &= w_{f,l} s_l + b_{f,l} \\ p_l &= \frac{e^{\beta_l}}{\sum_{r=1}^{L} e^{\beta_r}} \end{aligned}$$

3 Evaluation

This section describes the main experiment w.r.t the performance of our proposed attention mechanism, in comparison with existing emoji prediction systems. We use the data made available in the context of the SemEval 2018 Shared Task on Emoji Prediction (Barbieri et al., 2018). Given a tweet, the task consists of predicting an associated emoji from a predefined set of 20 emoji labels. We evaluate our model on the English split of the official task dataset. We also show results from additional experiments in which the label space ranged from 20 to 200 emojis. These *extended* experiments are performed on a corpus of around 100M tweets geolocalized in the United States and posted between October 2015 and May 2018.

Models. In order to put our proposed label-wise attention mechanism in context, we compare its performance with a set of baselines: (1) `FastText` (Joulin et al., 2017) (`FT`), which was the official baseline in the SemEval task; (2) 2 stacked Bi-LSTMs (`2-BiLSTMs`) without attention; and (3) 2 stacked Bi-LSTMs with standard attention (`2-BiLSTMs`$_a$) (Felbo et al., 2017). Finally, we denote as `2-BiLSTMs`$_l$ our proposed label-wise attentive Bi-LSTM architecture.

Lab	Syst	**F1**	**A@1**	**A@5**	**CE**
20*	`FastText`	30.97	42.57	72.45	4.56
	`2-BiLSTM`	33.52	45.76	75.54	3.88

	`2-BiLSTM`$_l$	**17.92**	22.80	47.41	**15.17**
200	`FastText`	13.31	18.80	38.99	51.06
	`2-BiLSTM`	16.16	21.05	42.64	24.68
	`2-BiLSTM`$_a$	16.30	21.13	42.50	24.60
	`2-BiLSTM`$_l$	**16.91**	**21.39**	**43.35**	**23.73**

Table 1: Experimental results of the two baselines, as well as single and label-wise attention modifications to the "vanilla" `2-BiLSTM` model.

Results. Table 1 shows the results of our model and the baselines in the emoji prediction task for the different evaluation splits. The evaluation metrics used are: **`F1`**, Accuracy@k (**`A@k`**, where $k \in \{1, 5\}$), and Coverage Error (**`CE`**[1]) (Tsoumakas et al., 2009). We note that the latter metric is not normally used in emoji prediction settings. However, with many emojis being "near synonyms" (in the sense of being often used almost interchangeably), it seems natural to evaluate the performance of an emoji prediction system in terms of how far we would need to go through the predicted emojis to recover the true label. The results show that our proposed `2-BiLSTMs`$_l$ method outperforms all baselines for F1 in three out of four settings, and for CE in all of them. In the following section we shed light on the reasons behind this performance, and we try to understand how these predictions were made.

---

[1] CE is computed as the average number of labels that need to be in the predictions for all true labels to be predicted.

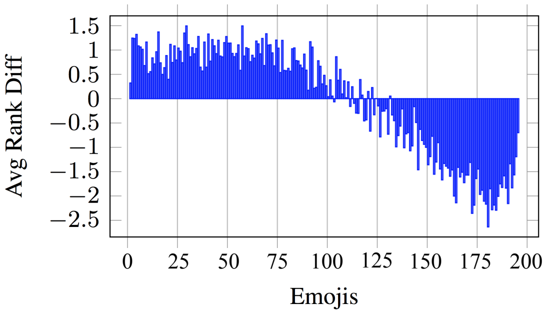

Figure 2: Difference in rank distributions. The x-axis represents emoji labels, ranked from most to least frequent. Lower scores indicate a higher average rank predicted by our proposed label-wise attention mechanism.

4 Analysis

By inspecting the predictions of our model, we found that the label-wise attention mechanism tends to be less heavily biased towards the most frequent emojis. This is reflected in the lower coverage error results in all settings, and becomes more noticeable as the number of labels grows. We verified this by computing the average difference between ranked predictions of the two attentive models in the 200-label setting (Figure 2). We can observe a sudden switch at more or less the median emoji, after which the label-wise attention model becomes increasingly accurate (relative to the standard attention model). This can be explained by the fact that infrequent emojis tend to be more situational (used in specific contexts and leaving less room for ambiguity or interchangeability), which the label-wise attention mechanism can take advantage of, as it explicitly links emojis with highly informative words. Let us illustrate this claim with a case in which the label-wise attention model predicts the correct emoji, unlike its single-attention counterpart:

a friendship is built over time , but sisterhood is given automatically. *Gold:* 👯

For the above example[2], the predictions of the single attention model were all linked to the *general* meaning of the message, that is love and friendship, leading it to predict associated emojis (❤️, 💕 and 💗), failing to capture the most relevant bit of information. On the other hand, our proposed model "picks on" the word *sisterhood*, and with

praying we have a snow day tomorrow (🙌)

Figure 3: Attention weights α and α_l of single and label-wise attentive models. *Gold*: 🙏.

the added context of the surrounding words, ranks the gold label[3] in 4th position, which would be a true positive as per **A@5**.

Let us explore what we argue are interesting cases of emoji usage (ranging from highly explicit to figurative or situtational intent). Figure 3 shows how the word (*praying*) and emojis such as 🙏 and 🙌 are strongly correlated. In addition, the bond between the word *snow* and the ❄️ emoji is also indisputable. However, a perhaps more surprising example is displayed in Figure 4, which is a negative example. Here, the ✔️ emoji was predicted with rank 1, and we see it being strongly associated with the ordinal *second*, suggesting that the model assumed this was some kind of "ticked enumeration" of completed tasks, which is indeed regular practice in Twitter. Finally, we found it remarkable that the ambiguous nature of the word *boarding* is also reflected in two different emojis being predicted with high probability (❄️ and ✈️), each of them showcasing one of the word's senses.

As an additional exploratory analysis, we computed statistics on those words with the highest average attention weights associated with one single emoji. One interesting example is the 🌲 emoji, which shows two clear usage patterns: one literal (a tree) and one figurative (*christmas* and *holidays*). Finally, as a final (and perhaps thought-provoking) finding, the highest attention weights associated to the 🏈 emoji were given to the words *game*, *boys* and *football*, in that order. In other words, the model relies more on the word *boys* than on the actual description of the emoji. This is in line with a previous study that showed how the current usage of emojis in Twitter is in some cases associated with gender stereotypes (Barbieri and Camacho-Collados, 2018).

5 Conclusion

In this paper we have presented a neural architecture for emoji prediction based on a label-wise attention mechanism, which, in addition to improving performance, provides a degree of interpretability about how different features are used for predictions, a topic of increasing interest in NLP (Linzen et al., 2016; Palangi et al., 2017). As we experimented with sets of emoji labels of different sizes, our proposed label-wise attention architecture proved especially well-suited for emojis which were infrequent in the training data, making the system less biased towards the most frequent. We see this as a first step to improve the robustness of recurrent neural networks in datasets with unbalanced distributions, as they were shown not to perform better than well-tuned SVMs on the emoji predicion task (Çöltekin and Rama, 2018).

As for future work, we plan to apply our label-wise attention mechanism to understand other interesting linguistic properties of human-generated text in social media, and other multi-class or multi-label classification problems.

Finally, code to reproduce our experiments and additional examples of label-wise attention weights from input tweets can be downloaded at `https://fvancesco.github.io/label_wise_attention/`.

Abstract

Recent advances in Neural Machine Translation (NMT) show that adding syntactic information to NMT systems can improve the quality of their translations. Most existing work utilizes some specific types of linguistically-inspired tree structures, like constituency and dependency parse trees. This is often done via a standard RNN decoder that operates on a linearized target tree structure. However, it is an open question of what specific linguistic formalism, if any, is the best structural representation for NMT. In this paper, we (1) propose an NMT model that can naturally generate the topology of an arbitrary tree structure on the target side, and (2) experiment with various target tree structures. Our experiments show the surprising result that our model delivers the best improvements with balanced binary trees constructed *without* any linguistic knowledge; this model outperforms standard *seq2seq* models by up to 2.1 BLEU points, and other methods for incorporating target-side syntax by up to 0.7 BLEU.[1]

1 Introduction

Most NMT methods use sequence-to-sequence (*seq2seq*) models, taking in a *sequence* of source words and generating a *sequence* of target words (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). While *seq2seq* models can *implicitly* discover syntactic properties of the source language (Shi et al., 2016), they do not explicitly model and leverage such information. Motivated by the success of adding syntactic information to Statistical Machine Translation (SMT) (Galley et al., 2004; Menezes and Quirk, 2007; Galley et al., 2006), recent works have established that explicitly leveraging syntactic information can improve NMT quality, either through syntactic encoders (Li et al., 2017; Eriguchi et al., 2016), multi-task learning objectives (Chen et al., 2017; Eriguchi et al., 2017), or direct addition of syntactic tokens to the target sequence (Nadejde et al., 2017; Aharoni and Goldberg, 2017). However, these syntax-aware models only employ the standard decoding process of *seq2seq* models, *i.e.* generating one target word at a time. One exception is Wu et al. (2017), which utilizes two RNNs for generating target dependency trees. Nevertheless, Wu et al. (2017) is specifically designed for dependency tree structures and is not trivially applicable to other varieties of trees such as phrase-structure trees, which have been used more widely in other works on syntax-based machine translation. One potential reason for the dearth of work on syntactic decoders is that such parse tree structures are not friendly to recurrent neural networks (RNNs).

In this paper, we propose *TrDec*, a method for incorporating tree structures in NMT. TrDec simultaneously generates a target-side tree topology and a translation, using the partially-generated tree to guide the translation process (§ 2). TrDec employs two RNNs: a *rule RNN,* which tracks the topology of the tree based on rules defined by a Context Free Grammar (CFG), and a *word RNN,* which tracks words at the leaves of the tree (§ 3). This model is similar to neural models of tree-structured data from syntactic and semantic parsing (Dyer et al., 2016; Alvarez-Melis and Jaakkola, 2017; Yin and Neubig, 2017), but with the addition of the word RNN, which is especially important for MT where fluency of transitions over the words is critical.

TrDec can generate any tree structure that can be represented by a CFG. These structures include linguistically-motivated *syntactic* tree representations, *e.g.* constituent parse trees, as well as *syntax-free* tree representations, *e.g.* balanced binary trees (§ 4). This flexibility of TrDec allows us to com-

pare and contrast different structural representations for NMT.

In our experiments (§ 5), we evaluate TrDec using both syntax-driven and syntax-free tree representations. We benchmark TrDec on three tasks: Japanese-English and German-English translation with medium-sized datasets, and Oromo-English translation with an extremely small dataset. Our findings are surprising – TrDec performs well, but it performs the best with balanced binary trees constructed *without* any linguistic guidance.

2 Generation Process

TrDec simultaneously generates the target sequence and its corresponding tree structure. We first discuss the high-level generation process using an example, before describing the prediction model (§ 3) and the types of trees used by TrDec (§ 4).

Fig. 1 illustrates the generation process of the sentence "`_The _cat _eat s _fi sh _.`", where the sentence is split into subword units, delimited by the underscore "`_`" (Sennrich et al., 2016). The example uses a syntactic parse tree as the intermediate tree representation, but the process of generating with other tree representations, *e.g.* syntax-free trees, follows the same procedure.

Trees used in TrDec have two types of nodes: *terminal nodes*, *i.e.* the leaf nodes that represent subword units; and *nonterminal nodes*, *i.e.* the nonleaf nodes that represent a span of subwords. Additionally, we define a *preterminal node* to be a nonterminal node whose children are all terminal nodes. In Fig. 1 *Left*, the green squares represent preterminal nodes.

TrDec generates a tree in a top-down, left-to-right order. The generation process is guided by a CFG over target trees, which is constructed by taking all production rules extracted from the trees of all sentences in the training corpus. Specifically, a *rule RNN* first generates the top of the tree structure, and continues until a preterminal is reached. Then, a *word RNN* fills out the words under the preterminal. The model switches back to the *rule RNN* after the *word RNN* finishes. This process is illustrated in Fig. 1 *Right*. Details are as follows:

Step 1. The source sentence is encoded by a sequential RNN encoder, producing the hidden states.

Step 2. The generation starts with a derivation tree with only a `Root` node. A *rule RNN,* initialized by the last encoder hidden state computes the probability distribution over all CFG rules whose left hand side (LHS) is `Root`, and selects a rule to apply to the derivation. In our example, the rule RNN selects `ROOT` $\mapsto$ `S`.

Step 3. The rule RNN applies production rules to the derivation in a top-down, left-to-right order, expanding the current *opening nonterminal* using a CFG rule whose LHS is the opening nonterminal. In the next two steps, TrDec applies the rules `S` $\mapsto$ `NP VP PUNC` and `NP` $\mapsto$ `pre` to the opening nonterminals `S` and `NP`, respectively. Note that after these two steps a preterminal node `pre` is created.

Step 4a. Upon seeing a preterminal node as the current opening nonterminal, TrDec switches to using a *word RNN*, initialized by the last state of the encoder, to populate this empty preterminal with phrase tokens, similar to a *seq2seq* decoder. For example the subword units `_The` and `_cat` are generated by the word RNN, ending with a special *end-of-phrase* token, *i.e.* ⟨eop⟩.

Step 4b. While the word RNN generates subword units, the rule RNN also updates its own hidden states, as illustrated by the blue cells in Fig. 1 *Right*.

Step 5. After the word RNN generates ⟨eop⟩, TrDec switches back to the rule RNN to continue generating the derivation from where the tree left off. In our example, this next stage is the opening nonterminal node `VP`. From here, TrDec chooses the rule `VP` $\mapsto$ `pre NP`.

TrDec repeats the process above, intermingling the rule RNN and the word RNN as described, and halts when the rule RNN generates the *end-of-sentence* token $\langle$eos$\rangle$, completing the derivation.

3 Model

We now describe the computations during the generation process discussed in § 2. At first, a source sentence $\mathbf{x}$, which is split into subwords, is encoded using a standard bi-directional Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997). This bi-directional LSTM outputs a set of hidden states, which TrDec will reference using an attention function (Bahdanau et al., 2015).

As discussed, TrDec uses two RNNs to generate a target parse tree. In our work, both of these RNNs use LSTMs, but with different parameters.

Rule RNN. At any time step t in the rule RNN, there are two possible actions. If at the previous time step $t-1$, TrDec generated a CFG rule, then the state $\mathbf{s}_t^{\text{tree}}$ is computed by:

$$\mathbf{s}_t^{\text{tree}} = \text{LSTM}([\mathbf{y}_{t-1}^{\text{CFG}}; \mathbf{c}_{t-1}; \mathbf{s}_p^{\text{tree}}; \mathbf{s}_t^{\text{word}}], \mathbf{s}_{t-1}^{\text{tree}})$$

where $\mathbf{y}_{t-1}^{\text{CFG}}$ is the embedding of the CFG rule at time step $t-1$; $\mathbf{c}_{t-1}$ is the context vector computed by attention at $\mathbf{s}_{t-1}^{\text{tree}}$, *i.e.* input feeding (Luong et al., 2015); $\mathbf{s}_p^{\text{tree}}$ is the hidden state at the time step that generates the parent of the current node in the partial tree; $\mathbf{s}_t^{\text{word}}$ is the hidden state of the most recent time step before t that generated a subword (note that $\mathbf{s}_t^{\text{word}}$ comes from the word RNN, discussed below); and $[\cdot]$ denotes a concatenation.

Meanwhile, if at the previous time step $t-1$, TrDec did not generate a CFG rule, then the update at time step t must come from a subword being generated by the word RNN. In that case, we also update the rule RNN similarly by replacing the embedding of the CFG rule with the embedding of the subword.

Word RNN. At any time step t, if the word RNN is invoked, its hidden state $\mathbf{s}_t^{\text{word}}$ is:

$$\mathbf{s}_t^{\text{word}} = \text{LSTM}([\mathbf{s}_p^{\text{tree}}; \mathbf{w}_{t-1}; \mathbf{c}_{t-1}], \mathbf{s}_{t-1}^{\text{word}}),$$

where $\mathbf{s}_p^{\text{tree}}$ is the hidden state of rule RNN that generated the CFG rule above the current terminal; $\mathbf{w}_{t-1}$ is the embedding of the word generated at time step $t-1$; and $\mathbf{c}_{t-1}$ is the attention context computed at the previous word RNN time step $t-1$.

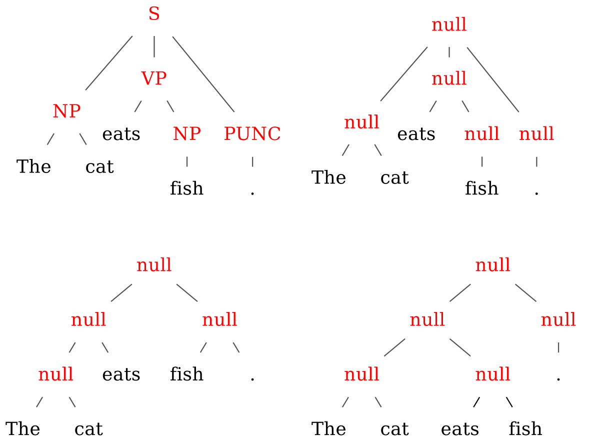

Figure 2: An example of four tree structures (Details of preterminals and subword units omitted for illustration purpose).

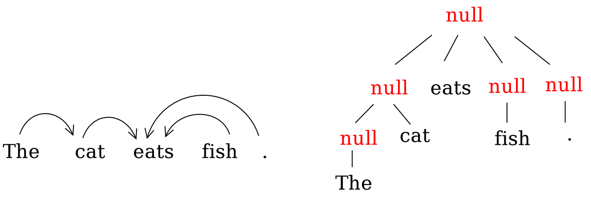

Figure 3: Conversion of a dependency tree for TrDec. *Left:* original dependency tree. *Right:* after conversion.

Softmax. At any step t, our softmax logits are $\mathbf{W} \cdot \tanh\,[\mathbf{s}_t^{\text{tree}}, \mathbf{s}_t^{\text{word}}]$, where $\mathbf{W}$ varies depending on whether a rule or a subword unit is needed.

4 Tree Structures

Unlike prior work on syntactic decoders designed for utilizing a specific type of syntactic information (Wu et al., 2017), TrDec is a flexible NMT model that can utilize any tree structure. Here we consider two categories of tree structures:

Syntactic Trees are generated using a third-party parser, such as Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007). Fig. 2 *Top Left* illustrates an example constituency parse tree. We also consider a variation of standard constituency parse trees where all of their nonterminal tags are replaced by a null tag, which is visualized in Fig. 2 *Top Right*.

In addition to constituency parse trees, TrDec can also utilize dependency parse trees via a simple procedure that converts a dependency tree into a constituency tree. Specifically, this procedure creates a parent node with null tag for each word, and then attaches each word to the parent node of its head word while preserving the word order. An example of this procedure is provided in Fig. 3.

Balanced Binary Trees are syntax-free trees constructed without any linguistic guidance. We use two slightly different versions of binary trees. Version 1 (Fig. 2 *Bottom Left*) is constructed by recursively splitting the target sentence in half and creating left and right subtrees from the left and right halves of the sentence respectively. Version 2 (Fig. 2 *Bottom Right*), is constructed by applying Version 1 on a list of nodes where consecutive words are combined together. All tree nodes in both versions have the null tag. We discuss these construction processes in more detail in Appendix A.1.

In the experiments detailed later, we evaluated TrDec with four different settings of tree structures: 1) the fully syntactic constituency parse trees; 2) constituency parse trees with null tags; 3) dependency parse trees; 4) a concatenation of both version 1 and version 2 of the binary trees, (which effectively doubles the amount of the training data and leads to slight increases in accuracy).

5 Experiments

Datasets. We evaluate TrDec on three datasets: 1) the KFTT (ja-en) dataset (Neubig, 2011), which consists of Japanese-English Wikipedia articles; 2) the IWSLT2016 German-English (de-en) dataset (Cettolo et al., 2016), which consists of TED Talks transcriptions; and 3) the LORELEI Oromo-English (or-en) dataset[2], which largely consists of texts from the Bible. Details are in Tab. 1. English sentences are parsed using Ckylark (Oda et al., 2015) for the constituency parse trees, and Stanford Parser (de Marneffe et al., 2006; Chen and Manning, 2014) for the dependency parse trees. We use byte-pair encoding (Sennrich et al., 2016) with 8K merge operations on ja-en, 4K merge operations on or-en, and 24K merge operations on de-en.

Dataset	Train	Dev	Test
ja-en	405K	1166	1160
de-en	200K	1024	1333
or-en	6.5K	358	359

Table 1: # sentences in each dataset.

Baselines. We compare TrDec against three baselines: 1) *seq2seq*: the standard *seq2seq* model with attention; 2) CCG: a syntax-aware translation model that interleaves Combinatory Categorial Grammar (CCG) tags with words on the target side of a *seq2seq* model (Nadejde et al., 2017); 3) CCG-null: the same model with CCG, but all syntactic tags are replaced by a null tag; and 4) LIN: a standard *seq2seq* model that generates linearized parse trees on the target side (Aharoni and Goldberg, 2017).

Results. Tab. 2 presents the performance of our model and the three baselines. For our model, we report the performance of TrDec-con, TrDec-con-null, TrDec-dep, and TrDec-binary (settings 1,2,3,4 in § 4). On the low-resource or-en dataset, we observe a large variance with different random seeds, so we run each model with 6 different seeds, and report the mean and standard deviation of these runs. TrDec-con-null and TrDec-con achieved comparable results, indicating that the syntactic labels have neither a large positive nor negative impact on TrDec. For ja-en and or-en, syntax-free TrDec outperforms all baselines. On de-en, TrDec loses to CCG-null, but the difference is not statistically significant ($p > 0.1$).

Model	**ja-en**	**de-en**	**or-en** (mean ± std)
seq2seq	21.10	32.26	10.90 ± 0.57
CCG	22.44	32.84	12.55 ± 0.60
CCG-null	21.31	**33.10**	11.96 ± 0.57
LIN	21.55	31.79	12.66 ± 0.61
TrDec-con	21.59	31.93	11.43 ± 0.58
TrDec-con-null	22.72	31.21	11.35 ± 0.55
TrDec-dep	21.41	31.23	8.40 ± 0.5
TrDec-binary	$\mathbf{23.14}^{*}$	32.65	$\mathbf{13.10}^{**} \pm \mathbf{0.61}$

Table 2: BLEU scores of TrDec and other baselines. Statistical significance is indicated with $*$ ($p < 0.05$) and $**$ ($p < 0.001$), compared with the best baseline.

Length Analysis. We performed a variety of analyses to elucidate the differences between the translations of different models, and the most conclusive results were through analysis based on the length of the translations. First, we categorize the ja-en test set into buckets by length of the reference sentences, and compare the models for each length category. Fig. 4 shows the gains in BLEU score over *seq2seq* for the tree-based models. Since TrDec-con outperforms TrDec-dep for all datasets, we only focus on TrDec-con for analyzing TrDec's performance with syntactic trees. The relative performance of CCG decreases on long sentences. However, TrDec, with both parse trees and syntax-free binary trees, delivers more improvement on longer sentences. This indicates that TrDec is bet-

---

[2] LDC2017E29

ter at capturing long-term dependencies during decoding. Surprisingly, TrDec-binary, which does not utilize any linguistic information, outperforms TrDec-con for all sentence length categories.

Second, Fig. 5 shows a histogram of translations by the length difference between the generated output and the reference. This provides an explanation of the difficulty of using parse trees. Ideally, this distribution will be focused around zero, indicating that the MT system is generating translations about the same length as the reference. However, the distribution of TrDec-con is more spread out than TrDec-binary, which indicates that it is more difficult for TrDec-con to generate sentences with appropriate target length. This is probably because constituency parse trees of sentences with similar number of words can have very different depth, and thus larger variance in the number of generation steps, likely making it difficult for the MT model to plan the sentence structure a-prior before actually generating the child sentences.

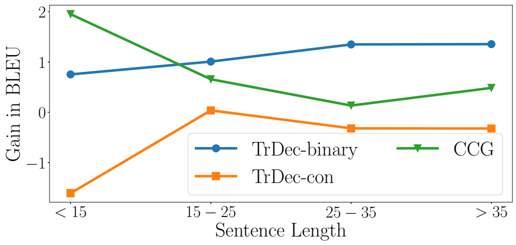

Figure 4: The gains of BLEU score over *seq2seq*.

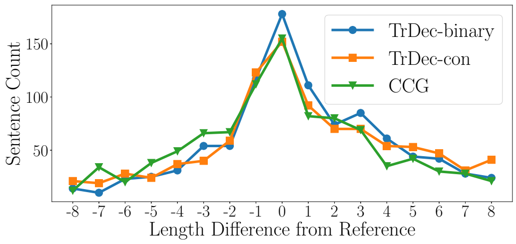

Figure 5: Distribution of length difference from reference.

6 Conclusion

We propose TrDec, a novel tree-based decoder for NMT, that generates translations along with the target side tree topology. We evaluate TrDec on both linguistically-inspired parse trees and synthetic, syntax-free binary trees. Our model, when used with synthetic balanced binary trees, outperforms CCG, the existing state-of-the-art in incorporating syntax in NMT models.

The interesting result that syntax-free trees outperform their syntax-driven counterparts elicits a natural question for future work: how do we better model syntactic structure in these models? It would also be interesting to study the effect of using source-side syntax together with the target-side syntax supported by TrDec.

Abstract

Neural machine translation (NMT) models are usually trained with the word-level loss using the teacher forcing algorithm, which not only evaluates the translation improperly but also suffers from exposure bias. Sequence-level training under the reinforcement framework can mitigate the problems of the word-level loss, but its performance is unstable due to the high variance of the gradient estimation. On these grounds, we present a method with a differentiable sequence-level training objective based on probabilistic n-gram matching which can avoid the reinforcement framework. In addition, this method performs greedy search in the training which uses the predicted words as context just as at inference to alleviate the problem of exposure bias. Experiment results on the NIST Chinese-to-English translation tasks show that our method significantly outperforms the reinforcement-based algorithms and achieves an improvement of 1.5 BLEU points on average over a strong baseline system.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014) has now achieved impressive performance (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017; Hassan et al., 2018; Chen et al., 2018; Lample et al., 2018) and draws more attention. NMT models are built on the encoder-decoder framework where the encoder network encodes the source sentence to distributed representations and the decoder network reconstructs the target sentence form the representations word by word.

Currently, NMT models are usually trained with the word-level loss (i.e., cross-entropy) under the teacher forcing algorithm (Williams and Zipser, 1989), which forces the model to generate translation strictly matching the ground-truth at the word level. However, in practice it is impossible to generate translation totally the same as ground truth. Once different target words are generated, the word-level loss cannot evaluate the translation properly, usually under-estimating the translation. In addition, the teacher forcing algorithm suffers from the *exposure bias* (Ranzato et al., 2015) as it uses different inputs at training and inference, that is ground-truth words for the training and previously predicted words for the inference. Kim and Rush (2016) proposed a method of sequence-level knowledge distillation, which use teacher outputs to direct the training of student model, but the student model still have no access to its own predicted words. Scheduled sampling(SS) (Bengio et al., 2015; Venkatraman et al., 2015) attempts to alleviate the exposure bias problem through mixing ground-truth words and previously predicted words as inputs during training. However, the sequence generated by SS may not be aligned with the target sequence, which is inconsistent with the word-level loss.

In contrast, sequence-level objectives, such as BLEU (Papineni et al., 2002), GLEU (Wu et al., 2016), TER (Snover et al., 2006), and NIST (Doddington, 2002), evaluate translation at the sentence or n-gram level and allow for greater flexibility, and thus can mitigate the above problems of the word-level loss. However, due to the non-differentiable of sequence-level objectives, previous works on sequence-level training (Ranzato et al., 2015; Shen et al., 2016; Bahdanau et al., 2016; Wu et al., 2016; He et al., 2016; Wu et al., 2017; Yang et al., 2017) mainly rely on reinforcement learning algorithms (Williams, 1992; Sutton et al., 2000) to find an unbiased gradient estimator for the gradient update. Sparse rewards in this situation often cause the high variance of gradient estimation, which consequently leads to unstable

training and limited improvements.

Lamb et al. (2016); Gu et al. (2017); Ma et al. (2018) respectively use the discriminator, critic and bag-of-words target as sequence-level training objectives, all of which are directly connected to the generation model and hence enable direct gradient update. However, these methods do not allow for direct optimization with respect to evaluation metrics.

In this paper, we propose a method to combine the strengths of the word-level and sequence-level training, that is the direct gradient update without gradient estimation from word-level training and the greater flexibility from sequence-level training. Our method introduces probabilistic n-gram matching which makes sequence-level objectives (e.g., BLEU, GLEU) differentiable. During training, it abandons teacher forcing and performs greedy search instead to take into consideration the predicted words. Experiment results show that our method significantly outperforms word-level training with the cross-entropy loss and sequence-level training under the reinforcement framework. The experiments also indicate that greedy search strategy indeed has superiority over teacher forcing.

2 Background

NMT is based on an end-to-end framework which directly models the translation probability from the source sentence $\boldsymbol{x}$ to the target sentence $\hat{\boldsymbol{y}}$:

$$P(\hat{\boldsymbol{y}}|\boldsymbol{x}) = \prod_{j=1}^{T} p(\hat{y}_j|\hat{\boldsymbol{y}}_{<\boldsymbol{j}}, \boldsymbol{x}, \theta), \qquad (1)$$

where T is the target length and θ is the model parameters. Given the training set $D = \{\mathrm{X}^{\mathrm{M}}, \mathrm{Y}^{\mathrm{M}}\}$ with M sentences pairs, the training objective is to maximize the log-likelihood of the training data as

$$\begin{aligned} \boldsymbol{\theta} &= \arg\max_{\theta}\{\mathcal{L}(\theta)\} \\ \mathcal{L}(\theta) &= \sum_{m=1}^{M}\sum_{j=1}^{l^m} \log(p(\hat{y}_j^m|\hat{\boldsymbol{y}}_{<\boldsymbol{j}}^m, \boldsymbol{x}^m, \theta)), \end{aligned} \qquad (2)$$

where the superior m indicates the m-th sentence in the dataset and l^m is the length of m-th target sentence.

In the above model, the probability of each target word $p(\hat{y}_j^m|\hat{\boldsymbol{y}}_{<\boldsymbol{j}}^{\boldsymbol{m}}, \boldsymbol{x}^{\boldsymbol{m}}, \theta)$ is conditioned on the previous target words. The scenario is that in the training time, the teacher forcing algorithm is employed and the ground truth words from the target sentence are fed as context, while during inference, the ground truth words are not available and the previous predicted words are instead fed as context. This discrepancy is called *exposure bias*.

3 Model

3.1 Sequence-Level Objectives

Many automatic evaluation metrics of machine translation, such as BLEU, GLEU and NIST, are based on the n-gram matching. Assuming that $\boldsymbol{y}$ and $\hat{\boldsymbol{y}}$ are the output sentence and the ground truth sentence with length T and T' respectively, the count of an n-gram $\boldsymbol{g} = (g_1, \ldots, g_n)$ in sentence $\boldsymbol{y}$ is calculated as

$$\mathrm{C}_{\boldsymbol{y}}(\boldsymbol{g}) = \sum_{t=0}^{T-n}\prod_{i=1}^{n} 1\{g_i = y_{t+i}\}, \qquad (3)$$

where $1\{\cdot\}$ is the indicator function. The matching count of the n-gram $\boldsymbol{g}$ between $\hat{\boldsymbol{y}}$ and $\boldsymbol{y}$ is given by

$$\mathrm{C}_{\boldsymbol{y}}^{\hat{\boldsymbol{y}}}(\boldsymbol{g}) = \min\left(\mathrm{C}_{\boldsymbol{y}}(\boldsymbol{g}), \mathrm{C}_{\hat{\boldsymbol{y}}}(\boldsymbol{g})\right). \qquad (4)$$

Then the precision p_n and the recall r_n of the predicted n-grams are calculated as follows

$$p_n = \frac{\sum_{\boldsymbol{g}\in\boldsymbol{y}} \mathrm{C}_{\boldsymbol{y}}^{\hat{\boldsymbol{y}}}(\boldsymbol{g})}{\sum_{\boldsymbol{g}\in\boldsymbol{y}} \mathrm{C}_{\boldsymbol{y}}(\boldsymbol{g})}, \qquad (5)$$

$$r_n = \frac{\sum_{\boldsymbol{g}\in\boldsymbol{y}} \mathrm{C}_{\boldsymbol{y}}^{\hat{\boldsymbol{y}}}(\boldsymbol{g})}{\sum_{\boldsymbol{g}\in\hat{\boldsymbol{y}}} \mathrm{C}_{\hat{\boldsymbol{y}}}(\boldsymbol{g})}. \qquad (6)$$

BLEU, the most widely used metric for machine translation evaluation, is defined based on the n-gram precision as follows

$$\mathrm{BLEU} = \mathrm{BP} \cdot \exp\left(\sum_{n=1}^{N} w_n \log p_n\right), \qquad (7)$$

where BP stands for the brevity penalty and w_n is the weight for the n-gram. In contrast, GLEU is the minimum of recall and precision of 1-4 grams where 1-4 grams are counted together:

$$\mathrm{GLEU} = \min(p_{1\text{-}4}, r_{1\text{-}4}). \qquad (8)$$

3.2 probabilistic Sequence-Level Objectives

In the output sentence $\boldsymbol{y}$, the prediction probability varies among words. Some words are translated by the model with high confidence while some words are translated with high uncertainty.

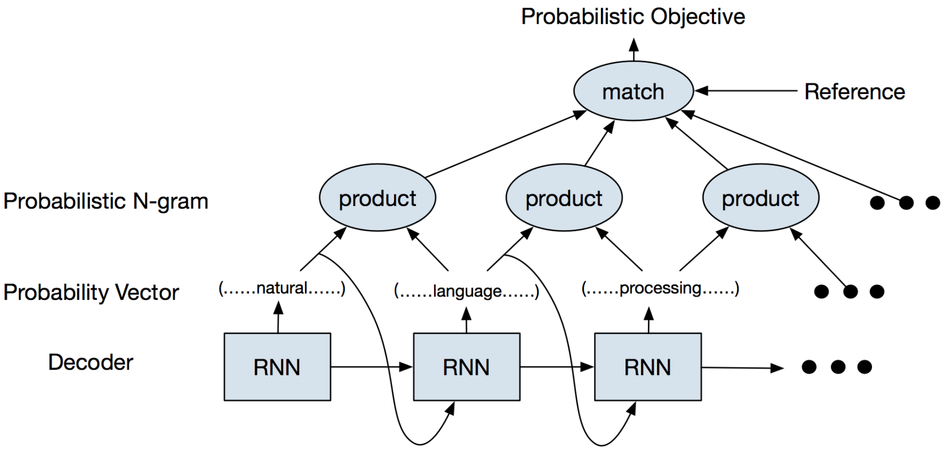

Figure 1: The overview of our model with greedy search. At each decoding step, the predicted word which has the highest probability in the probability vector is selected as context and fed into the RNN, and meanwhile this word and its probability are also used to calculate the probabilistic n-gram count.

However, when calculating the count of n-grams in Eq.(3), all the words in the output sentence are treated equally, regardless of their respective prediction probabilities.

To give a more precise description of n-gram counts which considers the variety of prediction probabilities, we use the prediction probability $p(y_j|\boldsymbol{y_{<j}},\boldsymbol{x},\theta)$ as the count of word y_j, and correspondingly the count of an n-gram is the product of these probabilistic counts of all the words in the n-gram, not *one* anymore. Then the probabilistic count of $\boldsymbol{g} = (g_1,\ldots,g_n)$ is calculated by summing over the output sentence $\boldsymbol{y}$ as

$$\widetilde{\mathrm{C}}_{\boldsymbol{y}}(\boldsymbol{g}) = \sum_{t=0}^{T-n}\prod_{i=1}^{n} 1\{g_i = y_{t+i}\}\cdot p(y_{t+i}|\boldsymbol{y_{<t+i}},\boldsymbol{x},\theta). \tag{9}$$

Now the probabilistic sequence-level objective can be got by replacing $\mathrm{C}_{\boldsymbol{y}}(\boldsymbol{g})$ with $\widetilde{\mathrm{C}}_{\boldsymbol{y}}(\boldsymbol{g})$ (the tilde over the head indicates the probabilistic version) and keeping the rest unchanged. Here, we take BLEU as an example and show how the probabilistic BLEU (denoted as P-BLEU) is defined. From this purpose, the matching count of n-gram $\boldsymbol{g}$ in Eq.(4) is modified as follows

$$\widetilde{\mathrm{C}}_{\boldsymbol{y}}^{\hat{\boldsymbol{y}}}(\boldsymbol{g}) = \min(\widetilde{\mathrm{C}}_{\boldsymbol{y}}(\boldsymbol{g}), \mathrm{C}_{\hat{\boldsymbol{y}}}(\boldsymbol{g})). \tag{10}$$

and the predict precision of n-grams changes into

$$\tilde{p}_n = \frac{\sum_{\boldsymbol{g}\in\boldsymbol{y}} \widetilde{\mathrm{C}}_{\boldsymbol{y}}^{\hat{y}}(\boldsymbol{g})}{\sum_{\boldsymbol{g}\in\boldsymbol{y}} \widetilde{\mathrm{C}}_{\boldsymbol{y}}(\boldsymbol{g})}. \tag{11}$$

Finally, the probabilistic BLEU (P-BLEU) is defined as

$$\text{P-BLEU} = \mathrm{BP}\cdot\exp(\sum_{n=1}^{N} w_n \log \tilde{p}_n), \tag{12}$$

Probabilistic GLEU (P-GLEU) can be defined in a similar way. Specifically, we denote the probabilistic precision of n-grams as P-Pn. The probabilistic precision is more reasonable than recall since the denominator in Eq.(11) plays a normalization role, so we modify the definition in Eq.(8) and define P-GLEU as simply the probabilistic precision of 1-4 grams.

The general probabilistic loss function is:

$$\mathcal{L}(\theta) = -\sum_{m=1}^{M} \mathcal{P}(\boldsymbol{y}^m, \hat{\boldsymbol{y}}^m), \tag{13}$$

where $\mathcal{P}$ represents the probabilistic sequence-level objectives, and $\boldsymbol{y}^m$ and $\hat{\boldsymbol{y}}^m$ are the predicted translation and the ground truth for the m-th sentence respectively. The calculation of the probabilistic objective is illustrated in Figure 1. This probabilistic loss can work with decoding strategies such as greedy search and teacher forcing. In this paper we employ greedy search rather than teacher forcing so as to use the previously predicted words as context and alleviate the exposure bias problem.

4 Experiment

4.1 Settings

We carry out experiments on Chinese-to-English translation.[1] The training data consists of 1.25M pairs of sentences extracted from LDC corpora[2]. Sentence pairs with either side longer than 50 were dropped. We use NIST 2002 (MT 02) as the validation set and NIST 2003-2006 (MT 03-08) as the test sets. We use the case insensitive 4-gram NIST BLEU score (Papineni et al., 2002) for the translation task.

We apply our method to an attention-based NMT system (Bahdanau et al., 2014) implemented by Pytorch. Both source and target vocabularies are limited to 30K. All word embedding sizes are set to 512, and the sizes of hidden units in both encoder and decoder RNNs are also set to 512. All parameters are initialized by uniform distribution over $[-0.1, 0.1]$. The mini-batch stochastic gradient descent (SGD) algorithm is employed to train the model with batch size of 40. In addition, the learning rate is adjusted by adadelta optimizer (Zeiler, 2012) with $\rho = 0.95$ and $\epsilon = 1e$-6. Dropout is applied on the output layer with dropout rate of 0.5. The beam size is set to 10.

4.2 Performance

Systems We first pretrain the baseline model by maximum likelihood estimation (MLE) and then refine the model using probabilistic sequence-level objectives, including P-BLEU, P-GLEU and P-P2 (probabilistic 2-gram precision). In addition, we reproduce previous works which train the NMT model through minimum risk training (MRT) (Shen et al., 2016) and REINFORCE algorithm (RF) (Ranzato et al., 2015). When reproducing their works, we set BLEU, GLEU and 2-gram precision as training objectives respectively and find out that GLEU yields the best performance. In the following, we only report the results with training objective GLEU.

Performance Table 1 shows the translation performance on test sets measured in BLEU score. Simply training NMT model by the probabilistic 2-gram precision achieves an improvement of 1.5 BLEU points, which significantly outperforms the reinforcement-based algorithms. We also test the precision of other n-grams and their combinations, but do not notice significant improvements over P-P2. Notice that our method only changes the loss function, without any modification on model structure and training data.

4.3 Why Pretraining

We use the probabilistic loss to finetune the baseline model rather than training from scratch. This is in line with our motivation: to alleviate the exposure bias and make the model exposed to its own output during training. In the very beginning of the training, the model's translation capability is nearly zero and the generated sentences are often meaningless and do not contain useful information for the training, so it is unreasonable to directly apply the greedy search strategy. Therefore, we first apply the teacher forcing algorithm to pretrain the model, and then we let the model generate the sentences itself and learn from its own outputs.

Another reason favoring pretraining is that pretraining can lower the training cost. The training cost of the introduced probabilistic loss is about three times higher than the cost of cross entropy. Without pretraining, the training time will be much higher than usual. Otherwise, the training cost is acceptable if the probabilistic loss is only for finetuning.

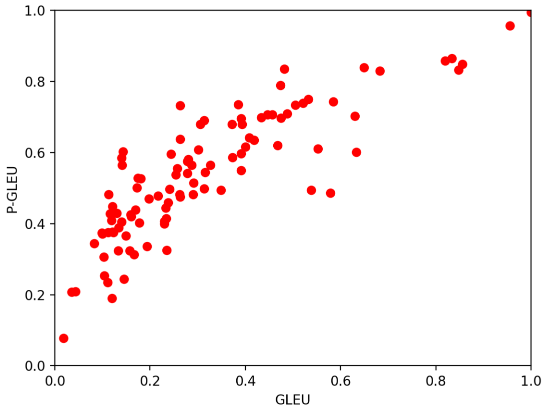

Figure 3: P-GLEU and GLEU scores on 100 pairs of sentences.

4.4 Effect of Decoding Strategy

The probabilistic loss, defined in Eq.(13), is computed from the model output $\boldsymbol{y}$ and reference $\hat{\boldsymbol{y}}$. In this section, we apply two different decoding strategies to generate $\boldsymbol{y}$: 1. teacher forcing, which uses the ground truth as decoder input. 2. greedy search, which feeds the word with maximum probability. By conducting this experiment, we attempt to figure out where the improvements come from: the modification of loss or the mitigation of exposure bias?

Figure 2 shows the learning curves of the two decoding strategies with training objective P-P2. Teacher forcing raises about 0.5 BLEU improvements and greedy search outperform the teacher forcing algorithm by nearly 1 BLEU point. We conclude that the probabilistic loss has its own advantage even when trained by the teacher forcing algorithm, and greedy search is effective in alleviating the exposure bias.

Notice that the greedy search strategy highly relys on the probabilistic loss and can not be conducted independently. Greedy search together with the word-level loss is very similar with the scheduled sampling(SS). However, SS is inconsistent with the word-level loss since the word-level loss requires strict alignment between hypothesis and reference, which can only be accomplished by the teacher forcing algorithm.

4.5 Correlation with Evaluation Metrics

In this section, we explore how the probabilistic objective correlates with the real evaluation metric. We randomly sample 100 pairs of sentences from the training set and compute their P-GLEU and GLEU scores (Wu et al. (2016) indicates that GLEU have better performance in the sentence-level evaluation than BLEU).

Directly computing the correlation between GLEU and P-GLEU gives the correlation coefficient 0.86, which indicates strong correlation. In addition, we draw the scatter diagram of the 100 pairs of sentences in Figure 3 with GLEU as x-axis and P-GLEU as y-axix. Figure 3 shows that P-GLEU correlates well with GLEU, suggesting that it is reasonable to directly train the NMT model with P-GLEU.

5 Conclusion

Word-level loss cannot evaluate the translation properly and suffers from the exposure bias, and sequence-level objectives are usually indifferentiable and require gradient estimation. We propose probabilistic sequence-level objectives based on n-gram matching, which relieve the dependence on gradient estimation and can directly train the NMT model. Experiment results show that our method significantly outperforms previous sequence-level training works and successfully alleviates the exposure bias through performing greedy search.

Abstract

In Neural Machine Translation (NMT), the decoder can capture the features of the entire prediction history with neural connections and representations. This means that partial hypotheses with different prefixes will be regarded differently no matter how similar they are. However, this might be inefficient since some partial hypotheses can contain only local differences that will not influence future predictions. In this work, we introduce recombination in NMT decoding based on the concept of the "equivalence" of partial hypotheses. Heuristically, we use a simple n-gram suffix based equivalence function and adapt it into beam search decoding. Through experiments on large-scale Chinese-to-English and English-to-Germen translation tasks, we show that the proposed method can obtain similar translation quality with a smaller beam size, making NMT decoding more efficient.

1 Introduction

Recently, end-to-end Neural Machine Translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2015) have achieved notable success. A remarkable characteristic of NMT is that the decoder, which is typically implemented using Recurrent Neural Network (RNN), can capture the features of the entire decoding history. This model does not depend on any independence assumptions and treats sequences with different prefixes as totally different hypotheses. However, many of the NMT output sequences are quite similar and they typically contain only local differences that do not influence future decoding significantly.

end with "*cities*" share similar patterns. Firstly, as shown in Figure 1, their hidden layer features are close in the latent space. Moreover, for future predictions, the model predicts identical sequences and gives similar scores for them. Although going through different paths, these partial hypotheses appear to be similar or likely equivalent.

Intuitively, for efficiency, we do not need to expand all of these partial hypotheses (states) since they have similar future predictions. In fact, this corresponds to the idea of hypothesis recombination (also known as state merging, which will be used interchangeably) from traditional Phrase-Based Statistical Machine Translation (PBSMT) (Koehn et al., 2003). Given a method to find mergeable states, we can employ recombination in NMT decoding as well.

In this paper, we adopt the mechanism of recombination in NMT decoding based on the definition of "equivalence" of partial hypotheses. Heuristically, we try a simple n-gram suffix based equivalence function and apply it to beam search without adding any neural computation cost. Through experiments on two large-scale translation tasks, we show that it can help to make the decoding more efficient.

Most recent NMT studies have focused on model improvement (Luong et al., 2015; Tu et al., 2016b; Gehring et al., 2017; Vaswani et al., 2017), and only a few have studied the search problem directly. For example, Khayrallah et al. (2017) and Stahlberg et al. (2016) explored searching on lattices generated by traditional Statistical Machine Translation (SMT). In addition, Freitag and Al-Onaizan (2017) investigated different beam search pruning strategies; however, they primarily focused on pruning candidates locally. (Niehues et al., 2017) analyzed the effects of modeling and searching, but focused on re-ranking analysis. Rather than considering candidates from other model's k-best lists, we focus on the own exploration space of a single NMT model and provide a method for more efficient searching.

2 Method

For state merging, "equivalence" should be defined from the aspect of future predictions: states with the same predictions in the future decoding process can be regarded as equivalent. We use an equivalence function $Eq(s_1, s_2)$ to denote that the two states s_1 and s_2 can be regarded as equivalent.

With the concept of equivalence, we can build the method of recombination over it. There are mainly two problems to solve:

1. How to merge states given function Eq? (§2.1)
2. How to obtain this equivalence function? (§2.2)

2.1 Search with Merging

To adopt an equivalence function $Eq(s_1, s_2)$ to merge states in a search process, we need to specify the logic of the merging mechanism. Here, without loss of generality, we specifically focus on the typical beam search.

We adopt merging in NMT beam search with a simple method: retaining the word-level search process and adding a state merger when pruning the beam at each time step. Algorithm 1 shows the proposed merging-enhanced pruning method.

Ordinary beam search only prunes candidates based on beam size (Lines 15-16), while the proposed method adds a merger to prune extra equivalent states (Lines 6-10). To manage the merging process, candidate list C are ordered[1] by model score and considered in turn. When checking equivalence for one candidate state c, we consider all current-step surviving states and their previous-step antecedences. We include previous-step states, because equivalent states may have different sequence lengths and thus not be in the same beam-search step. In Line 8, we define "sequence" as a function of obtaining the possible states that

---

[1] In plain beam search, the candidates may not need to be sorted. We use a local selector to make the sorting efficient: a local k-best selector is first applied on each previous-step candidate states, making the size of the candidate list at most $k * k$ rather than $k * |V|$, where $|V|$ is the vocabulary size.

can merge the current candidate c. If a candidate state c is not merged with any higher-ranked state, it is added to the surviving list C' (Line 13) and can possibly merge the lower-ranked ones later.

When deciding whether to merge, we also consider a criterion on model scores: we only merge state c when its score is lower than s'. Since we also consider previous-step states with different sequence lengths, a length reward λ is added for this comparison of partial hypotheses: $\text{score}(s) = \sum_{y \in s} \lambda + \log \text{p}(y)$. We also attempted length normalization, but found it performed slightly worse.

The merged partial hypotheses can be stored, and by assuming that their future predictions will be the same as their mergers, a lattice-like translation graph can be obtained. We can further extract k-best list from this structure using another beam-search on the lattice (also with length reward when comparing partial hypotheses). Note that this beam search process can be fast, since we reuse the model scores from previous search and no extra neural computations will be included.

2.2 Equivalence Function

Finding an exact equivalence function for NMT is difficult, because future predictions relies on the features from the entire previous sequence and any different sequences are not the same according to the NMT model. Here, we consider a n-gram suffix based heuristic approximation for this problem.

We adopt an approximate equivalence function:

$$\begin{aligned} Eq'(s_1, s_2) \;\equiv\; & s_1.suffix(n) = s_2.suffix(n) \\ & \wedge |s_1.length - s_2.length| < r \end{aligned}$$

Here, $suffix(n)$ represents the n-gram suffix of the sequence of a state, and r is the threshold for the length different of the two states.

This definition of equivalence only considers a subset of state features, which are inspired by PBSMT. In PBSMT, different sequences could lead to states with identical features based on n-gram suffix, and these states are exactly equivalent. Although this is not the case for NMT, the subset may encodes important and relevant features.

Although this function is simple and brings extra approximation, it has the merit of efficiency. In Algorithm 1, we can store the n-gram features of the surviving states in a hash-map and replace the for-loop checking (Line 6-10) with hashing, making the extra time-complexity O(1) for each state. During experiments, we found the extra cost brought by feature matching is far less than the cost of original neural computation.

3 Experiments and Analysis

The proposed method was evaluated on two translation tasks: NIST Chinese-English (Zh-En) and WMT English-German (En-De). For Zh-En, the training set comprised 1.4M sentences pairs from LDC corpora. NIST 02 was selected as the development set and NIST 03 to 06 were used for testing. For En-De, 4.5M WMT training data were utilized, the concatenation of newstest 2012 and 2013 was adopted as the development set, and newstest 2014 to 2016 were adopted as the test set.

We implemented[2] an attentional RNN-based NMT model and its decoder in Python with the DyNet toolkit (Neubig et al., 2017). All the experiments were carried out on one P100 GPU. For Zh-En, we set the vocabulary size of both sides to 30K, and for En-De, we adopted 50K BPE operations (Sennrich et al., 2016). The evaluation metric was tokenized BLEU (Papineni et al., 2002) calculated by `multi-bleu.perl`. Detailed settings can be found in the supplementary material.

We added a local threshold pruner to exclude unlikely words whose probabilities were less than 10% of the highest and adopted length normalization for final hypotheses ranking. For comparing partial hypotheses, the length reward λ was set to 1.0 and 0.4 for Zh-En and En-De, respectively. For the equivalence function, we utilized a suffix of 4-gram and a length difference threshold r of 2.

These hyper-parameters were set by preliminary experiments. For the length difference threshold r, we found that relatively small r like 1 or 2 was better than larger ones, which is reasonable since if the merged hypotheses differs too much in length, there are higher chances that they covered different information. For n-gram suffix, we found smaller n-grams made more bad merges and 4-gram is a reasonably good choice, slightly larger ones gave slightly worse results and also less chances of recombination.

3.1 Results

Figure 2 show the results of various beam sizes on the concatenation of all test sets. Separate results are given in the supplementary material.

As shown by the speed curves, merging adds little extra cost (less than 10%) to decoding at

---

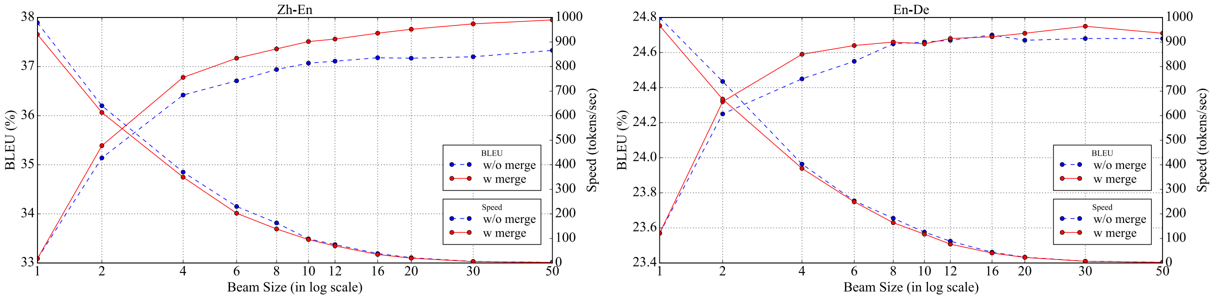

Figure 2: Translation quality and speed of Zh-En and En-De test sets (5453 sentences by concatenating NIST 03 to 06 and 8171 sentences by concatenating newstest 2014 to 2016, respectively).

the same beam size. Moreover, since bringing no extra neural computations, the proposed merging mechanism is transparent to neural architectures and easy to adopt. In our experiments, we used batched decoding on GPU and merging did not influence the efficiency of this implementation.

For translation quality, the results indicate that the proposed methods can yield improvements at various beam sizes for Zh-En and small beam sizes for En-De. Moreover, in some way, merging can make the search more efficient. For example, in both datasets, merge-enhanced searchers with beam-size 6 can obtain comparable or better results compared to those of ordinary searchers with beam-size 12 (on BLEU, 37.17 vs. 37.11 for Zh-En, 24.64 vs. 24.67 for En-De). As for decoding speed, the one of beam-size 6 can be more than twice of the one of beam-size 12 (over 200 tokens/second vs. around 100 tokens/second). That is to say, with merging, we can achieve similar translation quality with a smaller beam size, which leads to higher decoding speed.

The results show that for large beam sizes, expanding explored search space by increasing beam size or adopting merging helps more in Zh-En than En-De. A possible explanation for this is that in NIST Zh-En dataset, each source sentences has four references for evaluation, which encourages the diversity brought by expanding reached search space. In Table 2, we compare the BLEU scores with multiple and single references on several beam sizes, and the single-reference results does not always increase along the beam size like the multiple ones. The En-De dataset also has only one reference and is similar to this case.

The results also show that expanding explored search space does not always bring improvements. This concerns more on modeling than searching and corresponds with previous findings on the relations between NMT searching and modeling (Tu et al., 2016a; Niehues et al., 2017; Li et al., 2018).

Ref \ Beam	10	16	30	50
Multi-Ref	37.07	37.17	37.19	37.32
Single-Ref	18.23	18.29	18.23	18.26

Table 2: Comparisons of multi- and single-reference BLEU scores of NIST 03-06 with "w/o merging". "Multi-Ref" uses all four references, and "Single-Ref" only uses the second one, whose evaluations disagree most with "Multi-ref".

The potential of the proposed method might be better realized with improved NMT models.

3.2 Analysis

We further analyzed the merge-enhanced search process. For these analyses, we mainly checked decoding with a beam size of 10 on Zh-En dataset.

Frequency of Merging First, we investigated how often recombination occurs and how much it expands the explored output space. For a beam size of 10, with influences from the local pruner and the proposed merger, the average expanding size is 7.60 for each step, and the average number of merger-pruned partial hypotheses is 0.61 per step (22.5 per sentence). This indicates that a partial hypothesis is recombined in every two steps. The output translation graph can hold much more output space than the original k-best list, and we found that on average the possible output sequences were averagely 200 times the beam size. Figure 3 shows an example of the output translation graph.

Merging and Similarity of Hidden States It is nearly impossible to explore such a large space with an exact NMT model; thus, we depend on the assumption that merged hypotheses have nearly the same features. To evaluate this assumption, we calculated the similarity between the hidden layers of the merged partial hypotheses. Among the 122772 merge points in 5453 Zh-En sentences, the average cosine similarity (in range $[-1, 1]$) was 0.986, which indicates that the recombinations are reasonable. In addition, we tried adding simple cosine similarity constraints (using another

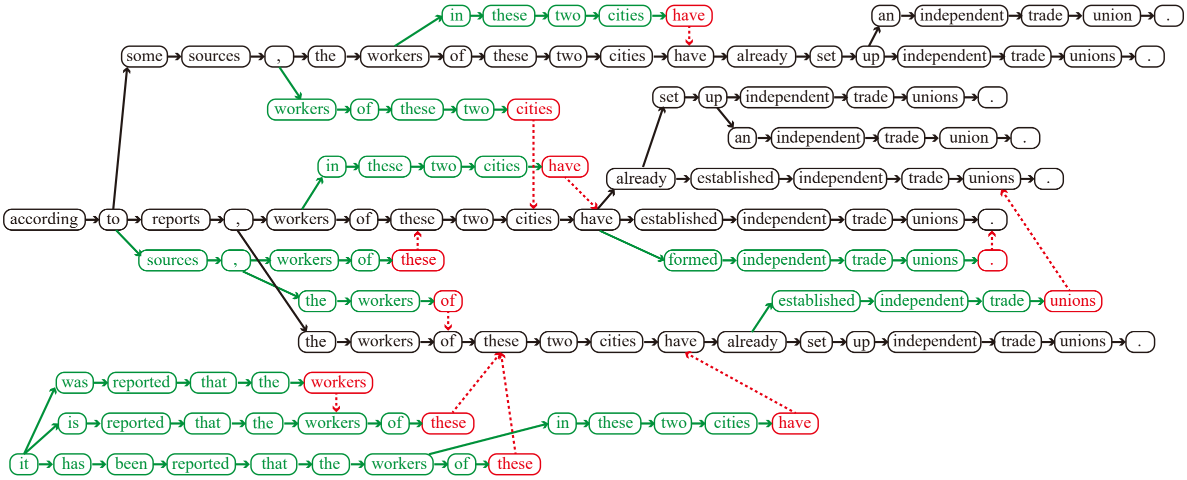

Figure 3: An example output translation graph. The red nodes and dashed arrows indicate merge points.

Beam	w/ merge	w/o merge
1	1.6% / 90.6%	1.6% / 90.6%
4	8.0% / 51.3%	5.2% / 54.8%
10	29.1% / 15.7%	–
16	44.5% / 11.8%	28.2% / 5.6%
30	64.6% / 20.3%	56.4% / 20.2%

Table 3: Comparisons of prediction model scores between different searching settings and a basic setting, which is "Beam=10, w/o merge". The pattern "$a\%$ / $b\%$" means that compared with the basic setting, $a\%$ of the sentences get higher model scores and $b\%$ get lower ones. For the rest (1-$a\%$-$b\%$), they give identical predictions.

threshold) in the equivalence function, however, we found that this does not bring obvious additional benefits.

Effects of Merging We further conducted comparisons between the predictions of ordinary and merge-enhanced beam search. First, we investigated the model scores of their predictions. As shown in Table 3, we selected "Beam=10, no merge" as the basic setting, and compared the predictions of other settings with it. Overall, the merge-enhanced searcher can obtain higher model score predictions, which suggests its stronger search ability, because the goal of searching is to return hypotheses with higher model scores.

Moreover, we tried a re-ranking experiment on 100-best lists with 4-checkpoint-model-ensemble, and only found similar slight improvements for plain and merge-enhanced search. Nevertheless, since merge-enhanced search can obtain a output translation graph, we expect that the graph can contain more diverse hypotheses.

To verify this, we compared the oracle BLEU scores within the reached space. To extract oracle hypotheses from the translation graphs, we simply adopted approximate Partial BLEU Oracle (Dreyer et al., 2007; Sokolov et al., 2012). Merge-based searcher could obtain an oracle score of 47.83, while ordinary beam searcher could only get 42.57. Only by increasing the beam size up to 100 could the ordinary beam searcher achieve a better result of 48.74. This indicates that recombination helps to touch more output space.

4 Conclusion and Discussion

In this work, 1) we show that decoding with heuristic recombination can obtain similar translation qualities with smaller beam sizes, thus increasing efficiency, and, 2) we empirically explore the decoding process and analyze the influences of recombination from various aspects.

Although the improvements brought by recombination depend on careful refinements of the model, this concerns more on modeling, since the goal of decoding is to find hypotheses with higher model scores. The potential of recombination may be further realized by improving how the output sequences are modeled. Another interesting topic will be the combination with SMT or extra larger language models (Wang et al., 2013, 2014).

For the equivalence function, there can also be extensions. For example, a model-based equivalence function can be trained by using the neural features (hidden layers in RNN). However, model-based equivalence functions may bring extra neural computation cost and be harder to efficiently implemented. In this work, we focus on the merging mechanism and leave the study of equivalence function for future work.

Has Machine Translation Achieved Human Parity?
A Case for Document-level Evaluation

Abstract

Recent research suggests that neural machine translation achieves parity with professional human translation on the WMT Chinese–English news translation task. We empirically test this claim with alternative evaluation protocols, contrasting the evaluation of single sentences and entire documents. In a pairwise ranking experiment, human raters assessing adequacy and fluency show a stronger preference for human over machine translation when evaluating documents as compared to isolated sentences. Our findings emphasise the need to shift towards document-level evaluation as machine translation improves to the degree that errors which are hard or impossible to spot at the sentence-level become decisive in discriminating quality of different translation outputs.

1 Introduction

Neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) has become the de-facto standard in machine translation, outperforming earlier phrase-based approaches in many data settings and shared translation tasks (Luong and Manning, 2015; Sennrich et al., 2016; Cromieres et al., 2016). Some recent results suggest that neural machine translation "approaches the accuracy achieved by average bilingual human translators [on some test sets]" (Wu et al., 2016), or even that its "translation quality is at human parity when compared to professional human translators" (Hassan et al., 2018). Claims of human parity in machine translation are certainly extraordinary, and require extraordinary evidence.[1] Laudably, Hassan et al. (2018) have released their data publicly to allow external validation of their claims. Their claims are further strengthened by the fact that they follow best practices in human machine translation evaluation, using evaluation protocols and tools that are also used at the yearly Conference on Machine Translation (WMT) (Bojar et al., 2017), and take great care in guarding against some confounds such as test set selection and rater inconsistency.

However, the implications of a statistical tie between two machine translation systems in a shared translation task are less severe than that of a statistical tie between a machine translation system and a professional human translator, so we consider the results worthy of further scrutiny. We perform an independent evaluation of the professional translation and best machine translation system that were found to be of equal quality by Hassan et al. (2018). Our main interest lies in the evaluation protocol, and we empirically investigate if the lack of document-level context could explain the inability of human raters to find a quality difference between human and machine translations. We test the following hypothesis:

> A professional translator who is asked to rank the quality of two candidate translations on the document level will prefer a professional human translation over a machine translation.

Note that our hypothesis is slightly different from that tested by Hassan et al. (2018), which could be phrased as follows:

> A bilingual crowd worker who is asked to directly assess the quality of candidate translations on the sentence level will prefer a professional human translation over a machine translation.

---

[1] The term "parity" may raise the expectation that there is evidence for equivalence, but the term is used in the definition of "there [being] no statistical significance between [two outputs] for a test set of candidate translations" by Hassan et al. (2018). Still, we consider this finding noteworthy given the strong evaluation setup.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4791–4796
Brussels, Belgium, October 31 - November 4, 2018.

As such, our evaluation is not a direct replication of that by Hassan et al. (2018), and a failure to reproduce their findings does not imply an error on either our or their part. Rather, we hope to indirectly assess the accuracy of different evaluation protocols. Our underlying assumption is that professional human translation is still superior to neural machine translation, but that the sensitivity of human raters to these quality differences depends on the evaluation protocol.

2 Human Evaluation of Machine Translation

Machine translation is typically evaluated by comparing system outputs to source texts, reference translations, other system outputs, or a combination thereof (for examples, see Bojar et al., 2016a). The scientific community concentrates on two aspects: adequacy, typically assessed by bilinguals; and target language fluency, typically assessed by monolinguals. Evaluation protocols have been subject to controversy for decades (e. g., Van Slype, 1979), and we identify three aspects with particular relevance to assessing human parity: granularity of measurement (ordinal vs. interval scales), raters (experts vs. crowd workers), and experimental unit (sentence vs. document).

2.1 Related Work

Granularity of Measurement Callison-Burch et al. (2007) show that ranking (*Which of these translations is better?*) leads to better inter-rater agreement than absolute judgement on 5-point Likert scales (*How good is this translation?*) but gives no insight about how much a candidate translation differs from a (presumably perfect) reference. To this end, Graham et al. (2013) suggest the use of continuous scales for direct assessment of translation quality. Implemented as a slider between 0 (*Not at all*) and 100 (*Perfectly*), their method yields scores on a 100-point interval scale in practice (Bojar et al., 2016b, 2017), with each raters' rating being standardised to increase homogeneity. Hassan et al. (2018) use source-based direct assessment to avoid bias towards reference translations. In the shared task evaluation by Cettolo et al. (2017), raters are shown the source and a candidate text, and asked: *How accurately does the above candidate text convey the semantics of the source text?* In doing so, they have translations produced by humans and machines rated independently, and parity is assumed if the mean score of the former does not significantly differ from the mean score of the latter.

Raters To optimise cost, machine translation quality is typically assessed by means of crowdsourcing. Combined ratings of bilingual crowd workers have been shown to be more reliable than automatic metrics and "very similar" to ratings produced by "experts"[2] (Callison-Burch, 2009). Graham et al. (2017) compare crowdsourced to "expert" ratings on machine translations from WMT 2012, concluding that, with proper quality control, "machine translation systems can indeed be evaluated by the crowd alone." However, it is unclear whether this finding carries over to translations produced by NMT systems where, due to increased fluency, errors are more difficult to identify (Castilho et al., 2017a), and concurrent work by Toral et al. (2018) highlights the importance of expert translators for MT evaluation.

Experimental Unit Machine translation evaluation is predominantly performed on single sentences, presented to raters in random order (e. g., Bojar et al., 2017; Cettolo et al., 2017). There are two main reasons for this. The first is cost: if raters assess entire documents, obtaining the same number of data points in an evaluation campaign multiplies the cost by the average number of sentences per document. The second is experimental validity. When comparing systems that produce sentences without considering document-level context, the perceived suprasentential cohesion of a system output is likely due to randomness and thus a confounding factor. While incorporating document-level context into machine translation systems is an active field of research (Webber et al., 2017), state-of-the-art systems still operate at the level of single sentences (Sennrich et al., 2017; Vaswani et al., 2017; Hassan et al., 2018). In contrast, human translators can and do take document-level context into account (Krings, 1986). The same holds for raters in evaluation campaigns. In the discussion of their results, Wu et al. (2016) note that their raters "[did] not necessarily fully understand each randomly sampled sentence sufficiently" because it was provided with no context. In such setups, raters cannot reward textual cohesion and coherence.

---

[2] "Experts" here are computational linguists who develop MT systems, who may not be expert translators.

2.2 Our Evaluation Protocol

We conduct a quality evaluation experiment with a 2×2 mixed factorial design, testing the effect of source text availability (adequacy, fluency) and experimental unit (sentence, document) on ratings by professional translators.

Granularity of Measurement We elicit judgements by means of pairwise ranking. Raters choose the better (with ties allowed) of two translations for each item: one produced by a professional translator (HUMAN), the other by machine translation (MT). Since our evaluation includes that of human translation, it is reference-free. We evaluate in two conditions: adequacy, where raters see source texts and translations (*Which translation expresses the meaning of the source text more adequately?*); and fluency, where raters only see translations (*Which text is better English?*).

Raters We recruit professional translators, only considering individuals with at least three years of professional experience and positive client reviews.

Experimental Unit To test the effect of context on perceived translation quality, raters evaluate entire documents as well as single sentences in random order (i. e., context is a within-subjects factor). They are shown both translations (HUMAN and MT) for each unit; the source text is only shown in the adequacy condition.

Quality Control To hedge against random ratings, we convert 5 documents and 16 sentences per set into spam items (Kittur et al., 2008): we render one of the two options nonsensical by shuffling its words randomly, except for 10 % at the beginning and end.

Statistical Analysis We test for statistically significant preference of HUMAN over MT or vice versa by means of two-sided Sign Tests. Let a be the number of ratings in favour of MT, b the number of ratings in favour of HUMAN, and t the number of ties. We report the number of successes x and the number of trials n for each test, such that $x = b$ and $n = a + b$.[3]

2.3 Data Collection

We use the experimental protocol described in the previous section for a quality assessment of Chinese to English translations of news articles. To this end, we randomly sampled 55 documents and 2×120 sentences from the WMT 2017 test set. We only considered the 123 articles (documents) which are native Chinese,[4] containing 8.13 sentences on average. Human and machine translations (REFERENCE-HT as HUMAN, and COMBO-6 as MT) were obtained from data released by Hassan et al. (2018).[5]

The sampled documents and sentences were rated by professional translators we recruited from ProZ:[6] 4 native in Chinese (2), English (1), or both (1) to rate adequacy, and 4 native in English to rate fluency. On average, translators had 13.7 years of experience and 8.8 positive client reviews on ProZ, and received US$ 188.75 for rating 55 documents and 120 sentences.

The averages reported above include an additional translator we recruited when one rater showed poor performance on document-level spam items in the fluency condition, whose judgements we exclude from analysis. We also exclude sentence-level results from 4 raters because there was overlap with the documents they annotated, which means that we cannot rule out that the sentence-level decisions were informed by access to the full document. To allow for external validation and further experimentation, we make all experimental data publicly available.[7]

3 Results

In the adequacy condition, MT and HUMAN are not statistically significantly different on the sentence level ($x{=}86$, $n{=}189$, $p{=}.244$). This is consistent with the results Hassan et al. (2018) obtained with an alternative evaluation protocol (crowdsourcing and direct assessment; see Section 2.1). However, when evaluating entire doc-

---

[3] Emerson and Simon (1979) suggest the inclusion of ties such that $x = b + 0.5t$ and $n = a + b + t$. This modification has no effect on the significance levels reported in this paper.

[4] While it is common practice in machine translation to use the same test set in both translation directions, we consider a direct comparison between human "translation" and machine translation hard to interpret if one is in fact the original English text, and the other an automatic translation into English of a human translation into Chinese. In concurrent work, Toral et al. (2018) expand on the confounding effect of evaluating text where the target side is actually the original document.

[5] `http://aka.ms/Translator-HumanParityData`

[6] `https://www.proz.com`

[7] `https://github.com/laeubli/parity`

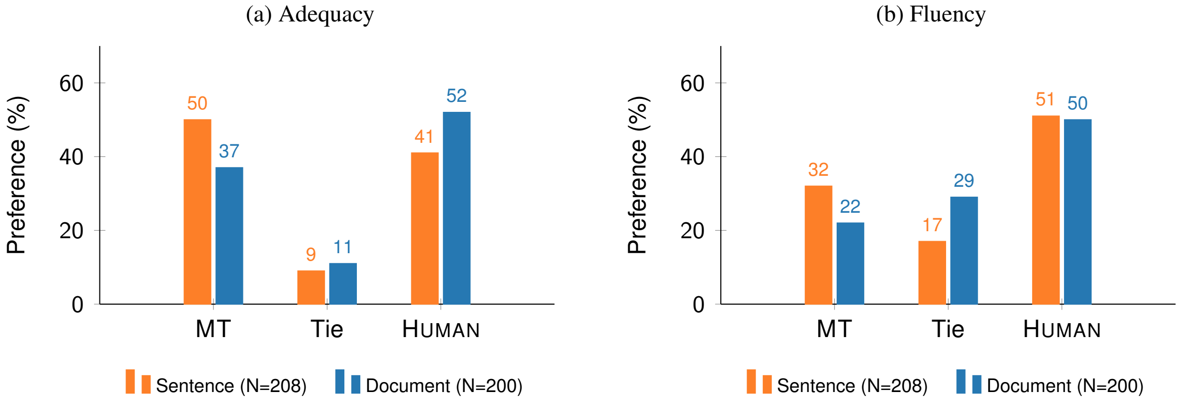

Figure 1: Raters prefer human translation more strongly in entire documents. When evaluating isolated sentences in terms of adequacy, there is no statistically significant difference between HUMAN and MT; in all other settings, raters show a statistically significant preference for HUMAN.

uments, raters show a statistically significant preference for HUMAN ($x=104$, $n=178$, $p<.05$). While the number of ties is similar in sentence- and document-level evaluation, preference for MT drops from 50 to 37 % in the latter (Figure 1a).

In the fluency condition, raters prefer HUMAN on both the sentence ($x=106$, $n=172$, $p<.01$) and document level ($x=99$, $n=143$, $p<.001$). In contrast to adequacy, fluency ratings in favour of HUMAN are similar in sentence- and document-level evaluation, but raters find more ties with document-level context as preference for MT drops from 32 to 22 % (Figure 1b).

We note that these large effect sizes lead to statistical significance despite modest sample size. Inter-annotator agreement (Cohen's κ) ranges from 0.13 to 0.32 (see Appendix for full results and discussion).

4 Discussion

Our results emphasise the need for suprasentential context in human evaluation of machine translation. Starting with Hassan et al.'s (2018) finding of no statistically significant difference in translation quality between HUMAN and MT for their Chinese–English test set, we set out to test this result with an alternative evaluation protocol which we expected to strengthen the ability of raters to judge translation quality. We employed professional translators instead of crowd workers, and pairwise ranking instead of direct assessment, but in a sentence-level evaluation of adequacy, raters still found it hard to discriminate between HUMAN and MT: they did not show a statistically significant preference for either of them.

Conversely, we observe a tendency to rate HUMAN more favourably on the document level than on the sentence level, even within single raters. Adequacy raters show a statistically significant preference for HUMAN when evaluating entire documents. We hypothesise that document-level evaluation unveils errors such as mistranslation of an ambiguous word, or errors related to textual cohesion and coherence, which remain hard or impossible to spot in a sentence-level evaluation. For a subset of articles, we elicited both sentence-level and document-level judgements, and inspected articles for which sentence-level judgements were mixed, but where HUMAN was strongly preferred in document-level evaluation. In these articles, we do indeed observe the hypothesised phenomena. We find an example of lexical coherence in a 6-sentence article about a new app "微信挪车", which HUMAN consistently translates into "WeChat Move the Car". In MT, we find three different translations in the same article: "Twitter Move Car", "WeChat mobile", and "WeChat Move". Other observations include the use of more appropriate discourse connectives in HUMAN, a more detailed investigation of which we leave to future work.

To our surprise, fluency raters show a stronger preference for HUMAN than adequacy raters (Figure 1). The main strength of neural machine translation in comparison to previous statistical approaches was found to be increased fluency, while adequacy improvements were less clear (Bojar et al., 2016b; Castilho et al., 2017b), and we expected a similar pattern in our evaluation. Does this indicate that adequacy is in fact a strength of

MT, not fluency? We are wary to jump to this conclusion. An alternative interpretation is that MT, which tends to be more literal than HUMAN, is judged more favourably by raters in the bilingual condition, where the majority of raters are native speakers of the source language, because of L1 interference. We note that the availability of document-level context still has a strong impact in the fluency condition (Section 3).

5 Conclusions

In response to recent claims of parity between human and machine translation, we have empirically tested the impact of sentence and document level context on human assessment of machine translation. Raters showed a markedly stronger preference for human translations when evaluating at the level of documents, as compared to an evaluation of single, isolated sentences.

We believe that our findings have several implications for machine translation research. Most importantly, if we accept our interpretation that human translation is indeed of higher quality in the dataset we tested, this points to a failure of current best practices in machine translation evaluation. As machine translation quality improves, translations will become harder to discriminate in terms of quality, and it may be time to shift towards document-level evaluation, which gives raters more context to understand the original text and its translation, and also exposes translation errors related to discourse phenomena which remain invisible in a sentence-level evaluation.

Our evaluation protocol was designed with the aim of providing maximal validity, which is why we chose to use professional translators and pairwise ranking. For future work, it would be of high practical relevance to test whether we can also elicit accurate quality judgements on the document-level via crowdsourcing and direct assessment, or via alternative evaluation protocols. The data released by Hassan et al. (2018) could serve as a test bed to this end.

One reason why document-level evaluation widens the quality gap between machine translation and human translation is that the machine translation system we tested still operates on the sentence level, ignoring wider context. It will be interesting to explore to what extent existing and future techniques for document-level machine translation can narrow this gap. We expect that this will require further efforts in creating document-level training data, designing appropriate models, and supporting research with discourse-aware automatic metrics.

Abstract

We compare the performance of the APT and AutoPRF metrics for pronoun translation against a manually annotated dataset comprising human judgements as to the correctness of translations of the PROTEST test suite. Although there is some correlation with the human judgements, a range of issues limit the performance of the automated metrics. Instead, we recommend the use of semi-automatic metrics and test suites in place of fully automatic metrics.

1 Introduction

As the general quality of machine translation (MT) increases, there is a growing interest in improving the translation of specific linguistic phenomena. A case in point that has been studied in the context of both statistical (Hardmeier, 2014; Guillou, 2016; Loáiciga, 2017) and neural MT (Bawden et al., 2017; Voita et al., 2018) is that of pronominal anaphora. In the simplest case, translating anaphoric pronouns requires the generation of corresponding word forms respecting the grammatical constraints on agreement in the target language, as in the following English-French example, where the correct form of the pronoun in the second sentence varies depending on which of the (equally correct) translations of the word *bicycle* was used in the first:

(1) a. I have a bicycle. **It** is red.
b. J'ai un vélo. **Il** est rouge. [ref]
c. J'ai une bicyclette. **Elle** est rouge. [MT]

However, the problem is more complex in practice because there is often no $1:1$ correspondence between pronouns in two languages. This is easily demonstrated at the corpus level by observing that the number of pronouns varies significantly across languages in parallel texts (Mitkov and Barbu, 2003), but it tends to be difficult to predict in individual cases.

In general MT research, significant progress was enabled by the invention of automatic evaluation metrics based on reference translations, such as BLEU (Papineni et al., 2002). Attempting to create a similar framework for efficient research, researchers have proposed automatic reference-based evaluation metrics specifically targeting pronoun translation: AutoPRF (Hardmeier and Federico, 2010) and APT (Miculicich Werlen and Popescu-Belis, 2017). We study the performance of these metrics on a dataset of English-French translations and investigate to what extent automatic evaluation based on reference translations provides insights into how well an MT system handles pronouns. Our analysis clarifies the conceptual differences between AutoPRF and APT, uncovering weaknesses in both metrics, and investigates the effects of the alignment correction heuristics used in APT. By using the fine-grained PROTEST categories of pronoun function, we find that the accuracy of the automatic metrics varies across pronouns of different functions, suggesting that certain linguistic patterns are captured better in the automatic evaluation than others. We argue that fully automatic wide-coverage evaluation of this phenomenon is unlikely to drive research forward, as it misses essential parts of the problem despite achieving some correlation with human judgements. Instead, semi-automatic evaluation involving automatic identification of correct translations with high precision and low recall appears to be a more achievable goal. Another more realistic option is a test suite evaluation with a very limited scope.

2 Pronoun Evaluation Metrics for MT

Two reference-based automatic metrics of pronoun translation have been proposed in the literature.

---

[*] Both authors contributed equally.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 4797–4802
Brussels, Belgium, October 31 - November 4, 2018.

The first (Hardmeier and Federico, 2010) is a variant of precision, recall and F-score that measures the overlap of pronouns in the MT output with a reference translation. It lacks an official name, so we refer to it as *AutoPRF* following the terminology of the DiscoMT 2015 shared task (Hardmeier et al., 2015). The scoring process relies on a word alignment between the source and the MT output, and between the source and the reference translation. For each input pronoun, it computes a *clipped count* (Papineni et al., 2002) of the overlap between the aligned tokens in the reference and the MT output. The clipped count of a given word is defined as the number of times it occurs in the MT output, limited by the number of times it occurs in the reference translation. The final metric is then calculated as the precision, recall and F-score based on these clipped counts.

Miculicich Werlen and Popescu-Belis (2017) propose a metric called *Accuracy of Pronoun Translation (APT)* that introduces several innovations over the previous work. It is a variant of accuracy, so it counts, for each source pronoun, whether its translation can be considered correct, without considering multiple alignments. Since word alignment is problematic for pronouns, the authors propose an heuristic procedure to improve alignment quality. Finally, it introduces the notion of pronoun equivalence, assigning partial credit to pronoun translations that differ from the reference translation in specific ways deemed to be acceptable. In particular, it considers six possible cases when comparing the translation of a pronoun in MT output and the reference. The pronouns may be: (1) *identical*, (2) *equivalent*, (3) *different/incompatible*, or there may be no translation in: (4) the MT output, (5) the reference, (6) either the MT output or the reference. Each of these cases may be assigned a weight between 0 and 1 to determine the level of *correctness*.

3 The PROTEST Dataset

We study the behaviour of the two automatic metrics using the PROTEST test suite (Guillou and Hardmeier, 2016). The test suite comprises 250 hand-selected personal pronoun tokens taken from the *DiscoMT2015.test* dataset of TED talk transcriptions and translations (Hardmeier et al., 2016) and annotated according to the ParCor guidelines (Guillou et al., 2014). It is structured according to a linguistic typology motivated by work on functional grammar by Dik (1978) and Halliday (2004). Pronouns are first categorised according to their *function*:

anaphoric: I have a bicycle. **It** is red.
event: He lost his job. **It** was a shock.
pleonastic: **It** is raining.
addressee reference: **You**'re welcome.

They are then subcategorised according to morphosyntactic criteria, whether the antecedent is a group noun, whether the ancedent is in the same or a different sentence, and whether an addressee reference pronoun refers to one or more specific people (deictic) or to people in general (generic).

Our dataset contains human judgements on the performance of nine MT systems on the translation of the 250 pronouns in the PROTEST test suite. The systems include five submissions to the DiscoMT 2015 shared task on pronoun translation (Hardmeier et al., 2015) – four phrase-based SMT systems AUTO-POSTEDIT (Guillou, 2015), UU-HARDMEIER (Hardmeier et al., 2015), IDIAP (Luong et al., 2015), UU-TIEDEMANN (Tiedemann, 2015), a rule-based system ITS2 (Loáiciga and Wehrli, 2015), and the shared task baseline (also phrase-based SMT). Three NMT systems are included for comparison: LIMSI (Bawden et al., 2017), NYU (Jean et al., 2014), and YANDEX (Voita et al., 2018).

Manual evaluation was conducted using the PROTEST graphical user interface and accompanying guidelines (Hardmeier and Guillou, 2016). The annotators were asked to make judgements (correct/incorrect) on the translations of the pronouns and antecedent heads whilst ignoring the correctness of other words (except in cases where it impacted the annotator's ability to make a judgement). The annotations were carried out by two bilingual English-French speakers, both of whom are native speakers of French. Our human judgements differ in important ways from the human evaluation conducted for the same set of systems at DiscoMT 2015 (Hardmeier et al., 2015), which was carried out by non-native speakers over an unbalanced data sample using a gap-filling methodology. In the gap-filling task annotators are asked to select, from a predefined list (including an uninformative catch-all group "other"), those pronouns that could fill the pronoun translation slot. Unlike in the PROTEST evaluation, the pronoun translations were obscured in the MT output. This avoided priming the annotators with the output of the candidate translation, but it occasionally caused valid translations to be rejected because they were missed by the annotator.

4 Accuracy versus Precision/Recall

There are three ways in which APT differs from AutoPRF: the scoring statistic, the alignment heuristic in APT, and the definition of pronoun equivalence.

APT is a measure of accuracy: It reflects the proportion of source pronouns for which an acceptable translation was produced in the target. AutoPRF, by contrast, is a precision/recall metric on the basis of clipped counts. Hardmeier and Federico (2010) motivate the use of precision and recall by pointing out that word alignments are not $1 : 1$, so each pronoun can be linked to multiple elements in the target language, both in the reference translation and in the MT output. Their metric is designed to account for all linked words in such cases.

To test the validity of this argument, we examined the subset of examples of 8 systems in our English-French dataset[1] giving rise to a clipped count greater than one[2] and found that these examples follow very specific patterns. All 143 cases included exactly one personal pronoun. In 99 cases, the additional matched word was the complementiser *que* ‘that’. In 31 and 4 cases, respectively, it was a form of the auxiliary verbs *avoir* ‘to have’ and *être* ‘to be’. One example matched both *que* and a form of *être*. Two had reflexive pronouns, and one an imperative verb form. With the possible exception of the two reflexive pronouns, none of this seems to be relevant to pronoun correctness. We conclude that it is more reasonable to restrict the counts to a single pronominal item per example. With this additional restriction, however, the recall score of AutoPRF becomes equivalent to a version of APT without equivalent pronouns and alignment correction. We therefore limit the remainder of our study to APT.

5 Effects of Word Alignment

APT includes an heuristic alignment correction procedure to mitigate errors in the word alignment between a source-language text and its translation (reference or MT output). We ran experiments to assess the correlation of APT with human judgements, with and without the alignment correction heuristics.

Score	APT-A		APT-B		PRO-TEST
Alig. corr.	+	−	+	−	
Reference	1.000	1.000	1.000	1.000	0.920
BASELINE	**0.544**	**0.536**	**0.574**	**0.566**	0.660
IDIAP	0.496	0.496	0.528	0.528	0.660
UU-TIED.	0.532	0.532	0.562	0.562	0.680
UU-HARD.	0.528	0.520	0.556	0.548	0.636
POSTEDIT	0.492	0.492	0.532	0.532	0.668
ITS2	0.436	0.428	0.462	0.454	0.472
LIMSI	0.364	0.364	0.388	0.388	0.576
NYU	0.424	0.420	0.456	0.452	0.616
YANDEX	**0.544**	**0.536**	0.570	0.562	**0.796**

Table 1: Comparison of APT scores with human judgements over the PROTEST test suite

Table 1 displays the APT results in both conditions and the proportion of pronouns in the PROTEST test suite marked as correctly translated. For better comparison with the PROTEST test suite results, we restricted APT to the pronouns in the test suite. We used two different weight settings:[3] **APT-A** uses weight 1 for *identical* matches and 0 for all other cases. **APT-B** uses weight 1 for *identical* matches, 0.5 for *equivalent* matches and 0 otherwise.

There is little difference in the APT scores when we consider the use of alignment heuristics. This is due to the small number of pronouns for which alignment improvements are applied for most systems (typically 0–12 per system). The exception is the ITS2 system output for which 18 alignment improvements are made. For the following systems we observe a very small increase in APT score for each of the two weight settings we consider, when alignment heuristics are applied: UU-HARDMEIER (+0.8), ITS2 (+0.8), BASELINE (+0.8), YANDEX (+0.8), and NYU (+0.4). However, these small improvements are not sufficient to affect the system rankings. It seems, therefore, that the alignment heuristic has only a small impact on the validity of the score.

To assess differences in correlation with human judgment for pairs of APT settings, we run Williams’s significance test (Williams, 1959; Graham and Baldwin, 2014). The test reveals that differences in correlation between the various configurations of APT and human judgements are not statistically significant ($p > 0.2$ in all cases).

---

[1] Excluding the YANDEX system, which was added later.

[2] A clipped count greater than one for a given pronoun translation indicates that the MT output and the reference translation aligned to this pronoun overlap in more than one token.

[3] Personal recommendation by Lesly Miculicich Werlen.

	c1	c2	Pearson	Spearman
With alignment heuristics	1	0	0.848	0.820
	1	0.5	0.853	0.815
Without alignment heuristics	1	0	0.850	0.820
	1	0.5	0.855	0.811

Table 3: Number of pronouns marked as correct/incorrect in the PROTEST human judgements, as identical (1), equivalent (2), and incompatible (3) by APT, and the percentage of disagreements, per category (Disagree [Dis.] / Examples [Ex.])

6 Metric Accuracy per Category

Like Miculicich Werlen and Popescu-Belis (2017), we use Pearson's and Spearman's correlation coefficients to assess the correlation between APT and our human judgements (Table 2). Although APT does correlate with the human judgements over the PROTEST test suite, the correlation is weaker than that with the DiscoMT gap-filling evaluations reported in Miculicich Werlen and Popescu-Belis (2017). A Williams significance test reveals that the difference in correlation (for those systems common to both studies) is not statistically significant ($p > 0.3$). Table 1 also shows that the rankings induced from the PROTEST and APT scores are rather different. The differences are due to the different ways in which the two metrics define pronoun correctness, and the different sources against which correctness is measured (reference translation vs. human judgement).

We also study how the results of APT (with alignment correction) interact with the categories in PROTEST. We consider a pronoun to be measured as *correct* by APT if it is assigned case 1 (identical) or 2 (equivalent). Likewise, a pronoun is considered *incorrect* if it is assigned case 3 (incompatible). We compare the number of pronouns marked as correct/incorrect by APT and by the human judges, ignoring APT cases in which no judgement can be made: no translation of the pronoun in the MT output, reference or both, and pronouns for which the human judges were unable to make a judgement due to factors such as poor overall MT quality, incorrect word alignments, etc. The results of this comparison are displayed in Table 3.

At first glance, we can see that APT disagrees with the human judgements for almost a quarter (24.3%) of the assessed translations. The distribution of the disagreements over APT cases is very skewed and ranges from 8% for case 1 to 32% for case 2 and 49% for case 3. In other words, APT identifies correct pronoun translations with good precision, but relatively low recall. We can also see that APT rarely marks pronouns as equivalent (case 2).

Performance for anaphoric pronouns is mixed. In general, there are three main problems affecting anaphoric pronouns (Table 4). 1) APT, which does not incorporate knowledge of anaphoric pronoun antecedents, does not consider pronoun-antecedent head agreement so many *valid alternative translations involving personal pronouns* are marked as incompatible (i.e. incorrect, case 3), but as correct by the human judges. Consider the following example, in which the pronoun *they* is deemed correctly translated by the YANDEX system (according to the human judges) as it agrees in number and grammatical gender with the translation of the antecedent *extraits (clips)*. However, the pronoun translation *ils* is marked as incorrect by APT as it does not match the translation in the reference (*elles*).

SOURCE: so what these two **clips** show is not just the devastating consequence of the disease, but **they** also tell us something about the shocking pace of the disease…

YANDEX: donc ce que ces deux **extraits**[masc.,pl.] montrent n'est pas seulement la conséquence dévastatrice de la maladie, mais **ils**[masc. pl.] nous disent aussi quelque chose sur le rythme choquant de la maladie…

REFERENCE: ce que ces deux **vidéos**[fem.,pl.] montrent, ce ne sont pas seulement les conséquences dramatiques de cette maladie, **elles**[fem. pl.] nous montrent aussi la vitesse fulgurante de cette maladie…

2) Substitutions between pronouns are governed by much more complex rules than the simple pronoun equivalence mechanism in APT. For example, the dictionary of pronouns used in APT lists *il* and *ce* as equivalent. However, while *il* can often replace *ce* as a pleonastic pronoun in French, it has a much stronger tendency to be interpreted as anaphoric, rendering pleonastic use unacceptable if there is a salient masculine antecedent in the context. 3) APT does not consider the use of *impersonal pronouns* such as *c'* in place of the feminine personal pronoun *elle* or the plural forms *ils* and *elles*.

Category	**V**	**E**	**I**	**O**
Anaphoric				
intra-sent. subj. *it*	22	9	8	8
intra-sent. non-subj. *it*	16	–	1	2
inter-sent. subj. *it*	35	6	22	–
inter-sent. non-subj. *it*	–	–	–	13
intra-sent. *they*	25	–	3	9
inter-sent. *they*	22	–	3	22
singular *they*	40	–	–	18
group *it/they*	21	–	–	10
Event it	–	16	–	44
Pleonastic it	–	11	–	35

V: Valid alternative translation **I**: Impersonal translation
E: Incorrect equivalence **O**: Other

Table 4: Common cases of disagreement for anaphoric, pleonastic, and event reference pronouns

As with anaphoric pronouns, APT incorrectly marks some *pleonastic* and *event* translations as equivalent, in disagreement with the human judges. Other common errors arise from 1) the use of alternative translations marked as incompatible (i.e. incorrect) by APT but correct by the human judges, for example *il* (personal) in the MT output when the reference contained the impersonal pronoun *cela* or *ça* (30 cases for pleonastic, 7 for event), or 2) the presence of *il* in both the MT output and reference marked by APT as identical but by the human judges as incorrect (3 cases for pleonastic, 15 event).

Some of these issues could be addressed by incorporating knowledge of pronoun function in the source language, of pronoun antecedents, and of the wider context of the translation surrounding the pronoun. However, whilst we might be able to derive language-specific rules for some scenarios, it would be difficult to come up with more general or language-independent rules. For example, *il* and *ce* can be anaphoric or pleonastic pronouns, but *il* has a more *referential* character. Therefore in certain constructions that are strongly pleonastic (e.g. clefts) only *ce* is acceptable. This rule would be specific to French, and would not cover other scenarios for the translation of pleonastic *it*. Other issues include the use of pronouns in impersonal constructions such as *il faut* [one must/it takes] in which evaluation of the pronoun requires consideration of the whole expression, or transformations between active and passive voice, where the perspective of the pronouns changes.

7 Conclusions

Our analyses reveal that despite some correlation between APT and the human judgements, fully automatic wide-coverage evaluation of pronoun translation misses essential parts of the problem. Comparison with human judgements shows that APT identifies good translations with relatively high precision, but fails to reward important patterns that pronoun-specific systems must strive to generate. Instead of relying on fully automatic evaluation, our recommendation is to emphasise high precision in the automatic metrics and implement semi-automatic evaluation procedures that refer negative cases to a human evaluator, using available tools and methods (Hardmeier and Guillou, 2016). Fully automatic evaluation of a very restricted scope may still be feasible using test suites designed for specific problems (Bawden et al., 2017).
