Deep learning has proven successful in a wide range of NLP tasks (Bahdanau et al., 2014; Bengio et al., 2003; Clark and Manning, 2016; Hermann et al., 2015; Sutskever et al., 2014). The versatility stems from its capacity of learning a compact representation of complex input patterns (Goodfellow et al., 2016). However, success of deep learning is bounded by its reliance on labeled examples, which are expensive and time-consuming to produce. Indirect supervision has emerged as a promising direction for breaching the annotation bottleneck. A powerful paradigm is *joint inference* (Chang et al., 2007; Poon and Domingos, 2008; Druck et al., 2008; Ganchev et al., 2010), which leverages linguistic and domain knowledge to impose constraints over interdependent label decisions. More recently, another powerful paradigm, often loosely called *weak supervision*, has gained in popularity. The key idea is to introduce labeling functions to automatically generate (noisy) training examples from unlabeled text. *Distant supervision* is a prominent example that used existing knowledge bases for this purpose (Craven and Kumlien, 1999; Mintz et al., 2009). *Data programming* went further by soliciting labeling functions from domain experts (Ratner et al., 2016; Bach et al., 2017).

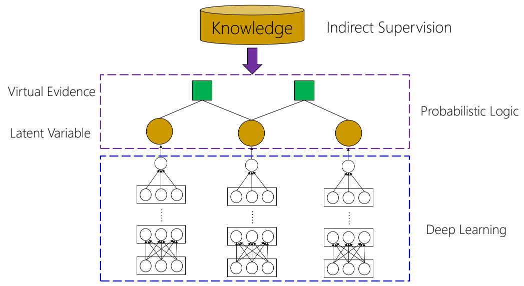

Figure 1: Deep Probabilistic Logic: A general framework for combining indirect supervision strategies by composing probabilistic logic with deep learning. Learning amounts to maximizing conditional likelihood of virtual evidence given input by summing up latent label decisions.

Indirect-supervision methods have achieved remarkable successes in a number of NLP tasks, but they also exhibit serious limitations. Distant supervision often produces incorrect labels, whereas labeling functions from data programming vary in

quality and coverage, and may contradict with each other on individual instances. Joint inference incurs greater modeling complexity and often requires specialized learning and inference procedures.

Since these methods draw on diverse and often orthogonal sources of indirect supervision, combining them may help address their limitations and amplify their strengths. Probabilistic logic offers an expressive language for such an integration, and is well suited for resolving noisy and contradictory information (Richardson and Domingos, 2006). Unfortunately, probabilistic logic generally incurs intractable learning and inference, often rendering end-to-end modeling infeasible.

In this paper, we propose **deep probabilistic logic (DPL)** as a unifying framework for indirect supervision (Figure 1). Specifically, we made four contributions. First, we introduce a modular design to compose probabilistic logic with deep learning, with a supervision module that represents indirect supervision using probabilistic logic, and a prediction module that performs the end task using a deep neural network. Label decisions are modeled as latent variables and serve as the interface between the two modules.

Second, we show that all popular forms of indirect supervision can be represented in DPL by generalizing virtual evidence (Subramanya and Bilmes, 2007; Pearl, 2014). Consequently, these diverse methods can be easily combined within a single framework for mutual amplification.

Third, we show that our problem formulation yields a well-defined learning objective (maximizing conditional likelihood of virtual evidence). We proposed a modular learning approach by decomposing the optimization over the supervision and prediction modules, using variational EM, which enables us to apply state-of-the-art methods for probabilistic logic and deep learning.

Finally, we applied DPL to biomedical machine reading (Quirk and Poon, 2017; Peng et al., 2017). Biomedicine offers a particularly attractive application domain for exploring indirect supervision. Biomedical literature grows by over one million each year[1], making it imperative to develop machine reading methods for automating knowledge curation (Figure 2). While crowd sourcing is hardly applicable, there are rich domain knowledge and structured resources to exploit for indirect supervision. Using cross-sentence relation extraction and entity linking as case studies, we show that distant supervision, data programming, and joint inference can be seamlessly combined in DPL to substantially improve machine reading accuracy, without requiring any manually labeled examples.[2]

2 Related Work

Distant supervision This paradigm was first introduced for binary relation extraction (Craven and Kumlien, 1999; Mintz et al., 2009). In its simplest form, distant supervision generates a positive example if an entity pair with a known relation co-occurs in a sentence, and samples negative examples from co-occurring entity pairs not known to have the given relation. It has recently been extended to cross-sentence relation extraction (Quirk and Poon, 2017; Peng et al., 2017). In principle, one simply looks beyond single sentences for co-occurring entity pairs. However, this can introduce many false positives and prior work used a small sliding window and filtering (minimal-span) to mitigate training noise. Even so, accuracy is relatively low. Both Quirk and Poon (2017) and Peng et al. (2017) used ontology-based string matching for entity linking, which also incurs many false positives, as biomedical entities are highly ambiguous (e.g., PDF and AAAS are gene names). Distant supervision for entity linking is relatively underexplored, and prior work generally focuses on Freebase entities, where links to the corresponding Wikipedia articles are available for learning (Huang et al., 2015).

Data Programming Instead of annotated examples, domain experts are asked to produce labeling functions, each of which assigns a label to an instance if the input satisfies certain conditions, often specified by simple rules (Ratner et al., 2016). This paradigm is useful for semantic tasks, as high-precision text-based rules are often easy to come by. However, there is no guarantee on broad coverage, and labeling functions are still noisy and may contradict with each other. The common denoising strategy assumes that labeling functions make random mistakes, and focuses on estimating their

---

[2] The DPL code and datasets will be made available at `http://hanover.azurewebsites.net`.

accuracy and correlation (Ratner et al., 2016; Bach et al., 2017). A more sophisticated strategy also models instance-level labels and uses instance embedding to estimate instance-level weight for each labeling function (Liu et al., 2017).

Joint Inference Distant supervision and data programming focus on infusing weak supervision on individual labels. Additionally, there is rich linguistic and domain knowledge that does not specify values for individual labels, but imposes hard or soft constraints on their joint distribution. For example, if two mentions are coreferent, they should agree on entity properties (Poon and Domingos, 2008). There is a rich literature on joint inference for NLP applications. Notable methodologies include constraint-driven learning (Chang et al., 2007), general expectation (Druck et al., 2008), posterior regularization (Ganchev et al., 2010), and probabilistic logic (Poon and Domingos, 2008). Constraints can be imposed on relational instances or on model expectations. Learning and inference are often tailor-made for each approach, including beam search, primal-dual optimization, weighted satisfiability solvers, etc. Recently, joint inference has also been used in denoising distant supervision. Instead of labeling all co-occurrences of an entity pair with a known relation as positive examples, one only assumes that at least one instance is positive (Hoffmann et al., 2011; Lin et al., 2016).

Probabilistic Logic Probabilistic logic combines logic's expressive power with graphical model's capability in handling uncertainty. A representative example is Markov logic (Richardson and Domingos, 2006), which define a probability distribution using weighted first-order logical formulas as templates for a Markov model. Probabilistic logic has been applied to incorporating indirect supervision for various NLP tasks (Poon and Domingos, 2007, 2008; Poon and Vanderwende, 2010), but its expressive power comes at a price: learning and inference are generally intractable, and end-to-end modeling often requires heavy approximation (Kimmig et al., 2012). In DPL, we limit the use of probabilistic logic to modeling indirect supervision in the supervision module, leaving end-to-end modeling to deep neural network in the prediction module. This alleviates the computational challenges in probabilistic logic, while leveraging the strength of deep learning in distilling complex patterns from high-dimension data.

Knowledge-Rich Deep Learning Infusing knowledge in neural network training is a long-standing challenge in deep learning (Towell and Shavlik, 1994). Hu et al. (2016a,b) first used logical rules to help train a convolutional neural network for sentiment analysis. DPL draws inspiration from their approach, but is more general and theoretically well-founded. Hu et al. (2016a,b) focused on supervised learning and the logical rules were introduced to augment labeled examples via posterior regularization (Ganchev et al., 2010). DPL can incorporate both direct and indirect supervision, including posterior regularization and other forms of indirect supervision. Like DPL, Hu et al. (2016b) also refined uncertain weights of logical rules, but they did it in a heuristic way by appealing to symmetry with standard posterior regularization. We provide a novel problem formulation using generalized virtual evidence, which shows that their heuristics is a special case of variational EM and opens up opportunities for other optimization strategies.

Deep generative models also combine deep learning with probabilistic models, but focus on uncovering latent factors to support generative modeling and semi-supervised learning (Kingma and Welling, 2013; Kingma et al., 2014). Knowledge infusion is limited to introducing structures among the latent variables (e.g., Markov chain) (Johnson et al., 2016). In DPL, we focus on learning a discriminative model for predicting the latent labels, using a probabilistic model defined by probabilistic logic to inject indirect supervision.

3 Deep Probabilistic Logic

In this section, we introduce deep probabilistic logic (DPL) as a unifying framework for indirect supervision. Label decisions are modeled as latent variables. Indirect supervision is represented as generalized virtual evidence, and learning maximizes the conditional likelihood of virtual evidence given input. We first review the idea of virtual evidence and show how it can be generalized to represent any form of indirect supervision. We then formulate the learning objective and show how it can be optimized using variational EM.

Given a prediction task, let $\mathcal{X}$ denote the set of possible inputs and $\mathcal{Y}$ the set of possible outputs. The goal is to train a prediction module $\Psi(x, y)$ that scores output y given input x. Without loss of generality, we assume that $\Psi(x, y)$ defines the conditional probability $P(y|x)$ using a deep neural network with a softmax layer at the top. Let $X = (X_1, \cdots, X_N)$ denote a sequence of inputs and $Y = (Y_1, \cdots, Y_N)$ the corresponding outputs. We consider the setting where Y are unobserved, and $\Psi(x, y)$ is learned using indirect supervision.

Virtual evidence Pearl (Pearl, 2014) first introduced the notion of virtual evidence, which has been used to incorporate label preference in semi-supervised learning (Reynolds and Bilmes, 2005; Subramanya and Bilmes, 2007; Li, 2009) and grounded learning (Parikh et al., 2015). Suppose we have a prior belief on the value of y, it can be represented by introducing a binary variable v as a dependent of y such that $P(v = 1|y = l)$ is proportional to the prior belief of $y = l$. $v = 1$ is thus an observed evidence that imposes soft constraints over y. Direct supervision (i.e., observed label) for y is a special case when the belief is concentrated on a specific value $y = l^*$ (i.e., $P(v = 1|y = l) = 0$ for any $l \neq l^*$). The virtual evidence v can be viewed as a reified variable for a potential function $\Phi(y) \propto P(v = 1|y)$. This enables us to generalize virtual evidence to arbitrary potential functions $\Phi(X, Y)$ over the inputs and outputs. In the rest of the paper, we will simply refer to the potential functions as virtual evidences, without introducing the reified variables explicitly.

DPL Let $K = (\Phi_1, \cdots, \Phi_V)$ be a set of virtual evidence derived from prior knowledge. DPL comprises of a supervision module over K and a prediction module over all input-output pairs (Figure 1), and defines a probability distribution:

$$P(K, Y|X) \propto \prod_v \Phi_v(X, Y) \cdot \prod_i \Psi(X_i, Y_i)$$

Without loss of generality, we assume that virtual evidences are log-linear factors, which can be compactly represented by weighted first-order logical formulas (Richardson and Domingos, 2006). Namely, $\Phi_v(X, Y) = \exp(w_v \cdot f_v(X, Y))$, where $f_v(X, Y)$ is a binary feature represented by a first-order logical formula. A hard constraint is the special case when $w_v = \infty$ (in practice, it suffices to set it to a large number, e.g., 10). In prior use of virtual evidence, w_v's are generally pre-determined from prior knowledge. However, this may be suboptimal. Therefore, we consider a general Bayesian learning setting where each w_v is drawn from a pre-specified prior distribution $w_v \sim P(w_v|\alpha_v)$. Fixed w_v amounts to the special case when the prior is concentrated on the preset value. For uncertain w_v's, we can compute their maximum a posteriori (MAP) estimates and/or quantify the uncertainty.

Distant supervision Virtual evidence for distant supervision is similar to that for direct supervision. For example, for relation extraction, distant supervision from a knowledge base of known relations will set $f_{KB}(X_i, Y_i) = \mathbb{I}[\texttt{In-KB}(X_i, r) \wedge Y_i = r]$, where $\texttt{In-KB}(X_i, r)$ is true iff the entity tuple in X_i is known to have relation r in the KB.

Data programming Virtual evidence for data programming is similar to that for distant supervision: $f_L(X_i, Y_i) = \mathbb{I}[L(X_i) = Y_i]$, where $L(X_i)$ is a labeling function provided by domain experts. Labeling functions are usually high-precision rules, but errors are still common, and different functions may assign conflicting labels to an instance. Existing denoising strategy assumes that each function makes random errors independently, and resolves the conflicts by weighted votes (Ratner et al., 2016). In DPL, this can be done by simply treating error probabilities as uncertain parameters and inferring them during learning.

Joint inference Constraints on instances or model expectations can be imposed by introducing the corresponding virtual evidence (Ganchev et al., 2010) (Proposition 2.1). The weights can be set heuristically (Chang et al., 2007; Mann and McCallum, 2008; Poon and Domingos, 2008) or iteratively via primal-dual methods (Ganchev et al., 2010). In addition to instance-level constraints, DPL can incorporate arbitrary high-order soft and hard constraints that capture the interdependencies among multiple instances. For example, identical mentions in proximity probably refer to the same entity, which is useful for resolving ambiguous mentions by leveraging their unambiguous coreferences (e.g., an acronym in apposition of the full name). This can be represented by the virtual evidence $f_{\texttt{Joint}}(X_i, Y_i, X_j, Y_j) = \mathbb{I}[\texttt{Coref}(X_i, X_j) \wedge Y_i = Y_j]$, where $\texttt{Coref}(X_i, X_j)$ is true iff X_i and X_j are coreferences. Similarly, the common denoising strategy for distant supervision replaces the mention-level constraints with type-level constraints (Hoffmann et al., 2011). Suppose that $X_E \subset X$ contains all X_i's with co-occurring entity tuple E. The new constraints simply impose that, for each E with known relation $r \in KB$, $Y_i = r$ for at least one $X_i \in X_E$. This can be represented by a high-order factor on $(X_i, Y_i : X_i \in X_E)$.

Algorithm 1 DPL Learning

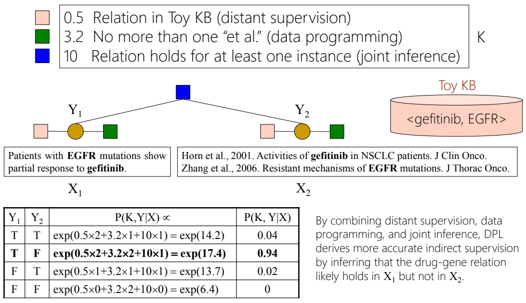
Parameter learning Learning in DPL maximizes the conditional likelihood of virtual evidences $P(K|X)$. We can directly optimize this objective by summing out latent Y to compute the gradient and run backpropagation. In this paper, however, we opted for a modular approach using variational EM. See Algorithm 1.

In the E-step, we compute a variational approximation $q(Y) = \prod_i q_i(Y_i)$ by minimizing its KL divergence with $P(Y|K, X)$, which amounts to computing marginal probabilities $q_i(Y_i) = P(Y_i|K, X) = \sum_{Y_{-i}} P(Y_i, Y_{-i}|K, X)$, with current parameters Φ, Ψ. This is a standard probabilistic inference problem. Exact inference is generally intractable, but there are a plethora of approximate inference methods that can efficiently produce an estimate. We use loopy belief propagation (Murphy et al., 1999) in this paper, by conducting message passing in $P(K, Y|X)$ iteratively. Note that this inference problem is considerably simpler than end-to-end inference with probabilistic logic, since the bulk of the computation is encapsulated by Ψ.

Inference with high-order factors of large size can be challenging, but there is a rich body of literature for handling such structured factors in a principled way. In particular, in distant supervision denoising, we alter the message passing schedule so that each at-least-one factor will compute messages to its variables jointly by renormalizing their current marginal probabilities with noisy-or (Keith et al., 2017), which is essentially a soft version of dual decomposition (CarøE and Schultz, 1999).

In the M-step, we treat the variational approximation $q_i(Y_i)$ as probabilistic labels, and use them to optimize Φ and Ψ via standard supervised learning, which is equivalent to minimizing the KL divergence between the probabilistic labels and the conditional likelihood of Y given X under the supervision module (Φ) and prediction module (Ψ), respectively. For the prediction module, this optimization reduces to standard deep learning. Likewise, for the supervision module, this optimization reduces to standard parameter learning for log-linear models (i.e., learning all w_v's that are not fixed). Given the probabilistic labels, it is a convex optimization problem with a unique global optimum. Here, we simply use gradient descent, with the partial derivative for w_v being $\mathbb{E}_{\Phi(Y,X)}\,[f_v(X, Y)] - \mathbb{E}_{q(Y)}\,[f_v(X, Y)]$. For a tied weight, the partial derivative will sum over all features that originate from the same template. The second expectation can be done by simple counting. The first expectation, on the other hand, requires probabilistic inference in the graphical model. But it can be computed using belief propagation, similar to the E-step, except that the messages are limited to factors within the supervision module (i.e., messages from Ψ are not longer included). Convergence is usually fast, upon which the marginal for each Y_i is available, and $\mathbb{E}_{\Phi(Y,X)}\,[f_v(X, Y)]$ is simply the fraction of Y that renders $f_v(X, Y)$ to be true. Again, this parameter learning problem is much simpler than end-to-end learning with probabilistic logic, as it focuses on refining uncertain weights for indirect supervision, rather than learning complex input patterns for label prediction (handled in deep learning).



Y_1	Y_2	$P(K,Y\|X) \propto$	$P(K, Y\|X)$
T	T	$\exp(0.5\times2+3.2\times1+10\times1) = \exp(14.2)$	0.04
T	**F**	$\mathbf{\exp(0.5\times2+3.2\times2+10\times1) = \exp(17.4)}$	**0.94**
F	T	$\exp(0.5\times1+3.2\times1+10\times1) = \exp(13.7)$	0.02
F	F	$\exp(0.5\times0+3.2\times2+10\times0) = \exp(6.4)$	0

By combining distant supervision, data programming, and joint inference, DPL derives more accurate indirect supervision by inferring that the drug-gene relation likely holds in X_1 but not in X_2.

Figure 3: Example of DPL combining various indirect supervision using probabilistic logic. The prediction module is omitted to avoid clutter.

Example Figure 3 shows a toy example on how DPL combines various indirect supervision for predicting drug-gene interaction (e.g., gefitinib can be used to treat tumors with EGFR mutations). Indirect supervision is modeled by probabilistic logic, which defines a joint probability distribution over latent labeling decisions for drug-gene mention pairs in unlabeled text. Here, distant supervision prefers classifying mention pairs of known relations, whereas the data programming formula opposes classifying instances resembling citations, and the joint inference formula ensures that at least one mention pair of a known relation is classified as positive. Formula weight signifies the confidence in the indirect supervision, and can be refined iteratively along with the prediction module.

Handling label imbalance One challenge for distant supervision is that negative examples are often much more numerous. A common strategy is to subsample negative examples to attain a balanced dataset. In preliminary experiments, we found that this was often suboptimal, as many informative negative examples were excluded from training. Instead, we restored the balance by up-weighting positive examples. In DPL, an additional challenge is that the labels are probabilistic and change over iterations. In this paper, we simply used hard EM, with binary labels set using 0.5 as the probability threshold, and the up-weighting coefficient recalculated after each E-step.

4 Biomedical Machine Reading

There is a long-standing interest in biomedical machine reading (e.g., Morgan et al. (2008); Kim et al. (2009)), but prior studies focused on supervised approaches. The advent of big biomedical data creates additional urgency for developing scalable approaches that can generalize to new reading tasks. For example, genome sequencing cost has been dropping faster than Moore's Law, yet oncologists can only evaluate tumor sequences for a tiny fraction of patients, due to the bottleneck in assimilating relevant knowledge from publications. Recently, Peng et al. (2017) formulated precision oncology machine reading as cross-sentence relation extraction (Figure 2) and developed the state-of-the-art system using distant supervision. While promising, their results still leave much room to improve. Moreover, they used heuristics to heavily filter entity candidates, with significant recall loss.

In this section, we use cross-sentence relation extraction as a case study for combining indirect supervision using deep probabilistic logic (DPL). First, we show that DPL can substantially improve machine reading accuracy in a head-to-head comparison with Peng et al. (2017), using the same entity linking method. Next, we apply DPL to entity linking itself and attain similar improvement. Finally, we consider further improving the recall by removing the entity filter. By applying DPL to joint entity linking and relation extraction, we more than doubled the recall in relation extraction while attaining comparable precision as Peng et al. (2017) with heavy entity filtering.

Evaluation Comparing indirect supervision methods is challenging as there is often no annotated test set for evaluating precision and recall. In such cases, we resort to the standard strategy used in prior work by reporting *sample precision* (estimated proportion of correct system extractions) and *absolute recall* (estimated number of correct system extractions). Absolute recall is proportional to recall and can be used to compare different systems (modulo estimation errors).

Datasets We used the same unlabeled text as Peng et al. (2017), which consists of about one million full text articles in PubMed Central (PMC)[3]. Tokenization, part-of-speech tagging, and syntactic parsing were conducted using SPLAT (Quirk et al., 2012), and Stanford dependencies (de Marneffe et al., 2006) were obtained using Stanford CoreNLP (Manning et al., 2014). For entity ontologies, we used DrugBank[4] and Human Gene Ontology (HUGO)[5]. DrugBank contains 8257 drugs; we used the subset of 599 cancer drugs. HUGO contains 37661 genes. For knowledge bases, we used the Gene Drug Knowledge Database (GDKD) (Dienstmann et al., 2015) and the Clinical Interpretations of Variants In Cancer (CIVIC)[6]. Together, they contain 231 drug-gene-mutation triples, with 76 drugs, 35 genes and 123 mutations.

4.1 Cross-sentence relation extraction

Let $e_1, \cdots, e_m$ be entity mentions in text T. Relation extraction can be formulated as classifying whether a relation R holds for $e_1, \cdots, e_m$ in T. To enable a head-to-head comparison, we used the same cross-sentence setting as Peng et al. (2017), where T spans up to three consecutive sentences and R represents the ternary interaction over drugs, genes, and mutations (whether the drug is relevant for treating tumors with the given gene mutation).

Entity linking In this subsection, we used the entity linker from Literome (Poon et al., 2014) to identify drug, gene, and mutation mentions, as in Peng et al. (2017). This entity linker first identifies candidate mentions by matching entity names

[5] `www.genenames.org`

[6] `civic.genome.wustl.edu`

Distant Supervision: GDKD, CIVIC
Data Programming (Entity) Mention matches entity name exactly. Mention not a stop word. Mention not following figure designation. Mention's POS tags indicate it is a noun.
Data Programming (Relation) Less than 30% of words are numbers in each sentence. No more than three consecutive numbers. No more than two "et al". No more than three tokens start with uppercase. No more than three special characters. No more than three keywords indicative of table or figure. Entity mentions do not overlap.
Joint Inference: Relation holds in at least one instance.

Table 1: DPL combines three indirect supervision strategies for cross-sentence relation extraction

or synonyms in domain ontologies, then applies heuristics to filter candidates. The heuristics are designed to enhance precision, at the expense of recall. For example, one heuristics would filter candidates of length less than four, which eliminates key cancer genes such as ER or AKT.

Prediction module We used the same graph LSTM as in Peng et al. (2017) to enable head-to-head comparison on indirect supervision strategies. Briefly, a graph LSTM generalizes a linear-chain LSTM by incorporating arbitrary long-ranged dependencies, such as syntactic dependencies, discourse relations, coreference, and connections between roots of adjacent sentences. A word might have precedents other than the prior word, and its LSTM unit is expanded to include a forget gate for each precedent. See Peng et al. (2017) for details.

Supervision module We used DPL to combine three indirect supervision strategies for cross-sentence relation extraction (Table 1). For distant supervision, we used GDKD and CIVIC as in Peng et al. (2017). For data programming, we introduced labeling functions that aim to correct entity and relation errors. Finally, we incorporated joint inference among all co-occurring instances of an entity tuple with the known relation by imposing the at-least-one constraint (i.e., the relation holds for at least one of the instances). For development, we sampled 250 positive extractions from DPL using only distant supervision (Peng et al., 2017) and excluded them from future training and evaluation.

Experiment results We compared DPL with the state-of-the-art system of Peng et al. (2017). We also conducted ablation study to evaluate the impact of indirect-supervision strategies. For a fair comparison, we used the same probability threshold in all cases (an instance is classified as positive if the normalized probability score is at least 0.5). For each system, sample precision was estimated by sampling 100 positive extractions and manually determining the proportion of correct extractions by an author knowledgeable about this domain. Absolute recall is estimated by multiplying sample precision with the number of positive extractions.

System	Prec.	Abs. Rec.	Unique
Peng 2017	0.64	6768	2738
DPL + `EMB`	**0.74**	**8478**	**4821**
DPL	0.73	7666	4144
− `DS`	0.29	7555	4912
− `DP`	0.67	4826	2629
− `DP (ENTITY)`	0.70	7638	4074
− `JI`	0.72	7418	4011

Table 2: Comparison of sample precision and absolute recall (all instances and unique entity tuples) in test extraction on PMC. DPL + `EMB` is our full system using PubMed-trained word embedding, whereas DPL uses the original Wikipedia-trained word embedding in Peng et al. (2017). Ablation: DS (distant supervision), DP (data programming), JI (joint inference).

Pred. Mod.	Prec.	Abs. Rec.	Unique
BiLSTM	0.60	6243	3427
Graph LSTM	0.73	7666	4144

Table 3: Comparison of sample precision and absolute recall (all instances and unique entity tuples) in test extraction on PMC. Both use same indirect supervision and Wikipedia-trained word embedding.

Table 2 shows the results. DPL substantially outperformed Peng et al. (2017), improving sample precision by ten absolute points and raising absolute recall by 25%. Combining disparate indirect supervision strategies is key to this performance gain, as evident from the ablation results. While distant supervision remained the most potent source of indirect supervision, data programming and joint inference each contributed significantly. Replacing out-of-domain (Wikipedia) word embedding with in-domain (PubMed) word embedding (Pyysalo et al., 2013) also led to a small gain.

Peng et al. (2017) only compared graph LSTM and linear-chain LSTM in automatic evaluation, where distant-supervision labels were treated as ground truth. They found significant but relatively small gains by graph LSTM. We conducted additional manual evaluation comparing the two in

Distant Supervision: HGNC
Data Programming No verbs in POS tags. Mention not a common word. Mention contains more than two characters or one word. More than 30% of characters are upper case. Mention contains both upper and lower case characters. Mention contains both character and digit. Mention contains more than six characters. Dependency label from mention to parent indicative of direct object.
Joint Inference Identical mentions nearby probably refer to the same entity. Appositive mentions probably refer to the same entity. Nearby mentions that match synonyms of same entity probably refer to the given entity.

Table 4: DPL combines three indirect supervision strategies for entity linking.

DPL. Surprisingly, we found rather large performance difference, with graph LSTM outperforming linear-chain LSTM by 13 absolute points in precision and raising absolute recall by over 20% (Table 3). This suggests that Peng et al. (2017) might have underestimated the performance gain by graph LSTM using automatic evaluation.

4.2 Entity linking

Let m be a mention in text and e be an entity in an ontology. The goal of entity linking is to predict $\texttt{Link}(\texttt{m}, \texttt{e})$, which is true iff m refers to e, for every candidate mention-entity pair m, e. We focus on genes in this paper, as they are particularly noisy.

Prediction module We used BiLSTM with attention over the ten-word windows before and after a mention. The embedding layer is initialized by word2vec embedding trained on PubMed abstracts and full text (Pyysalo et al., 2013). The word embedding dimension was 200. We used 5 epochs for training, with Adam as the optimizer. We set learning rate to 0.001, and batch size to 64.

Supervision module As in relation extraction, we combined three indirect supervision strategies using DPL (Table 4). For distant supervision, we obtained all mention-gene candidates by matching PMC text against the HUGO lexicon. We then sampled a subset of 200,000 candidate instances as positive examples. We sampled a similar number of noun phrases as negative examples. For data programming, we introduced labeling functions that used mention characteristics (longer names are less ambiguous) or syntactic context (genes are more likely to be direct objects and nouns). For joint inference, we leverage linguistic phenomena related to coreference (identical, appositive, or synonymous mentions nearby are likely coreferent).

System	Acc.	F1	Prec.	Rec.
String Match	0.18	0.31	0.18	1.00
DS	0.64	0.71	0.62	0.83
DS + DP	0.66	0.71	0.62	0.83
DS + DP + JI	**0.70**	**0.76**	0.68	0.86

Table 5: Comparison of gene entity linking results on a balanced test set. The string-matching baseline has low precision. By combining indirect supervision strategies, DPL substantially improved precision while retaining reasonably high recall.

	F1	Precision	Recall
GNormPlus	0.78	0.74	0.81
DPL	0.74	0.68	0.80

Table 6: Comparison of gene entity linking results on BioCreative II test set. GNormPlus is the state-of-the-art system trained on thousands of labeled examples. DPL used only indirect supervision.

Experiment results For evaluation, we annotated a larger set of sample gene-mention candidates and then subsampled a balanced test set of 550 instances (half are true gene mentions, half not). These instances were excluded from training and development. Table 5 compares system performance on this test set. The string-matching baseline has a very low precision, as gene mentions are highly ambiguous, which explains why Peng et al. (2017) resorted to heavy filtering. By combining indirect supervision strategies, DPL improved precision by over 50 absolute points, while retaining a reasonably high recall (86%). All indirect supervision strategies contributed significantly, as the ablation tests show. We also evaluated DPL on BioCreative II, a shared task on gene entity linking (Morgan et al., 2008). We compared DPL with GNormPlus (Wei et al., 2015), the state-of-the-art supervised system trained on thousands of labeled examples in BioCreative II training set. Despite using zero manually labeled examples, DPL attained comparable F1 and recall (Table 6). The difference is mainly in precision, which indicates opportunities for more indirect supervision.

4.3 Joint entity and relation extraction

An important use case for machine reading is to improve knowledge curation efficiency by offering extraction results as candidates for curators to vet. The key to practical adoption is attaining high recall with reasonable precision (Peng et al., 2017). The entity filter used in Peng et al. (2017) is not ideal in this aspect, as it substantially reduced recall. In this

System	Prec	Abs. Rec.	Unique
Peng 2017	0.31	11481	5447
DPL (RE)	0.52	17891	8534
+ EL (TRN)	0.55	**21881**	**11047**
+ EL (TRN/TST)	**0.61**	20378	10291

Table 7: Comparison of sample precision and absolute recall (all instances and unique entity tuples) when all gene mention candidates are considered. Peng et al. (2017) used distant supervision only. RE: DPL relation extraction. EL: using DPL entity linking in RE training (TRN) and/or test (TST).

Gene	Drug	Mut.	Gene-Mut.	Relation
27%	4%	20%	45%	24%

Table 8: Error analysis for DPL relation extraction.

subsection, we consider replacing the entity filter by the DPL entity linker Table 7. Specifically, we added one labeling function to check if the entity linker returns a normalized probability score above $p_{\texttt{TRN}}$ for gene mentions, and filtered test instances if the gene mention score is lower than $p_{\texttt{TST}}$. We set $p_{\texttt{TRN}} = 0.6$ and $p_{\texttt{TST}} = 0.3$ from preliminary experiments. The labeling function discouraged learning from noisy mentions, and the test-time filter skips an instance if the gene is likely wrong. Not surprisingly, without entity filtering, Peng et al. (2017) suffered large precision loss. All DPL versions substantially improved accuracy, with significantly more gains using the DPL entity linker.

4.4 Discussion

Scalability DPL is efficient to train, taking around 3.5 hours for relation extraction and 2.5 hours for entity linking in our PubMed-scale experiments, with 25 CPU cores (for probabilistic logic) and one GPU (for LSTM). For relation extraction, the graphical model of probabilistic logic contains around 7,000 variables and 70,000 factors. At test time, it is just an LSTM, which predicted each instance in less than a second. In general, DPL learning scales linearly in the number of training instances. For distant supervision and data programming, DPL scales linearly in the number of known facts and labeling functions. As discussed in Section 3, joint inference with high-order factors is more challenging, but can be efficiently approximated. For inference in probabilistic logic, we found that loopy belief propagation worked reasonably well, converging after 2-4 iterations. Overall, we ran variational EM for three iterations, using ten epochs of deep learning in each M-step. We found these worked well in preliminary experiments and used the same setting in all final experiments.

Figure 4: Example of relation-extraction errors corrected by DPL with additional indirect supervision.

Accuracy To understand more about DPL's performance gain over distant supervision, we manually inspected some relation-extraction errors fixed by DPL after training with additional indirect supervision. Figure 4 shows two such examples. While some data programming functions were introduced to prevent errors stemming from citations or flattened tables, none were directly applicable to these examples. This shows that DPL can generalize beyond the original indirect supervision.

While the results are promising, there is still much to improve. Table 8 shows estimated precision errors for relation extraction by DPL. (Some instances have multiple errors.) Entity linking can incorporate more indirect supervision. Joint entity linking and relation extraction can be improved by feeding back extraction results to linking. Improvement is also sorely needed in classifying mutations and gene-mutation associations. The prediction module can also be improved, e.g., by adding attention to graph LSTM. DPL offers a flexible framework for exploring all these directions.

5 Conclusion

We introduce DPL as a unifying framework for indirect supervision, by composing probabilistic logic with deep learning. Experiments on biomedical machine reading show that this enables novel combination of disparate indirect supervision methodologies, resulting in substantial gain in accuracy. Future directions include: combining DPL with deep generative models; exploring alternative optimization strategies; applications to other domains.

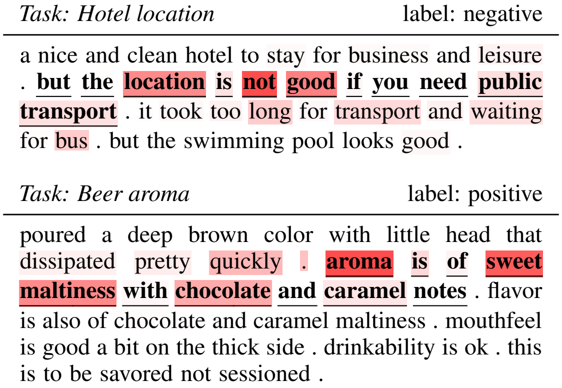
Abstract

Attention-based models are successful when trained on large amounts of data. In this paper, we demonstrate that even in the low-resource scenario, attention can be learned effectively. To this end, we start with discrete human-annotated rationales and map them into continuous attention. Our central hypothesis is that this mapping is general across domains, and thus can be transferred from resource-rich domains to low-resource ones. Our model jointly learns a domain-invariant representation and induces the desired mapping between rationales and attention. Our empirical results validate this hypothesis and show that our approach delivers significant gains over state-of-the-art baselines, yielding over 15% average error reduction on benchmark datasets.[1]



Task: Hotel location label: negative

a nice and clean hotel to stay for business and leisure . **but the location is not good if you need public transport** . it took too long for transport and waiting for bus . but the swimming pool looks good .

Task: Beer aroma label: positive

poured a deep brown color with little head that dissipated pretty quickly . **aroma is of sweet maltiness with chocolate and caramel notes** . flavor is also of chocolate and caramel maltiness . mouthfeel is good a bit on the thick side . drinkability is ok . this is to be savored not sessioned .

Figure 1: Examples of rationales versus oracle attention. Words are highlighted according to their relative attention scores. Human rationales are shown in bold with underlines.

1 Introduction

Attention-based models have become architectures of choice for many NLP tasks. In addition to significant performance gains, these models are attractive, as attention is often used as a proxy for human interpretable rationales. Their success, however, is conditioned on access to large amounts of training data. To make these models applicable in low-resource scenarios, we utilize this connection in the opposite direction. Specifically, we propose an approach to map human rationales to high-performing attention, and use this attention to guide models trained in low-resource scenarios.

The notions of rationale and attention are closely related. Both of them highlight word importance for the final prediction. In the case of rationale, the importance is expressed as a hard selection, while attention provides a soft distribution over the words. Figure 1 illustrates this relatedness. One obvious approach to improve low-resource performance is to directly use human rationales as a supervision for attention generation. The implicit assumption behind this method is that machine-generated attention should mimic human rationales. However, rationales on their own are not adequate substitutes for machine attention. Instead of providing a soft distribution, human rationales only provide the binary indication about relevance. Furthermore, rationales are subjectively defined and often vary across annotators. Finally, human rationales are not customized for a given model architecture. In contrast, machine attention is always derived as a part of a specific model architecture.

To further understand this connection, we empirically compare models informed by human rationales and those by high-quality attention. To obtain the latter, we derive an "oracle" attention using a large amount of annotations. This "oracle" attention is then used to guide a model that only has access to a small subset of this training data. Not only does this model outperform the oracle-free variant, but it also yields substantial gains over its counterpart trained with human ra-

tionales — 89.98 % vs 85.22 % average accuracy on three aspects of hotel review (see Section 4 for details). In practice, however, this "oracle" attention is not available. To employ this method, we need to find a way to obtain a substitute for the "oracle" attention.

In this paper, we show how to achieve this goal using rationales. Specifically, we learn a mapping from human rationales to high-quality attention (R2A). We hypothesize that this mapping is generalizable across tasks and thus can be transferred from resource-rich tasks.[2] Figure 1 illustrates that in both tasks, attention weighs rationale words in a similar fashion: highlighting task-specific nouns and adjectives, while downplaying functional words. To learn and apply this mapping we need access to rationales in both source and target tasks. In the target task, we assume rationales are provided by humans. In the source task(s), collecting rationales at scale is infeasible. Therefore, we use machine-generated rationales (Lei et al., 2016) as a proxy.

Our R2A model consists of three components. The first one is an attention-based model for the source task(s) that provides supervision for attention generation. The second component focuses on learning a domain-invariant representation to support transfer. The third component combines this invariant representation and rationales together to generate the attention. These three components are trained jointly to optimize the overall objective. Once the model is trained, we apply it to the target task to generate attention from human rationales. This attention is consequently used to supervise the training of the target classifier.

We evaluate our approach on two transfer settings: aspect transfer within single domain and domain transfer across multiple domains. Our experiments demonstrate that our approach delivers significant performance improvements over the baselines. For instance, the average error reduction over the best baseline in domain transfer is over 15%. In addition, both qualitative and quantitative analyses confirm that our R2A model is capable of generating high-quality attention for target tasks.

2 Related Work

Attention-based models Attention has been shown to be effective when the model is trained on large amounts of training data (Bahdanau et al., 2014; Luong et al., 2015; Rush et al., 2015; Yang et al., 2016; Lin et al., 2017; Chen et al., 2017; Vaswani et al., 2017). In this setting, typically no additional supervision is required for learning the attention. Nevertheless, further refining attention by extra supervision has been shown to be beneficial. Examples include using word alignments to learn attention in neural machine translation (Liu et al., 2016), employing argument words to supervise attention in event detection (Liu et al., 2017), utilizing linguistically-motivated annotations to guide attention in constituency parsing (Kamigaito et al., 2017). These supervision mechanisms are tailored to specific applications. In contrast, our approach is based on the connection between rationales and attention, and can be used for multiple applications.

Rationale-based models Zaidan et al. (2007) was the first to explore the value of rationales in low-resource scenarios. They hypothesize that the model confidence should decrease when the rationale words are removed from the inputs, and validate this idea for linear models. Recent work (Zhang et al., 2016) explores the potential of integrating rationales with more complex neural classifiers. In their model, human rationales are directly used to guide the sentence-level attention for a CNN-based classifier. To reach good performance, their model still requires a sufficient amount of training data. Our work differs from theirs as we discern the intrinsic difference between human rationales and machine attention. Moreover, we learn a model to map human rationales into high-quality attention so as to provide a richer supervision for low-resource models.

Transfer learning When labeled data on the target task is available, existing approaches typically transfer the knowledge by either fine-tuning an encoder trained on the source tasks(s) (Conneau et al., 2017; Peters et al., 2018) or multi-task learning on all tasks with a shared encoder (Collobert et al., 2011). In this paper, we explore the transferability of the task-specific attention through human rationales. We believe this will further assist learning in low-resource scenarios.

Our work is also related to unsupervised domain

---

[2] In this paper, we consider a more general setting where one domain contains multiple tasks. Also, we assume having one source domain. However, our proposed method is a general framework and can be easily adapted to problems with multiple source domains.

adaptation, as the R2A model has never seen any target annotations during training. Existing methods commonly adapt the classifier by aligning the representations between the source and target domains (Glorot et al., 2011; Chen et al., 2012; Zhou et al., 2016; Ganin et al., 2016; Zhang et al., 2017). In contrast, our model adapts the mapping from rationales to attention; thus after training, it can be applied to different target tasks.

3 Method

Problem formulation We assume that we have N source tasks $\{\mathcal{S}_i\}_{i=1}^N$, where each of them has sufficient amounts of labeled examples. Using existing methods (Lei et al., 2016), we can generate rationales for each source example automatically (see Appendix 1 for details). In the target task $\mathcal{T}$, we only have a limited amount of labeled examples with large amounts of unlabeled data. For those labeled examples, we assume access to human-annotated rationales.

Overview Our goal is to improve classification performance on the target task by learning a mapping from human rationales to high-quality machine attention (R2A). Given the scarcity of our target data, we learn this mapping on resource rich tasks where high-quality attention can be readily obtained during training. Next, the mapping between rationales and attention derived from the source tasks is exported into the target task. To enable this transfer, models have to operate over an invariant representation which we construct via an adversarial objective. Once the mapping is derived, we can translate human rationales in the target task into high-quality attention. This generated attention is then used to provide additional training signal for an attention-based classifier for the target task. The overall pipeline is shown in Figure 2.

Alternatively, we can view the R2A mapping as a meta model that produces a prior over the attention distribution across different tasks.

Model architecture Figure 3 illustrates the architecture of our R2A model, which consists of three components.

- **Multi-task learning** In order to learn the R2A mapping, we need annotation for the attention. This module generates high-quality attention as an intermediate result by minimizing the prediction error on the source tasks (Section 3.1).

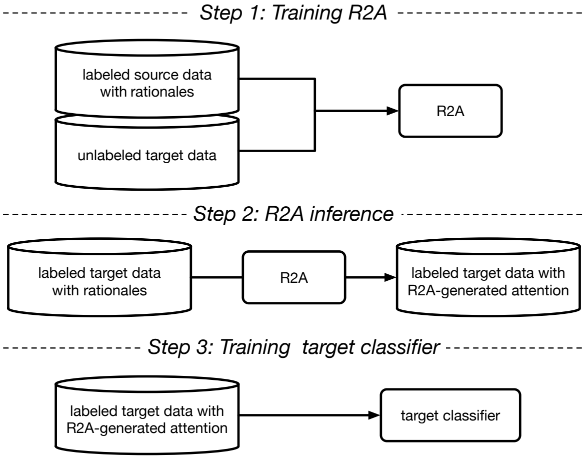

Figure 2: Overall pipeline of our approach (Section 3.4). The R2A mapping is learned from labeled source data and unlabeled target data. Then we applied it to the target task to derive attention based on human rationales. Finally, a target classifier is trained under the supervision of both the annotated labels and the R2A-generated attention.

- **Domain-invariant encoder** This module aims to transform the contextualized representation obtained from the first module into a domain-invariant version. We achieve this goal through domain adversarial training over the source data and the unlabeled target data (Section 3.2).
- **Attention generation** This module learns to predict the intermediate attention obtained from the first module based on the domain-invariant representation and the rationales (Section 3.3).

3.1 Multi-task learning

The goal of the multi-task learning module is to learn good attention for each source task. This learned attention will be used later to supervise the attention generation module. This module takes the input text from the source tasks and predicts the labels. To accomplish the previously stated goal, we minimize the prediction error over all labeled source data.

Let (x^t, y^t) be a training instance from any source task $t \in \{\mathcal{S}_1, \ldots \mathcal{S}_N\}$. We first encode the input sequence x^t into hidden states: $h^t = \mathbf{enc}(x^t)$, where $\mathbf{enc}$ is a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) that is shared across all source tasks. For each position i, the dense vector h_i^t encodes the content and context information of the word x_i^t. We then pass the

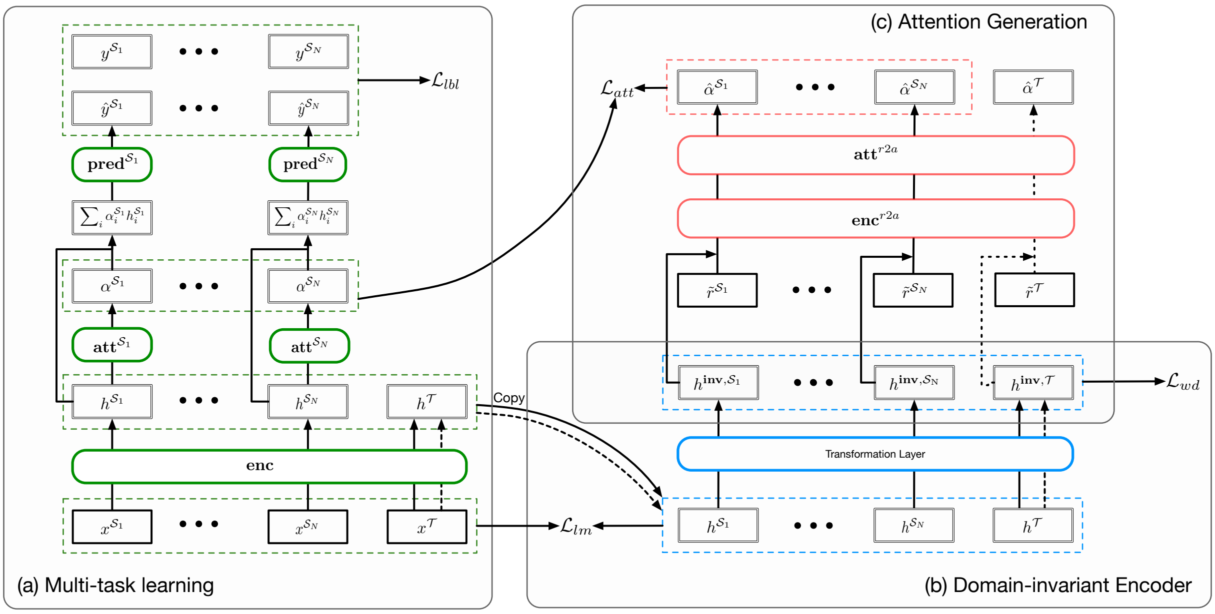

Figure 3: Architecture of the R2A model. The model is comprised of (a) a multi-task learning component, (b) a domain-invariant encoder, and (c) an attention generation component. Solid arrows denote computations for training, while dotted arrows denote computations for inference.

sequence h^t on to a task-specific attention module to produce attention $\alpha^t = \mathbf{att}^t(h^t)$ as follows:

$$\tilde{h}_i^t = \tanh(W_{\mathbf{att}}^t h_i^t + b_{\mathbf{att}}^t),$$
$$\alpha_i^t = \frac{\exp(\langle \tilde{h}_i^t, q_{\mathbf{att}}^t \rangle)}{\sum_j \exp(\langle \tilde{h}_j^t, q_{\mathbf{att}}^t \rangle)},$$

where $\langle \cdot, \cdot \rangle$ denotes inner product and $W_{\mathbf{att}}^t$, $b_{\mathbf{att}}^t$, $q_{\mathbf{att}}^t$ are learnable parameters. We predict the label of x^t using the weighted sum of its contextualized representation: $\hat{y}^t = \mathbf{pred}^t(\sum_i \alpha_i^t h_i^t)$, where $\mathbf{pred}^t$ is a task-specific multi-layer perceptron. We train this module to minimize the loss, $\mathcal{L}_{lbl}$, between the prediction and the annotated label for all source tasks. We use cross entropy loss for classification tasks and mean square loss for regression tasks.

3.2 Domain-invariant encoder

Supplied with large amounts of source data and unlabeled target data, this module has two goals: 1) learning a general encoder for both source and target corpora, and 2) learning domain-invariant representation. This module enables effective transfer—especially in the presence of significant variance between the source and target domains. We achieve the first goal by optimizing a language modeling objective and the second goal by minimizing the Wasserstein distance between the source and target distribution.

Let x be an input sequence, and $h \triangleq [\overrightarrow{h}; \overleftarrow{h}]$ be its corresponding contextualized representation obtained from $\mathbf{enc}$. Here, $\overrightarrow{h}$ and $\overleftarrow{h}$ denote the output sequence of the forward and backward LSTM, respectively. In order to support transfer, $\mathbf{enc}$ should be general enough to effectively represent both source and target corpora. For this reason, we ground the encoder by a language modeling component (Bengio et al., 2003; Mikolov et al., 2011). Specifically, we employ two Softmax classifiers to predict the word x_i based on $\overrightarrow{h}_{i-1}$ and $\overleftarrow{h}_{i+1}$ respectively. We minimize the cross-entropy loss $\mathcal{L}_{lm}$ over all source data and unlabeled target data.

The representation h is domain-specific as it is trained to encode useful features for language modeling and the source tasks. To obtain an invariant representation, we employ a transformation layer and propose to align the transformed representation so that it is not distinguishable whether it comes from the source or the target. Specifically, we transform the representation h_i at each position i linearly and obtain

$$h_i^{\mathbf{inv}} = W_{\mathbf{inv}} h_i + b_{\mathbf{inv}},$$

where $W_{\mathbf{inv}}$ and $b_{\mathbf{inv}}$ are learnable parameters. We minimize the Wasserstein distance (Arjovsky et al., 2017) between the distribution of $h^{\mathbf{inv}}$ from the source and the one from the target, denoted as $\mathbb{P}_{\mathcal{S}}$ and $\mathbb{P}_{\mathcal{T}}$, respectively. Since $h^{\mathbf{inv}}$ is a sequence of variable length, L, we summarize it by its first and last element via concatenation, $[h_1^{\mathbf{inv}}; h_L^{\mathbf{inv}}]$. The training objective is defined as:

$$\mathcal{L}_{wd} = \sup_{\|f\|_L \leq K} \mathbb{E}_{h^{\mathbf{inv}} \sim \mathbb{P}_{\mathcal{S}}} \left[f([h_1^{\mathbf{inv}}; h_L^{\mathbf{inv}}]) \right] - \mathbb{E}_{h^{\mathbf{inv}} \sim \mathbb{P}_{\mathcal{T}}} \left[f([h_1^{\mathbf{inv}}; h_L^{\mathbf{inv}}]) \right],$$

where the supremum is over all K-Lipschitz scalar functions f. Following Gulrajani et al. (2017), we approximate f by a multi-layer perceptron, and use gradient penalty to fulfill the Lipschitz constraint.

3.3 Attention generation

The goal of this module is to generate high-quality attention for each task. This module combines the domain-invariant representation together with task-specific rationales as its input and predicts task-specific attention scores. We minimize the distance between the predicted attention and the intermediate attention obtained from the multi-task learning module.

For any source task $t \in \{\mathcal{S}_i\}_{i=1}^N$, we denote r^t as the task-specific rationales corresponding to the input text x^t, and denote $h^{\mathbf{inv},t}$ as the domain-invariant representation of x^t. For each position i, we first concatenate r_i^t with the frequency of x_i^t occurring as a rationale from all training examples of this task. We denote this augmented sequence as $\tilde{r}^t$. This frequency term provides the unigram likelihood of each word being a rationale for the task. Then we employ a sequence encoder $\mathbf{enc}^{r2a}$ and an attention module $\mathbf{att}^{r2a}$ to predict the attention scores:

$$\begin{aligned} u^t &= \mathbf{enc}^{r2a}([h^{\mathbf{inv},t}; \tilde{r}^t]), \\ \tilde{u}_i^t &= \tanh(W_{\mathbf{att}}^{r2a} u_i^t + b_{\mathbf{att}}^{r2a}), \\ \hat{\alpha}_i^t &= \frac{\exp(\langle \tilde{u}_i^t, q_{\mathbf{att}}^{r2a} \rangle)}{\sum_j \exp(\langle \tilde{u}_j^t, q_{\mathbf{att}}^{r2a} \rangle)}, \end{aligned}$$

where $W_{\mathbf{att}}^{r2a}$, $b_{\mathbf{att}}^{r2a}$ and $q_{\mathbf{att}}^{r2a}$ are learnable parameters, and both $\mathbf{enc}^{r2a}$ and $\mathbf{att}^{r2a}$ are shareable across all tasks. We minimize the distance between $\hat{\alpha}^t$ and the α^t obtained from the first multi-task learning module over all source data:

$$\mathcal{L}_{att} = \sum_{(\alpha^t, \hat{\alpha}^t), t \in \{\mathcal{S}_i\}_{i=1}^N} \mathrm{d}(\alpha^t, \hat{\alpha}^t),$$

where $\mathrm{d}(\cdot,\cdot)$ can be any distance metric. In this paper, we consider a soft-margin cosine distance:

$$\mathrm{d}(a, b) \triangleq \max(0, 1 - \cos(a, b) - 0.1),$$

where $\cos(\cdot,\cdot)$ denotes the cosine similarity.

3.4 Pipeline

Training R2A We train the three aforementioned modules jointly using both the source data and the unlabeled target data. The overall objective is given by:

$$\mathcal{L} = \mathcal{L}_{lbl} + \lambda_{att}\mathcal{L}_{att} + \lambda_{lm}\mathcal{L}_{lm} + \lambda_{wd}\mathcal{L}_{wd}. \quad (1)$$

The λs are hyper-parameters that control the importance of each training objective and $\mathcal{L}$s represent the corresponding loss functions.

R2A inference Once the R2A model is trained, we can generate attention for each labeled target example based on its human-annotated rationales.

Training target classifier When testing the performance on the target task, of course, we are neither provided with labels nor rationales. In order to make predictions for the target task, we train a new classifier under the supervision of both the labels and the R2A-generated attention. Specifically, this target classifier shares the same architecture as the source one in the multi-task learning module. We minimize the prediction loss, $\mathcal{L}_{lbl}^{\mathcal{T}}$, on the labeled target data together with the cosine distance, $\mathcal{L}_{att}^{\mathcal{T}}$, between the R2A-generated attention and the attention generated by this target classifier. The joint objective for this target classifier is defined as

$$\mathcal{L} = \mathcal{L}_{lbl}^{\mathcal{T}} + \lambda_{att}^{\mathcal{T}}\mathcal{L}_{att}^{\mathcal{T}}, \quad (2)$$

where $\lambda_{att}^{\mathcal{T}}$ controls the importance of $\mathcal{L}_{att}^{\mathcal{T}}$. For better transfer, we initialize the encoder in the target classifier as $\mathbf{enc}$ from the trained R2A model.

4 Experimental Setup

4.1 Datasets

We evaluate our approach on two transfer settings: transfer among aspects within the same domain and transfer among different domains.

Aspect transfer We first consider the transfer problem between multiple aspects of one domain: beer review. We use a subset of the BeerAdvocate[3] review dataset (McAuley et al., 2012) introduced by Lei et al. (2016). This dataset contains reviews with ratings (in the scale of $[0, 1]$) from three aspects of the beer: look, aroma and palate. We treat

---

Beer Aspects	Source Train	Source Dev	Target Train‡	Target Dev	Target Test
Look	43,351	10,170	200	200	4,014
Aroma	39,825	8,772	200	200	4,212
Palate	30,041	7,152	200	200	3,804

Table 1: Statistics of the beer review dataset. ‡ denotes data with human-annotated rationales.

Hotel Aspects	Target Train‡	Target Dev	Target Test	Target Unlabeled
Location	200	200	1,808	14,472
Cleanliness	200	200	12,684	14,472
Service	200	200	18,762	14,472

Table 2: Statistics of the hotel review dataset. ‡ denotes data with human-annotated rationales.

any two aspects as the source and the other one as the target. We consider a classification setting for each target task. Specifically, reviews with ratings ≤ 0.4 are labeled as negative and those with ≥ 0.6 are labeled as positive. We form our dataset by randomly selecting an equal number of positive and negative examples. Then we randomly select 200 examples and ask human annotators to provide rationales (see Appendix 2 for details). These 200 examples are treated as our labeled training data for the target aspect. Unlabeled target data is not required since both source and target tasks are from the same domain. Table 1 summarizes the statistics of the beer review dataset.

Domain transfer Our second experiment focuses on domain transfer from beer reviews to different aspects of hotel reviews. We use the TripAdvisor[4] hotel review dataset (Wang et al., 2010), with the following three aspects as our transfer target: location, cleanliness, and service. For each aspect, reviews with ratings > 3 are labeled as positive and those with < 3 are labeled as negative. Similarly, we collect human rationales for 200 examples and treat them as our training data (see Appendix 2 for details). Table 2 summarizes the statistics of the hotel review dataset. In this experiment, data from all three aspects of the beer reviews are treated as the source tasks.

4.2 Baselines

We compare our approach (OURS) with four types of baselines:

Basic classifier We train a linear SVM using bag-of-ngrams representation on the labeled target data. We combine uni-gram, bi-grams, and tri-grams as features and use tf-idf weighting.

Rationale augmented classifiers We evaluate two previous methods that incorporate human rationales during training: 1) rationale augmented SVM (RA-SVM) (Zaidan et al., 2007), an SVM-based model that utilizes human rationales to regularize the decision boundary of the classifier; 2) rationale augmented CNN (RA-CNN) (Zhang et al., 2016). RA-CNN first trains a CNN-based sentence classifier to estimate the probability that a given sentence contains rationale words. Then RA-CNN scales the contribution of each sentence to the overall representation in proportion to these estimates. The final prediction is made from this overall representation.

Transfer methods We compare against two variants of our method: 1) TRANS, an attention-based classifier that does not use human rationales from the target task; 2) RA-TRANS, an attention-based classifier that directly uses human rationales to supervise the attention. Specifically, TRANS only optimizes the cross-entropy loss $\mathcal{L}_{lbl}^{\mathcal{T}}$ in the objective (Eq. (2)). For RA-TRANS, the term $\mathcal{L}_{att}^{\mathcal{T}}$ in the objective Eq. (2) is replaced by the cosine distance between human rationales and the attention generated by itself. Note that both models still have the ability to transfer, as their encoders are both initialized from $\mathbf{enc}$, which has been trained on source data and unlabeled target data.

Oracle We also report the performance of an ORACLE which shares the same architecture as ours but is supervised by the oracle attention. The oracle attention is derived from a held-out dataset with large-scale annotations for the target task (see Appendix 3 for details). This helps us analyze the contribution of our R2A approach in isolation of the inherent limitations of the target tasks.

4.3 Implementation details

We use pre-trained fastText embeddings (Bojanowski et al., 2017), a 200-dimension bi-directional LSTM (Hochreiter and Schmidhuber, 1997) for the language encoder, and a 50-dimension bi-directional LSTM for the R2A encoder. Dropout (Srivastava et al., 2014) is applied with drop rate 0.1 on the word embeddings and the last hidden layers of the classifiers. All

Table 4: Accuracy of transferring between domains. Models with † use labeled data from source domains and unlabeled data from the target domain. Models with ‡ use human rationales on the target task.

parameters are optimized using Adam (Kingma and Ba, 2014). We set the initial learning rate to 0.001 and divide it by 10 once the performance on the development set plateaus. For RA-TRANS, OURS and ORACLE, we tuned $\lambda^{\mathcal{T}}_{att}$ from $\{10^2, 10^1, 10^0, 10^{-1}, 10^{-2}\}$. For domain transfer, we set $\lambda_{lm} = 0.1$, $\lambda_{wd} = 0.01$ and $\lambda_{att} = 0.01$. For aspect transfer, we adapt the same hyperparameters, but set $\lambda_{wd} = 0$ as both source tasks and the target task come from the same domain. To encourage the R2A-generated attention to be consistent with the provided rationales in aspect transfer, we augment the overall training objective of R2A in Eq. (3.3) by a consistency regularization, which is computed from the cosine distance between the R2A-generated attention and the provided rationales.

In addition, computing $\mathcal{L}_{lm}$ is both time and memory inefficient because the complexity is linear to the size of the vocabulary, which can be very large. To expedite the training, we adopt a technique proposed by Mikolov et al. (2011), which randomly splits the entire vocabulary into a predefined number of bins and minimizes the loss of the bin prediction instead of the exact token prediction. We set the bin size as 100 for our experiment.

5 Results

Aspect transfer Table 3 summarizes the results of aspect transfer on the beer review dataset. Our model (OURS) obtains substantial gains in accuracy over the baselines across all three target aspects. It closely matches the performance of ORACLE with only 0.40% absolute difference.

Model	Hotel location	Hotel cleanliness	Hotel service
OURS	**84.52**	**90.66**	**89.93**
w/o $\mathcal{L}_{wd}$	82.36	89.79	89.61
w/o $\mathcal{L}_{lm}$	82.47	90.05	89.75

Table 5: Ablation study on domain transfer from beer to hotel.

Specifically, all rationale-augmented methods (RA-SVM, RA-TRANS and OURS) outperform their rationale-free counterparts on average. This confirms the value of human rationales in the low-resource settings. We observe that the transfer baseline that directly uses rationale as augmented supervision (RA-TRANS) underperforms ORACLE by a large margin. This validates our hypothesis that human rationales and attention are different.

Domain transfer Table 4 presents the results of domain transfer using 200 training examples. We use the three aspects of the beer review data together as our source tasks while use the three aspects of hotel review data as the target. Our model (OURS) shows marked performance improvement. The error reduction over the best baseline is 15.08% on average.

We compare the learning curve in Figure 4. We observe that the performance of our model steadily improves as more annotations are provided, and the improvement over other baselines is significant and consistent.

Ablation study Table 5 presents the results of an ablation study of our model in the setting of domain transfer. As this table indicates, both the language modeling objective and the Wasserstein

distance contribute similarly to the task, with the Wasserstein distance having a bigger impact.

Visualization of representation Figure 5 visualizes the hidden representation of 200 beer reviews and 200 hotel reviews using t-SNE (Maaten and Hinton, 2008). We observe that our model successfully aligns the source and the target feature distribution. This indicates the effectiveness of optimizing the Wasserstein distance objective.

Analysis of R2A-generated attention In order to validate that the trained R2A model is able to generate task-specific attention from human rationales, we perform both qualitative and quantitative analysis on the R2A-generated attention in the setting of domain transfer. It is worth pointing out that our R2A model has never seen any labeled hotel reviews during training.

Table 6 presents the average cosine distance between the R2A-generated attention and the oracle attention over the target training set. Compared with human rationales, the R2A-generated attention is much closer to the oracle attention. This explains the large performance boost of our method.

Figure 6 visualize the R2A-generated attention on the same hotel review with human rationales corresponding to three different aspects. We observe that the trained R2A model is able to produce task-specific attention scores corresponding to the provided human rationale. For example, given the rationale sentence "not the cleanest rooms but bed was clean and so was bathroom", R2A recognizes that not every token is equally important, and the attention should focus more on "clean", "cleanest", "rooms" and "bathroom".

Annotating rationales versus annotating more labeled data Providing rationales for the training data roughly doubles the annotation cost (Zaidan et al., 2007). Given the same annotation budget, a natural question is: shall we collect a few labeled examples with rationales or annotate more labeled examples? To answer this question, we vary the number of training examples in the target task. Figure 7 shows the corresponding learning curve of a classifier that is trained without rationales. The reference line represents the accuracy of our approach trained on 200 examples with rationales. We notice that in order to reach the same level of performance, the rationale-free classifier requires 800, 3100, and 1900 labeled examples on the three target tasks respectively.

---

[5] Since the hidden representation is a sequence of variable length, we applied t-SNE on the concatenation of the first and last element: $[h_1^{\mathbf{inv}}; h_L^{\mathbf{inv}}]$.

Task: Hotel location Oracle attention

you get what you pay for . not the cleanest rooms but bed was clean and so was bathroom . bring your own towels though as very thin . service was excellent , let us book in at 8:30am ! **for location and price , this ca n't be beaten** , but it is cheap for a reason . if you come expecting the hilton , then book the hilton ! for uk travellers , think of a blackpool b&b.

Task: Hotel location R2A-generated attention

Figure 6: Oracle attention versus R2A-generated attention on an example of hotel review for three different tasks. Words are highlighted according to the attention scores. Human rationales are shown in bold with underlines. The oracle attention is derived from large amounts of labeled hotel reviews. The R2A is trained on labeled beer reviews with unlabeled hotel reviews.

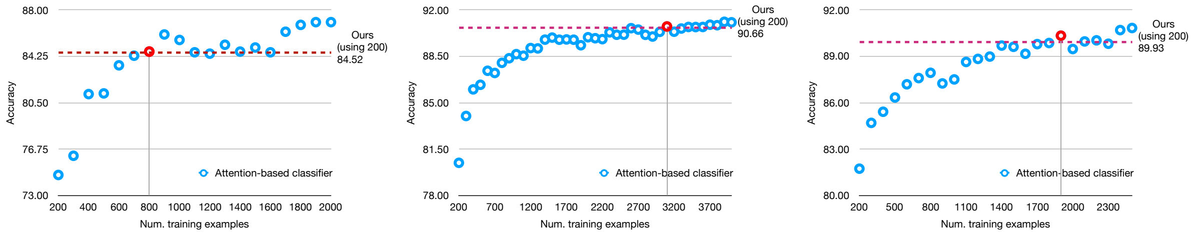

Figure 7: Learning curve of an attention-based classifier on three tasks: hotel location (left), hotel cleanliness (center), hotel service (right). The performance of our approach trained on 200 examples with human rationales is shown as a reference.

6 Conclusion

In this paper, we propose a novel approach that utilizes the connection between human rationales and machine attention to improve the performance of low-resource tasks. Specifically, we learn a transferrable mapping from rationales to high-quality attention on resource-rich tasks. The learned mapping is then used to provide an additional supervision for the target task. Experimental results on both aspect and domain transfer validate that the R2A-generated attention serves as a better form of supervision. Our model produces high-quality attention for low-resource tasks.

Abstract

Unsupervised representation learning algorithms such as word2vec and ELMo improve the accuracy of many supervised NLP models, mainly because they can take advantage of large amounts of unlabeled text. However, the supervised models only learn from task-specific labeled data during the main training phase. We therefore propose Cross-View Training (CVT), a semi-supervised learning algorithm that improves the representations of a Bi-LSTM sentence encoder using a mix of labeled and unlabeled data. On labeled examples, standard supervised learning is used. On unlabeled examples, CVT teaches auxiliary prediction modules that see restricted views of the input (e.g., only part of a sentence) to match the predictions of the full model seeing the whole input. Since the auxiliary modules and the full model share intermediate representations, this in turn improves the full model. Moreover, we show that CVT is particularly effective when combined with multi-task learning. We evaluate CVT on five sequence tagging tasks, machine translation, and dependency parsing, achieving state-of-the-art results.[1]

1 Introduction

Deep learning models work best when trained on large amounts of labeled data. However, acquiring labels is costly, motivating the need for effective semi-supervised learning techniques that leverage unlabeled examples. A widely successful semi-supervised learning strategy for neural NLP is pre-training word vectors (Mikolov et al., 2013). More recent work trains a Bi-LSTM sentence encoder to do language modeling and then incorporates its context-sensitive representations into supervised models (Dai and Le, 2015; Peters et al., 2018). Such pre-training methods perform unsupervised representation learning on a large corpus of unlabeled data followed by supervised training.

A key disadvantage of pre-training is that the first representation learning phase does not take advantage of labeled data – the model attempts to learn generally effective representations rather than ones that are targeted towards a particular task. Older semi-supervised learning algorithms like self-training do not suffer from this problem because they continually learn about a task on a mix of labeled and unlabeled data. Self-training has historically been effective for NLP (Yarowsky, 1995; McClosky et al., 2006), but is less commonly used with neural models. This paper presents Cross-View Training (CVT), a new self-training algorithm that works well for neural sequence models.

In self-training, the model learns as normal on labeled examples. On unlabeled examples, the model acts as both a teacher that makes predictions about the examples and a student that is trained on those predictions. Although this process has shown value for some tasks, it is somewhat tautological: the model already produces the predictions it is being trained on. Recent research on computer vision addresses this by adding noise to the student's input, training the model so it is robust to input perturbations (Sajjadi et al., 2016; Wei et al., 2018). However, applying noise is difficult for discrete inputs like text.

As a solution, we take inspiration from multi-view learning (Blum and Mitchell, 1998; Xu et al., 2013) and train the model to produce consistent predictions across different *views* of the input. Instead of only training the full model as a student, CVT adds auxiliary prediction modules – neural networks that transform vector representations into predictions – to the model and also trains them as students. The input to each student prediction module is a subset of the model's intermediate rep-

Brussels, Belgium, October 31 - November 4, 2018.

resentations corresponding to a restricted view of the input example. For example, one auxiliary prediction module for sequence tagging is attached to only the "forward" LSTM in the model's first Bi-LSTM layer, so it makes predictions without seeing any tokens to the right of the current one.

CVT works by improving the model's representation learning. The auxiliary prediction modules can learn from the full model's predictions because the full model has a better, unrestricted view of the input. As the auxiliary modules learn to make accurate predictions despite their restricted views of the input, they improve the quality of the representations they are built on top of. This in turn improves the full model, which uses the same shared representations. In short, our method combines the idea of representation learning on unlabeled data with classic self-training.

CVT can be applied to a variety of tasks and neural architectures, but we focus on sequence modeling tasks where the prediction modules are attached to a shared Bi-LSTM encoder. We propose auxiliary prediction modules that work well for sequence taggers, graph-based dependency parsers, and sequence-to-sequence models. We evaluate our approach on English dependency parsing, combinatory categorial grammar supertagging, named entity recognition, part-of-speech tagging, and text chunking, as well as English to Vietnamese machine translation. CVT improves over previously published results on all these tasks. Furthermore, CVT can easily and effectively be combined with multi-task learning: we just add additional prediction modules for the different tasks on top of the shared Bi-LSTM encoder. Training a unified model to jointly perform all of the tasks except machine translation improves results (outperforming a multi-task ELMo model) while decreasing the total training time.

2 Cross-View Training

We first present Cross-View Training and describe how it can be combined effectively with multi-task learning. See Figure 1 for an overview of the training method.

2.1 Method

Let $\mathcal{D}_l = \{(x_1, y_1), (x_2, y_2), ..., (x_N, y_N)\}$ represent a labeled dataset and $\mathcal{D}_{ul} = \{x_1, x_2, ..., x_M\}$ represent an unlabeled dataset We use $p_\theta(y|x_i)$ to denote the output distribution over classes produced by the model with parameters θ on input x_i. During CVT, the model alternates learning on a minibatch of labeled examples and learning on a minibatch of unlabeled examples. For labeled examples, CVT uses standard cross-entropy loss:

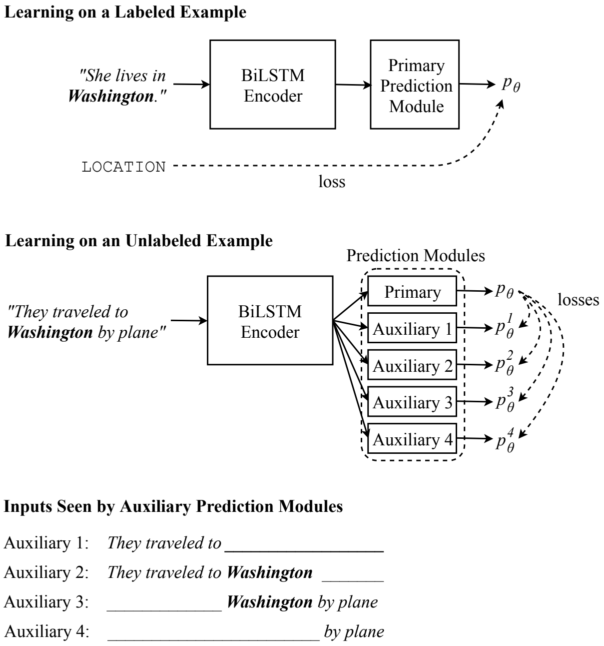

Figure 1: An overview of Cross-View Training. The model is trained with standard supervised learning on labeled examples. On unlabeled examples, auxiliary prediction modules with different views of the input are trained to agree with the primary prediction module. This particular example shows CVT applied to named entity recognition. From the labeled example, the model can learn that "Washington" usually refers to a location. Then, on unlabeled data, auxiliary prediction modules are trained to reach the same prediction without seeing some of the input. In doing so, they improve the contextual representations produced by the model, for example, learning that "traveled to" is usually followed by a location.

$$\mathcal{L}_{\text{sup}}(\theta) = \frac{1}{|\mathcal{D}_l|} \sum_{x_i, y_i \in \mathcal{D}_l} CE(y_i, p_\theta(y|x_i))$$

CVT adds k auxiliary prediction modules to the model, which are used when learning on unlabeled examples. A prediction module is usually a small neural network (e.g., a hidden layer followed by a softmax layer). Each one takes as input an intermediate representation $h^j(x_i)$ produced by the model (e.g., the outputs of one of the LSTMs in a Bi-LSTM model). It outputs a distribution over labels $p_\theta^j(y|x_i)$. Each h^j is chosen such that it only uses a part of the input x_i; the particular choice can depend on the task and model architecture. We propose variants for several tasks in Section 3. The auxiliary prediction modules are only used during training; the test-time prediction come from the primary prediction module that produces p_θ.

On an unlabeled example, the model first produces soft targets $p_\theta(y|x_i)$ by performing inference. CVT trains the auxiliary prediction modules to match the primary prediction module on the unlabeled data by minimizing

$$\mathcal{L}_{\text{CVT}}(\theta) = \frac{1}{|\mathcal{D}_{ul}|} \sum_{x_i \in \mathcal{D}_{ul}} \sum_{j=1}^{k} D(p_\theta(y|x_i), p_\theta^j(y|x_i))$$

where D is a distance function between probability distributions (we use KL divergence). We hold the primary module's prediction $p_\theta(y|x_i)$ fixed during training (i.e., we do not back-propagate through it) so the auxiliary modules learn to imitate the primary one, but not vice versa. CVT works by enhancing the model's representation learning. As the auxiliary modules train, the representations they take as input improve so they are useful for making predictions even when some of the model's inputs are not available. This in turn improves the primary prediction module, which is built on top of the same shared representations.

We combine the supervised and CVT losses into the total loss, $\mathcal{L} = \mathcal{L}_{\text{sup}} + \mathcal{L}_{\text{CVT}}$, and minimize it with stochastic gradient descent. In particular, we alternate minimizing $\mathcal{L}_{\text{sup}}$ over a minibatch of labeled examples and minimizing $\mathcal{L}_{\text{CVT}}$ over a minibatch of unlabeled examples.

For most neural networks, adding a few additional prediction modules is computationally cheap compared to the portion of the model building up representations (such as an RNN or CNN). Therefore our method contributes little overhead to training time over other self-training approaches for most tasks. CVT does not change inference time or the number of parameters in the fully-trained model because the auxiliary prediction modules are only used during training.

2.2 Combining CVT with Multi-Task Learning

CVT can easily be combined with multi-task learning by adding additional prediction modules for the other tasks on top of the shared Bi-LSTM encoder. During supervised learning, we randomly select a task and then update $\mathcal{L}_{\text{sup}}$ using a minibatch of labeled data for that task. When learning on the unlabeled data, we optimize $\mathcal{L}_{\text{CVT}}$ jointly across all tasks at once, first running inference with all the primary prediction modules and then learning from the predictions with all the auxiliary prediction modules. As before, the model alternates training on minibatches of labeled and unlabeled examples.

Examples labeled across many tasks are useful for multi-task systems to learn from, but most datasets are only labeled with one task. A benefit of multi-task CVT is that the model creates (artificial) all-tasks-labeled examples from unlabeled data. This significantly improves the model's data efficiency and training time. Since running prediction modules is computationally cheap, computing $\mathcal{L}_{\text{CVT}}$ is not much slower for many tasks than it is for a single one. However, we find the all-tasks-labeled examples substantially speed up model convergence. For example, our model trained on six tasks takes about three times as long to converge as the average model trained on one task, a 2x decrease in total training time.

3 Cross-View Training Models

CVT relies on auxiliary prediction modules that have restricted views of the input. In this section, we describe specific constructions of the auxiliary prediction modules that are effective for sequence tagging, dependency parsing, and sequence-to-sequence learning.

3.1 Bi-LSTM Sentence Encoder

All of our models use a two-layer CNN-BiLSTM (Chiu and Nichols, 2016; Ma and Hovy, 2016) sentence encoder. It takes as input a sequence of words $x_i = [x_i^1, x_i^2, ..., x_i^T]$. First, each word is represented as the sum of an embedding vector and the output of a character-level Convolutional Neural Network, resulting in a sequence of vectors $v = [v^1, v^2, ..., v^T]$. The encoder applies a two-layer bidirectional LSTM (Graves and Schmidhuber, 2005) to these representations. The first layer runs a Long Short-Term Memory unit (Hochreiter and Schmidhuber, 1997) in the forward direction (taking v^t as input at each step t) and the backward direction (taking v^{T-t+1} at each step) to produce vector sequences $[\overrightarrow{h}_1^1, \overrightarrow{h}_1^2, ... \overrightarrow{h}_1^T]$ and $[\overleftarrow{h}_1^1, \overleftarrow{h}_1^2, ... \overleftarrow{h}_1^T]$. The output of the Bi-LSTM is the concatenation of these vectors: $h_1 = [\overrightarrow{h}_1^1 \oplus \overleftarrow{h}_1^1, ..., \overrightarrow{h}_1^T \oplus \overleftarrow{h}_1^T]$. The second Bi-LSTM layer works the same, producing outputs h_2, except it takes h_1 as input instead of v.

3.2 CVT for Sequence Tagging

In sequence tagging, each token x_i^t has a corresponding label y_i^t. The primary prediction module for sequence tagging produces a probability distribution over classes for the t^{th} label using a one-hidden-layer neural network applied to the corresponding encoder outputs:

$$\begin{aligned} p(y^t|x_i) &= \text{NN}(h_1^t \oplus h_2^t) \\ &= \text{softmax}(U \cdot \text{ReLU}(W(h_1^t \oplus h_2^t)) + b) \end{aligned}$$

The auxiliary prediction modules take $\overrightarrow{h}_1(x_i)$ and $\overleftarrow{h}_1(x_i)$, the outputs of the forward and backward LSTMs in the first[2] Bi-LSTM layer, as inputs. We add the following four auxiliary prediction modules to the model (see Figure 2):

$$\begin{aligned} p_\theta^{\text{fwd}}(y^t|x_i) &= \text{NN}^{\text{fwd}}(\overrightarrow{h}_1^t(x_i)) \\ p_\theta^{\text{bwd}}(y^t|x_i) &= \text{NN}^{\text{bwd}}(\overleftarrow{h}_1^t(x_i)) \\ p_\theta^{\text{future}}(y^t|x_i) &= \text{NN}^{\text{future}}(\overrightarrow{h}_1^{t-1}(x_i)) \\ p_\theta^{\text{past}}(y^t|x_i) &= \text{NN}^{\text{past}}(\overleftarrow{h}_1^{t+1}(x_i)) \end{aligned}$$

The "forward" module makes each prediction without seeing the right context of the current token. The "future" module makes each prediction without the right context or the current token itself. Therefore it works like a neural language model that, instead of predicting which token comes next in the sequence, predicts which class of token comes next. The "backward" and "past" modules are analogous.

3.3 CVT for Dependency Parsing

In a dependency parse, words in a sentence are treated as nodes in a graph. Typed directed edges connect the words, forming a tree structure describing the syntactic structure of the sentence. In particular, each word x_i^t in a sentence $x_i = x_i^1, ..., x_i^T$ receives exactly one in-going edge (u, t, r) going from word x_i^u (called the "head") to it (the "dependent") of type r (the "relation"). We use a graph-based dependency parser similar to the one from Dozat and Manning (2017). This treats dependency parsing as a classification task where the goal is to predict which in-going edge $y_i^t = (u, t, r)$ connects to each word x_i^t.

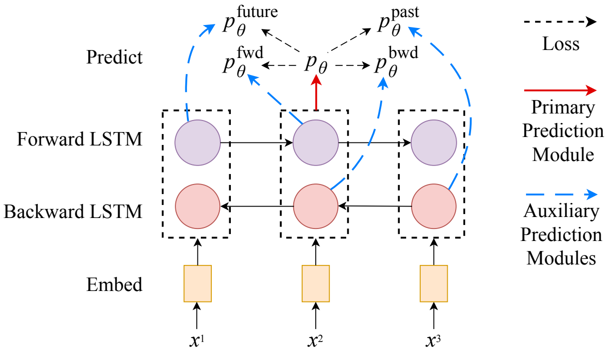

Figure 2: Auxiliary prediction modules for sequence tagging models. Each one sees a restricted view of the input. For example, the "forward" prediction module does not see any context to the right of the current token when predicting that token's label. For simplicity, we only show a one layer Bi-LSTM encoder and only show the model's predictions for a single time step.

First, the representations produced by the encoder for the candidate head and dependent are passed through separate hidden layers. A bilinear classifier applied to these representations produces a score for each candidate edge. Lastly, these scores are passed through a softmax layer to produce probabilities. Mathematically, the probability of an edge is given as:

$$p_\theta((u, t, r)|x_i) \propto e^{s(h_1^u(x_i) \oplus h_2^u(x_i), h_1^t(x_i) \oplus h_2^t(x_i), r)}$$

where s is the scoring function:

$$\begin{aligned} s(z_1, z_2, r) = \; & \text{ReLU}(W_{\text{head}} z_1 + b_{\text{head}})(W_r + W) \\ & \text{ReLU}(W_{\text{dep}} z_2 + b_{\text{dep}}) \end{aligned}$$

The bilinear classifier uses a weight matrix W_r specific to the candidate relation as well as a weight matrix W shared across all relations. Note that unlike in most prior work, our dependency parser only takes words as inputs, not words and part-of-speech tags.

We add four auxiliary prediction modules to our model for cross-view training:

$$\begin{aligned} p_\theta^{\text{fwd-fwd}}((u, t, r)|x_i) &\propto e^{s^{\text{fwd-fwd}}(\overrightarrow{h}_1^u(x_i), \overrightarrow{h}_1^t(x_i), r)} \\ p_\theta^{\text{fwd-bwd}}((u, t, r)|x_i) &\propto e^{s^{\text{fwd-bwd}}(\overrightarrow{h}_1^u(x_i), \overleftarrow{h}_1^t(x_i), r)} \\ p_\theta^{\text{bwd-fwd}}((u, t, r)|x_i) &\propto e^{s^{\text{bwd-fwd}}(\overleftarrow{h}_1^u(x_i), \overrightarrow{h}_1^t(x_i), r)} \\ p_\theta^{\text{bwd-bwd}}((u, t, r)|x_i) &\propto e^{s^{\text{bwd-bwd}}(\overleftarrow{h}_1^u(x_i), \overleftarrow{h}_1^t(x_i), r)} \end{aligned}$$

Each one has some missing context (not seeing either the preceding or following words) for the candidate head and candidate dependent.

---

[2] Modules taking inputs from the second Bi-LSTM layer would not have restricted views because information about the whole sentence gets propagated through the first layer.

3.4 CVT for Sequence-to-Sequence Learning

We use an encoder-decoder sequence-to-sequence model with attention (Sutskever et al., 2014; Bahdanau et al., 2015). Each example consists of an input (source) sequence $x_i = x_i^1, ..., x_i^T$ and output (target) sequence $y_i = y_i^1, ..., y_i^K$. The encoder's representations are passed into an LSTM decoder using a bilinear attention mechanism (Luong et al., 2015). In particular, at each time step t the decoder computes an attention distribution over source sequence hidden states as $\alpha_j \propto e^{h^j W_\alpha \bar{h}^t}$ where $\bar{h}^t$ is the decoder's current hidden state. The source hidden states weighted by the attention distribution form a context vector: $c_t = \sum_j \alpha_j h^j$. Next, the context vector and current hidden state are combined into an attention vector $a_t = \tanh(W_a[c_t, h_t])$. Lastly, a softmax layer predicts the next token in the output sequence: $p(y_i^t | y_i^{<t}, x_i) = \text{softmax}(W_s a_t)$.

We add two auxiliary decoders when applying CVT. The auxiliary decoders share embedding and LSTM parameters with the primary decoder, but have different parameters for the attention mechanisms and softmax layers. For the first one, we restrict its view of the input by applying attention dropout, randomly zeroing out a fraction of its attention weights. The second one is trained to predict the next word in the target sequence rather than the current one: $p_\theta^{\text{future}}(y_i^t | y_i^{<t}, x_i) = \text{softmax}(W_s^{\text{future}} a_{t-1}^{\text{future}})$. Since there is no target sequence for unlabeled examples, we cannot apply teacher forcing to get an output distribution over the vocabulary from the primary decoder at each time step. Instead, we produce hard targets for the auxiliary modules by running the primary decoder with beam search on the input sequence. This idea has previously been applied to sequence-level knowledge distillation by Kim and Rush (2016).

4 Experiments

We compare Cross-View Training against several strong baselines on seven tasks:

Combinatory Categorial Grammar (CCG) Supertagging: We use data from CCGBank (Hockenmaier and Steedman, 2007).

Text Chunking: We use the CoNLL-2000 data (Tjong Kim Sang and Buchholz, 2000).

Named Entity Recognition (NER): We use the CoNLL-2003 data (Tjong Kim Sang and De Meulder, 2003).

Fine-Grained NER (FGN): We use the OntoNotes (Hovy et al., 2006) dataset.

Part-of-Speech (POS) Tagging: We use the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993).

Dependency Parsing: We use the Penn Treebank converted to Stanford Dependencies version 3.3.0.

Machine Translation: We use the English-Vietnamese translation dataset from IWSLT 2015 (Cettolo et al., 2015). We report (tokenized) BLEU scores on the tst2013 test set.

We use the 1 Billion Word Language Model Benchmark (Chelba et al., 2014) as a pool of unlabeled sentences for semi-supervised learning.

4.1 Model Details and Baselines

We apply dropout during training, but not when running the primary prediction module to produce soft targets on unlabeled examples. In addition to the auxiliary prediction modules listed in Section 3, we find it slightly improves results to add another one that sees the whole input rather than a subset (but unlike the primary prediction module, does have dropout applied to its representations). Unless indicated otherwise, our models have LSTMs with 1024-sized hidden states and 512-sized projection layers. See the supplementary material for full training details and hyperparameters. We compare CVT with the following other semi-supervised learning algorithms:

Word Dropout. In this method, we only train the primary prediction module. When acting as a teacher it is run as normal, but when acting as a student, we randomly replace some of the input words with a `REMOVED` token. This is similar to CVT in that it exposes the model to a restricted view of the input. However, it is less data efficient. By carefully designing the auxiliary prediction modules, it is possible to train the auxiliary prediction modules to match the primary one across many different views of the input a once, rather than just one view at a time.

Virtual Adversarial Training (VAT). VAT (Miyato et al., 2016) works like word dropout, but adds noise to the word embeddings of the student instead of dropping out words. Notably, the noise is chosen adversarially so it most changes the model's prediction. This method was applied successfully to semi-supervised text classification

Table 1: Results on the test sets. We report the mean score over 5 runs. Standard deviations in score are around 0.1 for NER, FGN, and translation, 0.02 for POS, and 0.05 for the other tasks. See the supplementary materials for results with them included. The +Large model has four times as many hidden units as the others, making it similar in size to the models when ELMo is included. * denotes semi-supervised and † denotes multi-task.

by Miyato et al. (2017).

ELMo. ELMo incorporates the representations from a large separately-trained language model into a task-specific model. Our implementaiton follows Peters et al. (2018). When combining ELMo with multi-task learning, we allow each task to learn its own weights for the ELMo embeddings going into each prediction module. We found applying dropout to the ELMo embeddings was crucial for achieving good performance.

4.2 Results

Results are shown in Table 1. CVT on its own outperforms or is comparable to the best previously published results on all tasks. Figure 3 shows an example win for CVT over supervised learning.

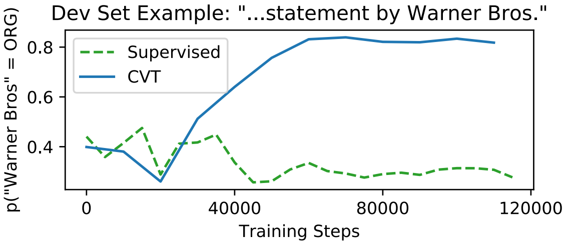

Figure 3: An NER example that CVT classifies correctly but supervised learning does not. "Warner" only occurs as a last name in the train set, so the supervised model classifies "Warner Bros" as a person. The CVT model also mistakenly classifies "Warner Bros" as a person to start with, but as it sees more of the unlabeled data (in which "Warner" occurs thousands of times) it learns that "Warner Bros" is an organization.

Of the prior results listed in Table 1, only TagLM and ELMo are semi-supervised. These methods first train an enormous language model on unlabeled data and incorporate the representations produced by the language model into a supervised classifier. Our base models use 1024 hidden units in their LSTMs (compared to 4096 in ELMo), require fewer training steps (around one pass over the billion-word benchmark rather than many passes), and do not require a pipelined training procedure. Therefore, although they perform on par with ELMo, they are faster and simpler to train. Increasing the size of our CVT+Multi-task model so it has 4096 units in its LSTMs like ELMo improves results further so they are significantly better than the ELMo+Multi-task ones. We suspect there could be further gains from combining our method with language model pre-training, which we leave for future work.

CVT + Multi-Task. We train a single shared-encoder CVT model to perform all of the tasks except machine translation (as it is quite different and requires more training time than the other ones). Multi-task learning improves results on all of the tasks except fine-grained NER, sometimes by large margins. Prior work on many-task NLP such as Hashimoto et al. (2017) uses complicated architectures and training algorithms. Our result shows that simple parameter sharing can be enough for effective many-task learning when the model is big and trained on a large amount of data.

Interestingly, multi-task learning works better in conjunction with CVT than with ELMo. We hypothesize that the ELMo models quickly fit to the data primarily using the ELMo vectors, which perhaps hinders the model from learning effective representations that transfer across tasks. We also believe CVT alleviates the danger of the model "forgetting" one task while training on the other ones, a well-known problem in many-task learning (Kirkpatrick et al., 2017). During multi-task CVT, the model makes predictions about unlabeled examples across all tasks, creating (artificial) all-tasks-labeled examples, so the model does not only see one task at a time. In fact, multi-task learning plus self training is similar to the Learning without Forgetting algorithm (Li and Hoiem, 2016), which trains the model to keep its predictions on an old task unchanged when learning a new task. To test the value of all-tasks-labeled examples, we trained a multi-task CVT model that only computes $\mathcal{L}_{\text{CVT}}$ on one task at a time (chosen randomly for each unlabeled minibatch) instead of for all tasks in parallel. The one-at-a-time model performs substantially worse (see Table 2).

Model	CCG	Chnk	NER	FGN	POS	Dep.
CVT-MT	95.7	97.4	96.0	86.7	97.74	94.4
w/out parallel	95.4	97.1	95.6	86.3	97.71	94.1

Table 2: Dev set performance of multi-task CVT with and without producing all-tasks-labeled examples.

Model Generalization. In order to evaluate how our models generalize to the dev set from the train set, we plot the dev vs. train accuracy for our different methods as they learn (see Figure 4). Both CVT and multi-task learning improve model generalization: for the same train accuracy, the models get better dev accuracy than purely supervised learning. Interestingly, CVT continues to improve in dev set accuracy while close to 100% train accuracy for CCG, Chunking, and NER, perhaps because the model is still learning from unlabeled data even when it has completely fit to the train set. We also show results for a smaller multi-task + CVT model. Although it generalizes at least as well as the larger one, it halts making progress on the train set earlier. This suggests it is important to use sufficiently large neural networks for multi-task learning: otherwise the model does not have the capacity to fit to all the training data.

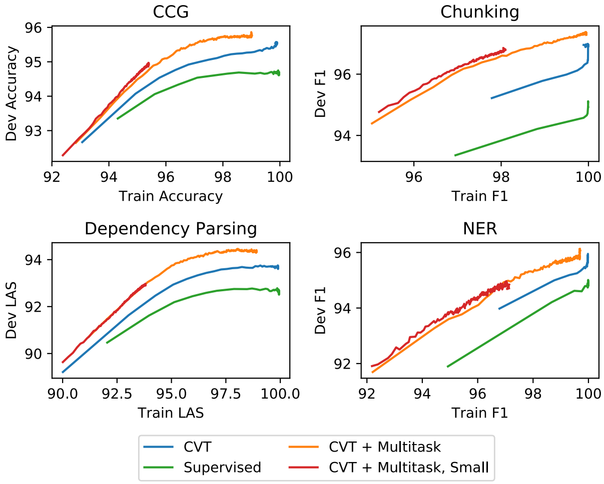

Figure 4: Dev set vs. Train set accuracy for various methods. The "small" model has 1/4 the LSTM hidden state size of the other ones (256 instead of 1024).

Auxiliary Prediction Module Ablation. We briefly explore which auxiliary prediction modules are more important for the sequence tagging tasks in Table 3. We find that both kinds of auxiliary prediction modules improve performance, but that the future and past modules improve results more than the forward and backward ones, perhaps because they see a more restricted and challenging view of the input.

Model	CCG	Chnk	NER	FGN	POS
Supervised	94.8	95.5	95.0	86.0	97.59
CVT	95.6	97.0	95.9	87.3	97.66
no fwd/bwd	–0.1	–0.2	–0.2	–0.1	–0.01
no future/past	–0.3	–0.4	–0.4	–0.3	–0.04

Table 3: Ablation study on auxiliary prediction modules for sequence tagging.

Training Models on Small Datasets. We explore how CVT scales with dataset size by varying the amount of training data the model has ac-

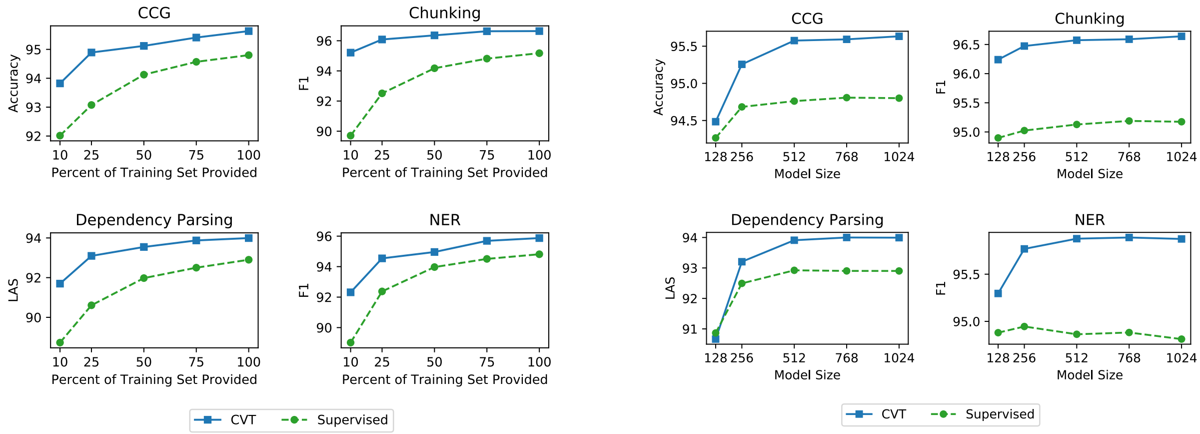

Figure 5: Left: Dev set performance vs. percent of the training set provided to the model. Right: Dev set performance vs. model size. The x axis shows the number of hidden units in the LSTM layers; the projection layers and other hidden layers in the network are half that size. Points correspond to the mean of three runs.

cess to. Unsurprisingly, the improvement of CVT over purely supervised learning grows larger as the amount of labeled data decreases (see Figure 5, left). Using only 25% of the labeled data, our approach already performs as well or better than a fully supervised model using 100% of the training data, demonstrating that CVT is particularly useful on small datasets.

Training Larger Models. Most sequence taggers and dependency parsers in prior work use small LSTMs (hidden state sizes of around 300) because larger models yield little to no gains in performance (Reimers and Gurevych, 2017). We found our own supervised approaches also do not benefit greatly from increasing the model size. In contrast, when using CVT accuracy scales better with model size (see Figure 5, right). This finding suggests the appropriate semi-supervised learning methods may enable the development of larger, more sophisticated models for NLP tasks with limited amounts of labeled data.

Generalizable Representations. Lastly, we explore training the CVT+multi-task model on five tasks, freezing the encoder, and then only training a prediction module on the sixth task. This tests whether the encoder's representations generalize to a new task not seen during its training. Only training the prediction module is very fast because (1) the encoder (which is by far the slowest part of the model) has to be run over each example only once and (2) we do not back-propagate into the encoder. Results are shown in Table 4.

Model	CCG	Chnk	NER	FGN	POS	Dep.
Supervised	94.8	95.6	95.0	86.0	97.59	92.9
CVT-MT frozen	95.1	96.6	94.6	83.2	97.66	92.5
ELMo frozen	94.3	92.2	91.3	80.6	97.50	89.4

Table 4: Comparison of single-task models on the dev sets. "CVT-MT frozen" means we pretrain a CVT + multi-task model on five tasks, and then train only the prediction module for the sixth. "ELMo frozen" means we train prediction modules (but no LSTMs) on top of ELMo embeddings.

Training only a prediction module on top of multi-task representations works remarkably well, outperforming ELMo embeddings and sometimes even a vanilla supervised model, showing the multi-task model is building up effective representations for language. In particular, the representations could be used like skip-thought vectors (Kiros et al., 2015) to quickly train models on new tasks without slow representation learning.

5 Related Work

Unsupervised Representation Learning. Early approaches to deep semi-supervised learning pretrain neural models on unlabeled data, which has been successful for applications in computer vision (Jarrett et al., 2009; LeCun et al., 2010) and NLP. Particularly noteworthy for NLP are algorithms for learning effective word embeddings (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014) and language model pretraining (Dai and Le, 2015; Ramachandran et al., 2017; Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2018). Pre-training on other tasks such as machine translation has also been studied (McCann et al., 2017). Other approaches train "thought vectors" representing sentences through unsupervised (Kiros et al., 2015; Hill et al., 2016) or supervised (Conneau et al., 2017) learning.

Self-Training. One of the earliest approaches to semi-supervised learning is self-training (Scudder, 1965), which has been successfully applied to NLP tasks such as word-sense disambiguation (Yarowsky, 1995) and parsing (McClosky et al., 2006). In each round of training, the classifier, acting as a "teacher," labels some of the unlabeled data and adds it to the training set. Then, acting as a "student," it is retrained on the new training set. Many recent approaches (including the consistentency regularization methods discussed below and our own method) train the student with soft targets from the teacher's output distribution rather than a hard label, making the procedure more akin to knowledge distillation (Hinton et al., 2015). It is also possible to use multiple models or prediction modules for the teacher, such as in tri-training (Zhou and Li, 2005; Ruder and Plank, 2018).

Consistency Regularization. Recent works add noise (e.g., drawn from a Gaussian distribution) or apply stochastic transformations (e.g., horizontally flipping an image) to the student's inputs. This trains the model to give consistent predictions to nearby data points, encouraging distributional smoothness in the model. Consistency regularization has been very successful for computer vision applications (Bachman et al., 2014; Laine and Aila, 2017; Tarvainen and Valpola, 2017). However, stochastic input alterations are more difficult to apply to discrete data like text, making consistency regularization less used for natural language processing. One solution is to add noise to the model's word embeddings (Miyato et al., 2017); we compare against this approach in our experiments. CVT is easily applicable to text because it does not require changing the student's inputs.

Multi-View Learning. Multi-view learning on data where features can be separated into distinct subsets has been well studied (Xu et al., 2013). Particularly relevant are co-training (Blum and Mitchell, 1998) and co-regularization (Sindhwani and Belkin, 2005), which trains two models with disjoint views of the input. On unlabeled data, each one acts as a "teacher" for the other model. In contrast to these methods, our approach trains a single unified model where auxiliary prediction modules see different, but not necessarily independent views of the input.

Self Supervision. Self-supervised learning methods train auxiliary prediction modules on tasks where performance can be measured without human-provided labels. Recent work has jointly trained image classifiers with tasks like relative position and colorization (Doersch and Zisserman, 2017), sequence taggers with language modeling (Rei, 2017), and reinforcement learning agents with predicting changes in the environment (Jaderberg et al., 2017). Unlike these approaches, our auxiliary losses are based on self-labeling, not labels deterministically constructed from the input.

Multi-Task Learning. There has been extensive prior work on multi-task learning (Caruana, 1997; Ruder, 2017). For NLP, most work has focused on a small number of closely related tasks (Luong et al., 2016; Zhang and Weiss, 2016; Søgaard and Goldberg, 2016; Peng et al., 2017). Many-task systems are less commonly developed. Collobert and Weston (2008) propose a many-task system sharing word embeddings between the tasks, Hashimoto et al. (2017) train a many-task model where the tasks are arranged hierarchically according to their linguistic level, and Subramanian et al. (2018) train a shared-encoder many-task model for the purpose of learning better sentence representations for use in downstream tasks, not for improving results on the original tasks.

6 Conclusion

We propose Cross-View Training, a new method for semi-supervised learning. Our approach allows models to effectively leverage their own predictions on unlabeled data, training them to produce effective representations that yield accurate predictions even when some of the input is not available. We achieve excellent results across seven NLP tasks, especially when CVT is combined with multi-task learning.

A Probabilistic Annotation Model for Crowdsourcing Coreference

Silviu Paun[1], Jon Chamberlain[2], Udo Kruschwitz[2], Juntao Yu[1] and Massimo Poesio[1]
[1]School of Electronic Engineering and Computer Science, Queen Mary University of London
[2]School of Computer Science and Electronic Engineering, University of Essex

Abstract

The availability of large scale annotated corpora for coreference is essential to the development of the field. However, creating resources at the required scale via expert annotation would be too expensive. Crowdsourcing has been proposed as an alternative; but this approach has not been widely used for coreference. This paper addresses one crucial hurdle on the way to make this possible, by introducing a new model of annotation for aggregating crowdsourced anaphoric annotations. The model is evaluated along three dimensions: the accuracy of the inferred mention pairs, the quality of the post-hoc constructed silver chains, and the viability of using the silver chains as an alternative to the expert-annotated chains in training a state of the art coreference system. The results suggest that our model can extract from crowdsourced annotations coreference chains of comparable quality to those obtained with expert annotation.

1 Introduction

The task of identifying and resolving anaphoric reference to discourse entities, known in NLP as coreference resolution, has long been considered a core aspect of language interpretation (Poesio et al., 2016b), also because of its role in applications such as summarization (Baldwin and Morton, 1998; Steinberger et al., 2007), information extraction (Humphreys et al.) or question answering (Morton, 1999; Zheng, 2002).

In the 1990s the field made a paradigmatic turn towards corpus based approaches initiated by campaigns such as MUC (Grishman and Sundheim, 1995; Chinchor, 1998) and since then we have seen the development of a range of data-driven approaches, spurred by the development of ever larger and richer datasets. Nowadays, a variety of datasets exist for several languages (Poesio et al., 2016a). These include medium-scale multilingual datasets such as ONTONOTES (Pradhan et al., 2007; Weischedel et al., 2011), which led to the most recent evaluation campaigns, in particular CONLL 2012 (Pradhan et al., 2012), and are used in most current research (Björkelund and Kuhn, 2014; Martschat and Strube, 2015; Clark and Manning, 2016; Lee et al., 2017). However, there are still many languages and domains for which no such resources are available, and even for English much larger corpora than ONTONOTES will eventually be required.

However, annotating data on the scale required to train state of the art systems using traditional expert annotation would be unaffordable. One alternative is to employ **crowdsourcing**, either via platforms like Amazon Mechanical Turk and Crowdflower, or using **Games-With-A-Purpose** (Poesio et al., 2017). Studies such as (Snow et al., 2008; Raykar et al., 2010) have shown that when a sufficiently large number of workers is employed, expert-level quality can be achieved, at a fraction of the cost required to create such resources using traditional methods. The one effort to create a large-scale coreference corpus entirely through crowdsourcing, the *Phrase Detectives* project (Poesio et al., 2013; Chamberlain et al., 2016; Chamberlain, 2016), employs the *Phrase Detectives* game with a purpose. The *Phrase Detectives* corpus consists of 843 documents for a total of 1.2 million tokens and 392,741 markables; at present, 563 documents for a total of 360,000 tokens have been annotated.[1] A second coreference corpus created using crowdsourcing (in the context of a trivia game) also exists, the

---

[1] Note that although the *Phrase Detectives* corpus is slightly smaller in terms of tokens than the currently largest coreference corpus for English, the CONLL 2012 dataset (Pradhan et al., 2012), it has about twice the number of markables, 390,000 vs. 190,000.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1926–1937
Brussels, Belgium, October 31 - November 4, 2018.

Quiz Bowl dataset (Guha et al., 2015).[2]

However, such existing corpora are not widely used yet. One of the reasons for this is the lack of suitable **aggregation methods** for anaphora. Crowdsourced annotations require aggregation methods to select among the different interpretations produced by the crowd. Standard practice for crowdsourced data analysis has seen a shift in recent years from simple majority vote to much more effective aggregation methods (Smyth et al., 1994; Quoc Viet Hung et al., 2013; Sheshadri and Lease, 2013; Carpenter, 2008; Hovy et al., 2013; Passonneau and Carpenter, 2014). Probabilistic models of annotation, in particular, make it possible to characterize the accuracy of the annotators and correct for their bias (Dawid and Skene, 1979; Passonneau and Carpenter, 2014), to account for item-level effects (e.g.: difficulty) (Whitehill et al., 2009), and to employ different pooling strategies (Carpenter, 2008). However, existing models of annotation cannot be used for anaphora. Such methods assume that coders choose between a fixed set of general labels, the same labels across all annotated items. In anaphoric annotation, by contrast, coders relate markables to coreference chains which depend on the markables that are annotated in that given document (Passonneau, 2004; Artstein and Poesio, 2008)

Contributions In this paper we propose a mention pair-based approach to aggregating crowdsourced anaphoric annotations. Concretely, we introduce a new model of annotation capable of inferring the most likely mention pairs from crowd-annotated anaphoric relations. We then use these pairs to build the most likely coreference chains. This approach to building chains is evaluated on both crowdsourced and synthetic (via simulation) coreference datasets. The evaluations include assessing the accuracy of the inferred mention pairs; the quality of the chains; and the viability of using these chains derived from mention pairs as an alternative to gold chains when training a state of the art coreference system. We conclude by also demonstrating the quality of the proposed model in a standard annotation task. The implementation is available as supplementary material.

2 A Mention-Pair Model of Annotation

Traditional models of annotation (Dawid and Skene, 1979; Smyth et al., 1994; Raykar et al., 2010; Hovy et al., 2013) are specified assuming the annotations are chosen among a general set of classes that is consistent across the annotated items. This is the case in a type of annotation closely related to anaphoric annotation, **information status** annotation (Nissim et al., 2004; Riester et al., 2010). In this type of annotation, an annotator marks a mention as either **discourse old** (DO) – referring to an existing entity (coreference chain) – or as **discourse-new** (DN) – introducing a new coreference chain, but without specifying *which* coreference chain the mention belongs to, if any. We will refer below to categories such as DN and DO as **(general) classes**.

Traditional models of annotation can model this type of annotation, but not the task of anaphoric annotation proper. In standard annotation schemes for anaphora/coreference (Poesio et al., 2016a) the annotator may mark a mention as referring to a discourse new entity as above; but in case the mention is identified as discourse-old, this entity, or **coreference chain**–the set of coreferring mentions–is also specified. The available coreference chains differ from document to document.

Our proposal for a probabilistic model of this type of annotation is based on one of the most widely used models of coreference *resolution*: the **mention pair** model. In the mention pair model, the task of linking the mention to a coreference chain/entity is split in two parts: classifying mention pairs as coreferring or not, and subsequent clustering (Soon et al., 2001; Hoste, 2016). The model we propose addresses the first part.

More formally, the crowdsourced data to be modeled consists of I mentions (indexed by i) annotated by a total of J coders (indexed by j). Each mention i has N_i annotations (indexed by n), for a total of M_i distinct **labels** (indexed by m). Each label m of mention i belongs to a **class** $z_{i,m}$. The label of a mention could be the ID of the antecedent, in case that mention is annotated as belonging to the discourse old (general) class; or could be discourse new or another general class (e.g.: property, non referring). In these latter cases, the labels coincide with the classes they

---

[2] Another corpus creation project using crowdsourcing (and also games) for anaphoric annotation is the *Groningen Meaning Bank* (Bos et al., 2017). However, in the GMB crowdsourcing is not used to generate interpretations: players correct automatically annotated interpretations rather than providing the annotations themselves. Another crucial difference is that interpretations are not aggregated in the sense discussed below; rather, an expert adjudicates between the interpretations produced by players.

belong to.

An important difficulty we had to address is label sparsity. The solution we propose is to transform the mention-level annotations into a series of binary decisions with respect to each candidate label. In the extended literature this is often referred to as the binary relevance method (Tsoumakas and Katakis, 2007; Madjarov et al., 2012). We then model these (label-level) decisions as the result of the sensitivity (the true positive rate) and specificity (the true negative rate) of the annotators which we assume are class dependent. This latter assumption allows inferring different levels of annotator ability for each class (e.g.: capturing that DO labels are generally harder compared to DN).

The graphical model of our **Mention Pair Annotations** model (MPA) is presented in Figure 1, while the generative process is given below:

- For every class $h \in \{1, 2, ..., K\}$:
  - Draw class specific true label likelihood $\pi_h \sim \mathsf{Beta}(a, b)$
- For every annotator $j \in \{1, 2, ..., J\}$:
  - For every class $h \in \{1, 2, ..., K\}$:
    - Draw sensitivity $\alpha_{j,h} \sim \mathsf{Beta}(d, e)$
    - Draw specificity $\beta_{j,h} \sim \mathsf{Beta}(t, u)$
- For every mention $i \in \{1, 2, ..., I\}$:
  - For every candidate label $m \in \{1, 2, ..., M_i\}$:
    - Draw true label indicator $c_{i,m} \sim \mathsf{Bern}(\pi_{z_{i,m}})$
    - For every position $n \in \{1, 2, ..., N_i\}$:
      - If $c_{i,m} = 1$ then draw decision $y_{i,m,n} \sim \mathsf{Bern}(\alpha_{jj[i,m,n],z_{i,m}})$[3]
      - Otherwise, draw decision $y_{i,m,n} \sim \mathsf{Bern}(1 - \beta_{jj[i,m,n],z_{i,m}})$

The model addresses the first part of the mention pair framework: the posterior of the true label indicators is used to link each mention with the most likely label, obtaining the mention pairs. The coreference chains are then built by following the link structure from the inferred pairs.

Note that for a traditional annotation task with no distinction between generic classes and specific labels the MPA model is equivalent to training K binary Bayesian versions of the Dawid and Skene (1979) model (one for each general class) on data processed using the binary relevance method. Note also that whereas traditional models of annotation assume one true class per annotated item, an implicit benefit of our approach is allowing for potentially multiple true classes, which can be useful to detect ambiguity (Poesio and Artstein, 2005), but we don't exploit that in this work.

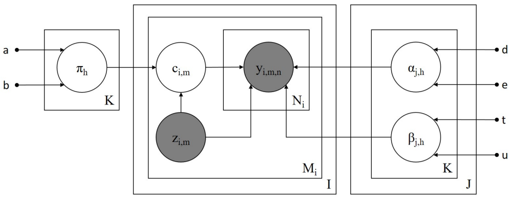

Figure 1: Plate diagram for MPA

2.1 Parameter Estimation

We infer the parameters of the proposed model using Variational Inference (VI). Unlike Markov Chain Monte Carlo (MCMC) approaches (e.g.: Gibbs Sampling, Hamiltonian Monte Carlo), VI is deterministic, fast, and benefits from a clear convergence criterion (Blei et al., 2017).

Specifically we approximate the intractable posterior $p(\theta|D)$ with a variational distribution $q(\theta)$ such that the Kullback-Leibler (KL) divergence between the two distributions is minimized. It can be shown this minimization is equivalent to maximizing the evidence lower bound (ELBO) below:

$$\begin{aligned}\mathcal{L} &= E_q[\log p(\pi, \alpha, \beta, c, y|a, b, d, e, t, u, z)] \\ &- E_q[\log q(\pi, \alpha, \beta, c|\lambda, \eta, \gamma, \mu, \theta, \epsilon, \phi, \zeta)]\end{aligned} \quad (1)$$

We need a variational distribution q that is tractable under expectations. Following common practice (Blei et al., 2003; Hoffman et al., 2013; Blei et al., 2017), we choose q to be in the mean field variational family where each hidden variable is independent and governed by its own parameter. Elegant solutions have been derived for models whose complete conditionals are in the exponential family (Blei and Jordan, 2006; Hoffman et al., 2013). Concretely, we used the fact that the natural parameters of the variational distributions are equal to the expected value of the natural parameters of the corresponding complete conditionals.

The derivations are standard in the VI literature (see, for example, Hoffman et al., 2013). (To save space, we only provide here the update formulas of

---

[3] Notation: jj[i,m,n] returns the index of the annotator who made the n-th decision on the m-th label of mention i.

the variational parameters; supplementary details are in the Appendix.)

Equations (2) and (3) give the variational update formulas for the class-level true label likelihood. We have $q(\pi_h|\lambda_h, \eta_h) = \mathsf{Beta}(\lambda_h, \eta_h)$, where:

$$\lambda_h = a + \sum_{i,m}^{I,M_i} I(z_{i,m} = h) E_q[I(c_{i,m} = 1)] \quad (2)$$

$$\eta_h = b + \sum_{i,m}^{I,M_i} I(z_{i,m} = h) E_q[I(c_{i,m} = 0)] \quad (3)$$

In Equation (4) and (5) we list the variational update formulas for the class-level annotator sensitivity. We have $q(\alpha_{j,h}|\gamma_{j,h}, \mu_{j,h}) = \mathsf{Beta}(\gamma_{j,h}, \mu_{j,h})$, where:

$$\begin{aligned} \gamma_{j,h} = d + \sum_{i,m,n}^{I,M_i,N_i} & I(jj[i,m,n] = j) \\ & I(z_{i,m} = h) I(y_{i,m,n} = 1) E_q[I(c_{i,m} = 1)] \end{aligned} \quad (4)$$

$$\begin{aligned} \mu_{j,h} = e + \sum_{i,m,n}^{I,M_i,N_i} & I(jj[i,m,n] = j) \\ & I(z_{i,m} = h) I(y_{i,m,n} = 0) E_q[I(c_{i,m} = 1)] \end{aligned} \quad (5)$$

In Equations (6) and (7) we list the variational update formulas for the class-level annotator specificity. We have $q(\beta_{j,h}|\theta_{j,h}, \epsilon_{j,h}) = \mathsf{Beta}(\theta_{j,h}, \epsilon_{j,h})$, where:

$$\begin{aligned} \theta_{j,h} = t + \sum_{i,m,n}^{I,M_i,N_i} & I(jj[i,m,n] = j) \\ & I(z_{i,m} = h) I(y_{i,m,n} = 0) E_q[I(c_{i,m} = 0)] \end{aligned} \quad (6)$$

$$\begin{aligned} \epsilon_{j,h} = u + \sum_{i,m,n}^{I,M_i,N_i} & I(jj[i,m,n] = j) \\ & I(z_{i,m} = h) I(y_{i,m,n} = 1) E_q[I(c_{i,m} = 0)] \end{aligned} \quad (7)$$

In Equations (8) and (9) we list the variational update formulas for the true label indicator. We have $q(c_{i,m}|\phi_{i,m}) = \mathsf{Bern}(\phi_{i,m})$, where $\zeta_{i,m} = 1 - \phi_{i,m}$ and:

$$\begin{aligned} \log \phi_{i,m} \propto\ & E_q[\log \pi_{z_{i,m}}] + \\ & + \sum_{n=1}^{N_i} I(y_{i,m,n} = 1) E_q[\log \alpha_{jj[i,m,n], z_{i,m}}] + \\ & + I(y_{i,m,n} = 0) E_q[\log(1 - \alpha_{jj[i,m,n], z_{i,m}})] \end{aligned} \quad (8)$$

$$\begin{aligned} \log \zeta_{i,m} \propto\ & E_q[\log(1 - \pi_{z_{i,m}})] + \\ & + \sum_{n=1}^{N_i} I(y_{i,m,n} = 0) E_q[\log \beta_{jj[i,m,n], z_{i,m}}] + \\ & + I(y_{i,m,n} = 1) E_q[\log(1 - \beta_{jj[i,m,n], z_{i,m}})] \end{aligned} \quad (9)$$

Finally, for the above formulas, we used the fact that $E_q[I(c_{i,m} = 1)] = \phi_{i,m}$. The other expectations can be easily calculated noting that for a distribution part of the exponential family, the first derivative of the log normalizer is equal to the expected value of the sufficient statistics (Blei et al., 2003). For example, $E_q[\log \pi_{z_{i,m}}] = \Psi(\lambda_{z_{i,m}}) - \Psi(\lambda_{z_{i,m}} + \eta_{z_{i,m}})$, where $\Psi(.)$ is the digamma function. Similar observations apply to the α and β related expectations.

The algorithm, known as Coordinate Ascent Variational Inference (CAVI) (Blei et al., 2017), involves iterating between Equations (2), (3), (4), (5), (6), (7), (8) and (9) until convergence. The ELBO expressed in Equation (1) is guaranteed to increase at every step. Convergence is achieved when the ELBO plateaus. Throughout the experiments we used non-informative, uniform priors.

3 Evaluation

We carried out a series of evaluations of increasing complexity of our MPA model. We first assess the accuracy of the inferred mention pairs. Second, we cluster the pairs into appropriate coreference chains and evaluate the quality of these chains. Third, we assess the viability of using silver chains as an alternative to the gold chains when training a state of the art coreference system. Finally, we conclude the evaluation with a performance check in a standard annotation task.

3.1 Datasets

The largest coreference dataset with crowdsourced annotations is the *Phrase Detectives* corpus. A subset of this corpus is the *Phrase Detectives 1.0* dataset (Chamberlain et al., 2016), which also includes gold annotations and can therefore be used to evaluate the accuracy of MPA at mention-pair and coreference chain inference, but is too small to train a state-of-the-art coreference system. To carry out this second type of evaluation we used the approach, common in the crowdsourcing literature (Carpenter, 2008; Raykar et al., 2010; Hovy et al., 2013; Felt et al., 2014), of generating simulated datasets by corrupting the gold standard

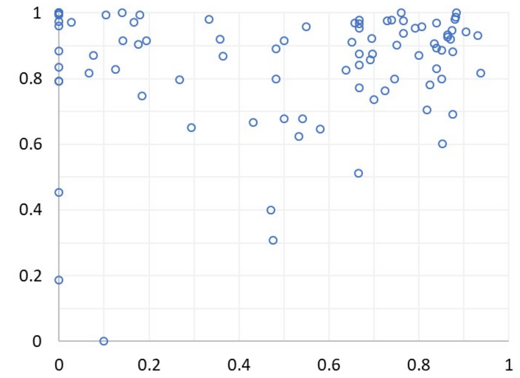

Figure 2: Sensitivity profiles extracted from the PD corpus: DO (x-axis) vs. DN (y-axis)

of an existing corpus. For this purpose, we use the CONLL-2012 dataset (Pradhan et al., 2012), at present the standard dataset for coreference resolution.

3.1.1 Crowdsourced Data

The *Phrase Detectives (PD) 1.0* dataset has been annotated using the *Phrase Detectives* game with a purpose.[4] The annotation scheme for PD is based on that for the ARRAU corpus (Poesio et al., 2018). Players have to label predefined[5] markables with one of the following categories: **non-referring** (e.g., for expletives), **discourse-new**, **discourse-old** (in which case an antecedent is also marked, the most recent mention belonging to the antecedent's coreference chain), or **property** (for appositions and copular structures). The PD 1.0 dataset is the portion of the corpus that contains, in addition to the annotations by the players, a gold label for each markable. The coreference chains are obtained using a simple clustering of the mention pairs. An important limitation of this corpus is its small size (around 6000 markables from 45 documents), making it unfit for the training and evaluation of state of the art supervised systems.

3.1.2 Synthetic Data

The CONLL-2012 dataset specifies gold chains, not mention pairs. So we need first to extract appropriate mention pairs from these chains. To do this, for each mention we select as gold label the closest mention from its gold chain (or discourse new if the mention is the first in its chain).

Simulation	Profile Type	Error Distribution
1	Synthetic	Uniform
2	Synthetic	Sparse
3	PD-inspired	Uniform
4	PD-inspired	Sparse

Table 1: Simulation summary

Data	Method	Accuracy avg.	Accuracy s.d.

	MPA	94.36	0.33

Table 2: Mention pair accuracy results. Each simulated scenario is randomly generated 10 times (summary is in terms of average result and standard deviation)

The simulations are then generated by extracting from each gold label a number of 'crowdsourced labels' produced by (simulated) annotators with varying degrees of ability. We considered a range of simulated scenarios, all sharing the following settings:

- 10 distinct annotators per mention and 20 distinct mentions per annotator. The annotators receive random mentions to annotate.[6]
- Each annotator is assigned randomly a **profile**. The profiles indicate the sensitivity of the annotators with respect to discourse old and new. For example, the (DO 0.8, DN 0.9) profile indicates that, given a mention whose true class is DO, the annotator has 0.8 probability of getting it right; and of 0.9 for DN. We considered both profiles reflecting the actual profiles of players in *Phrase Detectives* (Chamberlain, 2016) and synthetic profiles.
- 5 choices for the annotators to choose from for each mention: the correct label, the DN

---

[4] `http://www.phrasedetectives.org`

[5] In standard annotation projects markables are predefined for better agreement. The markables used in PD are automatically identified, but players can highlight errors in markable identification that can then be corrected.

[6] This equal load reflects work distribution as found in microtask crowdsourcing rather than in games such as *Phrase Detectives*, where a few players do most of the work (Chamberlain, 2016).

label (without including it twice if this is the correct label), and the 3 (or 4 if the correct label is DN) incorrect DO antecedents situated closest to the mention.

The range of options considered in the simulation is specified by two aspects: the sensitivity from the annotator profiles and the distribution of the errors they make. We use the following two profile types:

- Synthetic profiles: 5 profiles covering a wide range of abilities (DO 0.8, DN 0.9), (DO 0.7, DN 0.8), (DO 0.4, DN 0.5), (DO 0.3, DN 0.4), (DO 0.2, DN 0.3). The profiles roughly correspond to two experts and three novices whose class sensitivities are relatively close – with extra mass associated with DN because this class is generally easier compared to DO.

- *Phrase Detectives* inspired profiles: from the PD annotators who annotated more than 10 DO and 10 DN mentions (thresholds set to have a minimum confidence) we extracted a total of 89 profiles. This gave us much more interesting sensitivity pairs compared to the ones from the synthetic profiles, i.e., contrasting class abilities – see Figure 2.

We also considered a range of ways in which annotators may make mistakes:

- Distribute the errors uniformly random given the remaining mass (1 - sensitivity)

- Distribute the errors in a sparse manner, i.e., assume that some errors will be more likely than others. This can be achieved by drawing randomly from a 4-dimensional (4 = number of errors) uniform Dirichlet for each mention. The annotator probabilities over the 5 choices will then consist of their sensitivity, and the error distribution normalized with respect to the remaining mass.

The settings just discussed lead to 4 simulations summarized in Table 1.

3.2 Evaluation 1: Mention Pair Accuracy

We use MPA to link each mention with the most likely label based on the posterior of the true label indicators. We then assess the accuracy of the inferred mention pairs against the gold standard, i.e., the agreement with the gold mention pairs. In this task the proposed model is compared against a majority vote baseline where each mention is paired with the most voted label.[7]

The evaluation is conducted on the crowd-sourced annotated PD 1.0 dataset and on simulated data generated from the CONLL-2012 test set. The results, summarized in Table 2, indicate the mention pairs inferred by our model (MPA) obtain a much better level of agreement with the gold mention pairs, compared with the output of the majority vote (MV) baseline. MV implicitly assumes equal expertise among the annotators, which has repeatedly been shown to be false in annotation practice (Poesio and Artstein, 2005; Passonneau and Carpenter, 2014; Plank et al., 2014).

3.3 Evaluation 2: Silver Chain Quality

After the mention pairs have been inferred using MPA, producing the coreference chains – we will henceforth refer to the coreference chains thus ob-

tained as **silver** coreference chains[8] – is a straightforward clustering task: we simply follow the link structure from the pairs. In this Section we assess the quality of the silver chains using standard coreference metrics – in particular, the Extended Scorer introduced in (Poesio et al., 2018) which extends the official CONLL scorer to include in the evaluation system-predicted singletons and non referring expressions, both of which are annotated in *Phrase Detectives*; when singletons and non-referring expressions are not considered, the Extended Scorer is identical to the official scorer.

As in the previous experiment, the evaluation is conducted on the crowdsourced annotated PD 1.0 dataset and on simulated data generated from the CONLL-2012 test set. We compare silver chains produced using our MPA model, using MV, and using the Stanford deterministic coreference system (Stanford) (Lee et al., 2011). To run the latter on PD 1.0, we used the default annotators of the CoreNLP toolkit (Manning et al., 2014) to supply the information required by the coreference system and switched off the post-processing to output singleton clusters; for the CONLL-2012 data we set the $dcoref.replicate.conll = true$ to run exactly the same method as Lee et al. (2011). On both datasets we evaluated on gold mentions.

Table 3 summarizes the results on the crowdsourced annotated PD 1.0 dataset. The silver chains obtained using our MPA model are of a far better quality than those of baseline alternatives such as MV and Stanford. Note also that even the simple MV baseline built from crowdsourced annotations yields much better chains compared to a standard coreference system such as the Stanford system. This underlines the advantage of crowdsourced annotations for coreference over automatically produced annotations. In Table 4 we present the scores of MPA and MV on cases of non referring. In this case, as well, the probabilistic model substantially outperforms the MV baseline.

In Table 5 we present the results obtained on simulated data from the CONLL-2012 test set. The results follow a similar trend to those observed using actual annotations: a much better quality of the chains produced using the mention pairs inferred by our MPA model, across all the simulated

---

[8] Our use of the term 'silver standard' should not be confused with the other common use of standard generated out of automatic annotations.

Table 6: Results of a state of the art coreference system trained on silver chains obtained in different ways. Each simulated scenario is randomly generated 10 times (summary is in terms of average result and standard deviation)

scenarios. Furthermore, the MV baseline achieves better chains compared to the Stanford system in 3 out of 4 simulation settings, again showcasing the potential of crowdsourced annotations.

3.4 Training on Silver Chains

In this Section we assessed the viability of using the (silver) chains extracted from crowdsourcing as an alternative to gold chains when training a state of the art coreference system. Concretely, we train the best-performing current system Lee et al. (2017) on chains produced using our MPA model, the MV baseline and the Stanford deterministic system (Lee et al., 2011) (used mainly for calibration, i.e., an alternative baseline that's not based on crowdsourced annotations). We also include the results obtained using actual gold chains.

The results are in Table 6. Across all simulated scenarios, the silver chains produced by our MPA model obtain the closest performance to training on gold chains, and the best result is only 1 percentage point less than the result with gold chains. Again, the MV chains lead to better performance than those obtained using a system (Stanford). These results, once again, indicate the utility of crowdsourced annotations for coreference tasks.

3.5 Traditional Crowdsourcing Tasks

In this Section we show that MPA is state of the art also on traditional crowdsourcing datasets, where annotations fall into general classes that are consistent across the annotated items. This evaluation was done on the datasets (*WSD*, *RTE* and *TEMP*) introduced by Snow et al. (2008) and widely used as benchmarks in the literature on annotation models (Hovy et al., 2013; Carpenter, 2008).

We compare the results against a majority vote baseline and two well-known state of the art models: a Bayesian version of the Dawid and Skene (1979) (DS) model and MACE (Hovy et al., 2013). We implement DS ourselves using variational inference, while for MACE, we simply report the published results. As in Hovy et al. (2013) the assessment is done in terms of accuracy against the gold standard. The results, presented in Table 7, indicate the proposed model achieves performance on par with the state of the art.

4 Related Work

To our knowledge, this is the first paper proposing a model of crowdsourced annotations for coreference. We did draw inspiration however from existing mention pair models of coreference and traditional models of annotation.

The so-called mention pair model is one of the early machine learning approaches to coreference resolution, made popular by Soon et al. (2001). The model is based on a two step procedure: a classification step which identifies the coreferent mention pairs, followed by a clustering step which builds the coreference chains from the aforementioned pairs. The diversity of mention pair models comes from the distinct approaches taken for each of the two steps (Hoste, 2016). Although we follow a similar two step procedure, there are also important differences. Our way of identifying the mention pairs is completely unsupervised, and relies entirely on the crowdsourced annotations. Furthermore, we pair every mention with only one label, reducing the second step of clustering mention pairs into appropriate coreference chains to a simple grouping task guided by a unique path which arises from the pairs.

All existing probabilistic models of annotation (Dawid and Skene, 1979; Smyth et al., 1994; Raykar et al., 2010; Hovy et al., 2013; Passonneau and Carpenter, 2014) assume the annotations fall into a general set of classes that is consistent across the annotated items. This is clearly not the case in a coreference resolution task, a limitation we had to address. We first transformed the annotations into a series of (per label) binary decisions, approach often referred to, in the multi-class classification literature, as the binary relevance method (Tsoumakas and Katakis, 2007; Madjarov et al., 2012). The transformation avoids modeling the sparse labels directly. We further exploited the fact that the annotations fall into a general set of classes and assumed the inter-label decisions are the result of the class-dependent ability of the annotators.

5 Conclusions

Crowdsourced annotations are an increasingly popular alternative to expert annotation. Even so, their viability for coreference annotation had not been explored so far. This paper is a first step to filling this gap. We introduced a mention pair-based approach to aggregating crowdsourced anaphoric annotations and assessed the quality of the inferred pairs, of the post-hoc constructed coreference chains, and the viability of using the inferred chains as an alternative to gold chains when training a state of the art coreference system. Throughout the experiments, the model introduced was superior to baseline alternatives such as majority vote and chains obtained automatically using a coreference system, across both genuinely crowdsourced and simulated coreference datasets. Furthermore, even the annotation-based baseline achieved results consistently better than those obtained by automatic coreference resolvers, strengthening the case for using crowdsourced annotations to create coreference datasets.

A Supplementary Parameter Estimation Details

This Section gives supplementary details for the derivations involved in the parameter estimation process.

In Equation (10) we derive the complete conditional of the class-specific true label likelihood:

$$\begin{aligned}
p(\pi_h|...) &\propto p(\pi_h|a,b) \prod_{i,m}^{I,M_i} p(c_{i,m}|\pi_h)^{I(z_{i,m}=h)} \\
&\propto \pi_h^{a-1}(1-\pi_h)^{b-1} \times \\
&\times \prod_{i,m}^{I,M_i} \pi_h^{I(c_{i,m}=1)I(z_{i,m}=h)} \\
&\times (1-\pi_h)^{I(c_{i,m}=0)I(z_{i,m}=h)} \\
&\propto \pi_h^{a-1+\sum_{i,m}^{I,M_i} I(z_{i,m}=h)I(c_{i,m}=1)} \\
&(1-\pi_h)^{b-1+\sum_{i,m}^{I,M_i} I(z_{i,m}=h)I(c_{i,m}=0)} \\
&\propto \mathsf{Beta}(a + \sum_{i,m}^{I,M_i} I(z_{i,m}=h)I(c_{i,m}=1), \\
b &+ \sum_{i,m}^{I,M_i} I(z_{i,m}=h)I(c_{i,m}=0))
\end{aligned} \tag{10}$$

The corresponding variational distribution has the same form, i,e, $q(\pi_h|\lambda_h, \eta_h) = \mathsf{Beta}(\lambda_h, \eta_h)$. Taking the expectation of the natural parameters of the above distribution gives the variational update formulas for the class-level true label likelihood expressed in the paper. For example, for the λ_h variational parameter we have:

$$\begin{aligned}
\lambda_h &= a + \sum_{i,m}^{I,M_i} I(z_{i,m}=h) E_q[I(c_{i,m}=1)] \\
&= a + \sum_{i,m}^{I,M_i} I(z_{i,m}=h) \phi_{i,m}
\end{aligned} \tag{11}$$

Similar steps were taken to derive the variational parameters associated with the sensitivity α and specificity β.

In Equation (12) we derive the complete conditional associated with the positive outcome of the true label indicator:

$$\begin{aligned}
p(c_{i,m}=1|...) &\propto p(c_{i,m}=1|\pi_{z_{i,m}}) \times \\
&\times \prod_{n}^{N_i} p(y_{i,m,n}|\alpha_{jj[i,m,n],z_{i,m}}) \\
&\propto \pi_{z_{i,m}} \prod_{n}^{N_i} \alpha_{jj[i,m,n],z_{i,m}}^{I(y_{i,m,n}=1)} \\
&(1-\alpha_{jj[i,m,n],z_{i,m}})^{I(y_{i,m,n}=0)} \\
&\propto \exp\{\log \pi_{z_{i,m}} + \\
&\sum_{n=1}^{N_i} I(y_{i,m,n}=1) \log \alpha_{jj[i,m,n],z_{i,m}} + \\
&I(y_{i,m,n}=0) \log(1-\alpha_{jj[i,m,n],z_{i,m}})\}
\end{aligned} \tag{12}$$

The corresponding variational distribution has the same form, i,e, $q(c_{i,m}|\phi_{i,m}) = \mathsf{Bern}(\phi_{i,m})$. Taking the necessary expectations leads to the update formula expressed in the paper. Concretely, we have:

$$\begin{aligned}
\log \phi_{i,m} &\propto E_q[\log \pi_{z_{i,m}}] + \\
&+ \sum_{n=1}^{N_i} I(y_{i,m,n}=1) E_q[\log \alpha_{jj[i,m,n],z_{i,m}}] + \\
&+ I(y_{i,m,n}=0) E_q[\log(1-\alpha_{jj[i,m,n],z_{i,m}})] \\
&\propto \Psi(\lambda_{z_{i,m}}) - \Psi(\lambda_{z_{i,m}} + \eta_{z_{i,m}}) + \\
&+ \sum_{n=1}^{N_i} I(y_{i,m,n}=1)[\Psi(\gamma_{jj[i,m,n],z_{i,m}}) - \\
&\Psi(\gamma_{jj[i,m,n],z_{i,m}} + \mu_{jj[i,m,n],z_{i,m}})] + \\
&+ I(y_{i,m,n}=0)[\Psi(\mu_{jj[i,m,n],z_{i,m}}) - \\
&\Psi(\gamma_{jj[i,m,n],z_{i,m}} + \mu_{jj[i,m,n],z_{i,m}})]
\end{aligned} \tag{13}$$

The update formula for the negative outcome of the true label indicator $\zeta_{i,m}$ is derived in a similar manner. Following the above derivations should also make it straightforward to expand the ELBO.

For completeness, we make a note of the digamma function $\Psi()$ – this is the first derivative of the $\log \Gamma$ function and can be computed using a Taylor approximation.

A Deterministic Algorithm for Bridging Anaphora Resolution

Yufang Hou
IBM Research Ireland
`yhou@ie.ibm.com`

Abstract

Previous work on bridging anaphora resolution (Poesio et al., 2004; Hou et al., 2013b) use syntactic preposition patterns to calculate word relatedness. However, such patterns only consider NPs' head nouns and hence do not fully capture the semantics of NPs. Recently, Hou (2018) created word embeddings (*embeddings_PP*) to capture associative similarity (i.e., relatedness) between nouns by exploring the syntactic structure of noun phrases. But *embeddings_PP* only contains word representations for nouns. In this paper, we create new word vectors by combining *embeddings_PP* with *GloVe*. This new word embeddings (*embeddings_bridging*) are a more general lexical knowledge resource for bridging and allow us to represent the meaning of an NP beyond its head easily. We therefore develop a deterministic approach for bridging anaphora resolution, which represents the semantics of an NP based on its head noun and modifications. We show that this simple approach achieves the competitive results compared to the best system in Hou et al. (2013b) which explores Markov Logic Networks to model the problem. Additionally, we further improve the results for bridging anaphora resolution reported in Hou (2018) by combining our simple deterministic approach with Hou et al. (2013b)'s best system *MLN II*.

1 Introduction

Anaphora plays a major role in discourse comprehension and accounts for the coherence of a text. In contrast to *identity anaphora* which indicates that a noun phrase refers back to the same entity introduced by previous descriptions in the discourse, *bridging anaphora* or *associative anaphora* links anaphors and antecedents via lexico-semantic, frame or encyclopedic relations. *Bridging resolution* is the task to recognize bridging anaphors (e.g., **distribution arrangements** in Example 1[1]) and find links to their antecedents (e.g., *dialysis products* in Example 1).

(1) While the discussions between Delmed and National Medical Care have been discontinued, Delmed will continue to supply *dialysis products* through National Medical after their exclusive agreement ends in March 1990, Delmed said. In addition, Delmed is exploring **distribution arrangements** with Fresenius USA, Delmed said.

Most previous empirical research on bridging (Poesio and Vieira, 1998; Poesio et al., 2004; Markert et al., 2003; Lassalle and Denis, 2011; Hou et al., 2013b) focus on *bridging anaphora resolution*, a subtask of bridging resolution that aims to choose the antecedents for bridging anaphors. For this substask, most previous work (Poesio et al., 2004; Lassalle and Denis, 2011; Hou et al., 2013b) calculate semantic relatedness between an anaphor and its antecedent based on word co-occurrence counts using certain syntactic patterns. However, such patterns only consider head noun knowledge and hence are not sufficient for bridging relations which require the semantics of modification. In Example 1, in order to find the antecedent (*dialysis products*) for the bridging anaphor "**distribution arrangements**", we have to understand the semantics of the modification "**distribution**".

Over the past few years, word embeddings gained a lot popularity in the NLP community. State-of-the-art word vectors such as word2vec skip-gram (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) have been shown to perform well across a variety of NLP tasks, including textual entailment (Rocktäschel et al., 2016), reading

---

[1] All examples, if not specified otherwise, are from ISNotes (Markert et al., 2012). Bridging anaphors are typed in boldface, antecedents in italics throughout this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1938–1948
Brussels, Belgium, October 31 - November 4, 2018.

comprehension (Chen et al., 2016) and coreference resolution (Lee et al., 2017).

Recently, Hou (2018) found that these vanilla word embeddings capture both "genuine" similarity and relatedness, and hence they are not suitable for bridging anaphora resolution which requires lexical association knowledge instead of semantic similarity information between synonyms or hypernyms. Hou (2018) created word embeddings for bridging (*embeddings_PP*) by exploring the syntactic structure of noun phrases (NPs) to derive contexts for nouns in the GloVe model.

However, *embeddings_PP* only contains the word representations for nouns. In this paper, we improve *embeddings_PP* by combining it with *GloVe*. The resulting word embeddings (*embeddings_bridging*) are a more general lexical knowledge resource for bridging anaphora resolution. Compared to *embeddings_PP*, the coverage of lexicon in *embeddings_bridging* is much larger. Also the word representations for nouns without the suffix "_PP" are more accurate because they are trained on many more instances in the vanilla *GloVe*. Based on this general vector space, we develop a deterministic algorithm to select antecedents for bridging anaphors. Our approach combines the semantics of an NP's head with the semantics of its modifications by vector average using *embeddings_bridging*. We show that this simple, efficient method achieves the competitive results on ISNotes for the task of bridging anaphora resolution compared to the best system in Hou et al. (2013b) which explores Markov Logic Networks to model the problem.

The main contributions of our work are: (1) a general word representation resource[2] for bridging; and (2) a simple yet competitive deterministic approach for bridging anaphora resolution which models the meaning of an NP based on its head noun and modifications.

2 Related Work

Lexical/world knowledge for bridging: Hou et al. (2013a) explored various lexico-semantic features for bridging anaphora recognition. Hou (2016) proposed an attention-based LSTM model with pre-trained word embeddings for information status classification and reported moderate results for bridging recognition. Previous work on bridging anaphora resolution (Poesio et al., 2004; Lassalle and Denis, 2011; Hou et al., 2013b) explored word co-occurrence counts in certain syntactic preposition patterns to calculate word relatedness. For instance, the big hit counts of the query "*the door of the house*" in large corpora could indicate that *door* and *house* stand in a part-of relation. These patterns encode associative relations between nouns which cover a variety of bridging relations. Unlike previous work which only consider a small number of prepositions per anaphor, the PP context model (Hou, 2018) uses all prepositions for all nouns in big corpora. It also includes the possessive structure of NPs. In this paper, we further improve Hou (2018)'s *embeddings_PP* by combining it with the vanilla *GloVe*. The resulting word embeddings (*embeddings_bridging*) are a more general lexical knowledge resource for bridging resolution. In addition, it enables efficient computation of word association strength through low-dimensional matrix operations.

Bridging anaphora resolution: regarding the methods to select antecedents for bridging anaphors, Poesio et al. (2004) applied a pairwise model combining lexical semantic features as well as salience features to perform mereological bridging resolution in the GNOME corpus[3]. To address the data sparseness problem (e.g., some part-of relations are not covered by WordNet), they used the Web to estimate the part-of relations expressed by certain syntactic constructions. Based on the method proposed by Poesio et al. (2004), Lassalle and Denis (2011) developed a system that resolves mereological bridging anaphors in French. The system was enriched with meronymic information extracted from raw texts. Such information was extracted in a bootstrapping fashion by iteratively collecting meronymic pairs and the corresponding syntactic patterns. Lassalle and Denis (2011) evaluated their system on mereological bridging anaphors annotated in the DEDE corpus and reported an accuracy of 23%.

Markert et al. (2012) released a corpus called ISNotes which contains unrestricted bridging annotations. Based on this corpus, Hou et al. (2013b) proposed a joint inference framework for bridging anaphora resolution using Markov logic networks (Domingos and Lowd, 2009). The framework resolves all bridging anaphors in one document together by modeling that semantically re-

---

Table 1: Examples of noun phrases as well as the extracted noun pairs in *embeddings_PP*. Bold indicates the head noun of an NP.

lated anaphors are likely to share the same antecedent.

ISNotes is a challenging corpus for bridging. First, bridging anaphors are not limited to definite NPs as in previous work (Poesio et al., 1997, 2004; Lassalle and Denis, 2011). Also in ISNotes, the semantic relations between anaphor and antecedent are not restricted to meronymic relations. We therefore choose ISNotes to evaluate our algorithm for bridging anaphora resolution. Our approach is deterministic and simple, but achieves the competitive results compared to the advanced machine learning-based approach (Hou et al., 2013b). We also improve the result reported in Hou (2018) on the same corpus by combining our deterministic approach with the best system from Hou et al. (2013b).

Just recently, two new corpora (Rösiger, 2018a; Poesio et al., 2018) with bridging annotations have become available and we notice that the definitions of bridging in these corpora are different from the bridging definition in ISNotes. We apply our algorithm with small adaptations to select antecedents for bridging anaphors on these corpora. The moderate results demonstrate that *embeddings_bridging* is a general word representation resource for bridging.

3 Word Representations for Bridging

3.1 Word Embeddings Based on PP Contexts (*embeddings_PP*)

We briefly describe Hou (2018)'s *embeddings_PP* in this section. *embeddings_PP* released by Hou (2018) contains 100-dimensional vectors for 276k nouns. It is trained over 197 million noun pairs extracted from the automatically parsed Gigaword corpus (Parker et al., 2011; Napoles et al., 2012). The author generates these noun pairs by exploring the syntactic prepositional and possessive structures of noun phrases. These two structures encode a variety of bridging relations between anaphors and their antecedents. For instance, the prepositional structure in "*the door of the house*" indicates the part-of relation between "*door*" and "*house*". More specifically, for NPs containing the prepositional structure (e.g., **X** *preposition* **Y**) or the possessive structure (e.g., **Y** *'s* **X**), the author extracts the noun pair "X_PP–Y". Note that the head of the NP is always on the left and the noun modifier is always on the right. In addition, the suffix "_PP" is added for the nouns on the left. Table 1 shows a few examples of noun phrases together with the extracted noun pairs.

Hou (2018) showed that the suffix "_PP" plays an important role for the model to learn the asymmetric relations between the head nouns and their noun modifiers from the extracted noun pairs. For instance, among the top five nearest neighbors in *embeddings_PP*, "president_PP" is mostly related to countries or organizations (e.g., "federation", "republic", or "USA"), while "president" is mostly related to words which have the same semantic type as "president" (e.g., "minister", "mayor", or "governor").

3.2 Word Representations for Bridging (*embeddings_bridging*)

embeddings_PP described in the previous section only contains word representations for nouns. To improve the coverage of lexical information, we create a general word representation resource *embeddings_bridging* by merging *embeddings_PP* with the original GloVe vectors trained on Gigaword and Wikipedia datasets. Specifically, given the 100 dimension word embeddings *embeddings_PP* and *GloVe*, we first create a 100 dimension vector v_{filler} with the value of each dimension as 0.1[4]. Let $v1_w$ represent the vector for the word w in *GloVe*, $v2_w$ represent the vector for the word w in *embeddings_PP*, if a word w appears

---

[4] Theoretically, any 100 dimension random vector with uniform distribution could be used as v_{filler}.

PART–WHOLE	*Activity: Stage*	{buying: shopping}	**0.32**	0.30	0.25

Table 3: Spearman's rank correlation coefficient ρ for typical *PART–WHOLE* bridging relations using *embeddings_bridging*, *embeddings_PP* and *GloVe*.

both in *GloVe* and in *embeddings_PP*, its vector in *embeddings_bridging* is the concatenation of $v1_w$ and $v2_w$. For the word w_1 which only appears in *GloVe*, its vector in *embeddings_bridging* is the concatenation of $v1_{w_1}$ and v_{filler}. Finally, for the word w_2 which only appears in *embeddings_PP* (all the words with the suffix "*_PP*"), we construct its vector by concatenating v_{filler} and $v2_{w_2}$. The resulting 200 dimension word embeddings (*embeddings_bridging*) is a general lexical resource for bridging. Table 2 compares the main features between *embeddings_bridging* and *embeddings_PP*. In the next section, we will compare *embeddings_bridging* with *embeddings_PP* and the original *GloVe* on a few typical bridging relations in the task of measuring relational similarity (Jurgens et al., 2012). Moreover, in Section 5.3 and Section 5.4, we show that using *embeddings_bridging* yields better results than using *embeddings_PP* for bridging anaphora resolution.

3.3 Measuring Relational Similarity on Typical Bridging Relations

We evaluate our *embeddings_bridging* quantitatively using a few typical bridging relations from SemEval-2012 Task 2 (Jurgens et al., 2012). The shared task aims to rank word pairs by the degree to which they are prototypical members of a given relation class. For instance, given the prototypical word pairs {*wedding–bride, rodeo–cowboy, banquet–food*} for the relation *Event:Feature*, we would like to know among the input word pairs {*school–students, circus–clown, meal–food, lion–zoo*}, which one represents the relation best.

SemEval-2012 Task 2 contains 79 relation classes chosen from Bejar et al. (1991). These relations fall into ten main categories, including *SIMILAR*, *PART–WHOLE*, *CONTRAST* and more. Each relation class is paired with a few prototypical word pairs and a list of around 40 word pairs which are ranked by humans according to their degree of similarity to the corresponding relation. We choose all typical bridging relations under the *PART–WHOLE* category and evaluate our *embeddings_bridging* in terms of ranking the list of word pairs for each relation. Spearman's rank correlation coefficient ρ is used to evaluate a system by comparing the system's ranking of the word pairs against the gold standard ranking.

Following Zhila et al. (2013), we calculate the relational similarity between word pairs using cosine similarity. Let (w_1, w_2) and (w_3, w_4) be the two word pairs, v_1, v_2, v_3, v_4 be the corresponding vectors for these words. We first normalize all word vectors to unit vectors, then the relational similarity between (w_1, w_2) and (w_3, w_4) is calculated as:

$$\frac{(v1 - v2) \cdot (v3 - v4)}{\parallel v1 - v2 \parallel \parallel v3 - v4 \parallel} \tag{1}$$

For each chosen relation class, we rank the list of word pairs according to their mean relational similarity to the given prototypical word pairs. Table 3 shows the results of Spearman's rank correlation coefficient ρ for each typical bridging relation using *embeddings_bridging*, *embeddings_PP*, and *GloVe*, respectively. Note that when using *embeddings_bridging* and *embeddings_PP*, we add the suffix "_PP" to the potential bridging anaphor for

bridging anaphor: **distribution arrangements**				
Ante. Candidates	**Head**	**Head + Modifiers**	$dist_h$	$dist_{hm}$
the discussions between Delmed and National Medical Care	{*discussions*}	{*discussions*}	0.05	-0.10
Delmed	{*delmed*}	{*delmed*}	—	—
National Medical Care	{*care*}	{*care*}	**0.08**	0.10
dialysis products	{*products*}	{*dialysis, products*}	0.06	**0.17**
National Medical	{*medical*}	{*medical*}	0.02	-0.01
their	{*their*}	{*their*}	-0.05	-0.01
their exclusive agreement	{*agreement*}	{*exclusive, agreement*}	0.07	0.03

Table 4: The cosine similarities between the bridging anaphor **distribution arrangements** and its antecedent candidates for Example 1. $dist_h$ indicates the cosine similarity between {**arrangements_PP**} and the candidate head, $dist_{hm}$ the cosine similarity between {**distribution_PP**, **arrangements_PP**} and Head+Modifiers. "–" means *Delmed* is not present in *embeddings_bridging* and therefore we neglect this candidate.

each word pair (e.g., {wedding: bride_PP}). As shown in Table 3, using *embeddings_bridging* performs better than both using *embeddings_PP* and using the vanilla GloVe vectors on these four part-of relation classes. This partially indicates that *embeddings_bridging* could capture lexical knowledge for bridging relations.

4 A Deterministic Algorithm for Bridging Anaphora Resolution

In this section, we describe our deterministic algorithm based on *embeddings_bridging* for bridging anaphora resolution. For each anaphor a, we construct the list of antecedent candidates E_a using NPs preceding a from the same sentence as well as from the previous two sentences. Hou et al. (2013b) found that globally salient entities are likely to be the antecedents of all anaphors in a text. We approximate this by adding NPs from the first sentence of the text to E_a. This is motivated by the fact that ISNotes is a newswire corpus and globally salient entities are often introduced in the beginning of an article. We exclude an NP from E_a if it is a bridging anaphor because a bridging anaphor is rarely to be an antecedent for another bridging anaphor. We also exclude NPs whose semantic types are "time" from E_a if a is not a time expression. This is because time expressions are related to a lot of words in the corpus in which we learned *embeddings_bridging* from. Therefore we only keep them as the antecedent candidates for bridging anaphors whose semantic types are "time" (see Example 2).

(2) As a presidential candidate in *1980*, George Bush forthrightly expressed his position on abortion in an interview with Rolling Stone magazine published **that March**.

Given an anaphor a and its antecedent candidate list E_a, we predict the most semantically related NP among all NPs in E_a as the antecedent for a. In case of a tie, the closest one is chosen to be the predicted antecedent.

The relatedness is measured via cosine similarity between the vector representation of the anaphor and the vector representation of the candidate. More specifically, given a noun phrase np_1, we first construct a list N which consists of the head and all common nouns (e.g., *earthquake victims*), adjectives (e.g., *economical sanctions*), and ed/ing participles (e.g., *the collapsed roadway* and *the landing site*) appearing before the head. If np_1 contains a post-modifier NP np_2 via the preposition "of", we also add the above premodifiers and the head of np_2 to the list N (e.g., *the policies of racial segregation*). Finally, the noun phrase np_1 is represented as a vector v using the following formula, where the suffix "_PP" is added to each n if np_1 is a bridging anaphor and its semantic type is not time:

$$v = \frac{\sum_{n \in N} embeddings\_bridging_n}{|N|} \qquad (2)$$

The underlying intuition of adding NP modifications to the list N is that the above mentioned modifiers also represent core semantics of an NP, therefore we should consider them when selecting antecedents for bridging anaphors. For instance, as shown in Table 4, for Example 1, the cosine similarity between {**arrangements_PP**} and

$\{$*products*$\}$ is 0.06, while the cosine similarity between $\{$**distribution_PP**, **arrangements_PP**$\}$ and $\{$*dialysis*, *products*$\}$ is 0.17.

If none of the words in N is present in *embeddings_bridging*, we simply neglect the noun phrase $np1$. Note that we do not add the suffix "_PP" to a bridging anaphor representing time information, because such an anaphor is likely to have the same semantic type antecedent (see Example 2). Therefore we use semantic similarity instead of relatedness to find its antecedent.

5 Experiments

5.1 Dataset

For the task of bridging anaphora resolution, we use the dataset ISNotes[5] released by Markert et al. (2012). This dataset contains around 11,000 NPs annotated for information status including 663 bridging NPs and their antecedents in 50 texts taken from the WSJ portion of the OntoNotes corpus (Weischedel et al., 2011). As stated in Section 2, bridging anaphors in ISNotes are not limited to definite NPs as in previous work (Poesio et al., 1997, 2004; Lassalle and Denis, 2011). The semantic relations between anaphor and antecedent in the corpus are quite diverse: only 14% of anaphors have a part-of/attribute-of relation with the antecedent and only 7% of anaphors stand in a set relationship to the antecedent. 79% of anaphors have "other" relation with their antecedents. This includes encyclopedic or frame relations such as *restaurant* – **the waiter** as well as context-specific relations such as *palms* – **the thieves**. In Example 1, "*dialysis products*" is the "theme" of the **distribution arrangements**. More specifically, "*dialysis products*" belongs to the frame element "Individuals" in the "Dispersal" frame that is triggered by "**distribution arrangements**".

5.2 Experimental Setup

Following Hou et al. (2013b)'s experimental setup, we resolve bridging anaphors to entity antecedents. Entity information is based on the OntoNotes coreference annotation. We also use the OntoNotes named entity annotation to assign NPs the semantic type "*time*" if their entity types are "date" or "time".

In Hou et al. (2013b), features are extracted by using entity information. For instance, the raw hit counts of the preposition pattern query (e.g., **arrangements** of *products*) for a bridging anaphor a and its antecedent candidate e is the maximum count among all instantiations of e. In our experiments, we simply extend the list of antecedent candidates E_a (described in Section 4) to include all instantiations of the original entities in E_a. Note that our simple antecedent candidate selection strategy (described in Section 4) allows us to include 76% of NP antecedents compared to 77% in *pairwise model III* from Hou et al. (2013b) where they add top 10% salient entities as additional antecedent candidates. In Hou et al. (2013b), salient entities on each text are measured through the lengths of the coreference chains based on the gold coreference annotation.

Following Hou et al. (2013b), we measure *accuracy* on the number of bridging anaphors, instead of on all links between bridging anaphors and their antecedent instantiations. We calculate how many bridging anaphors are correctly resolved among all bridging anaphors.

5.3 Using NP Head Alone

Given an anaphor a and its antecedent candidate list E_a, we predict the most related NP among all NPs in E_a as the antecedent for a[6]. The relatedness is measured via cosine similarity between the head of the anaphor (plus the postfix "_PP" if the anaphor is not a time expression) and the head of the candidate. We run experiments on the following four word embeddings: the original GloVe vectors trained on Gigaword and Wikipedia 2014 dump (*GloVe_GigaWiki14*), GloVe vectors that we trained on Gigaword only (*GloVe_Giga*), word vectors from Hou (2018) (*embeddings_PP*), and our word representation resource described in Section 3.2 (*embeddings_bridging*). Note that for the first two word vectors, we do not add the suffix "_PP" to the anaphor's head since such words do not exist in *GloVe_GigaWiki14* and *GloVe_Giga*.

Table 5 lists the results for bridging anaphora resolution based on different word representation resources[7]. We notice that there is not

---

[5] `http://www.h-its.org/en/research/nlp/isnotes-corpus`

[6] In case of a tie, the closest one is chosen to be the predicted antecedent.

[7] Note that the results for the first three word embeddings are slight better than the ones reported in Hou (2018). This is due to the improved antecedent candidate selection strategy described in Section 4.

	acc
GloVe_GigaWiki14	21.42
GloVe_Giga	21.87
embeddings_PP	**33.03**
embeddings_bridging	**34.84**

Table 5: Results of using NP head alone for bridging anaphora resolution based on different word representation resources. Bold indicates statistically significant differences over the baselines (two-sided paired approximate randomization test, $p < 0.01$).

much difference between *GloVe_GigaWiki14* and *GloVe_Giga*. We find that using *embeddings_PP* achieves an accuracy of 33.03% on the ISNotes corpus, which outperforms the results based on *GloVe_GigaWiki14* and *GloVe_Giga* by a large margin. Using *embeddings_bridging* further improves the result by 1.8%. Although the improvement is not significant, we suspect that the representations for words without the suffix "_PP" in *embeddings_bridging* are more accurate because they are trained on many more instances in the vanilla GloVe vectors (*GloVe_GigaWiki14*).

5.4 Using NP Head + Modifiers

We carried out experiments using the deterministic algorithm described in Section 4 together with different word embeddings. Again we do not add the suffix "_PP" to the bridging anaphors for *GloVe_GigaWiki14* and *GloVe_Giga*.

Table 6 lists the best results of the two models for bridging anaphora resolution from Hou et al. (2013b). *pairwise model III* is a pairwise mention-entity model based on various semantic, syntactic and lexical features. *MLN model II* is a joint inference framework based on Markov logic networks (Domingos and Lowd, 2009). It models that semantically or syntactically related anaphors are likely to share the same antecedent and achieves an accuracy of 41.32% on the ISNotes corpus.

The results for *GloVe_GigaWiki14* and *GloVe_Giga* are similar on two settings (*using NP head* vs. *using NP head + modifiers*). For *embeddings_PP*, the result on *using NP head + modifiers* (31.67%) is worse than the result on *using NP head* (33.03%). However, if we apply *embeddings_PP* to a bridging anaphor's head and modifiers, and only apply *embeddings_PP* to the head noun of an antecedent candidate, we get an accuracy of 34.53%. Although the differences are not significant, it confirms that the information from the modifiers of the antecedent candidates in *embeddings_PP* hurts the performance. This corresponds to our observations in the previous section that the representations for words without the suffix "_PP" in *embeddings_PP* are not as good as in *embeddings_bridging* due to less training instances.

	acc
models from Hou et al. (2013b)	
pairwise model III	36.35
MLN model II	**41.32**
NP head + modifiers	
GloVe_GigaWiki14	20.52
GloVe_Giga	20.81
embeddings_PP	31.67
embeddings_bridging	**39.52**

Table 6: Results of using NP head plus modifications in different word representations for bridging anaphora resolution compared to the best results of two models from Hou et al. (2013b). Bold indicates statistically significant differences over the other models (two-sided paired approximate randomization test, $p < 0.01$).

Finally, our method based on *embeddings_bridging* achieves an accuracy of 39.52%, which is competitive to the best result (41.32%) reported in Hou et al. (2013b). There is no significant difference between *NP head + modifiers* based on *embeddings_bridging* and *MLN model II* (randomization test with $p < 0.01$).

To gain an insight into the contribution of *embeddings_bridging* on different relation types, we analyze the results of our method using *embeddings_bridging* on three relation types: *set-of*, *part-of*, and *other*. The accuracies on these three relation types are 17.78%, 50.0%, and 39.16%, respectively. This suggests that in the future we should include more context for bridging anaphors that hold the *set-of* relation to their antecedents, because the head nouns of such anaphors often do not bear any specific meanings (e.g., **Another**).

5.5 Analysis of Modifiers

To better understand the role of NP modifiers in our method, we carried out experiments on *embeddings_bridging* using different set of modifiers (see Table 7). It seems that among all three types of modifiers, compared to using NP head alone, adding noun modifiers has the positive impact (36.65% on *NP head + noun modifiers* vs. 34.84% on *NP head*). Although adding only ad-

embeddings_bridging	**acc**
NP head	34.84
+ *all modifiers*	39.52
+ *noun modifiers*	**36.65**
+ *adjective modifiers*	34.84
+ *ed/ing participle modifiers*	34.84
+ *noun&adjective modifiers*	**38.31**
+ *noun&ed/ing participle modifiers*	**36.80**
+ *adjective&ed/ing participle modifiers*	34.84

Table 7: Results of using NP head plus different modifications in *embeddings_bridging*.

jective modifiers does not have influence on results, combining them with noun modifiers yields some improvement over adding only noun modifiers (38.31% on *NP head* + *noun&adjective modifiers* vs. 36.65% on *NP head* + *noun modifiers*). On the other hand, ed/ing participle modifiers only have a small positive impact over *NP head* + *noun modifiers* when combining with noun modifiers.

5.6 Combining *NP Head* + *Modifiers* with *MLN II*

For bridging anaphora resolution, Hou (2018) integrates a much simpler deterministic approach by combining an NP head with its noun modifiers (appearing before the head) based on *embeddings_PP* into the *MLN II* system (Hou et al., 2013b). Similarly, we add a constraint on top of *MLN II* using our deterministic approach (*NP head* + *modifiers*) based on *embeddings_bridging*. Table 8 lists the results of different systems[8] for bridging anaphora resolution in ISNotes. It shows that combining our deterministic approach (*NP Head* + *modifiers*) with *MLN II* slightly improves the result compared to Hou (2018).

Although combining *NP Head* + *modifiers* with *MLN II* achieves significant improvement over *NP Head* + *modifiers*, we think the latter has its own value. Our deterministic algorithm is simpler and more efficient compared to *MLN model II* + *embeddings_bridging*, which contains many complicated features and might be hard to migrate to other bridging corpora. Moreover, our algorithm is "unsupervised" and requires no training when applied to other English bridging corpora.

5.7 Resolving Bridging Anaphors in Other Corpora

Recently, two new corpora containing bridging annotation have become available. The BASHI corpus (Rösiger, 2018a) contains 459 bridging NPs and their antecedents in 50 World Street Journal articles. Similar to ISNotes, BASHI includes both definite and indefinite referential bridging anaphors. In addition, comparative anaphora is also considered as bridging anaphora in BASHI.

Another new corpus for bridging is the second release of the ARRAU corpus, which contains 5,512 bridging pairs in three different domains (Poesio et al., 2018). However, most bridging links in ARRAU are purely lexical bridging pairs, and only a small subset of the annotated pairs contains truly anaphoric bridging anaphors (Rösiger et al., 2018). Following Rösiger et al. (2018), we focus on resolving bridging anaphors in the news text domain (RST).

Based on *embeddings_bridging*, we apply our deterministic algorithm with small adaptations to resolve bridging anaphors to entity antecedents on the BASHI and ARRAU (RST) corpora. Specifically, for the BASHI corpus, we do not add NPs from the first sentence to the list of antecedent candidates E_a. This is because the phenomenon of globally salient antecedents being linked to all anaphors in a text is less obvious in BASHI. In addition, comparative anaphors often have the same semantic class as their antecedents, therefore we do not add the suffix "_PP" to a bridging anaphor if it is a comparative anaphor.

For the ARRAU corpus, we construct the list of antecedent candidates E_a using NPs preceding a from the same sentence as well as from the previous ten sentences. Since most bridging pairs in ARRAU are lexical bridging (e.g., *Tokyo* – **Japan**, *other nations* – **Britain**) and anaphors often have the same semantic type as their antecedents, we do not add the suffix "_PP" to bridging anaphors.

Table 9 lists the results of bridging anaphora resolution in the BASHI and ARRAU corpora, respectively. On the test set of the ARRAU (RST) corpus, Rösiger (2018b) proposed a modi-

---

[8] We also reimplement the algorithms from Schulte im Walde (1998) and Poesio et al. (2004) as baselines (Table 8). Schulte im Walde (1998) resolved bridging anaphors to the closest antecedent candidate in a high-dimensional space. We use the 2,000 most frequent words (adjectives, common nouns, proper nouns, and lexical verbs) from Gigaword as the context words. Poesio et al. (2004) applied a pairwise model combining lexical semantic features and salience features to perform mereological bridging resolution in the GNOME corpus. We use a Naive Bayes classifier with standard settings in WEKA (Witten and Frank, 2005) and apply the best first strategy to select the antecedent for each anaphor.

	System	acc
Baselines	*Schulte im Walde (1998)*	13.68
	Poesio et al. (2004)	18.85
Models from Hou et al. (2013b)	*pairwise model III*	36.35
	MLN model II	41.32
Hou (2018)	*MLN model II + embeddings_PP (NP head + noun pre-modifiers)*	**45.85**
This work	*embeddings_bridging (NP head + modifiers)*	39.52
	MLN model II + embeddings_bridging (NP head + modifiers)	**46.46**

Table 8: Results of different systems for bridging anaphora resolution in ISNotes. Bold indicates statistically significant differences over the other models (two-sided paired approximate randomization test, $p < 0.01$).

Corpus	Bridging Type	# of Anaphors	acc

BASHI	referential, excluding comparative anaphora	344	29.94
ARRAU (RST Train)	mostly lexical, some referential	2,325	31.44
ARRAU (RST Test)	mostly lexical, some referential	639	32.39

Table 9: Results of resolving bridging anaphors in other corpora. Number of bridging anaphors is reported after filtering out a few problematic cases on each corpus.

fied rule-based system based on Hou et al. (2014)'s work and reported an accuracy of 39.8% for bridging anaphora resolution. And our algorithm achieves an accuracy of 32.39% using only *embeddings_bridging*. Overall, the reasonable performance on these two corpora demonstrates that *embeddings_bridging* is a general word representation resource for bridging.

6 Conclusions

We improve the word representation resource *embeddings_PP* (Hou, 2018) by combining it with *GloVe*. The resulting word embeddings (*embeddings_bridging*) are a more general word representation resource for bridging. Based on *embeddings_bridging*, we propose a deterministic approach for choosing antecedents for bridging anaphors. We show that this simple and efficient method achieves the competitive result on bridging anaphora resolution compared to the advanced machine learning-based approach in Hou et al. (2013b) which is heavily dependent on a lot of carefully designed complex features. We also demonstrate that using *embeddings_bridging* yields better results than using *embeddings_PP* for bridging anaphora resolution.

For the task of bridging anaphora resolution, Hou et al. (2013b) pointed out that considering only head noun knowledge is not enough and future work needs to explore wider context to resolve context-specific bridging relations. In this work we explore the context within NPs—that is, we combine the semantics of certain modifications and the head by vector average using *embeddings_bridging*. But in some cases, knowledge about NPs themselves is not enough for resolving bridging. For instance, in Example 3, knowing that **any loosening** has the ability to "rekindle inflation" from the context of the second sentence can help us to find its antecedent "*the high rates*" (which is used to against inflation).

(3) Chancellor of the Exchequer Nigel Lawson views *the high rates* as his chief weapon against inflation, which was ignited by tax cuts and loose credit policies in 1986 and 1987. Officials fear that **any loosening** this year could rekindle inflation or further weaken the pound against other major currencies.

In the future, we will study how to integrate context outside of NPs for the task of choosing antecedents for bridging anaphors. Also we hope that our word representation resource will facilitate other related research problems such as semantic role labeling.

Acknowledgments

The author appreciates the valuable feedback from the anonymous reviewers and would like to thank Massimo Poesio for sharing the ARRAU corpus.

Abstract

We introduce an automatic system that achieves state-of-the-art results on the Winograd Schema Challenge (WSC), a common sense reasoning task that requires diverse, complex forms of inference and knowledge. Our method uses a knowledge hunting module to gather text from the web, which serves as evidence for candidate problem resolutions. Given an input problem, our system generates relevant queries to send to a search engine, then extracts and classifies knowledge from the returned results and weighs them to make a resolution. Our approach improves F1 performance on the full WSC by 0.21 over the previous best and represents the first system to exceed 0.5 F1. We further demonstrate that the approach is competitive on the Choice of Plausible Alternatives (COPA) task, which suggests that it is generally applicable.

1 Introduction

The importance of common-sense reasoning in natural language processing, particularly for syntactic and semantic disambiguation, has long been recognized. Almost 30 years ago, Dahlgren et al. (1989) proposed systems that use common sense to disambiguate parse trees, word senses, and quantifier scope. Although the resolution of certain ambiguities depends chiefly on linguistic patterns (e.g., the number and gender of an antecedent for pronoun disambiguation), many cases depend on world knowledge, shared points of reference, and an understanding of what is plausible—concepts often grouped under the term "common sense."

Various tasks have been devised to test common-sense reasoning in automatic systems. Two of the most popular are the *Winograd Schema Challenge* (WSC) (Levesque et al., 2011) and the *Choice of Plausible Alternatives* (COPA) (Roemmele et al., 2011). Both require a system to assess the relative plausibility of two scenarios.

WSC problems are short passages containing a target pronoun that must be correctly resolved to one of two possible antecedents. They come in pairs which differ slightly and result in adverse correct resolutions. As an example:

(1) a. Jim yelled at Kevin because *he* was so upset. (Answer: Jim)
b. Jim comforted Kevin because *he* was so upset. (Answer: Kevin)

WSC problem pairs ("twins," using the terminology of Hirst (1988)) are carefully controlled such that heuristics involving syntactic salience, the number and gender of the antecedent, or other simple syntactic and semantic cues are ineffective. This distinguishes the task from the standard coreference resolution problem. Performant systems must make common sense inferences; i.e., that someone who yells is likely to be upset, and that someone who is upset tends to be comforted. Additional examples are shown in Table 1.

WSC problems are simple for people to solve (human participants in one study performed at 92% accuracy (Bender, 2015)) but difficult for automatic systems. This is because common sense reasoning encompasses many types of reasoning (causal, spatio-temporal, etc.) and requires a wide breadth of knowledge.

COPA is a related task that tests a system's ability to recognize causality (Roemmele et al., 2011). Each instance comprises a premise and two candidate causes or effects, where the correct choice is the candidate that is more *plausible*.

Previous approaches to common sense reasoning, for instance based on logical formalisms (Bailey et al., 2015) or deep neural models (Liu et al., 2016), have solved only restricted subsets of the WSC with high precision. They have been tailored

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1949–1958
Brussels, Belgium, October 31 - November 4, 2018.

1 a)	The man couldn't lift his son because he was so weak. (Answer: the man)
1 b)	The man couldn't lift his son because he was so heavy. (Answer: son)
2 a)	The older students were bullying the younger ones, so we punished them. (Answer: the older students)
2 b)	The older students were bullying the younger ones, so we rescued them. (Answer: the younger ones)
3 a)	Sam tried to paint a picture of shepherds with sheep, but they ended up looking more like golfers. (Answer: shepherds)
3 b)	Sam tried to paint a picture of shepherds with sheep, but they ended up looking more like dogs. (Answer: sheep)

Table 1: Examples of Winograd instances.

for manually selected subsets that demand a specific type of reasoning (Sharma et al., 2015; Liu et al., 2016). Others have developed systems for relaxed common sense datasets with looser constraints (Rahman and Ng, 2012; Peng et al., 2015; Kruengkrai et al., 2014). In parallel, more general work on common sense reasoning aims to develop a repository of common knowledge using semi-automatic methods (e.g., Cyc (Lenat, 1995) and ConceptNet (Liu and Singh, 2004)). However, such knowledge bases are necessarily incomplete.

In this work, we propose a general method to resolve common sense problems like WSC and COPA. Contrary to previous work, we aim to solve *all* problem instances rather than a restricted subset. Our method is based on on-the-fly *knowledge hunting* and operates in four stages. First, it parses an input problem into a representation schema. Next it generates search queries from the populated schema. It sends these to a search engine, and the next stage parses and filters the results. Finally, it classifies and weighs the results as evidence for respective candidate resolutions.

Our approach arises from the hypothesis that there is too much common sense to encode it all statically; e.g., within a knowledge base or a neural model (using existing techniques). Even modern NLP corpora composed of billions of words are unlikely to offer good coverage of common sense, or if they do, instances of specific knowledge are likely to be "long-tailed" and difficult for statistical systems to model effectively. Information retrieval (IR) techniques can sidestep these issues by returning targeted results and by using the *entire* indexed internet as a knowledge source. Scenarios that appear in natural text can offer implicit or explicit evidence for the plausibility of related scenarios in common sense problems. To solve (1a), the following search result contains the relevant knowledge without the original ambiguity:

(2) I got really upset with her and I started to yell at her because...

Here, the same entity, *I*, is the subject of both *upset* and *yell at*, which is strong evidence for resolving the original statement. This information can be extracted from a syntactic parse of the retrieved passage with standard NLP tools.

As we will demonstrate experimentally, our knowledge hunting approach achieves an F1 score of 0.51 on the WSC, improving significantly over the previous state-of-the-art (0.3 F1). When tested on the similar COPA task, a simplified knowledge hunting system performs competitively with the previous best. To our knowledge, this is the first method that tackles multiple common sense tasks with strong performance on each. Thus, knowledge-hunting embodies some of the general capabilities that we desire of automatic systems for common sense reasoning.[1]

2 Related Work

There is increasing interest in using IR approaches to address difficult coreference problems. For example, a recent system (Rahman and Ng, 2012) uses web query information to retrieve evidence for the coreference decision in a Winograd-like corpus. Other systems (Kobdani et al., 2011; Ratinov and Roth, 2012; Bansal and Klein, 2012; Zheng et al., 2013; Peng et al., 2015; Sharma et al., 2015) rely on similar techniques, i.e., using search-query counts or co-occurrence statistics and word alignment methods to relate antecedents with pronouns.

Most recent approaches have tackled the Winograd problem by simplifying it in one of two ways. First, systems have been developed exclusively for Rahman and Ng's expanded Winograd-like corpus. These include Rahman and Ng (2012)'s system itself, achieving 73% accuracy, and Peng et al. (2015)'s system (76%). Kruengkrai et al.

---

[1] Code to reproduce these results are available at https://github.com/aemami1/Wino-Knowledge-Hunter

(2014) use sentence alignment of web query snippets to achieve 70% accuracy on a subset of the expanded corpus. Many instances in this corpus can be resolved using associations between candidate antecedents and the query predicate. For example, "Lions eat zebras because they are predators." Many of the above systems simply query "Lions are predators" versus "zebras are predators" to make a resolution decision. This exploitation is often the top contributor to such systems' overall accuracy (Rahman and Ng, 2012), but fails to apply in the majority (if not all) of the original Winograd instances.[2] Our work alleviates this issue by generating search queries that are based exclusively on the predicates of the Winograd instance, not the antecedents, and by considering the strength of the evidence.

Other systems do tackle the original, more difficult Winograd instances, but only a small, author-selected subset. The selection is based often on knowledge-type constraints. Sharma et al. (2015)'s knowledge-hunting module focused on a subset of 71 instances that exhibit *causal* relationships; Liu et al. (2016)'s neural association model focused on a similar causal subset of 70 instances, for which events were extracted manually; and finally, a recent system by Huang and Luo (2017) focused on 49 instances. While these approaches demonstrate that difficult coreference problems can be resolved when they adhere to certain knowledge or structural constraints, they may fail to generalize to other settings. This factor often goes unnoticed when systems are compared only in terms of precision; accordingly, we use an F1-driven comparison that does not enable precision boosting at the cost of recall.

Concurrently with our work, Trinh and Le (2018) introduced a system composed of 14 ensembled language models, pre-trained in an unsupervised manner, that achieves up to 63.7% accuracy on the Winograd Schema Challenge. Compared to our approach, their method requires training multiple language models with vast amounts of data, which is much more expensive.

Other Common-sense Tasks: There are various other Turing-test alternatives that directly or indirectly assess common-sense reasoning. These include Pronoun Disambiguation Problems (more generalized, Winograd-like passages without the twist of a special word or twin) (Morgenstern et al., 2016), the Narrative cloze task (Taylor, 1953), or its more difficult counterpart, the NarrativeQA Reading Comprehension Challenge (Kočiskỳ et al., 2017).

The COPA task was proposed by Roemmele et al. (2011), who also measured the performance of several systems. The most successful used Pointwise Mutual Information (PMI) statistics (Church and Hanks, 1990) between words in the premise and each alternative obtained from a large text corpus (as an implicit way to estimate causal association). More recent work showed that applying the same PMI-based technique on a corpus of stories yields better results (Gordon et al., 2011). The current state-of-the-art approaches leverage co-occurrence statistics extracted using causal cues (Luo et al., 2016; Sasaki et al., 2017).

Extended Work: Previously, Emami et al. (2018) proposed a similar knowledge hunting framework to tackle the Winograd Schema Challenge. This work modifies and extends their approach. Our modifications include a query-filtering step and various other tweaks that improve results by 0.05 F1 for our best model. In addition, we added further experiments and an ablation study that explores the performance of different model components. Finally, we adapted our method to a new dataset, COPA, on which we achieve respectable results. Accordingly, we change the general takeaway of the previous work from a method with strong performance on a single dataset to one that generalizes and performs well on various tasks.

3 Knowledge Hunting Framework

Our framework takes as input a problem instance and processes it through four stages to make a final coreference decision. First, it fits the instance to a semantic representation schema. Second, it generates a set of queries that capture the predicates in the instance's clauses and sends these to a search engine, which retrieves text snippets that closely match the schema. The returned snippets are then parsed and filtered. Finally, the snippets are resolved to their respective antecedents and the results are mapped to a best guess for the original instance's resolution. We detail these stages below, grounding our description in Winograd instances.

---

[2] This is why we do not evaluate our method directly on the expanded corpus.

3.1 Semantic Representation Schema

The first step is to perform a partial parse of each instance into a shallow semantic representation; that is, a general skeleton of each of the important semantic components in the order that they appear. This is performed using rules related to the syntactic parse of the sentence determined by Stanford CoreNLP (Manning et al., 2014).

In general, Winograd instances can be separated into a *context* clause, which introduces the two competing antecedents, and a *query* clause, which contains the target pronoun to be resolved. We use the following notation to define the components in our representation schema:

E_1, E_2	the candidate antecedents
$Pred_C$	the context predicate
$+$	discourse connective
P	the target pronoun
$Pred_Q$	the query predicate

E_1 and E_2 are noun phrases in the sentence. In the WSC, these two are specified without ambiguity. $Pred_C$ is the context predicate composed of the verb phrase that relates both antecedents to some event. The context contains E_1, E_2, and the context predicate $Pred_C$. The context and the query clauses are often connected by a discourse connective $+$. The query contains the target pronoun, P, which is also specified unambiguously. In addition, preceding or succeeding P is the query predicate, $Pred_Q$, a verb phrase involving the target pronoun. Table 2 shows sentence pairs in terms of each of these components.

3.2 Query Generation

Based on the parse, the system generates queries to send to a search engine. The goal is to retrieve text snippets that resemble the original instance. Queries are of the form:

$+Term_C$ $+Term_Q$ $-$“Winograd”$-E_1$

We assume that the search queries are composed of two components, $Term_C$ and $Term_Q$, which are strings that represent the events occurring in the first (context) and second (query) clause of the sentence, respectively. By excluding search results that may contain *Winograd* or E_1, we ensure that we do not cheat by retrieving some rewording of the original Winograd instance.

The next task is to construct two query sets, C and Q, whose elements are possible entries for $Term_C$ and $Term_Q$, respectively. We identify the root verbs in the context and query clauses, along with any modifying adjective, using the dependency parse of the sentence determined by Stanford CoreNLP (Manning et al., 2014). We add the root verbs and adjectives into the sets C and Q along with their broader verb phrases (again identified directly using the dependency tree).

Augmenting the query set with WordNet We use WordNet (Kilgarriff, 2000) to construct an augmented query set that contains synonyms for the verbs and adjectives involved in a representation. In particular, we include the synonyms listed for the top synset of the same part of speech as the extracted verb or adjective.

Query filtering Automated query generation sometimes yields terms that are irrelevant to the disambiguation task. This can add noise to the results. To address this, we implement a semantic similarity algorithm that filters root verbs and modifying adjectives from the query sets according to their relevance to other terms. We estimate relative relevance using Wu-Palmer (Wu and Palmer, 1994) similarity scores from WordNet and filter as follows. For each passage, the semantic filter (i) computes similarity scores for every possible combination of $\{Term_C, Term_Q\}$ (if both $Term_C$ and $Term_Q$ are single words); (ii) determines the maximum similarity score s; and (iii) discards any term whose highest similarity score from step (i) is less than αs, where $0 < \alpha < 1$. We tune α, a hyperparameter, on Rahman and Ng’s expanded corpus (Rahman and Ng, 2012).

We hypothesize that terms in the query and context clauses more pertinent to the task have higher mutual similarity scores than irrelevant terms. To illustrate this, consider the query sets generated for Example 2a, Table 1: {“bullying”, “younger”, “older”} and {“punished”}. Applying the semantic filter yields the new sets {“bullying”} and {“punished”}, where the irrelevant terms *younger* and *older* have been removed.

Manual query construction To understand the impact of the query generation step, we also manually produced representations for all Winograd instances. We limited the size of these sets to five to prevent a blowing-up of search space during knowledge extraction. In Table 3, we show ex-

Pair	$Pred_C$	E_1	E_2	$Pred_Q$	P	Alternating Word (POS)
1	couldn't lift	the man	his son	was so heavy	he	weak/heavy (adjective)
2	were bullying	the older students	the younger ones	punished	them	punished/rescued (verb)
3	tried to paint	shepherds	sheep	ended up looking more like	they	golfers/dogs (noun)

Table 2: Winograd sentence pairs from Table 1, parsed into the representation schema that we define.

Sentence: The trophy doesn't fit into the brown suitcase because it is too large.

Query Generation Method	C	Q
Automatic	{"doesn't fit into", "brown", "fit" }	{"large", "is too large"}
Automatic, with synonyms	{"doesn't fit into", "brown", "accommodate", "fit", "suit" }	{"large", "big", "is too large" }
Manual	{"doesn't fit into", "fit into","doesn't fit" }	{"is too large", "too large", "large" }

Table 3: Query generation techniques on an example Winograd sentences

amples of generated queries for C and Q using the various techniques.

3.3 Parsing the Search Results

From the search results, we obtain a set of text snippets that we filter for similarity to the original problem instance. First, $Term_C$ and $Term_Q$ are restricted to occur in the same snippet, but are allowed to occur in any order. We filter the passed sentences further to ensure that they contain at least two entities that corefer. These may be structured as follows:

$$\begin{array}{lcl} E_1'\ Pred_C'\ E_2' & + & E_3'\ Pred_Q' \\ E_1'\ Pred_C'\ E_2' & + & Pred_Q'\ E_3' \\ E_1'\ Pred_C' & + & E_3'\ Pred_Q' \\ E_1'\ Pred_C' & + & Pred_Q'\ E_3' \end{array}$$

We call these *evidence sentences*. They exhibit a structure similar to the corresponding Winograd instance, but with different entities and event order. $Pred_C'$ and $Pred_Q'$ (resulting from the queries $Term_C$ and $Term_Q$, resp.) should be similar if not identical to $Pred_C$ and $Pred_Q$ from the Winograd sentence. However, E_1', E_2', and E_3' may not have the same semantic type, potentially simplifying their coreference resolution. A sentence for which E_3' refers to E_1' is subsequently labelled *evidence-agent*, and one for which E_3' refers to E_2', *evidence-patient*. The exception to this rule is when an event occurs in the passive voice (e.g., *was called*), which reverses the conventional order of the agent and patient. Another exception is in the case of *causative alternation*, where a verb can be used both transitively and intransitively. The latter case can also reverse the conventional order of the agent and patient (e.g., *he opened the door* versus *the door opened*).

As an example of coreference simplification, a valid evidence sentence is: *He tried to call* ***her*** *but* ***she*** *wasn't available.* Here, the sentence can be resolved on the basis of the gender of the antecedents; E_3' (the pronoun *she*) refers to the patient, E_2'. Accordingly, the sentence is considered an evidence-patient.

3.4 Antecedent Selection

We collect and reason about the set of retrieved sentences using a selection process that (i) resolves E_3' to either E_1' or E_2' using CoreNLP's coreference resolution module (rendering them evidence-agent or evidence-patient); and (ii) uses both the count and individual features of the evidence sentences to resolve the original Winograd instance. For example, the more similar evidence-**agents** there are for the sentence *Paul tried to call George on the phone, but he wasn't successful*, the more likely it is that the process would guess *Paul*, the **agent**, to be the correct referent of the target pronoun.

To map each sentence to either an evidence-agent or evidence-patient, we developed a rule-based algorithm that uses the syntactic parse of an input sentence. This algorithm outputs an evidence label along with a list of features. The features indicate: which two entities co-refer according to Stanford CoreNLP's resolver, and to which category of E_1', E_2', or E_3' each belong; the token length of the sentence's search terms, $Term_C$ and $Term_Q$; the order of the sentence's search terms; whether the sentence is in active or passive voice; and whether or not the verb is causative alternating. Some of these features are straightforward to extract (like token length and order, and coreferring entities given by CoreNLP), while others require various heuristics. To map each coreferring entity in the snippet to E_1', E_2', or E_3' (corresponding loosely to context subject, context object, and query entity, respectively), we consider their position relative to the predicates in the original Winograd instance. That is, E_1' precedes $Term_C$, E_2' succeeds $Term_C$, and E_3' may precede or succeed $Term_Q$ depending on the Winograd instance. To determine the voice, we use a list of auxiliary verbs and verb phrases (e.g., *was*, *had been*, *is*, *are being*) that switch the voice from active to passive (e.g., "they are being bullied" vs "they bullied") whenever one of these precedes $Term_C$ or $Term_Q$ (if they are verbs). Similarly, to identify causative alternation, we use a list of causative alternating verbs (e.g., *break*, *open*, *shut*) to identify the phenomenon whenever $Term_C$ or $Term_Q$ is used intransitively.

These features determine the evidence label, evidence-agent (EA) or evidence-patient (EP), according to the following rules:

$$L(e) = \begin{cases} \text{EA}, & \text{if } E_3' \text{ refers to } E_1', \text{ active (1)} \\ \text{EA}, & \text{if } E_3' \text{ refers to } E_2', \text{ passive (2)} \\ \text{EP}, & \text{if } E_3' \text{ refers to } E_2', \text{ active (3)} \\ \text{EP}, & \text{if } E_3' \text{ refers to } E_1', \text{ passive (4)} \\ \text{EP}, & \text{if } E_3' \text{ refers to } E_1', \text{ causative (5)} \end{cases}$$

Cases (2), (4), and (5) account for the passive and causative constructions, which alter the mapping from syntactic role to semantic role.

In addition to determining the evidence label, the features are used in a heuristic that generates scores (called *strengths*) for each evidence sentence:

$$\mathit{Str}(e) = \mathit{LenScore}(e) + \mathit{OrderScore}(e)$$

$$\mathit{LenScore}(e) = \begin{cases} 2, & \text{if } len(Term_Q) > 1 \\ 2, & \text{if } len(Term_C) > 1 \\ 1, & \text{otherwise} \end{cases}$$

$$\mathit{OrderScore}(e) = \begin{cases} 2, & \text{if } Term_C \prec Term_Q \\ 1, & \text{if } Term_Q \prec Term_C \end{cases}$$

As an example of scoring for an actual snippet, let us consider "She **tried to call** for him and then search for him herself, but **wasn't successful**," returned for $Term_C$=*tried to call*, and $Term_Q$=*wasn't successful*.

Here, both $Term_Q$ and $Term_C$ are multi-word search terms, and $Term_C$ precedes $Term_Q$ as in the original Winograd sentence. Its overall evidence strength is 4, the highest possible score. On the other hand, for the retrieved snippet "Has your husband **tried** Sudafed and was it **successful**?" for $Term_Q$=*tried*, and $Term_C$=*successful*, the evidence strength would be 3. We designed the scoring system to capture the structural similarity of a snippet to its corresponding Winograd instance. We observed that a greater quantity of snippets can be retrieved for less specific search terms, but with increasing noise; we sought to account for this with the features described above. Note also that our use of the word *features* is intentional. While the weights assigned for the length and order scores could be optimized, as parameters, we consider it inappropriate to do so on the WSC since it is widely used as a *test set*. We set these weights according to our best guess and validated our choices through experiments on the set of Winograd-like sentences provided in Rahman and Ng (2012).

We run the above four processes on all snippets retrieved for the input Winograd instance. The sum of strengths for the evidence-agents is finally compared to that of the evidence-patients to make the resolution decision.

4 Experiments and Results

We tested several versions of our framework on the original 273 Winograd sentences (135 pairs and one triple). These vary in the method of query generation: automatic *vs.* automatic with synonyms *vs.* manual. We compared these systems with previous work on the basis of Precision (P), Recall (R), and F1.

We used Stanford CoreNLP's coreference resolver (Raghunathan et al., 2010) during query generation to identify the predicates from the syntactic parse, as well as during antecedent selection to retrieve the coreference chain of a candidate evidence sentence. Python's Selenium package was used for web-scraping and Bing-USA and Google (top two pages per result) were the search engines. The search results comprise a list of document snippets that contain the queries (for example, "yelled at" and "upset"). We extract the sentence/s within each snippet that contain the query terms, with the added restriction that the terms should be within 70 characters of each other to encourage relevance.

	# Correct	P	R	F1
AGQ	77	0.56	0.28	0.38
AGQ+F	80	0.63	0.29	0.40
AGQS	114	0.57	0.42	0.48
AGQS+F	119	0.60	**0.44**	**0.51**
S2015	49	**0.92**	0.18	0.30
Systems with manual information:				
L2017	43	0.61	0.15	0.25
MGQ	118	0.60	0.43	0.50

Table 4: Coverage and performance on the original Winograd Schema Challenge (273 sentences).

Table 4 shows the precision, recall, and F1 of our framework's variants: automatically generated queries (AGQ), automatically generated queries with synonyms (AGQS), and manually generated queries (MGQ). We test the automatic systems with (+F) and without the semantic similarity filter. We compare these to the systems of Sharma et al. (2015) (S2015) and Liu et al. (2017) (L2017). The system developed by Liu et al. (2017) uses elements extracted manually from the problem instances, so is most closely comparable to our MGQ method. Our best automated framework, AGQS+F, outperforms S2015 by 0.21 F1, achieving much higher recall (0.44 vs 0.18). Our results show that the framework with manually generated queries (MGQ) performs better than its automatic counterpart, AGQ, with an F1 of 0.50. AGQS+F slightly outperforms MGQ despite being fully automatic.

The power of our approach lies in its generality, i.e., its improved coverage of the problem set. It produces an answer for over 70% of instances. This surpasses previous methods, which only admit specific instance types, by nearly 50%.

The random baseline on this binary task achieves a P/R/F1 of 0.5. We can artificially raise the F1 performance of all systems above 0.5 by randomly guessing an answer in cases where the system makes no decision. For AGQS+F, for example, if we take a random decision on the cases (74) with no retrieved evidence, we get an accuracy of 57.1%. However, we think it is important that systems are compared transparently based on which instances they admit and when they are capable of making a prediction.

5 Error Analysis

To get a sense of the performance of our heuristics in classifying evidence sentences in the antecedent selection step, we manually labelled sentences retrieved by the AGQS system for 40 Winograd instances. The categories are evidence-agent, evidence-patient, or neither (insufficient evidence). This amounts to a total of 876 evidence sentences. We compared these labels to those assigned by our system. In total, 703 of the 876 evidence sentences were labelled correctly (81%). Of the 173 incorrect cases, 110 were marked as insufficient evidence. Our system is forced to label these as agent or patient.

Evidence sentences were insufficient for a variety of reasons. Most frequently, they were structurally incomplete or grammatically incorrect, despite passing as valid through CoreNLP and our initial coreference heuristics. In general, our coreference heuristics filter strongly: over all Winograd instances, they filter a total of 50,110 retrieved sentences down to only 3,097 (0.0617 acceptance rate). As for the 63 cases of sufficient evidence sentences that were labelled incorrectly, the issue was either errors in the coreference information from the CoreNLP pipeline or errors in our heuristics for reasoning about the coreference information. We show examples of these various sources of error in supplementary Table S1. At any rate, the corrected labels (with the 110 insufficient evidence removed and the 63 cases corrected) did not result in a shift in any of the 40 coreference decisions.

In Table 5, we show a sample resolution that our system makes on a problem instance,[3] including some evidence that was retrieved and labelled automatically and the evidence strengths that led to the resolution. These examples reveal that, indeed, general knowledge of what is plausible appears in natural text. Our system successfully leverages this knowledge for common sense reasoning.

---

[3] We provide more examples in a supplementary file.

WSC Instance:	The man couldn't lift his son because he was so weak. Answer: the man (**Agent**)
Evidence and labels: (query terms in bold)	"However I **was so weak** that I **couldn't lift**" → **EA** "She **was so weak** she couldn't **lift**" → **EA** "I could not stand without falling immediately and I **was so weak** that I **couldn't lift**" → **EA** "It hurts to **lift** my leg and its kind of **weak**" → **EP**
Stats and resolution:	Agent evidence strength: 97 Patient evidence strength: 72 Number of scraped sentences: 109 Resolution: **Agent**

Table 5: Example Resolution for a WSC problem.

We also include an example evidence snippet that yields a "misleading" label. Generally, sources of misleading snippets include incomplete or imprecise query generation (e.g. in Table 5, querying only "lift" instead of "couldn't lift"), errors in the automatic parsing of sentences (e.g., in supplementary Table S1.1.b, "lift" is incorrectly labelled as a verb via the parse tree, despite being a noun), and insufficient filtering of noisy sentences that are not relevant to the problem instance or are incomplete (e.g. in supplementary Table S1.2.b, the sentence is incomplete and indicates a misleading resolution).

6 Generalization to COPA

To investigate the generality of our knowledge-hunting approach, we adapted it to the Choice of Plausible Alternatives (COPA). We evaluated our basic automatic models that did not use the semantic similarity filter for this check.

COPA has a slightly different form that necessitates some modifications. As an example,

(3) The climbers reached the peak of the mountain. What happened as a result?
   a. They encountered an avalanche.
   b. **They congratulated each other.**

During query generation, as before, the set C contains terms extracted from the context sentence. Instead of a single set Q as in the WSC, we generate two query sets Q_1 and Q_2, that contain terms extracted for the first and second candidate sentences. Because entities in the candidate sentences can contribute to the answer (unlike in the WSC), we modified the query generation rules to extract more than just predicates. Specifically, the extraction procedure uses the syntactic parse tree of the phrase to back-off from extracting the clause containing the subject and verb phrase, to only the verb phrase, to only the verbs or adjectives that are rooted in the verb phrase. For the running example, our system generates these three sets: C={"The climbers reached the peak", "reached the peak", "reached"}, Q_1={"They encountered an avalanche", "encountered an avalanche", "encountered"}, and Q_2={"They congratulated each other", "congratulated each other", "congratulated"}.

We query the web for sentences that contain terms in (C, Q_1) and (C, Q_2), with one added restriction: for problem instances in which the relation is *cause*, the system only extracts sentences in which $Term_C$ precedes $Term_{Q_1}$ or $Term_{Q_2}$; when the relation is *result* (as in our running example), $Term_C$ succeeds $Term_{Q_1}$ or $Term_{Q_2}$. As for the WSC, the final decision is determined from the evidence snippets according to their strengths.

	Dev	Test
Goodwin et al. (2012)	–	63.4
AGQS	64.0	65.1
Gordon et al. (2011)	62.8	65.4
AGQ	65.8	66.2[4]
Luo et al. (2016)	–	70.2
Sasaki et al. (2017)	–	**71.2**

Table 6: Model accuracy (%) on COPA.

We tuned the system's evidence-scoring heuristics on COPA's 500 validation instances. In Table 6, we compare our system's performance on the 500 test instances to previous work on the basis of precision (which in the full-coverage case equates to accuracy). Our simpler AGQ method achieves 66.2% accuracy, which is respectable, although not state-of-the-art. As indicated by the lower performance of AGQS, synonyms from WordNet did not improve performance on COPA. Without the semantic-similarity filtering, synonyms may add noise to the retrieved results. It has also been shown that multi-word expressions are prevalent and important for COPA (Sasaki et al., 2017), which we have not

---

[4] This precision can be inflated to 67.2 by randomly guessing on the 10 examples for which there were no search results.

specifically attempted to handle with our method. We believe that this is a promising direction of improvement for our approach in future work.

7 Conclusion

We developed a knowledge-hunting framework to tackle the Winograd Schema Challenge, a task that requires common-sense knowledge and reasoning. Our system involves a semantic representation schema and an antecedent selection process that acts on web-search results. We evaluated the performance of our framework on the original set of WSC instances, achieving F1-performance that significantly exceeded the previous state-of-the-art. A simple port of our approach to COPA suggests that it has the potential to generalize. In the future we will study how this commonsense reasoning technique can contribute to solving "edge cases" and difficult examples in more general coreference tasks.

Abstract

This paper addresses the problem of mapping natural language text to knowledge base entities. The mapping process is approached as a composition of a phrase or a sentence into a point in a multi-dimensional entity space obtained from a knowledge graph. The compositional model is an LSTM equipped with a dynamic disambiguation mechanism on the input word embeddings (a *Multi-Sense LSTM*), addressing polysemy issues. Further, the knowledge base space is prepared by collecting random walks from a graph enhanced with textual features, which act as a set of semantic bridges between text and knowledge base entities. The ideas of this work are demonstrated on large-scale text-to-entity mapping and entity classification tasks, with state of the art results.

1 Introduction

The task of associating a well-defined action, concept or piece of knowledge to a natural language utterance or text is a common problem in natural language processing and generic artificial intelligence (Tellex et al., 2011), and can emerge in many different forms. In NLP, the ability to code text into an entity of a knowledge graph finds applications in tasks such as question answering and information retrieval, or any task that involves some form of mapping a definition to a term (Hill et al., 2016; Rimell et al., 2016). Further, it can be invaluable in providing solutions to domain-specific challenges, for example medical concept normalisation (Limsopatham and Collier, 2016) and identification of adverse drug reactions (O'Connor et al., 2014).

This paper details a model for efficiently mapping unrestricted text at the level of phrases and sentences to the entities of a knowledge base (KB)—a task also referred to as text *grounding* or *normalisation*. The model aims at characterising short focused texts, such as definitions or tweets. Given a medical KB, for example, a tweet of the form "Can't sleep, too tired to think straight" would be mapped to the entity *Insomnia*, while in the context of a lexical ontology the definition "Device that detects planets" would be associated to the entity *Telescope*.

Note that such a task cannot be approached as standard classification, since the "classes" (entities) are usually in one-to-one correspondence with the available inputs. To address this we propose the use of a continuous vector space for embedding the entities of the KB graph, where text is projected by a neural network. We rely on the notion of distributional semantics, where a word is represented as a multi-dimensional vector obtained either by collecting co-occurrence statistics with a selected set of contexts or by directly optimising an objective function in a neural network-based architecture (Collobert and Weston, 2008). Interestingly, similar techniques can be used for the multi-dimensional representation of nodes in a KB graph; for example, by collecting random walks following the edges of a graph it is possible for one to construct an artificial "corpus", to which a distributional model applies in the usual way (Perozzi et al., 2014).

By exploiting this representational compatibility, we treat the process of text-to-entity mapping as a transformation from a textual vector space where words live, to a KB vector space created from a graph and populated by vectors representing entities. A sentence is coded as a sequence of word vectors, composed by a modified Long Short-Term Memory network (LSTM—Hochreiter and Schmidhuber, 1997) into a multi-dimensional point in the entity space. One of our aims is to specifically deal with lexical ambiguity and polysemy which can be an important factor

Brussels, Belgium, October 31 - November 4, 2018.

for the task at hand. To this end, each word is associated with a number of sense embeddings, and the LSTM is extended with an attentional disambiguation mechanism that dynamically selects and updates the right sense vector for each word given its context during training. We dub this formulation *Multi-Sense LSTM* (MS-LSTM).

An important issue is the provision of a set of reliable anchors; that is, points in one-to-one correspondence between the two representations that would enforce some degree of structural similarity between pieces of text and KB entities and thus make the mapping more efficient. We deal with this problem by extending the original KB graph with nodes corresponding to *textual features*, i.e. to words strongly associated to a specific entity and collected from various resources. A novel sampling strategy is detailed for incorporating these nodes to random walks, which are then fed to the skipgram model for producing an entity space. The results indicate that the textual nodes, being words *and* KB entities at the same time, do an extremely effective job in transforming the geometry of the entity space to the benefit of mapping the textual modality.

The proposed model is evaluated in three tasks: text-to-entity mapping on a dataset extracted from SNOMED CT[1], a medical knowledge base of 327,000 concepts; a reverse dictionary task based on WordNet (Miller, 1998), where the goal is to associate a multi-word definition to the correct lemma (Hill et al., 2016); and document classification on the Cora dataset (McCallum et al., 2000). The results demonstrate the effectiveness of our methods by improving the current state of the art.

2 Background

Aligning meaning between text and entities in a knowledge graph is a task traditionally based on heuristic methods exploiting text features such as string matching, word weighting, syntactic relations, or dictionary lookups (McCallum et al., 2005; Lu et al., 2011; O'Connor et al., 2014). Machine learning techniques have been also exploited in various forms, for example Leaman et al. (2013) use a pairwise learning-to-rank technique to learn the similarity between different terms, while Limsopatham and Collier (2015) apply statistical machine translation to "translate" social media text to domain-specific terminology. There is little work based on neural networks; the most relevant to us is a study by Hill et al. (2016), who tested a number of compositional neural architectures trained to approximate word embeddings on a reverse dictionary task. Compared to their work, this paper proposes the use of a distinct target space for representing ontological knowledge, where every entity in the graph lives.

The goal of a graph embedding method is to embed components of a knowledge graph into a low-dimensional space. One research direction focuses on the relations, i.e. the edges of the graph (Bordes et al., 2013; Socher et al., 2013; Xiao et al., 2016) and aims at tasks such as link prediction and KB completion. Such work is outside the scope of the current paper, the subject of which is the efficient low-dimensional representation of *entities* (nodes). In this line of research, a prevalent method involves the collection of a set of random walks, starting from each node in the graph (Perozzi et al., 2014; Grover and Leskovec, 2016). There is a direct analogy between such a set of random walks and a text corpus: each node corresponds to a word and the sequence of nodes visited during a random walk is analogous to a sentence. Thus, any distributional model that takes as input this artificial "corpus" can generate multi-dimensional representations of the nodes in the graph. Random walks have also been used for KB inference (Lao et al., 2011) with success.

While random walk-based methods are not the only way to construct graph spaces—alternatives include factorisation (Ahmed et al., 2013) and deep autoencoders (Wang et al., 2016)—they have been found very effective in capturing multiple aspects of the graph structure (Wang et al., 2017; Goyal and Ferrara, 2017). The current paper proposes a random walk generation strategy that improves and complements existing approaches.

The idea of using textual features to improve the entity vectors is not well explored, and most of the existing work focuses again on the representation of relations (Xie et al., 2016; Wang et al., 2014; Wang and Li, 2016) as opposed to entities. Closer to us is the work of Yamada et al. (2017) and Yang et al. (2015), with the latter to incorporate text features in the concept embeddings by exploiting matrix factorisation properties.

Representing the meaning of words using a number of sense vectors is an old and well-established idea in NLP—see for example (Schütze, 1998; Reisinger and Mooney, 2010; Neelakantan et al., 2014). However, most of the relevant research is evaluated on intrinsic tasks

---

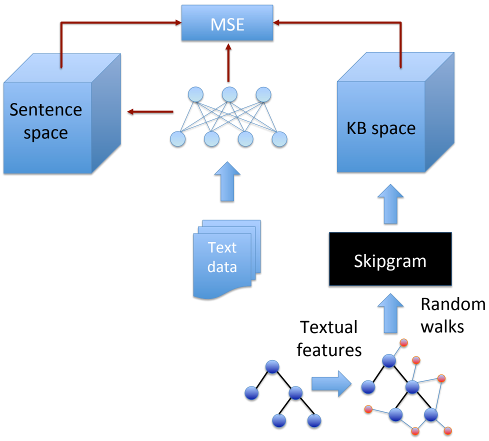

Figure 1: The text-to-entity mapping system in a nutshell. The red nodes indicate textual features, while “MSE” stands for mean squared error.

such as word similarity, while in the few works based in real end tasks, disambiguation is usually treated as a prior stand-alone step (Kartsaklis and Sadrzadeh, 2013; Li and Jurafsky, 2015; Pilehvar et al., 2017). The crucial difference of this work is that the ambiguity resolution mechanism is part of the compositional model itself, and the sense embeddings are trained simultaneously with the rest of the parameters. A close work is by Cheng and Kartsaklis (2015), who used a siamese network with an integrated disambiguation mechanism for paraphrase detection. For more information on multi-sense embeddings see (Camacho-Collados and Pilehvar, 2018).

3 Methodology

Fig. 1 provides a high-level illustration of our methodology, consisting of two stages: (1) the KB graph is extended with weighted textual features, and an artificial “corpus” of random walks is created and used as input to the skipgram model (Mikolov et al., 2013) for generating an enhanced KB space—this part is covered in §3.1; (2) the transformation from text to entities is performed by a supervised multi-sense compositional model, which generates a point in the KB space for every input text. This is achieved with an LSTM recurrent network, equipped with an attentional mechanism that provides a finer level of granularity to the different ways a word is used in the data—we detail this part in §3.2.

3.1 Textual features for entity vectors

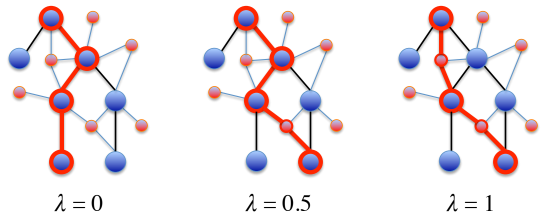
For our KB space, we follow the generic recipe proposed by Perozzi et al. (2014) and we assemble an artificial corpus of random walks from the KB graph, which is then used as input to the skipgram model (Mikolov et al., 2013). For a random walk of nodes $n_1 n_2 \ldots n_T$ and a context window size c, skipgram maximises the following quantity:

$$\frac{1}{T}\sum_{t=1}^{T}\sum_{-c\leq j\leq c, j\neq 0}\log p(n_{t+j}|n_t) \qquad (1)$$

i.e. for a target node n_t, the objective is to predict all other nodes in the same context. As a consequence, two vectors of the resulting space will be close if their corresponding nodes occur in topological proximity within the graph. However, while such a topology allows perhaps for meaningful comparisons between points in this space, it is not directly compatible with the task of mapping text to entities. The reason is that the communities formed in a KB graph (and thus the topology of the resulting vector space) mostly reflect domain-specific hierarchies and ontological relationships that are not necessarily evident by the textual representations referring to the entities. An important question therefore with regard to the proposed methodology is how to provide meaningful links between the two representations that would allow for the efficient translation of one form (text) to another (entities).

In this work, we address this problem by associating every node in the graph with a set of textual features, each one of which is weighted according to their importance with respect to the node. Our methodology is as follows: For each entity, we collect all available textual descriptions found in the knowledge base itself and the English portion of BabelNet (Navigli and Ponzetto, 2012), which is a very large dictionary integrating numerous resources, such as WordNet, Wikipedia, FrameNet and many others. The textual descriptions are treated as short documents, and each word in them is assigned a specific TF-IDF value, forming the set of textual features for the specific entity.

The KB graph is extended in the following way: Let T_c be the set of textual features for an entity c; then, for each t in T_c, we add an edge (c, t) with weight tf-idf$_c(t)$, where tf-idf$_c(t)$ is the TF-IDF value of t with respect to c. In contrast to Perozzi et al. (2014) who utilise a uniform node sampling strategy, we define the random walk generation process as follows: Given a randomly selected node n, let $C_n = \{c_1, c_2, \cdots c_N\}$ be the set of all entity nodes in its immediate vicinity, and $T_n = \{t_1, t_2, \cdots t_M\}$ the set of all textual features



$\lambda = 0$ $\lambda = 0.5$ $\lambda = 1$

Figure 2: Effect of λ parameter. Blue nodes indicate entities, red nodes textual features, and red paths refer to random walks. As λ increases, the probability of "hops" between originally unlinked nodes increases accordingly.

of n; the next node x in the path is drawn from a categorical distribution defined as below:

$$P_X(x) = \begin{cases} (1-\lambda)\dfrac{1}{N} & \text{if } x \in C_n \\ \lambda\dfrac{\text{tf-idf}_n(t_i)}{\sum_{j=1}^{M}\text{tf-idf}_n(t_j)} & \text{if } x \in T_n \end{cases} \tag{2}$$

for X a discrete random variable with range $C_n \cup T_n$. In the above, λ defines the proportion of the probability mass allocated to textual features, when both C_n and T_n are non-empty; if one of the sets is empty, all of the probability mass is allocated to the other set, and λ becomes irrelevant. Further, in contrast to what is the case for the textual nodes, the probabilities of the entity nodes in Equation 2 are defined uniformly, since we lack any mechanism for fine-tuning them in a way that objectively reflects the importance of the nodes.

It is instructive to examine how the above sampling strategy works. As expected, setting $\lambda = 0$ will result in a sampling process that ignores the textual features and produces a path comprised solely of entity nodes; this is equivalent to the original model by Perozzi et al. (2014), known as DeepWalk. On the other hand, the effect of setting $\lambda = 1$ is less intuitive: Recall that, by construction, each textual node is connected only to entity nodes; that is, when the current node is textual, the next node will be always sampled from C_n. Therefore, setting $\lambda = 1$ creates paths following an alternating pattern, where each entity node is followed by a textual node, which in turn is followed by an entity node. Values of λ between 0 and 1 scale this behaviour accordingly (Fig. 2).

Advantages. The introduction of textual features in the graph achieves two goals. Firstly, the textual nodes serve as links between entities which, although perhaps related to each other in some way, lie in different parts of the KB graph (e.g. being parts of different hierarchies). As a result, points that would normally be unjustifiably apart of each other in the vector space are now brought closer, providing additional coherence. This behaviour is controlled by the λ parameter, as Fig. 2 shows. Fig. 3 presents an illustrative example, taken from a real random walk on SNOMED CT.

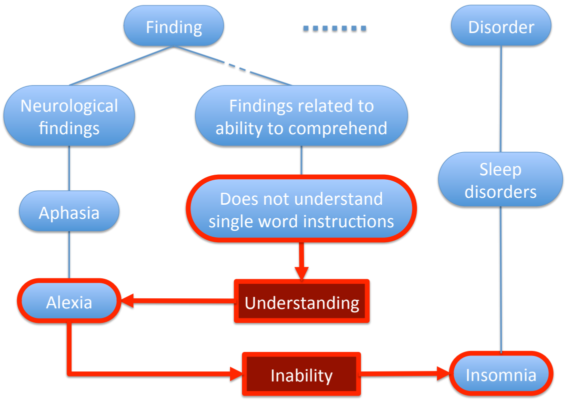


Figure 3: Linking of distant concepts with textual features (red boxes) for $\lambda = 1$. The textual feature *understanding* correctly links a related medical finding (lying on a different branch) to the condition known as *alexia*. Further, due to the presence of *inability* in their contexts, the vectors of *alexia* and *insomnia* (concepts originally quite far apart in the graph) will now have a common part reflecting that they are both conditions related to forms of incompetence.

The second advantage of introducing textual features in the graph is a consequence of the dual nature of these features in the context of learning: they essentially represent words, but since they are also nodes of the graph, they get vector representations exactly as every other normal entity in the knowledge base. The textual features, therefore, paired with their assigned vectors, form a set of *anchors* that links pieces of text with the KB space, and can be used to support the training process of the mapping system. In §4.1 we will see that this approach leads to substantial improvements in the accuracy of the model.

3.2 A multi-sense LSTM

We now proceed to present our neural architecture for text-to-entity mapping. The goal of the model is, given a certain piece of text, to produce a point in the KB space corresponding to an appropriate entity or concept. The model is trained on pairs of texts and entity vectors created from a graph extended with textual features, as discussed in §3.1.

Our architecture needs to explicitly take into account the fact that the task at hand is very sen-

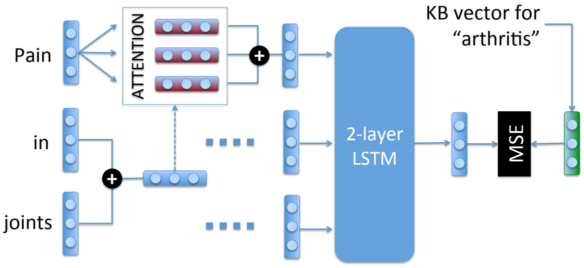

Figure 4: Detailed architecture of the Multi-Sense LSTM (MS-LSTM), shown here for the first word of a phrase. Red vectors refer to senses, while the green vector is a target vector.

sitive to lexical ambiguity. Specifically, while it is true that the level of homonymy (words having more than one disjoint meanings) is substantially decreased when we move from the generic domain to more specialised domains, on the other hand the increase in polysemy (words with many slightly different meanings) is exponential. As an example, while the lemma for the word "fever" in a dictionary usually contains two or three definitions, the term occurs in many dozens of different forms and contexts in SNOMED. Note that most of the different uses of the term correspond to distinct KB nodes, a fact that makes the job of a text-to-entity mapping system especially hard.[2] This motivates the employment of a dedicated mechanism that would handle the extra complexity imposed by the polysemous words.

The compositional setting of this paper, equipped with such a mechanism, is shown in Fig. 4. It consists of a generic word embedding layer, a word sense disambiguation layer, and two consecutive LSTM networks responsible for encoding the embeddings into a vector in the KB space. The objective is to minimise the mean squared error between the predicted vectors and the target vectors (prepared as in §3.1):

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N} \|y_i - f(x_i)\|^2 \qquad (3)$$

where N is the number of training examples, x the input text, y the target entity vector, and f the neural network.

To address the polysemy issues discussed above, every word is associated with a single generic embedding and k sense embeddings, where k is a fixed number. These sense embeddings can be seen as centroids of clusters denoting different uses of the word in the training set, and are dynamically updated during training. Specifically, for each word w_i in a training example, a context vector c_i is computed as the average of the *generic* vectors of all other words in the sentence. The probability of each sense vector s_{ij} given this context is then calculated via an attentional mechanism equipped with a softmax layer, as follows:

$$p(s_{ij}|c_i) = \frac{\exp\,(w_j'^{\intercal} s_{ij}')}{\sum_{l=1}^{k} \exp\,(w_l'^{\intercal} s_{il}')} \qquad (4)$$

where $s_{ij}' = \tanh(W s_{ij} + U c_i)$, and W, U and W' the parameters of the attentional network. Each sense vector is subsequently updated by addition of the context vector weighted by its similarity with the specific sense:

$$s_{ij}^{t+1} = s_{ij}^{t} + (s_{ij}^{t}{}^{\intercal} c_i^t) c_i^t \qquad (5)$$

The output of the attention is a weighted sum of the sense vectors given their probabilities (i.e. we apply *soft attention*), which is used as input to the compositional network—a 2-layer LSTM. The overall model is optimised on the MSE of the LSTM's output vector and the target entity vector. At inference time, a predicted vector $\hat{y}$ can be classified to the entity with the closest vectorial representation according to some metric.

4 Experiments

The ideas presented in the previous sections are evaluated on three tasks, two of which are related to text-to-entity mapping, and one to classification of KB entities. The purpose of the classification task (§4.3) is to provide a direct comparison of the textually enhanced vectors against vectors produced by the original graph, but *independently* of the compositional part. On the other hand, the text mapping experiments (§§4.1, 4.2) evaluate the overall architecture of Fig. 1 (including the compositional model and the dynamic disambiguation mechanism) on appropriate end tasks. Comparisons are provided with the most relevant previous work. Specifically, in all tasks, no inclusion of textual features corresponds to the standard DeepWalk model of Perozzi et al. (2014); in §4.2 our compositional architecture is compared to the work of Hill et al. (2016) in their reverse dictionary task; and §4.3 compares our method for textually enhancing the entity space with that of Yang et al. (2015), and other state-of-the-art deep models. The last subsection, §4.4, examines a few selected cases from a qualitative perspective.

---

[2] See also §4.4 for some concrete examples.

4.1 Text-to-entity mapping

We begin with a large scale text-to-entity mapping experiment. We construct a dataset of 21,000 medical concepts extracted from SNOMED CT, each of which is associated with a multi-word textual description, taken from the knowledge base or BabelNet. The criterion for including a concept in the dataset was the availability of at least one textual description with 4 or more words. The objective of the task is to associate each one of these descriptions to the correct concept. Given a predicted vector $\hat{v}$, we assemble a list of all candidate concept vectors ranked by their cosine similarity with $\hat{v}$. We compute strict accuracy (based on how many times the vector of the correct concept is at the top of the list) and accuracy on the first 20 elements of the list. Further, we also present results based on the mean reciprocal rank (MRR).

In all experiments, we create KB vectors of 150 dimensions by applying the skipgram objective on a set of random walks of length 20, and with window size of 5. The graph is extended with 102,500 textual nodes weighted by their TF-IDF values with regard to the corresponding entities and selected as described in §3.1 (textual features that occur in the testing set are not taken into account). Each node in the graph serves as the starting point of 10 random walks. For the compositional model, we use embeddings of 150 dimensions, and 200-dimensional hidden states. The attentional mechanism is implemented as a 2-layer MLP, with 50 units allocated to the hidden layer for each sense. The overall model contains two dropout layers for regularisation purposes, and is optimised with Adam (Kingma and Ba, 2015) ($\alpha = 0.001$, $\beta_1 = 0.9$, $\beta_2 = 0.999$).[3]

Following usual practice, we split our dataset in three parts: a training set (14,754 instances), a testing set (4,187 instances), and a development set (2,000 instances). We use the dev set to optimise the two main hyper-parameters of our model, namely the probability mass given to textual features (λ) and the number of senses for each word (k). The experiments on the dev set showed that increasing the probability mass for the inclusion of textual features in the random walks leads to consistently better performance for all tested models, so for the main experiment we set λ to its highest possible value, 1.00.[4] Further, a number of senses equal to 3 achieved the highest performance.

Model	Target space	MRR	Acc	Acc-20
Baseline 1	W2V-GoogleNews	0.25	0.19	0.41
Baseline 2	W2V-PubMed	0.17	0.12	0.31
Least squares	DeepWalk	0.19	0.10	0.49
	TF vectors	**0.49**	**0.37**	**0.79**
CCA	DeepWalk	0.36	0.24	0.70
	TF vectors	**0.71**	**0.60**	**0.94**
Standard LSTM (150 dim.)	DeepWalk	0.30	0.20	0.58
	TF vectors	**0.82**	**0.73**	**0.97**
Standard LSTM ($k \times 150$ dim.)	DeepWalk	0.33	0.23	0.59
	TF vectors	**0.86**	**0.80**	**0.97**
MS-LSTM	DeepWalk	0.36	0.26	0.60
	TF vectors	**0.89**	**0.84**	**0.98**
MS-LSTM + anchors	TF vectors	**0.94**	**0.90**	**1.00**

Table 1: Results for the SNOMED dataset. For the MS-LSTM we set $k = 3$, while *TF vectors* refers to our textually enhanced vectors ($\lambda = 1$). The difference between MS-LSTM and LSTM is s.s. with $p < 0.01$ according to a two-tailed z-test.

We compare our MS-LSTM with a number of baselines: In *Baselines 1* and *2* a vector for each textual description is computed as the average of pre-computed word vectors, and compared to concept vectors prepared in a similar way, i.e. by averaging pre-computed vectors for all words in the qualified name of the entities. We used two different word spaces, a standard Word2Vec space created from Google News[5] and a custom Word2Vec model trained on a corpus of 4B tokens from medical articles indexed in PubMed[6]. In *Least squares* and *CCA*, an averaged vector for each textual description is again computed as before, and a linear mapping is learned between the textual space and the KB space, using least squares and canonical correlation analysis (Hardoon et al., 2004).

In *Standard LSTM*, we use a configuration similar to that of Fig. 4, but *without* the multi-sense aspect; here, the word embeddings are just parameters of the model randomly initialised before training. Further, we also test a standard LSTM where the length of the single embeddings is k times bigger (k is the number of senses in the MS-LSTM), so that the overall dimensionality of embeddings in LSTM and MS-LSTM is the same.

The results are presented in Table 1. Each model is tested against two target KB spaces, one consisting of simple DeepWalk vectors[7] and one of textually enhanced vectors (TF vectors, $\lambda = 1$) according to the procedure of §3.1. There are three observations: (1) Using the enhanced vectors as a

---

[3] Python code will be released at https://github.com/cambridgeltl/SIPHS.

[4] Recall that this means half of the nodes in a random walk will be textual (see Fig. 2).

[5] https://code.google.com/archive/p/word2vec

[6] http://www.ncbi.nlm.nih.gov/pubmed/

[7] In our setting, this is equivalent to having $\lambda = 0$.

target space improves the performance of *all* tested models by a large margin; (2) the MS-LSTM configuration of Fig. 4 achieves the highest overall performance, showing that explicitly handling polysemy during the composition is beneficial for the task at hand; and (3) despite the equal dimensionality between the two models, the standard LSTM with the long embeddings presents performance inferior to that of the MS-LSTM.

The last row of the table presents results after extending the training dataset with the textual anchors, that is, all the textual features paired with their learned KB vectors, as described in the *Advantages* section in §3.1. Specifically, recall that each textual feature (a word or a two-word compound), being also a node in the graph, is associated with a vector according to the process of §3.1. It is possible for one then to use these (*textual feature*, *vector*) pairs as additional examples during the training of the MS-LSTM. The last row of Table 1 shows the results after extending the training set with the 102,500 textual features. This setting achieves the highest performance, increasing further the strict accuracy by 6%, to 0.90.

4.2 Reverse dictionary

We proceed to the reverse dictionary task of Hill et al. (2016), the goal of which is to return a candidate term given a definition. Many forms of this task have been proposed in the past, see for example (Kartsaklis et al., 2012; Turney, 2014; Rimell et al., 2016). In (Hill et al., 2016), the authors test a number of supervised models under two evaluation modes: (1) "seen", in which the testing instances are also included in the training set; and (2) "unseen", where the evaluation is done on a held-out set. In both cases the datasets consisted of 500 term-definition pairs from WordNet.

We treat WordNet as a graph, the edges of which are defined by the various relationships between the synsets. This graph is further extended with 96,734 textual nodes extracted from the synset descriptions. We compute synset vectors of 150 dimensions, on random walks of length 20 and with window size of 5. For the seen evaluation, we train the compositional model on the totality of WordNet 3.0 synsets (117,659) and their descriptions. For the unseen evaluation, we remove from the graph any textual features occurring in the testing part, and create a new set of synset vectors; further, any testing instance is removed from the training set of the compositional model. The evaluation is done by comparing the predicted vector with the vectors of all WordNet synsets (a search space of 117,659 points) and creating a ranked list as before, by cosine similarity. Following (Hill et al., 2016), we compute accuracy on top-10 and top-100. λ and k are tuned on a dev set of 2,000 synsets, showing a behaviour very similar to that of the SNOMED task.

Model	Acc-10	Acc-100
Seen (500 WordNet definitions)		
OneLook (Hill et al., 2016)	0.89	0.91
RNN cosine (Hill et al., 2016)	0.48	0.73
Std LSTM (150 dim.) + TF vec.	0.86	0.96
Std LSTM ($k \times 150$ dim.) + TF vec.	0.93	0.98
MS-LSTM +TF vectors	**0.95**	**0.99**
MS-LSTM +TF vectors + anchors	**0.96**	**0.99**
Unseen (500 WordNet definitions)		
RNN w2v cosine (Hill et al., 2016)	0.44	0.69
BOW w2v cosine (Hill et al., 2016)	0.46	0.71
Std LSTM (150 dim.) + TF vec.	0.72	0.88
Std LSTM ($k \times 150$ dim.) + TF vec.	0.77	0.90
MS-LSTM + TF vectors	**0.79**	**0.90**
MS-LSTM + TF vectors + anchors	**0.80**	**0.91**

Table 2: Results for the reverse dictionary task, compared with the highest numbers reported by Hill et al. (2016). *TF vectors* refers to textually enhanced vectors with $\lambda = 1$. For the MS-LSTM, k is set to 3.

Table 2 shows the results, based on a MS-LSTM setup similar to that of §4.1. Note that the MS-LSTM achieves 0.95-0.96 top-10 accuracy for the seen evaluation, significantly higher not only than the best model of Hill et al. (2016), but also higher than OneLook, a commercial system with access to more than 1000 dictionaries. It also presents considerably higher performance in the unseen evaluation. We are not aware of any other models with higher performance on the specific task.

4.3 Document classification

Our last experiment is a document classification task, performed on Cora (McCallum et al., 2000), a dataset containing 2708 machine learning papers linked by citation relationships into a graph. Each document is a short text extracted from the title or the abstract of the paper. The task is to predict the category of a document (a total of 7 classes), given its vector—so here we only evaluate the textually enhanced vectors as inputs to a classifier, independently of the compositional part.

In Table 3 we report results for two evaluation settings. In Evaluation 1, we provide a comparison with the method of Yang et al. (2015) who include textual features in graph embeddings based on matrix factorisation, and two topic models used as baselines in their paper. Using the same clas-

Model	Accuracy
Evaluation 1 (training ratio=0.50)	
PLSA (Hofmann, 1999)	0.68
NetPLSA (Mei et al., 2008)	0.85
TADW (Yang et al., 2015)	0.87
Linear SVM + DeepWalk vectors	0.85
Linear SVM + TF vectors	**0.88**
Evaluation 2 (training ratio=0.05)	
Planetoid (Yang et al., 2016)	0.76
GCN (Kipf and Welling, 2017)	0.81
GAT (Veličković et al., 2018)	**0.83**
Linear SVM + DeepWalk vectors	0.72
Linear SVM + TF vectors	**0.82**

Table 3: Results for the Cora dataset. *TF vectors* refers to textually enhanced KB vectors ($\lambda = 0.5$). Difference between our best models and GAT/GCN/TADW are *not* s.s.

sification algorithm (a linear SVM) and training ratio (0.50) with them, we present state-of-the-art results for vectors of 150 dimensions, prepared by a graph extended with 1422 textual features. We set $\lambda = 0.5$ by tuning on a dev set of 677 randomly selected entries from the training data.[8]

In Evaluation 2, using the same linear SVM classifier and λ as before, we reduce the training ratio to 0.05 in order to make our task comparable to the experiments reported by Veličković et al. (2018) for a number of deep learning models: specifically, the graph attention network (GAT) of Veličković et al. (2018), the graph convolutional network (GCN) of Kipf and Welling (2017), and the Planetoid model of Yang et al. (2016). Again, our simple setting presents results within the state of the art range, comparable to (or better than) those of much more sophisticated models that have been specifically designed for the task of node classification. We consider this as a strong indication for the effectiveness of the textually enhanced vectors as representations of KB entities.

Fig. 5 provides a visualisation of the Cora classes based on node vectors created with $\lambda = 0$ and $\lambda = 0.5$, correspondingly, demonstrating the impact of textual features in terms of cluster coherence and separation.

4.4 Qualitative evaluation

Table 4 compares the performance of the multi-sense approach with that of the single-sense model for a number of selected cases of text mapping. The predictions in the top part (for definitions taken from the unseen evaluation of the reverse dictionary task) show that, in contrast to the single-sense model, the multi-sense approach was able to capture subtle variations of meaning between different synsets due to polysemy, as motivated in §3.2. The lower part of the table contains short phrases with ambiguous words, specifically selected to demonstrate the effect of the multi-sense approach. In all these cases, the multi-sense model was able to effectively disambiguate the ambiguous parts of the phrase by using the available context, and predict a very relevant synset; in contrast, the predictions of the single-sense model were based on choosing a wrong sense.

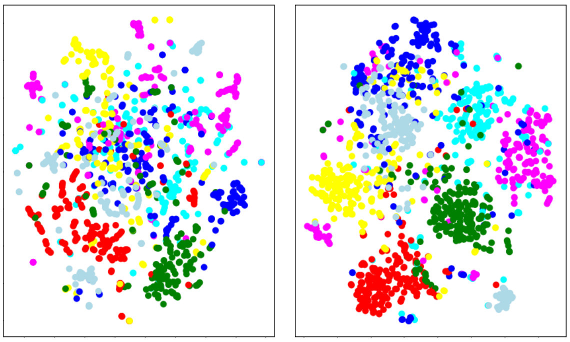

Figure 5: Visualisation of the Cora classes based on a 2D t-SNE projection of the node vectors before the inclusion of textual features (left) and after (right).

Finally, Table 5 presents the derived senses for word *table*, expressed as lists of nearest neighbouring words in the space. The model was able to effectively distinguish between a table as a kitchen furniture (sense 2), and a table as a structured way of presenting data (senses 1 and 3).

5 Discussion

The experimental work shows that using a graph embedding space as a target for mapping text to entities is an effective approach. This was mostly evident in the reverse dictionary task of §4.2, where the model was found to perform substantially better than previous approaches by Hill et al. (2016), who used a compositional architecture similar to ours but optimised on the *word* embeddings of the target terms. Note that this is suboptimal in the sense that, unless specific measures are taken, a word embedding reflects ambiguous meaning; therefore, trying to associate a definition like "keyboard musical instrument with pipes" to the vector for word "organ" introduces a certain amount of noise in the model, since the definition will be partly associated with features related to

---

[8] We also attempted a second classification experiment on a dataset of 200k concepts extracted from SNOMED, observing a similar behaviour of λ (details are not reported due to space). This difference in the behaviour of λ between text-to-entity mapping and classification tasks is discussed in §5.

Definition from the unseen dataset of the reverse dictionary task	$k = 3$ (correct pred.)	$k = 1$ (wrong pred.)
the branch of engineering that deals with things smaller than 100 nm	nanotechnology	microelectronics
floor consisting of open space at the top of a house just below roof	loft	balcony
a board game for two players; pieces move according to dice throws	backgammon	checkers
an address of a religious nature	sermon	rogation

Example short phrase with ambiguous words	$k = 3$ prediction	$k = 1$ prediction
a rechargeable cell	nickel-cadmium battery	karyolysis (*biological process*)
a state capital	Curitiba (*Brazilian state capital*)	assert (*verb*)
the lap of a person	upper side of thighs	lapper (*garment*)
a band named Queen	band leader	neckband (*garment*)

Table 4: Qualitative comparison of a few selected cases for multi- and single-sense LSTMs.

Sense 1.	formulation, uncommonly, rauwolfia, cardiology, hypodermic, malleability, points, optic, dendrite, rubiaceae, nonparametric, meninges, deviation, anesthetics
Sense 2.	tableware, meal, expectation, heartily, kitchen, hum, eating, forestay, suitors, croupier, companionship, restaurant, dishes, candles, cup, tea
Sense 3.	reassigned, projective, ultracentrifuge, polemoniaceous, thyronine, assumptions, lymphocyte, atomic, difficulties, intracellular, virgil, elementary, cartesian

the "body part" sense of the word. In our model, homonymy issues are resolved by design: each point in the target space corresponds to a well-defined unambiguous concept or synset. Further, the attentional mechanism of Fig. 4 handles subtle variations of each distinct sense due to polysemy.

The effectiveness of the textual feature mechanism was demonstrated in every task we attempted, but to different extents. As our tuning on the dev sets showed, for tasks closer to text-to-entity mapping (§§4.1-4.2) the more the textual features in the random walks, the better the results were. However, the best performance on the classification task came by λ values between 0.50 and 0.75, i.e. by walks visiting more entity nodes than textual nodes. The reason is that entity classification is a task very sensitive to the topology of the KB graph, since entities belonging to a specific class are very likely to be located at the same sub-hierarchy, hence in topological proximity. On the other hand, one of the motivations for introducing textual features was exactly to broaden the context of a node by connecting distant parts of the graph (see Figures 2-3). So, while small amounts of textual features can be still useful for classification purposes, excessive use introduces unwanted noise in the model.

The dynamic disambiguation mechanism integrated in the compositional architecture improved further the performance of the model. This finding is consistent with previous work on simpler tensor-based models, which showed that applying some form of word sense disambiguation when composing word vectors can provide consistent improvements on end tasks such as sentence similarity and paraphrase detection (Kartsaklis and Sadrzadeh, 2013; Kartsaklis et al., 2013).

6 Conclusion and future work

We presented and evaluated a text-to-entity mapping system based on a continuous KB space enhanced with textual features and capable of handling polysemy. The reasonable next step will be to extend our methods for modelling the *relations* (edges) of a KB graph, which will allow applications in tasks such as link prediction and KB completion. Furthermore, having a mechanism that translates arbitrary text to points in a continuous space creates many opportunities for interesting research. For example, while the size of a knowledge base is finite, the space itself consists of infinite number of points, each one of which corresponds to a valid—yet not explicitly stated in the KB—entity of the same domain. The exciting question of how can we exploit this extra information—for instance in order to *enrich* the knowledge base with new data—constitutes one of our future directions.

Acknowledgments

The authors would like to thank Victor Prokhorov and Ehsan Shareghi for useful discussions on the paper, as well as the anonymous reviewers for their suggestions. The idea of a dynamic disambiguation mechanism embedded in a neural architecture originally appeared in (Cheng and Kartsaklis, 2015) as part of a generic multi-prototype embedding model. Kartsaklis and Collier acknowledge support by EPSRC grant EP/M005089/1; Pilehvar and Collier are supported by MRC grant No. MR/M025160/1. We are also grateful to NVIDIA Corporation for the donation of a Titan XP GPU.

Abstract

Concepts, which represent a group of different instances sharing common properties, are essential information in knowledge representation. Most conventional knowledge embedding methods encode both entities (concepts and instances) and relations as vectors in a low dimensional semantic space equally, ignoring the difference between concepts and instances. In this paper, we propose a novel knowledge graph embedding model named TransC by differentiating concepts and instances. Specifically, TransC encodes each concept in knowledge graph as a sphere and each instance as a vector in the same semantic space. We use the relative positions to model the relations between concepts and instances (i.e., `instanceOf`), and the relations between concepts and sub-concepts (i.e., `subClassOf`). We evaluate our model on both link prediction and triple classification tasks on the dataset based on YAGO. Experimental results show that TransC outperforms state-of-the-art methods, and captures the semantic transitivity for `instanceOf` and `subClassOf` relation. Our codes and datasets can be obtained from `https://github.com/davidlvxin/TransC`.

1 Introduction

Knowledge graphs (KGs) aim at semantically representing the world's truth in the form of machine-readable graphs composed of triple facts. Knowledge graph embedding encodes each element (entities and relations) in knowledge graph into a continuous low-dimensional vector space. The learned representations make the knowledge graph essentially computable and have been proved to be helpful for knowledge graph completion and information extraction (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015b; Ji et al., 2015, 2016).

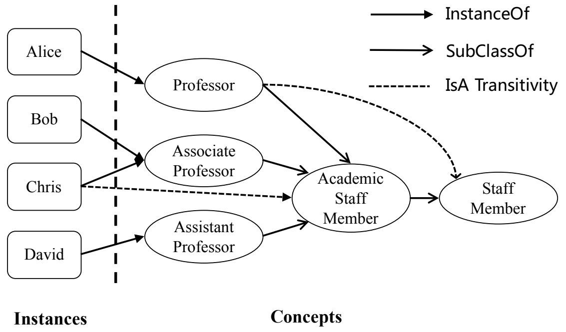

Figure 1: An example of concepts, instances, and isA transitivity.

In recent years, various knowledge graph embedding methods have been proposed, among which the translation-based models are simple and effective with good performances. Inspired by word2vec (Mikolov et al., 2013), given a triple (h, r, t), TransE learns vector embeddings $\mathbf{h}$, $\mathbf{r}$ and $\mathbf{t}$ which satisfy $\mathbf{r} \approx \mathbf{t} - \mathbf{h}$. Afterwards, TransH (Wang et al., 2014), TransR/CTransR (Lin et al., 2015b) and TransD (Ji et al., 2015), etc are proposed to address the problem of TransE when modeling 1-to-N, N-to-1, and N-to-N relations. As extensions of RESCAL(Nickel et al., 2011), which is a bilinear model, HolE(Nickel et al., 2016), DistMult(Yang et al., 2014) and ComplEx(Trouillon et al., 2016) achieve the state-of-the-art performances. Meanwhile, there are also some different methods using a variety of external information such as entity types (Xie et al., 2016), textual descriptions (Wang and Li, 2016), as well as logical rules to strengthen representations of knowledge graphs (Wang et al., 2015; Guo et al., 2016; Rocktäschel et al., 2015).

However, all these methods ignore to distinguish between concepts and instances, and regard both as entities to make a simplification. Actually, concepts and instances are organized differently in many real world datasets like YAGO (Suchanek

Brussels, Belgium, October 31 - November 4, 2018.

et al., 2007), Freebase (Bollacker et al., 2008), and WordNet (Miller, 1995). Hierarchical concepts in these knowledge bases provide a natural way to categorize and locate instances. Therefore, the common simplification in previous work will lead to the following two drawbacks:

Insufficient concept representation: Concepts are essential information in knowledge graph. A concept is a fundamental category of existence (Rosch, 1973) and can be reified by all of its actual or potential instances. Figure 1 presents an example of concepts and instances about university staffs. Most knowledge embedding methods encode both concepts and instances as vectors, cannot explicitly represent the difference between concepts and instances.

Lack transitivity of both isA relations: `instanceOf` and `subClassOf` (generally known as isA) are two special relations in knowledge graph. Different from most other relations, isA relations exhibit transitivity, e.g., the dotted lines in Figure 1 represent the facts inferred by isA transitivity. The indiscriminate vector representation for all relations in previous work cannot reserve this property well (see Section 5.3 for details).

To address these issues, we propose a novel translation embedding model named TransC in this paper. Inspired by (Tenenbaum et al., 2011), concepts in people's mind are organized hierarchically and instances should be close to concepts that they belong to. Hence in TransC, each concept is encoded as a sphere and each instance as a vector in the same semantic space, and relative positions are employed to model the relations between concepts and instances. More specifically, `instanceOf` relation is naturally represented by checking whether an instance vector is inside a concept sphere. For the `subClassOf` relation, we enumerate and quantify four possible relative positions between two concept spheres. We also define loss functions to measure the relative positions and optimize knowledge graph embeddings. Finally, we incorporate them into translation-based models to jointly learn the knowledge representations of concepts, instances and relations.

Experiments on real world datasets extracted from YAGO show that TransC outperforms previous work like TransE, TransD, HolE, DistMult and ComplEx in most cases. The contributions of this paper can be summarized as follows:

1. To the best of our knowledge, we are the first to propose and formalize the problem of knowledge graph embedding which differentiates between concepts and instances.

2. We propose a novel knowledge embedding method named TransC, which distinguishes between concepts and instances and deals with the transitivity of isA relations.

3. We construct a new dataset based on YAGO for evaluation. Experiments on link prediction and triple classification demonstrate that TransC successfully addresses the above problems and outperforms state-of-the-art methods.

2 Related Work

There are a variety of models for knowledge graph embedding. We divide them into three kinds and introduce them respectively.

2.1 Translation-based Models

TransE (Bordes et al., 2013) regards a relation $\mathbf{r}$ as a translation from $\mathbf{h}$ to $\mathbf{t}$ for a triple (h, r, t) in training set. The vector embeddings of this triple should satisfy $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. Hence, $\mathbf{t}$ should be the nearest neighbor of $\mathbf{h} + \mathbf{r}$, and the loss function is

$$f_r(h, t) = ||\mathbf{h} + \mathbf{r} - \mathbf{t}||_2^2. \qquad (1)$$

TransE is suitable for 1-to-1 relations, but it has problems when handling 1-to-N, N-to-1, and N-to-N relations.

TransH (Wang et al., 2014) attempts to alleviate the problems of TransE above. It regards a relation vector $\mathbf{r}$ as a translation on a hyperplane with $\mathbf{w}_r$ as the normal vector. The vector embeddings will be first projected to the hyperplane of relation r and get $\mathbf{h}_\perp = \mathbf{h} - \mathbf{w}_r^\top \mathbf{h} \mathbf{w}_r$ and $\mathbf{t}_\perp = \mathbf{t} - \mathbf{w}_r^\top \mathbf{t} \mathbf{w}_r$. The loss function of TransH is

$$f_r(h, t) = ||\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp||_2^2. \qquad (2)$$

TransR/CTransR (Lin et al., 2015b) addresses the issue in TransE and TransH that some entities are similar in the entity space but comparably different in other specific aspects. It sets a transfer matrix $\mathbf{M}_r$ for each relation r to map entity embedding to relation vector space. Its loss function is

$$f_r(h, t) = ||\mathbf{M}_r \mathbf{h} + \mathbf{r} - \mathbf{M}_r \mathbf{t}||_2^2. \qquad (3)$$

TransD (Ji et al., 2015) considers the different types of entities and relations at the same time. Each relation-entity pair (r, e) will have a mapping matrix $\mathbf{M}_{re}$ to map entity embedding into relation vector space. And the projected vectors could be defined as $\mathbf{h}_\perp = \mathbf{M}_{rh}\mathbf{h}$ and $\mathbf{t}_\perp = \mathbf{M}_{rt}\mathbf{t}$. The loss function of TransD is

$$f_r(h, t) = ||\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp||_2^2. \tag{4}$$

There are many other translation-based models in recent years. For example, TranSparse (Ji et al., 2016) simplifies TransR by enforcing the sparseness on the projection matrix, PTransE (Lin et al., 2015a) considers relation paths as translations between entities for representation learning, (Xiao et al., 2016a) proposes a manifold-based embedding principle (ManifoldE) for precise link prediction, TransF (Feng et al., 2016) regards relation as translation between head entity vector and tail entity vector with flexible magnitude, (Xiao et al., 2016b) proposes a new generative model TransG, and KG2E (He et al., 2015) uses Gaussian embedding to model the data uncertainty. All these models can be seen in (Wang et al.).

2.2 Bilinear Models

RESCAL(Nickel et al., 2011) is the first bilinear model. It associates each entity with a vector to capture its latent semantics. Each relation is represented as a matrix which models pairwise interactions between latent factors.

Many extensions of RESCAL have been proposed by restricting bilinear functions in recent years. For example, DistMult (Yang et al., 2014) simplifies RESCAL by restricting the matrices representing relations to diagonal matrices. HolE(Nickel et al., 2016) combines the expressive power of RESCAL with the efficiency and simplicity of DistMult. It represents both entities and relations as vectors in $\mathbb{R}^d$. ComplEx(Trouillon et al., 2016) extends DistMult by introducing complex-valued embeddings so as to better model asymmetric relations.

2.3 External Information Learning Models

External information like textual information is significant for knowledge representation. TEKE (Wang and Li, 2016) uses external context information in a text corpus to represent both entities and words into a joint vector space with alignment models. DKRL (Xie et al., 2016) directly learns entity representations from entity descriptions. (Wang et al., 2015; Guo et al., 2016; Rocktäschel et al., 2015) use logical rules to strengthen representations of knowledge graphs.

All models above do not differentiate between concepts and instances. To the best of our knowledge, our proposed TransC is the first attempt which represents concepts, instances, and relations differently in the same space.

3 Problem Formulation

In this section, we formulate the problem of knowledge graph embedding with concepts and instances. Before that, we first introduce the input knowledge graph.

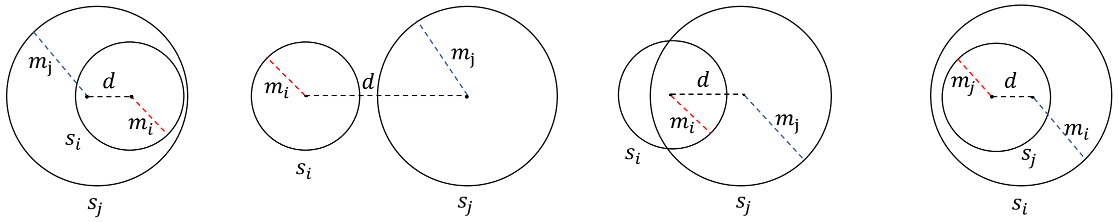
Knowledge Graph $\mathcal{KG}$ describes concepts, instances, and the relations between them. It can be formalized as $\mathcal{KG} = \{\mathcal{C}, \mathcal{I}, \mathcal{R}, \mathcal{S}\}$. $\mathcal{C}$ and $\mathcal{I}$ denote the sets of concepts and instances respectively. Relation set $\mathcal{R}$ can be formalized as $\mathcal{R} = \{r_e, r_c\} \cup \mathcal{R}_l$, where r_e is an `instanceOf` relation, r_c is a `subClassOf` relation, and $\mathcal{R}_l$ is the instance relation set. Therefore, the triple set $\mathcal{S}$ can be divided into three disjoint subsets:

1. `InstanceOf` triple set $\mathcal{S}_e = \{(i, r_e, c)_k\}_{k=1}^{n_e}$, where $i \in \mathcal{I}$ is an instance, $c \in \mathcal{C}$ is a concept, and n_e is the size of $\mathcal{S}_e$.

2. `SubClassOf` triple set $\mathcal{S}_c = \{(c_i, r_c, c_j)_k\}_{k=1}^{n_c}$, where $c_i, c_j \in \mathcal{C}$ are concepts, c_i is a sub-concept of c_j, and n_c is the size of $\mathcal{S}_c$.

3. Relational triple set $\mathcal{S}_l = \{(h, r, t)_k\}_{k=1}^{n_l}$, where $h, r \in \mathcal{I}$ are head instance and tail instance, $r \in \mathcal{R}_l$ is an instance relation, and n_l is the size of $\mathcal{S}_l$.

Given knowledge graph $\mathcal{KG}$, **knowledge graph embedding with concepts and instances** aims at learning embeddings for instances, concepts, and relations in the same space $\mathbb{R}^k$. For each concept $c \in \mathcal{C}$, we learn a sphere $s(\mathbf{p}, m)$ with $\mathbf{p} \in \mathbb{R}^k$ and m denoting the sphere center and radius. For each instance $i \in \mathcal{I}$ and instance relation $r \in \mathcal{R}_l$, we learn a low-dimensional vector $\mathbf{i} \in \mathbb{R}^k$ and $\mathbf{r} \in \mathbb{R}^k$ respectively. Specifically, the `instanceOf` and `subClassOf` representations are well-designed so that the transitivity of isA relations can be reserved, namely, `instanceOf-subClassOf`



(a) $d < |m_i - m_j| \wedge m_i < m_j$ (GOAL) (b) $d \geq |m_i + m_j|$ (c) $|m_i - m_j| \leq d < |m_i + m_j|$ (d) $d < |m_i - m_j| \wedge m_i \geq m_j$

Figure 2: Four relative positions between sphere s_i and s_j.

transitivity shown in Equation 5:

$$(i, r_e, c_1) \in S_e \wedge (c_1, r_c, c_2) \in S_c \rightarrow (i, r_e, c_2) \in S_e, \quad (5)$$

and `subClassOf-subClassOf` transitivity shown in Equation 6:

$$(c_1, r_c, c_2) \in S_c \wedge (c_2, r_c, c_3) \in S_c \rightarrow (c_1, r_c, c_3) \in S_c. \quad (6)$$

Based on the definition, how to model concepts and isA relations is critical to solve this problem.

4 Our Approach

To differentiate between concepts and instances for knowledge graph embedding, we propose a novel method named TransC. We define different loss functions to measure the relative positions in embedding space, and then jointly learn the representations of concepts, instances, and relations based on the translation-based models.

4.1 TransC

We have three kinds of triples in our triple set $\mathcal{S}$ and define different loss function for them respectively.

InstanceOf Triple Representation. For a given `instanceOf` triple (i, r_e, c), if it is a true triple, $\mathbf{i}$ should be inside the sphere s to represent the `instanceOf` relation between them. Actually, there is another relative position that $\mathbf{i}$ is outside the sphere s. In this condition, the embeddings still need to be optimized. The loss function is defined as

$$f_e(i, c) = ||\mathbf{i} - \mathbf{p}||_2 - m. \quad (7)$$

SubClassOf Triple Representation. For a `subClassOf` triple (c_i, r_c, c_j), just like before, concepts c_i, c_j are encoded as spheres $s_i(\mathbf{p}_i, m_i)$ and $s_j(\mathbf{p}_j, m_j)$. We first denote the distance between the centers of the two spheres as

$$d = ||\mathbf{p}_i - \mathbf{p}_j||_2. \quad (8)$$

If (c_i, r_c, c_j) is a true triple, sphere s_i should be inside sphere s_j (Figure 2a) to represent the `subClassOf` relation between them. Actually, there are three other relative positions between sphere s_i and s_j (as shown in Figure 2). We also have three loss functions under these three conditions:

1. s_i is separate from s_j (Figure 2b). The embeddings still need to be optimized. In this condition, the two spheres need to get closer in optimalization. Therefore, the loss function is defined as

$$f_c(c_i, c_j) = ||\mathbf{p}_i - \mathbf{p}_j||_2 + m_i - m_j. \quad (9)$$

2. s_i intersects with s_j (Figure 2c). This condition is similar to condition 1. The loss function is defined as

$$f_c(c_i, c_j) = ||\mathbf{p}_i - \mathbf{p}_j||_2 + m_i - m_j. \quad (10)$$

3. s_j is inside s_i (Figure 2d). It is different from our target and we should reduce m_j and increase m_i. Hence, the loss function is

$$f_c(c_i, c_j) = m_i - m_j. \quad (11)$$

Relational Triple Representation. For a relational triple (h, r, t), TransC will learn low-dimensional vectors $\mathbf{h}, \mathbf{t}, \mathbf{r} \in \mathbb{R}^k$ for instances and relations. Just like TransE (Bordes et al., 2013), the loss function of this kind of triples is defined as

$$f_r(h, t) = ||\mathbf{h} + \mathbf{r} - \mathbf{t}||_2^2. \quad (12)$$

After having embeddings above, TransC can easily deal with the transitivity of isA relations. If we have true triples (i, r_e, c_i) and (c_i, r_c, c_j), which means $\mathbf{i}$ is inside the sphere s_i and s_i is inside s_j, we can get a result that $\mathbf{i}$ is also inside the sphere s_j. It can be concluded that (i, r_e, c_j) is a true triple and TransC can handle `instanceOf`-`subClassOf` transitivity. Similarly, if we have true triples (c_i, r_c, c_j) and (c_j, r_c, c_k), we can get a result that sphere s_i is inside sphere s_k. It means (c_i, r_e, c_k) is a true triple and TransC can deal with `subClassOf`-`subClassOf` transitivity.

In experiments, we enforce constrains as $||\mathbf{h}||_2 \leq 1$, $||\mathbf{r}||_2 \leq 1$, $||\mathbf{t}||_2 \leq 1$ and $||\mathbf{p}||_2 \leq 1$.

4.2 Training Method

For `instanceOf` triples, we use ξ and ξ' to denote a positive triple and a negative triple. $\mathcal{S}_e$ and $\mathcal{S}'_e$ are used to describe the positive triple set and negative triple set. Then we can define a margin-based ranking loss for `instanceOf` triples:

$$\mathcal{L}_e = \sum_{\xi \in \mathcal{S}_e} \sum_{\xi' \in \mathcal{S}'_e} [\gamma_e + f_e(\xi) - f_e(\xi')]_+, \tag{13}$$

where $[x]_+ \triangleq \max(0, x)$ and γ_e is the margin separating positive triplets and negative triplets. Similarly, for `subClassOf` triples, we will have a ranking loss:

$$\mathcal{L}_c = \sum_{\xi \in \mathcal{S}_c} \sum_{\xi' \in \mathcal{S}'_c} [\gamma_c + f_c(\xi) - f_c(\xi')]_+, \tag{14}$$

and for relational triples, we will have a ranking loss:

$$\mathcal{L}_l = \sum_{\xi \in \mathcal{S}_l} \sum_{\xi' \in \mathcal{S}'_l} [\gamma_l + f_r(\xi) - f_r(\xi')]_+. \tag{15}$$

Finally, we define the overall loss function as linear combinations of these three functions:

$$\mathcal{L} = \mathcal{L}_e + \mathcal{L}_c + \mathcal{L}_l. \tag{16}$$

The goal of training TransC is to minimize the above function, and iteratively update embeddings of concepts, instances, and concepts.

Every triple in our training set has a label to indicate whether the triple is positive or negative. But existing knowledge graph only contains positive triples. We need to generate negative triples by corrupting positive triples. For a relational triple (h, r, t), we replace h or t to generate a negative triple (h', r, t) or (h, r, t'). For example, we get h' by randomly picking from a set $\mathcal{M}_t = \mathcal{M}_1 \cup \mathcal{M}_2 \cup \cdots \cup \mathcal{M}_n$, where n is the number of concepts that t belongs to and $\mathcal{M}_i = \{a | a \in \mathcal{I} \wedge (a, r_e, c_i) \in \mathcal{S}_e \wedge (t, r_e, c_i) \in \mathcal{S}_e \wedge t \neq a\}$. For the other two kinds of triples, we follow the same policy to generate negative triples. We also use two strategies "unif" and "bern" described in (Wang et al., 2014) to replace instances or concepts.

Table 1: Statistics of YAGO39K and M-YAGO39K.

5 Experiments and Analysis

We evaluate our method on two typical tasks commonly used in knowledge graph embedding: link prediction (Bordes et al., 2013) and triple classification (Socher et al., 2013).

5.1 Datasets

Most previous work used FB15K and WN18 (Bordes et al., 2013) for evaluation. But these two datasets are not suitable for our model because FB15K mainly consists of instances and WN18 mainly contains concepts. Therefore, we use another popular knowledge graph YAGO (Suchanek et al., 2007) for evaluation, which contains a lot of concepts from WordNet and instances from Wikipedia. We construct a subset of YAGO named YAGO39K for evaluation through the following steps:

(1) We randomly select some relational triples like (h, r, t) from the whole YAGO dataset as our relational triple set $\mathcal{S}_l$.

(2) For every instance and instance relation existed in our relational triples, we save it to construct instance set $\mathcal{I}$ and instance relation set $\mathcal{R}_l$ respectively.

(3) For every `instanceOf` triple (i, r_e, c) in YAGO, if $i \in \mathcal{I}$, we save this triple to construct `instanceOf` triple set $\mathcal{S}_e$.

(4) For every concept existed in `instanceOf` triple set $\mathcal{S}_e$, we save it to construct concept set $\mathcal{C}$.

(5) For every `subClassOf` triple (c_i, r_c, c_j) in YAGO, if $c_i \in \mathcal{C} \wedge c_j \in \mathcal{C}$, we save this triple to construct `subClassOf` triple set $\mathcal{S}_c$.

(6) Finally, we achieve our triple set $\mathcal{S} = \mathcal{S}_e \cup \mathcal{S}_c \cup \mathcal{S}_l$ and our relation set $\mathcal{R} = \{r_e, r_c\} \cup \mathcal{R}_l$.

To evaluate every model's performance in handling the transitivity of isA relations, we generate some new triples based on YAGO39K using the transitivity of isA relations. These new triples will

Table 2: Experimental results on link prediction and triple classification for relational triples. Hits@N uses results of "Filter" evaluation setting.

be added to valid and test datasets of YAGO39K to create a new dataset named M-YAGO39K. Specific steps are described as follows:

(1) For every `instanceOf` triple (i, r_e, c) in valid and test dataset, if (c, r_c, c_j) exists in training dataset, we save a new `instanceOf` triple (i, r_e, c_j).

(2) For every `subClassOf` triple (c_i, r_c, c_j) in valid and test dataset, if (c_j, r_c, c_k) exists in training dataset, we save a new `subClassOf` triple (c_i, r_c, c_k).

(3) We add these new triples to valid and test dataset of YAGO39K to get M-YAGO39K.

The statistics of YAGO39K and M-YAGO39K are shown in Table 1.

5.2 Link Prediction

Link Prediction aims to predict the missing h or t for a relational triple (h, r, t). In this task, we need to give a ranking list of candidate instances from the knowledge graph, instead of only giving one best result.

For every test relational triple (h, r, t), we remove the head or tail instance and replace it with all instances existed in knowledge graph, and rank these instances in ascending order of distances calculated by loss function f_r. Just like (Bordes et al., 2013), we use two evaluation metrics in this task: (1) the mean reciprocal rank of all correct instances (MRR) and (2) the proportion of correct instances that rank no larger than N (Hits@N). A good embedding model should achieve a high MRR and a high Hits@N. We note that a corrupted triple may also exist in knowledge graph, which should also be regarded as a correct prediction. However, the above evaluations do not handle this issue and may underestimate the results. Hence, we filter out every triple appeared in our knowledge graph before getting the ranking list. The first evaluation setting is called "Raw" and the second one is called "Filter." We report the experiment results on both settings.

In this task, we use dataset YAGO39K for evaluation. We select learning rate λ for SGD among {0.1, 0.01, 0.001}, the three margins γ_l, γ_e and γ_c among {0.1, 0.3, 0.5, 1, 2}, the dimension of instance vectors and relation vectors n among {20, 50, 100}. The best configurations are determined according to the Hits@10 in valid set. The optimal configurations are: $\gamma_l = 1$, $\gamma_e = 0.1$, $\gamma_c = 1$, $\lambda = 0.001$, $n = 100$ and taking L_2 as dissimilarity. We train every model for 1000 rounds in this task.

Evaluation results on YAGO39K are shown in Table 2. From the table, we can conclude that: (1) TransC significantly outperforms other models in terms of Hits@N. This indicates that TransC can use isA triples' information better than other models, which is helpful for instance representation learning. (2) TransC performs a little bit worse than DistMult in some settings. The reason may be that we determine the best configurations only according to the Hits@10, which may lead to a low MRR. (3) The "bern" sampling trick works well for TransC.

5.3 Triple Classification

Triple Classification aims to judge whether a given triple is correct or not, which is a binary classification task. This triple can be a relational triple, an `instanceOf` triple or a `subClassOf` triple.

Negative triples are needed for evaluation of binary classification. Hence, we construct some negative triples following the same setting in (Socher et al., 2013). There are as many true triples as negative triples in both valid and test set.

For triple classification, we set a threshold δ_r for every relation r. For a given test triple, if its

Table 4: Experimental results on `subClassOf` triple classification(%).

loss function is smaller than δ_r, it will be classified as positive, otherwise negative. δ_r is obtained by maximizing the classification accuracy on valid set.

In this task, we use dataset YAGO39K and M-YAGO39K for evaluation. Parameters are selected in the same way as in link prediction. The best configurations are determined by accuracy in valid set. The optimal configurations for YAGO39K are: $\gamma_l = 1$, $\gamma_e = 0.1$, $\gamma_c = 0.1$, $\lambda = 0.001$, $n = 100$ and taking L_2 as dissimilarity. The optimal configurations for M-YAGO39K are: $\gamma_l = 1$, $\gamma_e = 0.1$, $\gamma_c = 0.3$, $\lambda = 0.001$, $n = 100$ and taking L_2 as dissimilarity. For both datasets, we traverse all the training triples for 1000 rounds.

Our datasets have three kinds of triples. Hence, we do experiments on them respectively. Experimental results for relational triples, `instanceOf` triples, and `subClassOf` triples are shown in Table 2, Table 3, and Table 4 respectively. In Table 3 and Table 4, a rising arrow means performance of this model have a promotion from YAGO39K to M-YAGO39K and a down arrow means a drop.

From Table 2, we can learn that: (1) TransC outperforms all previous work in relational triple classification. (2) The "bern" sampling trick works better than "unif" in TransC.

From Table 3 and Table 4, we can conclude that: (1) On YAGO39K, some compared models perform better than TransC in `instanceOf` triple classification. This is because that `instanceOf` has most triples (53.5%) among all relations in YAGO39K. This relation is trained superabundant times and nearly achieves the best performance, which has an adverse effect on other triples. TransC can find a balance between them and all triples achieve a good performance. (2) On YAGO39K, TransC outperforms other models in `subClassOf` triple classification. As shown in Table 1, `subClassOf` triples are much less than `instanceOf` triples. Hence, other models can not achieve the best performance under the bad influence of `instanceOf` triples. (3) On M-YAGO39K, TransC outperforms previous work in both `instanceOf` triple classification and `subClassOf` triple classification, which indicates that TransC can handle the transitivity of isA relations much better than other models. (4) After comparing experimental results in YAGO39K and M-YAGO39K, we can find that most previous work's performance suffers a big drop in `instanceOf` triple classification and a small drop in `subClassOf` triple classification. This shows that previous work can not deal with `instanceOf-subClassOf` transitivity well. (5) In TransC, nearly all performances have a significant promotion from YAGO39K to M-YAGO39K. Both `instanceOf-subClassOf` transitivity and `subClassOf-subClassOf` transitivity are solved well in TransC.

5.4 Case Study

We have shown that TransC have a good performance for knowledge graph embedding and dealing with transitivity of isA relations. In this section, we present an example of finding new `instanceOf` triples and `subClassOf` triples using results of TransC.

As shown in Figure 3, *New York City* is an instance and others are concepts. The solid lines represent the triples from our datasets and the dotted lines represent the facts inferred by our model. TransC can find two new `instanceOf` triples (*New York City*, `instanceOf`, *City*) and (*New York City*, `instanceOf`, *Municipality*). It can also find a new `subClassOf` triple (*Port Cities*, `subClassOf`, *City*). Following the transitivity of isA relations, we can know all these three new triples are right. Unfortunately, most previous work regards these three triples as wrong, which means they can not handle transitivity of isA relations well.

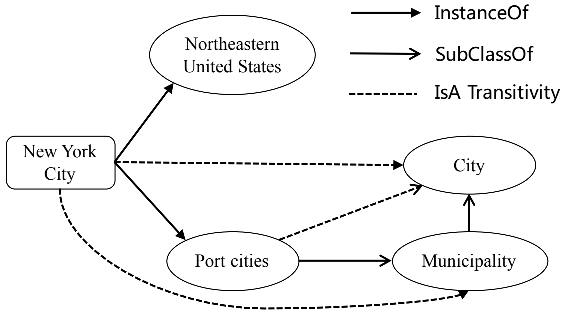

Figure 3: An inference example of TransC.

6 Conclusion and Future Work

In this paper, we propose a new knowledge embedding model named TransC. TransC embeds instances, concepts, and relations in the same space to deal with the transitivity of isA relations. We create a new dataset YAGO39K for evaluation. Experiment results show that TransC outperforms previous translation-based models in most cases. Besides, It can also handle the transitivity of isA relations much better than other models. In our future work, we will explore the following research directions: (1) Sphere is a simple model to represent a concept in semantic space, but it still have some limits since it is too naive. we will try to find a more expressive model instead of spheres to represent concepts. (2) A concept may have different meanings in different triples. We will try to use several typical vectors of instances as a concept's centers to represent different meanings of a concept. Then a concept can have different embeddings in different triples.

Abstract

Knowledge graphs (KGs) are the key components of various natural language processing applications. To further expand KGs' coverage, previous studies on knowledge graph completion usually require a large number of training instances for each relation. However, we observe that long-tail relations are actually more common in KGs and those newly added relations often do not have many known triples for training. In this work, we aim at predicting new facts under a challenging setting where only one training instance is available. We propose a one-shot relational learning framework, which utilizes the knowledge extracted by embedding models and learns a matching metric by considering both the learned embeddings and one-hop graph structures. Empirically, our model yields considerable performance improvements over existing embedding models, and also eliminates the need of re-training the embedding models when dealing with newly added relations.[1]

1 Introduction

Large-scale knowledge graphs (Suchanek et al., 2007; Vrandečić and Krötzsch, 2014; Bollacker et al., 2008; Auer et al., 2007; Carlson et al., 2010) represent every piece of information as binary relationships between entities, usually in the form of triples *i.e.* *(subject, predicate, object)*. This kind of structured knowledge is essential for many downstream applications such as Question Answering and Semantic Web.

Despite KGs' large scale, they are known to be highly incomplete (Min et al., 2013). To automatically complete KGs, extensive research efforts (Nickel et al., 2011; Bordes et al., 2013; Yang et al., 2014; Trouillon et al., 2016; Lao and Cohen, 2010; Neelakantan et al., 2015; Xiong et al., 2017; Das et al., 2017; Chen et al., 2018) have been made to build relational learning models that could infer missing triples by learning from existing ones. These methods explore the statistical information of triples or path patterns to infer new facts of existing relations; and have achieved considerable performance on various public datasets.

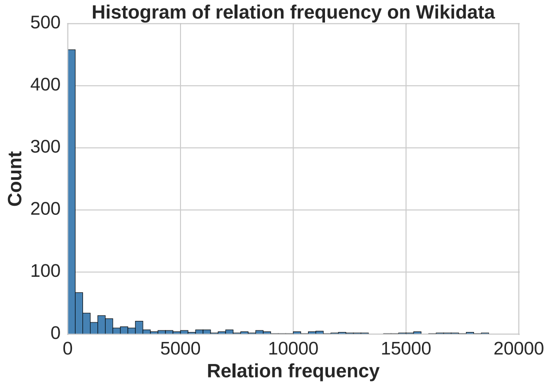

Figure 1: The histogram of relation frequencies in Wikidata. There are a large portion of relations that only have a few triples.

However, those datasets (*e.g.* FB15k, WN18) used by previous models mostly only cover common relations in KGs. For more practical scenarios, we believe the desired KG completion models should handle two key properties of KGs. First, as shown in Figure 1, a large portion of KG relations are actually long-tail. In other words, they have very few instances. But intuitively, the fewer training triples that one relation has, the more KG completion techniques could be of use. Therefore, it is crucial for models to be able to complete relations with limited numbers of triples. However, existing research usually assumes the availability of sufficient training triples for all relations, which

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1980–1990
Brussels, Belgium, October 31 - November 4, 2018.

limits their usefulness on sparse long-tail relations.

Second, to capture up-to-date knowledge, real-world KGs are often dynamic and evolving at any given moment. New relations will be added whenever new knowledge is acquired. If a model can predict new triples given only a small number of examples, a large amount of human effort could be spared. However, to predict target relations, previous methods usually rely on well-learned representations of these relations. In the dynamic scenario, the representations of new relations cannot be sufficiently trained given limited training instances, thus the ability to adapt to new relations is also limited for current models.

In contrast to previous methods, we propose a model that depends only on the entity embeddings and local graph structures. Our model aims at learning a matching metric that can be used to discover more similar triples given one reference triple. The learnable metric model is based on a permutation-invariant network that effectively encodes the one-hop neighbors of entities, and also a recurrent neural network that allows multi-step matching. Once trained, the model will be able to make predictions about any relation while existing methods usually require fine-tuning to adapt to new relations. With two newly constructed datasets, we show that our model can achieve consistent improvement over various embedding models on the one-shot link prediction task.

In summary, our contributions are three-fold:

- We are the first to consider the long-tail relations in the link prediction task and formulate the problem as few-shot relational learning;
- We propose an effective one-shot learning framework for relational data, which achieves better performance than various embedding-based methods;
- We also present two newly constructed datasets for the task of one-shot knowledge graph completion.

2 Related Work

Embedding Models for Relational Learning Various models have been developed to model relational KGs in continous vector space and to automatically infer missing links. RESCAL (Nickel et al., 2011) is one of the earlier work that models the relationship using tensor operations. Bordes et al. (2013) proposed to model relationships in the 1-D vector space. Following this line of research, more advanced models such as DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016) and ConvE (Dettmers et al., 2017) have been proposed. These embedding-based models usually assume enough training instances for all relations and entities and do not pay attention to those sparse symbols. More recently, several models (Shi and Weninger, 2017; Xie et al., 2016) have been proposed to handle unseen entities by leveraging text descriptions. In contrast to these approaches, our model deals with long-tail or newly added relations and focuses on one-shot relational learning without any external information, such as text descriptions of entities or relations.

Few-Shot Learning Recent deep learning based few-shot learning approaches fall into two main categories: (1) *metric based approaches* (Koch, 2015; Vinyals et al., 2016; Snell et al., 2017; Yu et al., 2018), which try to learn generalizable metrics and the corresponding matching functions from a set of training tasks. Most methods in this class adopt the general matching framework proposed in deep siamese network (Koch, 2015). One example is the Matching Networks (Vinyals et al., 2016), which make predictions by comparing the input example with a small labeled support set; (2) *meta-learner based approaches* (Ravi and Larochelle, 2017; Munkhdalai and Yu, 2017; Finn et al., 2017; Li et al., 2017), which aim to learn the optimization of model parameters (by either outputting the parameter updates or directly predicting the model parameters) given the gradients on few-shot examples. One example is the LSTM-based meta-learner (Ravi and Larochelle, 2017), which learns the step size for each dimension of the stochastic gradients. Besides the above categories, there are also some other styles of few-shot learning algorithms, *e.g.* Bayesian Program Induction (Lake et al., 2015), which represents concepts as simple programs that best explain observed examples under a Bayesian criterion.

Previous few-shot learning research mainly focuses on vision and imitation learning (Duan et al., 2017) domains. In the language domain, Yu et al. (2018) proposed a multi-metric based approach for text classification. To the best of our knowledge, this work is the first research on few-shot learning for knowledge graphs.

3 Background

3.1 Problem Formulation

Knowledge graphs $\mathcal{G}$ are represented as a collection of triples $\{(h, r, t)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $\mathcal{E}$ and $\mathcal{R}$ are the entity set and relation set. The task of knowledge graph completion is to either predict unseen relations r between two existing entities: $(h, ?, t)$ or predict the tail entity t given the head entity and the query relation: $(h, r, ?)$. As our purpose is to infer unseen facts for newly added or existing long-tail relations, we focus on the latter case. In contrast to previous work that usually assumes enough triples for the query relation are available for training, this work studies the case where only one training triple is available. To be more specific, the goal is to rank the true tail entity t_{true} higher than other candidate entities $t \in \mathcal{C}_{h,r}$, given only an example triple (h_0, r, t_0). The candidates set is constructed using the entity type constraint (Toutanova et al., 2015). It is also worth noting that when we predict new facts of the relation r, we only consider a closed set of entities, *i.e.* no unseen entities during testing. For open-world settings where new entities might appear during testing, external information such as text descriptions about these entities are usually required and we leave this to future work.

3.2 One-Shot Learning Settings

This section describes the settings for the training and evaluation of our one-shot learning model.

The goal of our work is to learn a metric that could be used to predict new facts with one-shot examples. Following the standard one-shot learning settings (Vinyals et al., 2016; Ravi and Larochelle, 2017), we assume access to a set of training tasks. In our problem, each training task corresponds to a KG relations $r \in \mathcal{R}$, and has its own training/testing triples: $T_r = \{D_r^{train}, D_r^{test}\}$. This task set is often denoted as the *meta-training* set, $\mathbb{T}_{meta-train}$.

To imitate the one-shot prediction at evaluation time, there is only one triple (h_0, r, t_0) in each D_r^{train}. The $D_r^{test} = \{(h_i, r, t_i, \mathcal{C}_{h_i,r})\}$ consists of the testing triples of r with ground-truth tail entities t_i for each query (h_i, r), and the corresponding tail entity candidates $\mathcal{C}_{h_i,r} = \{t_{ij}\}$ where each t_{ij} is an entity in $\mathcal{G}$. The metric model can thus be tested on this set by ranking the candidate set $\mathcal{C}_{h_i,r}$ given the test query (h_i, r) and the labeled triple in D_r^{train}. We denote an arbitrary ranking-loss function as $\ell_\theta(h_i, r, t_i | \mathcal{C}_{h_i,r}, D_r^{train})$, where θ represents the parameters of our metric model. This loss function indicates how well the metric model works on tuple $(h_i, r, t_i, \mathcal{C}_{h_i,r})$ while observing only one-shot data from D_r^{train}. The objective of training the metric model, *i.e.* the meta-training objective, thus becomes:

$$\min_\theta \mathbb{E}_{T_r} \left[\sum_{(h_i,r,t_i,\mathcal{C}_{h_i,r}) \in D_r^{test}} \frac{\ell_\theta(h_i, r, t_i | \mathcal{C}_{h_i,r}, D_r^{train})}{|D_r^{test}|} \right], \tag{1}$$

where T_r is sampled from the meta-training set $\mathbb{T}_{meta-train}$, and $|D_r^{test}|$ denotes the number of tuples in D_r^{test}.

Once trained, we can use the model to make predictions on new relations $r' \in \mathcal{R}'$, which is called the *meta-testing* step in literature. These meta-testing relations are unseen from meta-training, *i.e.* $\mathcal{R}' \cap \mathcal{R} = \phi$. Each meta-testing relation r' also has its own one-shot training data $D_{r'}^{train}$ and testing data $D_{r'}^{test}$, defined in the same way as in meta-training. These meta-testing relations form a meta-test set $\mathbb{T}_{meta-test}$.

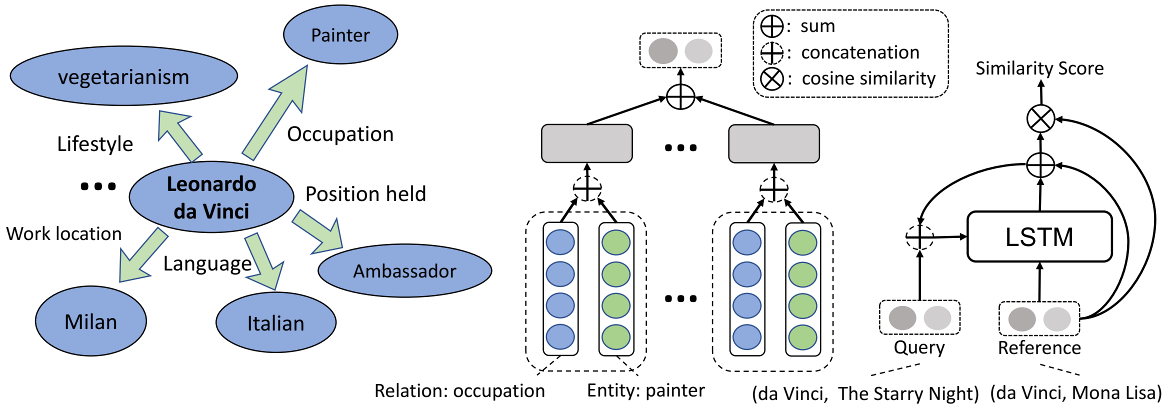
Moreover, we leave out a subset of relations in $\mathbb{T}_{meta-train}$ as the meta-validation set $\mathbb{T}_{meta-validation}$. Because of the assumption of one-shot learning, the meta-testing relations do not have validation sets like in the traditional machine learning setting. Otherwise, the metric model will actually see more than one-shot labeled data during meta-testing, thus the one-shot assumption is violated.

Finally, we assume that the method has access to a *background knowledge graph* $\mathcal{G}'$, which is a subset of $\mathcal{G}$ with all the relations from $\mathbb{T}_{meta-train}$, $\mathbb{T}_{meta-validation}$ and $\mathbb{T}_{meta-test}$ removed.

4 Model

In this section, we describe the proposed model for similarity metric learning and also the corresponding loss function ℓ we use to train our model.

The core of our proposed model is a similarity function $\mathcal{M}((h, t), (h', t') | \mathcal{G}')$. Thus for any query relation r, as long as there is one known fact (h_0, r, t_0), the model could predict the likelihood of testing triples $\{(h_i, r, t_{ij}) | t_{ij} \in \mathcal{C}_{h_i,r}\}$, based on the matching score between each (h_i, t_{ij}) and (h_0, t_0). The implementation of the above matching function involves two sub-problems: (1) the representations of entity pairs; and (2) the comparison function between two entity-pair representations. Our overall model, as shown in Figure 2,



a) Local graph of entity *Leonardo da Vinci* **b) Neighbor Encoder** **c) Matching Processor**

Figure 2: a) and b): Our **neighbor encoder** operating on entity *Leonardo da Vinci*; c): The **matching processor**.

deals with the above two problems with two major components respectively:

- **Neighbor encoder** (Figure 2b), aims at utilizing the local graph structure to better represent entities. In this way, the model can leverage more information that KG provides for every entity within an entity pair.
- **Matching processor** (Figure 2c), takes the vector representations of any two entity pairs from the neighbor encoder; then performs multi-step matching between two entity-pairs and outputs a scalar as the similarity score.

4.1 Neighbor Encoder

This module is designed to enhance the representation of each entity with its local connections in knowledge graph.

Although the entity embeddings from KG embedding models (Bordes et al., 2013; Yang et al., 2014) already have relational information encoded, previous work (Neelakantan et al., 2015; Lin et al., 2015a; Xiong et al., 2017) showed that explicitly modeling the structural patterns, such as paths, is usually beneficial for relationship prediction. In view of this, we propose to use a neighbor encoder to incorporate graph structures into our metric-learning model. In order to benefit from the structural information while maintaining the efficiency to easily scale to real-world large-scale KGs, our neighbor encoder only considers entities' local connections, *i.e.* the one-hop neighbors.

For any given entity e, its local connections form a set of (*relation, entity*) tuples. As shown in Figure 2a, for the entity *Leonardo da Vinci*, one of such tuples is (*occupation, painter*). We refer this neighbor set as as $\mathcal{N}_e = \{(r_k, e_k) | (e, r_k, e_k) \in \mathcal{G}'\}$. The purpose of our neighbor encoder is to encode $\mathcal{N}_e$ and output a vector as the latent representation of e. Because this is a problem of encoding sets with varying sizes, we hope the encoding function can be (1) invariant to permutations and also (2) insensitive to the size of the neighbor set. Inspired by the results from (Zaheer et al., 2017), we use the following function f that satisfies the above properties:

$$f(\mathcal{N}_e) = \sigma(\frac{1}{|\mathcal{N}_e|} \sum_{(r_k,e_k)\in\mathcal{N}_e} C_{r_k,e_k}). \tag{2}$$

where C_{r_k,e_k} is the feature representation of a relation-entity pair (r_k, e_k) and σ is the activation function. In this paper we set $\sigma = \tanh$ which achieves the best performance on $\mathbb{T}_{meta-validation}$.

To encode every tuple $(r_k, e_k) \in \mathcal{N}_e$ into C_{r_k,e_k}, we first use an embedding layer **emb** with dimension d (which can be pre-trained using existing embedding-based models) to get the vector representations of r_k and e_k:

$$v_{r_k} = \mathbf{emb}(r_k), v_{e_k} = \mathbf{emb}(e_k)$$

Dropout (Srivastava et al., 2014) is applied here to the vectors v_{r_k}, v_{e_k} to achieve better generalization. We then apply a feed-forward layer to encode the interaction within this tuple:

$$C_{r_k,e_k} = W_c(v_{r_k} \oplus v_{e_k}) + b_c, \tag{3}$$

where $W_c \in R^{d\times 2d}, b_c \in R^d$ are parameters to be learned and $\oplus$ denotes concatenation.

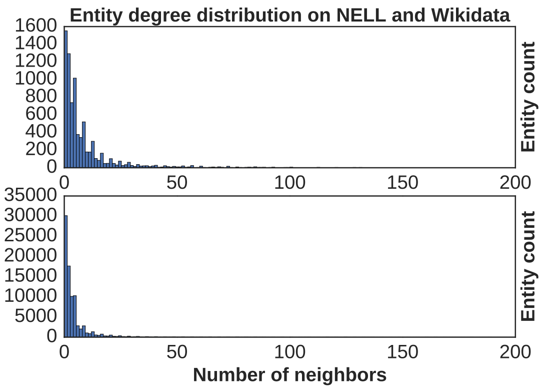


Figure 3: The distribution of entities' degrees (numbers of neighbors) on our two datasets. Since we work on closed-set of entities, we draw the figure by considering the intersection between entities in our background knowledge $\mathcal{G}'$ and the entities appearing in $\mathbb{T}_{meta-train}$, $\mathbb{T}_{meta-validation}$ or $\mathbb{T}_{meta-test}$. Note that all triples in $\mathbb{T}_{meta-train}$, $\mathbb{T}_{meta-validation}$ or $\mathbb{T}_{meta-test}$ are removed from $\mathcal{G}'$. Upper: NELL; Lower: Wikidata.

To enable batching during training, we manually specify the maximum number of neighbors and use all-zero vectors as "dummy" neighbors. Although different entities have different degrees (number of neighbors), the degree distribution is usually very concentrated, as shown in Figure 3. We can easily find a proper bound as the maximum number of neighbors to batch groups of entities.

The neighbor encoder module we propose here is similar to the Relational Graph Convolutional Networks (Schlichtkrull et al., 2017) in the sense that we also use the shared kernel $\{W_c, b_c\}$ to encode the neighbors of different entities. But unlike their model that operates on the whole graph and performs multiple steps of information propagation, we only encode the local graphs of the entities and perform one-step propagation. This enables us to easily apply our model to large-scale KGs such as Wikidata. Besides, their model also does not operate on pre-trained graph embeddings. We leave the investigation of other graph encoding strategies, e.g. (Xu et al., 2018; Song et al., 2018), to future work.

4.2 Matching Processor

Given the neighbor encoder module, now we discuss how we can do effective similarity matching based on our recurrent matching processor. By applying $f(\mathcal{N}_e)$ to the reference entity pair (h_0, t_0) and any query entity pair (h_i, t_{ij}), we get two neighbor vectors for each: $[f(\mathcal{N}_{h_0}); f(\mathcal{N}_{t_0})]$ and $[f(\mathcal{N}_{h_i}); f(\mathcal{N}_{t_{ij}})]$. To get a similarity score that can be used to rank (h_i, t_{ij}) among other candidates, we can simply concatenate the $f(\mathcal{N}_h)$ and $f(\mathcal{N}_t)$ in each pair to form a single pair representation vector, and calculate the cosine similarity between pairs. However, this simple metric model turns out to be too shallow and does not give good performance. To enlarge our model's capacity, we leverage a LSTM-based (Hochreiter and Schmidhuber, 1997) recurrent "processing" block (Vinyals et al., 2015, 2016) to perform multi-step matching. Every process step is defined as follows:

Algorithm 1 One-shot Training

```
Input:
a) Meta-training task set $\mathbb{T}_{meta-training}$;
b) Pre-trained KG embeddings (excluding relation in $\mathbb{T}_{meta-training}$);
c) Initial parameters $\theta$ of the metric model;
for epoch = 0:M-1 do
    Shuffle the tasks in $\mathcal{T}_{meta-learning}$
    for $T_r$ in $\mathcal{T}_{meta-learning}$ do
        Sample one triple as the reference
        Sample a batch $B^+$ of query triples
        Pollute the tail entity of query triples to get $B^-$
        Calculate the matching scores for triple in $B^+$ and $B^-$
        Calculate the batch loss $\mathcal{L} = \sum_B \ell$
        Update $\theta$ using gradient $g \propto \nabla \mathcal{L}$
    end for
end for
```

$$
\begin{aligned}
h'_{k+1}, c_{k+1} &= LSTM(q, [h_k \oplus s, c_k]) \\
h_{k+1} &= h'_{k+1} + q \\
score_{k+1} &= \frac{h_{k+1} \odot s}{\|h_{k+1}\| \, \|s\|},
\end{aligned}
\tag{4}
$$

where $LSTM(x, [h, c])$ is a standard LSTM cell with input x, hidden state h and cell state c, and $s = f(\mathcal{N}_{h_0}) \oplus f(\mathcal{N}_{t_0}), q = f(\mathcal{N}_{h_i}) \oplus f(\mathcal{N}_{t_{ij}})$ are the concatenated neighbor vectors of the reference pair and query pair. After K processing steps[2], we use $score_K$ as the final similarity score between the query and support entity pair. For every query $(h_i, r, ?)$, by comparing (h_i, t_{ij}) with (h_0, t_0), we can get the ranking scores for every $t_{ij} \in \mathcal{C}_{h_i,r}$.

4.3 Loss Function and Training

For a query relation r and its reference/training triple (h_0, r, t_0), we collect a group of positive (true) query triples $\{(h_i, r, t_i^+) | (h_i, r, t_i^+) \in \mathcal{G}\}$ and construct another group negative (false) query

---

[2] K is a hyperparameter to be tuned.

triples $\{(h_i, r, t_i^-)|(h_i, r, t_i^-) \notin \mathcal{G}\}$ by polluting the tail entities. Following previous embedding-based models, we use a hinge loss function to optimize our model:

$$\ell_\theta = max(0, \gamma + score_\theta^- - score_\theta^+), \quad (5)$$

where $score_\theta^+$ and $score_\theta^-$ are scalars calculated by comparing the query triple $(h_i, r, t_i^+/t_i^-)$ with the reference triple (h_0, r, t_0) using our metric model, and the margin γ is a hyperparameter to be tuned. For every training episode, we first sample one task/relation T_r from the meta-training set $\mathbb{T}_{meta-training}$. Then from all the known triples in T_r, we sample one triple as the reference/training triple D_r^{train} and a batch of other triples as the positive query/test triples D_r^{test}. The detail of the training process is shown in Algorithm 1. Our experiments are discussed in the next section.

5 Experiments

5.1 Datasets

Dataset	# Ent.	# R.	# Triples	# Tasks
NELL-One	68,545	358	181,109	67
Wiki-One	4,838,244	822	5,859,240	183

Table 1: Statistics of the Datasets. # Ent. denotes the number of unique entities and # R. denotes the number of all relations. # Tasks denotes the number of relations we use as one-shot tasks.

Existing benchmarks for knowledge graph completion, such as FB15k-237 (Toutanova et al., 2015) and YAGO3-10 (Mahdisoltani et al., 2013) are all small subsets of real-world KGs. These datasets consider the same set of relations during training and testing and often include sufficient training triples for every relation. To construct datasets for one-shot learning, we go back to the original KGs and select those relations that do not have too many triples as one-shot task relations. We refer the rest of the relations as background relations, since their triples provide important background knowledge for us to match entity pairs.

Our first dataset is based on NELL (Mitchell et al., 2018), a system that continuously collects structured knowledge by reading webs. We take the latest dump and remove those inverse relations. We select the relations with less than 500 but more than 50 triples[3] as one-shot tasks. To show that our model is able to operate on large-scale KGs, we follow the similar process to build another larger dataset based on Wikidata (Vrandečić and Krötzsch, 2014). The dataset statistics are shown in Table 1. Note that the Wiki-One dataset is an order of magnitude larger than any other benchmark datasets in terms of the numbers of entities and triples. For NELL-One, we use 51/5/11 task relations for training/validation/testing. For Wiki-One, the division ratio is 133:16:34.

5.2 Implementation Details

In our experiments, we consider the following embedding-based methods: RESCAL (Nickel et al., 2011), TransE (Bordes et al., 2013), DistMult (Yang et al., 2014) and ComplEx (Trouillon et al., 2016). For TransE, we use the code released by Lin et al. (2015b). For the other models, we have tried the code released by Trouillon et al. (2016) but it gives much worse results than TransE on our datasets. Thus we use our own implementations based on PyTorch (Paszke et al., 2017) for comparison. When evaluating existing embedding models, during training, we use not only the triples of background relations but also all the triples of the training relations and the one-shot training triple of those validation/test relations. However, since the proposed metric model does not require the embeddings of query relations, we only include the triples of the background relations for embedding training. As TransE and DistMult use 1-D vectors to represent entities and relations, they can be directly used in our natching model. While for RESCAL, since it uses matrices to represent relations, we employ mean-pooling over these matrices to get 1-D embeddings. For the ComplEx model, we use the concatenation of the real part and imaginary part. The hyperparameters of our model are tuned on the validation task set and can be found in the appendix.

Apart from the above embedding models, a more recent method (Dettmers et al., 2017) applies convolution to model relationships and achieves the best performance on several benchmarks. For every query $(h, r, ?)$, their model enumerates the whole entity set to get positive and negative triples for training. We find that this training paradigm takes lots of computational resources when dealing with large entity sets and cannot scale to real-world KGs such as Wikidata[4] that have millions

---

[3] We want to have enough triples for evaluation.

[4] On a GPU card with 12GB memory, we fail to run their ConvE model on Wiki-One with batch size 1.

Table 2: Link prediction results on validation/test relations. KG embeddings baselines are shown at the top of the table and our one-shot learning (GMatching) results are shown at the bottom. **Bold** numbers denote the best results on meta-validation/meta-test. Underline numbers denote the model selection results from all KG embeddings baselines, or from all one-shot methods, i.e. selecting the method with the best validation score and reporting the corresponding test score.

of entities. For the scalability concern, our experiments only consider models that use negative sampling for training.

5.3 Results

The main results of our methods are shown in Table 2. We denote our method as "GMatching" since our model is trained to match local graph patterns. We use mean reciprocal rank (MRR) and Hits@K to evaluate different models. We can see that our method produces consistent improvements over various embedding models on these one-shot relations. The improvements are even more substantial on the larger Wiki-One dataset. To investigate the learning power of our model, we also try to train our metric model with randomly initialized embeddings. Surprisingly, although the results are worse than the metric models with pre-trained embeddings, they are still superior to the baseline embedding models. This suggests that, by incorporating the neighbor entities into our model, the embeddings of many relations and entities actually get updated in an effective way and provide useful information for our model to make predictions on test data.

It is worth noting that once trained, our model can be used to predict any newly added relations without fine-tuning, while existing models usually need to be re-trained to handle those newly added symbols. On a large real-world KG, this re-training process can be slow and highly computational expensive.

Remark on Model Selection Given the existence of various KG embedding models, one interesting experiment is to incorporate model selection into hyper-parameter tuning and choose the best validation model for testing.

If we think about comparing KG embedding and metric learning as two approaches, the results from the model selection process can then be used as the "final" measurement for comparison. For example, the baseline KG embedding achieves best MRR on Wiki-One with RESCAL (11.9%), so we report the corresponding testing MRR (7.2%) as the final model selection result for KG embedding approach. In this way, at the top half of Table 2, we select the best KG embedding method according to the validation performance. The results are highlighted with underlines. Similarly, we select the best metric learning approach at the bottom.

Our metric-based method outperforms KG embedding by a large margin from this perspective as well. Taking MRR as an example, the selected metric model achieves 17.1% on NELL-One and 20.0% on Wiki-One; while the results of KG embedding are 9.3% and 7.2%. The improvement is 7.8% and 12.8% respectively.

5.4 Analysis on Neighbor-Encoder

As our model leverages entities' local graph structures by encoding the neighbors, here we try to investigate the effect of the neighbor set by restricting the maximum number of neighbors. If the size of the true neighbor set is larger than the maximum limit, the neighbors are then selected by random sampling. Figure 4 shows the learning curves of different settings. These curves are based on the Hits@10 calculated on the validation set. We see that encoding more neighbors

for every entity generally leads to better performance. We also observe that the model that encodes 40 neighbors in maximum actually yields worse performance than the model that only encodes 30 neighbors. We think the potential reason is that for some entity pairs, there are some local connections that are irrelevant and provide noisy information to the model.

5.5 Ablation Studies

We conduct ablation studies using the model that achieves the best Hits@10 on the NELL-One dataset. The results are shown in Table 4. We use Hits@10 on validation and test set for comparison, as the hyperparameters are selected using this evaluation metric. We can see that both the matching processor[5] and the neighbor encoder play important roles in our model. Another important observation is that the scaling factor $1/\mathcal{N}_e$ turns out to be very essential for the neighbor encoder. Without scaling, the neighbor encoder actually gives worse results compared to the simple embedding-based matching.

5.6 Performance on Different Relations

When testing various models, we observe that the results on different relations are actually of high variance. Table 3 shows the decomposed results on NELL-One generated by our best metric model (GMatching-ComplEx) and its corresponding embedding method. For reference, we also report the embedding model's performance under standard training settings where 75% of the triples (instead of only one) are used for training and the rest are used for testing. We can see that relations with smaller candidate sets are generally easier and our model could even perform better than the embedding model trained under standard settings. For some relations such as *athleteInjuredHisBodypart*, their involved entities have very few connections in KG. It is as expected that one-shot learning on these kinds of relations is quite challenging. Those relations with lots of (>3000) candidates are challenging for all models. Even for embedding model with more training triples, the performance on some relations is still very limited. This suggests that the knowledge graph completion task is still far from being solved.

---

[5] Matching without Matching Processor is equivalent to matching using simple cosine similarity.

6 Conclusion

This paper introduces a one-shot relational learning framework that could be used to predict new facts of long-tail relations in KGs. Our model leverages the local graph structure of entities and learns a differentiable metric to match entity pairs. In contrast to existing methods that usually need finetuning to adapt to new relations, our trained model can be directly used to predict any unseen relation and also achieves much better performance in the one-shot setting. Our future work might consider incorporating external text data and also enhancing our model to make better use of multiple training examples in the few-shot learning case.

A Hyperparameters

For the NELL dataset, we set embedding size as 100. For Wikidata, we set the embedding size as 50 for faster training with millions of triples. The embeddings are trained for 1,000 epochs. The other hyperparamters are tuned using the Hits@10 metric[6] on the validation tasks. For matching steps, the optimal setting is 2 for NELL-One and 4 for Wiki-One. For the number of neighbors, we find that the maximum limit 50 works the best for both datasets. For parameter updates, we use Adam (Kingma and Ba, 2014) with the initial learning rate 0.001 and we half the learning rate after 200k update steps. The margin used in our loss function is 5.0. The dimension of LSTM's hidden size is 200.

Abstract

Many important entity types in web documents, such as dates, times, email addresses, and course numbers, follow or closely resemble patterns that can be described by Regular Expressions (REs). Due to a vast diversity of web documents and ways in which they are being generated, even seemingly straightforward tasks such as identifying mentions of date in a document become very challenging. It is reasonable to claim that it is impossible to create a RE that is capable of identifying such entities from web documents with perfect precision and recall. Rather than abandoning REs as a go-to approach for entity detection, this paper explores ways to combine the expressive power of REs, ability of deep learning to learn from large data, and human-in-the loop approach into a new integrated framework for entity identification from web data. The framework starts by creating or collecting the existing REs for a particular type of an entity. Those REs are then used over a large document corpus to collect weak labels for the entity mentions and a neural network is trained to predict those RE-generated weak labels. Finally, a human expert is asked to label a small set of documents and the neural network is fine tuned on those documents. The experimental evaluation on several entity identification problems shows that the proposed framework achieves impressive accuracy, while requiring very modest human effort.

1 Introduction

Named Entity Recognition (NER) is the task of automatically locating, extracting, and classifying contiguous pieces of strings, which represent entities of interest, in text. Classification (or typing) seeks to assign pre-defined categories (e.g., person, organization, location, expressions of time, monetary values, and emails) to each extracted piece of text. NER is a subtask of the broader problem of Information Extraction (IE) from text (Chang et al., 2006; Etzioni et al., 2005; Finkel and Manning, 2009; Nadeau and Sekine, 2007; Shen et al., 2015). Named entities usually refer to entity names that describe unique identifiers of people, locations, movies, events, and organizations. There is a large class of entities that are not “named," such as expressions of time, emails, and course identifiers. Their main characteristic is that they often follow an underlying syntactical pattern, which can be fully described or well approximated by Regular Expressions (REs).

Despite being the workhorse of many entity recognition tasks, REs have a number of drawbacks. The construction of highly accurate REs is difficult and requires specific technical skills. For a simple task such as recognizing emails, there are 361 REs proposed in RegExLib.com. Moreover, REs are brittle and difficult to maintain. These obstacles have motivated the work on automatic inference of REs (Banko et al., 2007; Li et al., 2008; Bartoli et al., 2018) where the objective it to develop approaches that are fast and deployable in real time. However, the existing approaches tend to require large number of examples to cover both the alphabet and the possible syntactic patterns. Moreover, they often produce overly complicated or long REs or combinations of REs (Bartoli et al., 2016). One of the most complete REs for emails has nearly 6,500 characters (Millner, 2008)!

Web documents are an important domain for data extraction. Importantly, the Web is not a place where data follows "underlying syntactical pattern" at scale. A datetime RE for New York Times news articles may not work for the articles at Le Figaro or Al Jazeera. Small typos throw off REs and produce nothing. This is a concrete Web example `data-timestamp="Thu Oct 05 2017 10:33:05` **`-0500"`**`>` that contains an unexpected space before "`-0500`". This small typo

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1991–2000
Brussels, Belgium, October 31 - November 4, 2018.

can easily deem a complex and painstakingly constructed datetime RE obsolete. At such scale, any attempt to fully understand an RE and debug it in case it fails is futile. New automated or semi-automated tools are needed to either supersede REs or to work in tandem with REs. In this work, we focus on the later.

In this paper, we target the problem of detecting presence of entity mentions that follow or closely resemble patterns that can be described by REs. Unlike much of the previous body of work on this topic, we do not focus on learning/inferring highly accuracte REs for entity identification (Prasse et al., 2012; Bui and Zeng-Treitler, 2014; Li et al., 2008; Banko et al., 2007; Brauer et al., 2011; Bartoli et al., 2016). We aim instead to show that deep learning can leverage imperfect REs and achieve very high accuracy while requiring only a modest human involvement.

Suppose the goal is to recognize *datetime* string expressions. We use some reasonable REs R for datetime to generate a weakly labeled training dataset from a large corpus of Web documents, e.g., news articles. We train a deep neural network on this data. Denote this model $\boldsymbol{M_{RE}}$. To our surprise, $\boldsymbol{M_{RE}}$ is already capable of recognizing the presence of datetime expressions beyond those recognized by R. Furthermore, with the addition of a very small number of training samples (between 20 - 50 instances) from a human labeler, we obtain a model $\boldsymbol{M_{RE+human}}$ that is superior to $\boldsymbol{M_{RE}}$ by a significant margin. In general, complex systems do not generalize easily with the addition of new data, because the amount of labeled data required to provide a good coverage grows exponentially with the complexity of the problem (Chiu and Nichols, 2015; Lample et al., 2016; Huang et al., 2015; Mahajan et al., 2018). We show that there is an opportunity for faster convergence to a generalized recognizer for this class of entities.

The main contributions in this paper are:

- We show how starting from REs R that recognizes a fraction of entities of a given type $\mathcal{E}$ (say, email) we can pretrain a deep neural network (NN) model which can be a richer recognizer of entities of type $\mathcal{E}$ than R.
- We show that we can fine tune the pretrained model to recognize an even larger set of entities of type $\mathcal{E}$ with the addition of a small number of labeled instances, as small as 20.

The paper is organized as follows. Section 2 gives an overview of the related work. Section 3 describes our method. Section 4 presents our methodology for parameter learning and experimental setup. Section 5 gives the experimental results. Finally, Section 6 concludes the paper.

2 Related Work

This section will mention several lines of research we deem the most related to our work.

The problem of inducing regular expressions has been an active area of work for more than two decades. One line of work focuses on improving the initial REs by identifying the true or false matches (Li et al., 2008; Murthy et al., 2012; Cetinkaya, 2007; Cochran et al., 2015). Another line of work attempts to directly induce REs from positive and negative sample strings (Fernau, 2009; Denis, 2001). The common approaches include generation of prefix and suffix automatons that represent overlapping syntactical features of the entities on character and token level (Brauer et al., 2011) and the automatic creation of REs based on genetic programming (Bartoli et al., 2012, 2014, 2016, 2018).

Constraining NN training to comply with known rules has also been an active research topic. Hu et al. (2016) proposes integration of constraints coming in the form of first order logic rules during training of NNs. Alashkar et al. (2017) trains an NN by minimizing a joint loss based on prediction of labels and adhering to the predefined rules. Locascio et al. (2016) proposed training LSTM NN to generate REs from sample pieces of text. Luo et al. (2018) incorporates knowledge of REs into training of NNs at three different levels: as the input features to NNs, as regularizations of the outputs of NN layers, or as a reward/penalty in the loss functions in NNs.

Unlike the aforementioned work, we do not attempt to learn explicit REs and do not force the outputs of NN layers match predetermined rules. Instead, we leverage REs as a means of generating a large quantity of weak labels from unlabeled data and using such data to pre-train an NN to recognize the provided REs. We fine tune such an NN on human-labeled data to exceed accuracy of the REs. A similar approach is effective in other domains. For example, Felbo et al. (2017) proposed pre-training an NN on millions of tweets labeled by emojis before fine tuning it for sentiment anal-

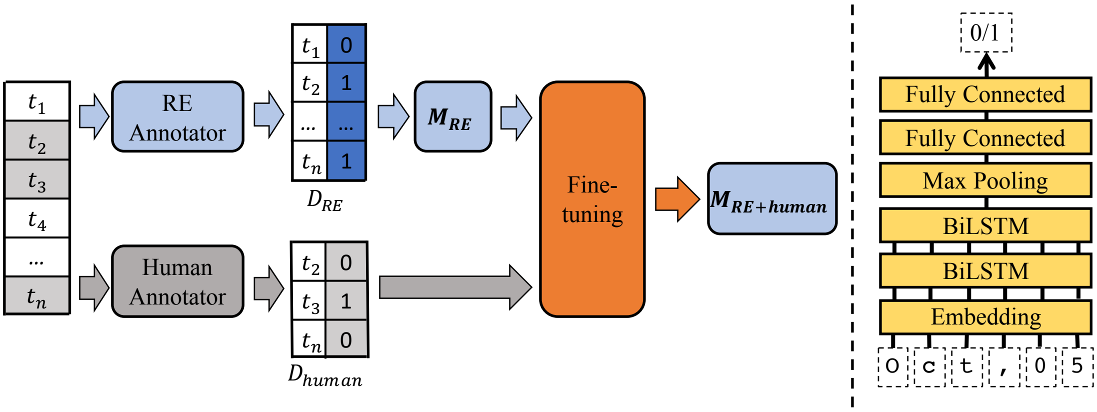

Figure 1: Overview of the solution (left) and deep learning architecture (right) used to train model $\boldsymbol{M_{RE}}$.

ysis. Mahajan et al. (2018) pre-trained an NN on billions of images labeled by hashtags before fine tuning it to various computer vision tasks.

3 Methodology

We describe the proposed framework here.

Problem Definition: Given a text string t and an entity type $\mathcal{E}$, the task is to predict whether t contains an entity mention of type $\mathcal{E}$. We treat this task as binary classification. To build the classifier, we assume that we are given a large corpus of unlabeled text strings $T = \{t_1, t_2, ..., t_n\}$. The challenge is to train the classifier with the minimal human effort. We allow a human expert to help in two ways: (1) construct a new RE or find an RE created by others, and (2) label an unlabeled string. For the purposes of this paper, we assume that one or more REs suitable for entity identification are already available and that human effort refers only to string labeling. The available REs might have an arbitrary precision and recall. We will analyze the impact of the RE quality on classification accuracy in the experimental section.

Solution Framework: An overview of the proposed framework is illustrated in Figure 1.

STEP 1. All of the unlabeled strings from T are fed into an RE annotator. If any of the provided REs t_i recognizes t_i, it is weakly labeled as $y_i = 1$, otherwise it is weakly labeled as $y_i = 0$.

STEP 2. An NN model $\boldsymbol{M_{RE}}$ is trained based on the weakly labeled data $D_{RE} = \{(t_i, y_i)|i = 1, 2, ..., n\}$. Given a large number of sample strings, it is expected that we can train an NN with high accuracy on D_{RE}.

STEP 3. A subset of m strings from T are sampled randomly and a human annotator labels each of the sampled strings. String t_i is labeled as $y_i = 1$ if the annotator recognizes an entity type $\mathcal{E}$ in t_i and as $y_i = 0$, if not. We denote the resulting strongly labeled data set as $D_{human} = \{(t_i, y_i)|i = 1, 2, ..., m\}$, where $m \ll n$.

STEP 4. The pre-trained NN $\boldsymbol{M_{RE}}$ is fine tuned with D_{human} data. We call the resulting NN $\boldsymbol{M_{RE+human}}$. For comparison, we also train a randomly initialized NN directly on D_{human}. We call this NN $\boldsymbol{M_{human}}$. The expectation is that the pre-trained NN captures very useful information about the entity type $\mathcal{E}$ and that fine tuning is more effective than training a new NN from scratch.

RE Annotator: Let us denote the set of REs available for a specific entity type $\mathcal{E}$ as R. R may be either created by human experts or generated automatically by tools like (Li et al., 2008; Bartoli et al., 2018), which require a human-labeled subset of T. Both approaches are human-intensive.

Deep Learning Architectures: We do not have a preference over any deep learning architecture to train $\boldsymbol{M_{RE}}$, as long as it can handle character-level inputs and produce binary outputs. We have no strict assumption about the strings in T. They may contain sentences from a formal news article, pieces of HTML code, or a mixture of formal texts and informal texts. For this reason, we treat t_i as a sequence of characters by default. NN architectures that meet our condition include but are not limited to: CNNs (Kim, 2014), BiLSTMs (Lai et al., 2015), and BiLSTM with self-attentions (Lin et al., 2017). For this paper we implemented a BiLSTM architecture. However, we also tested a CNN architecture, reaching similar conclusions. Our architecture contains an embedding layer to project each character into a vector, 2

Table 1: Dataset Summary.

BiLSTM layers to encode a sequence of character embeddings into a sequence of hidden vectors, and a max pooling layer followed by 2 fully-connected layers to project the hidden vectors into binary labels (Figure 1, on the right).

Fine-tuning: Once we have a model M_{RE} trained on weak labels, there are multiple ways to improve the weak model with human annotations to get $M_{RE+human}$. One common way is to freeze the parameters of all other layers of M_{RE} and fine-tune the last fully-connected layer (Donahue et al., 2014). Felbo et al. (2017) propose a *'chain-thaw'* strategy, which freezes all layers, then sequentially unfreezes and fine-tunes a single layer at a time. We exploit a less costly strategy as proposed in (Erhan et al., 2010), which uses the weights learned in M_{RE} to initialize $M_{RE+human}$, and start training $M_{RE+human}$ immediately with human annotations.

4 Experiment Design

We aim to answer three research questions in our experiments: **Q1**. Is it possible to train an accurate NN classifier with a limited number of human generated labels? **Q2**. What is the difference between REs and an NN pretrained on those REs? **Q3**. Does the quality of REs matter?

4.1 Data Sets

We use four datasets which are described in Table 1 in our experiments:

- Date Time: We download 6,000 news articles provided in the dataset One Week of Global News Feeds in Kaggle [1]. After chunking each news article, we get 761,002 strings.
- Course Number: The documents to produce chuncked strings are from The 4 Universities Data Set at CMU World Wide Knowledge Base (Web->KB) project[2]. This dataset has 44,651 strings.
- Bill Date: 600 US Congress bills from the THOMAS online database are used to identify the entity mentions of type datetime provided by (Bartoli et al., 2016). We generate 49,002 chuncked strings for this task. Each text instance contains the bill date (and time) and the location (index) of the datetime substring in the text.
- Email Address: The dataset is a collection of publicly available Enron email addresses from (Li et al., 2008; Brauer et al., 2011). It has 29,035 chuncked strings in total.

To answer the above 3 questions, we manually label 6,000 random strings from each data set. We create our training and testing data from this sample. The remaining strings are used to create D_{RE}. We list the human effort spent on labelling each data set in Table 1.

As an example of human annotations is the string `data-timestamp="Thu Oct 05 2017 10:33:05 -0500">Ex-dep`, which contains an entity of type datetime. The string `<scriptsrc='/js/prev-next-stories. 20170925144113.js'defer>` is an example of a negative instance. We give examples of positive and negative instances in Table 1. The presence of an entity mention of a desired type is highlighted in **bold** in positive instances.

Our human annotated data sets are attached as supplementary materials.

4.2 Regular Expression Generation

The number and the source of REs used to train the deep model M_{RE} are listed in Table 2.

For the recognition of Date/Time entity

Task	$\|R\|$	Source	Labor
Date Time	25	Experts	5 hrs
Course Number	4	Li et al. (2008) Murthy et al. (2012)	-
Bill Date	5	Murthy et al. (2012)	-
Email Address	5	RE Library[3]	-

Table 2: Summary of REs.

mentions, we create 25 distinct REs in total (a member of our team who is familiar with REs generated the 25 REs, then the rest of the team checked these REs). For example, the RE `(20[0-9][0-9])(0[1-9]|1[0-2])(\d{2})([01][0-9]|2[0-3])([0-5][0-9])([0-5][0-9])` identifies datetime entities in the format `YYYYMMDDhhmmss`, while the RE `(20[0-9][0-9])-(0[1-9]|1[0-2])-(\d{2})T([01][0-9]|2[0-3]):([0-5][0-9]):([0-5][0-9])Z` identifies datetime entities in the format `YYYY-MM-DDThh:mm:ssZ`.

For the task of course number identification, we used four REs, one of which is borrowed from the results learned by ReLIE (Li et al., 2008), and the remaining three are from (Murthy et al., 2012). The regular expressions to extract the entity mentions of date are all from (Murthy et al., 2012). For email address, we use the top five REs from the RE Library[3] website.

4.3 Experimental Setup

Models in Comparison We compare 5 models on the 4 data sets: (1) ***Naive***, which always predicts 0, because 0 is the majority class on all 4 tasks. (2) ***RE***, which uses the set of REs R designed by experts or tools to weakly label the strings. Although we have multiple REs for each task, R can be any subset of the available REs. (3) M_{RE}, which is the pretrained model of weak labels generated by R in model (2). (4) M_{human}, which is the model trained with human annotations. (5) $M_{RE+human}$, which is the fine tuned model M_{RE}.

Evaluation Metrics For each data set, we divide the 6,000 strings with human annotations into 5 folds. We leave one fold as our test data. The training data is selected from the other 4 folds. We report four scores for each model: Accuracy (ACC), F1, Precision, and Recall. We report the average results over three random repetitions in Section 5.

Hyperparameters We use 100 dimensions in the embedding layer. We set the activation function in the first fully connected layers as `tanh`. The batch size is set to 300. We also add dropout layers after the embedding layer, the max pooling layer, and the first fully-connected layer to avoid overfitting, with drop out rate at 0.5. Our implementation is in PyTorch. We tune the learning rate (`lr`), the hidden units size (`nhidden`) in BiLSTM layers and the output size (`nfc`) of the first fully-connected layer by 5-fold cross validation using a random 6,000 sample from D_{RE}, for the sake of expediency. The ranges of selection are: `lr` $\in [0.0002, 0.0005, 0.001, 0.002, 0.004, 0.008, 0.015]$, `nhidden` $\in [50, 75, 100, 125, 150, 200]$ and `nfc` $\in [20, 50, 100, 200, 500]$. We use the *random search* algorithm proposed in (Bergstra and Bengio, 2012) that has been proved more effective than *grid search*. The hyperparameters used to train M_{human} and $M_{RE+human}$ are identical to those used to train M_{RE}.

We train 2 epochs for M_{RE} on weakly labeled data. M_{human} and $M_{RE+human}$ are trained for 50 epochs on strongly labeled data.

5 Experimental Results

In this section, we evaluate the proposed framework with extensive experiments on the 4 entity recognition tasks. We use the empirical results to understand how the quality of initial REs impacts our conclusions.

5.1 Entity Mention Detection with Limited Human Annotations

We report the comparisons of the 5 models in Table 3 when we only have 20 human annotations. We use all the available REs in each task in this experiment. Comparing the last two rows of each task, $M_{RE+human}$ always outperforms M_{human} by a large margin according to all 4 evaluation metrics on all 4 data sets. The F1, Precision and Recall scores are more than twice larger for all of tasks. The pretraining strategy is quite effective despite the very limited human annotation.

In addition, $M_{RE+human}$ is much better than ***RE*** in the datetime and Course Number tasks. Its Recall scores increase by 19.1% and 14.4%, respectively, in the two tasks. This means the human

$\boldsymbol{M_{RE+human}}$	94.36	**39.95**	87.88	**27.59**	97.75	90.95	83.60	**100.00**

Table 3: The comparisons in the presence of very few human annotations: $|D_{human}| = 20$.

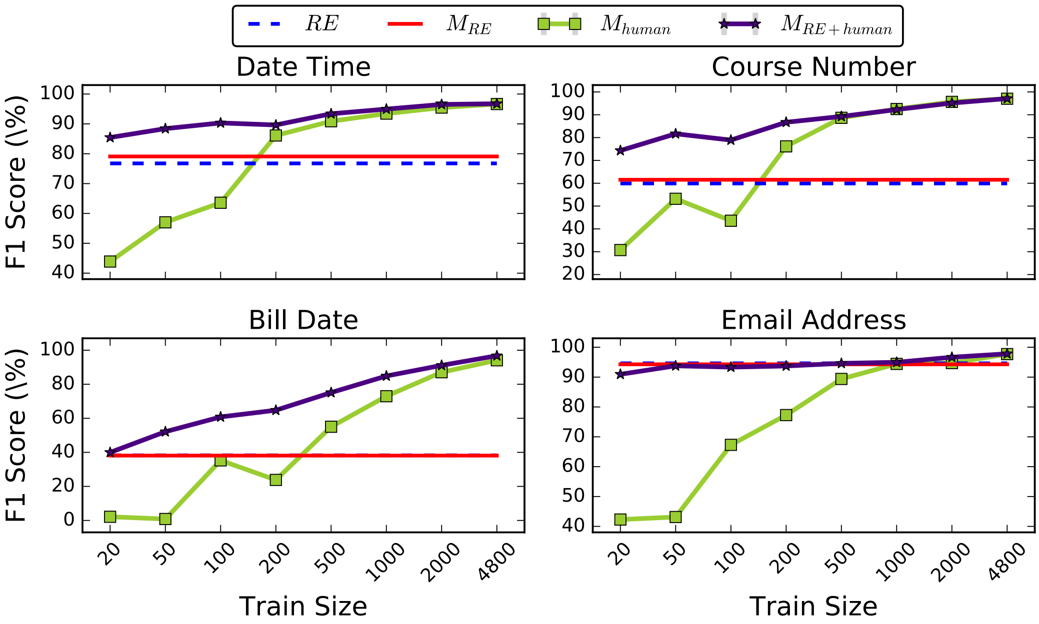

Figure 2: Trend of F1 when varying the number of human annotations.

annotations greatly increase the coverage of the initial REs for entity mentions. The Bill Date task is hard, since the initial REs already achieve Precision = 98% and entity mentions are really rare (ACC = 93% in ***Naive*** model). We still are able to improve the Recall by 15%, but at the expense of reduced Precision. This only gives a slight improvement in F1 (4.5%) and unchanged Accuracy. The Email Address task is even harder, with 90% Precision and 100% Recall from the initial REs. We fail to improve the accuracy with only 20 human annotations in this task.

To summarize, the answer to **Q1**, it is possible to train accurate NNs with limited amount of human generated labels and large amount of weak labels generated automatically.

5.2 Effect of the Number of Human Annotations

In Figure 2 we show how F1 varies with the size of the strongly labeled dataset, $|D_{human}| = [20, 50, 100, 200, 500, 1000, 2000, 4800]$. The observed trend is consistent over all 4 tasks: the larger the set of human annotations the better the performance of both $\boldsymbol{M_{human}}$ and $\boldsymbol{M_{RE+human}}$. For the first 2 tasks, $\boldsymbol{M_{RE+human}}$ surpasses all other competitors at 20; it takes 50 human annotations in Bill Date

Table 4: Examples of misclassified strings by $\boldsymbol{M_{RE}}$ and ***RE*** for Date Time task. The first columns shows number of misclassified strings, number of positives, and number of negaives. The last column represent human label and classifications by ***RE***, and $\boldsymbol{M_{RE}}$. Datetime is in bold for positive human annotation.

task, and $2,000$ in Email Address task.

5.3 Case Studies

From Table 3, we observe that $\boldsymbol{M_{RE}}$ achieves higher F1 scores than ***RE*** by about 2.3% on Date Time and 1.6% on Course Number tasks. This is a seemingly surprising outcome; NN trained on weak labels does better on human labeled test data than the REs used to generate the weak labels. To provide an insight, in Table 4 we illustrate example strings on which ***RE*** and $\boldsymbol{M_{RE}}$ disagree. *Group 1* consists of 19 strings where ***RE*** is correct and $\boldsymbol{M_{RE}}$ is not. *Group 2* consists of 48 strings where ***RE*** is incorrect and $\boldsymbol{M_{RE}}$ is correct. Looking at the examples in the first and last 2 rows of the table, we find strings that match RE with `YYYYMMDDhhmmss` format. This is an unusual form and it is expected that it might not always correspond to datetime entity. We hypothesize that the neural network encountered many negative strings in the weakly labeled data that have a similar form and learned that this form is not a reliable predictor of datetime.

Rows 6 - 8 in Table 4 illustrate the resilience of $\boldsymbol{M_{RE}}$ to small variations in the original REs. For example, despite *an extra space* in row 6, *a missing colon* in row 7, and *a mixture of spoken language* in row 8, $\boldsymbol{M_{RE}}$ is able to detect those entities, but REs are not. We give cases where $\boldsymbol{M_{RE}}$ makes mistakes in rows 3 - 5, showing that the NN is not able to learn the underlying REs with 100% accuracy.

To summarize, the answer to **Q2**, it appears that NNs are more noise resilient than REs.

5.4 Impact of the Initial REs

In this subsection, we investigate the impact of the choice of REs R on the accuracy of NN models. Since ***Naive*** and $\boldsymbol{M_{human}}$ models are not affected by R, we compare only three models in this subsection: ***RE***, $\boldsymbol{M_{RE}}$ and $\boldsymbol{M_{RE+human}}$. We select 4 out of the 25 REs in the datetime task for this study. The 4 REs are of different quality. We list the 4 REs in Figure 3. An example pattern that RE1 matches is `20180503101212`, for RE2 it is `2018-05-03 10:12:12`, for RE3 it is `2018-05-03T10:12:12Z` in UTC time zone and for RE4 it is `2018-05-03 10:12:12+00:00` or `2018-05-03 10:12:12-00:00`. We also consider the quality of NNs trained on weak labels from the whole set of 25 REs, denoted as All.

In Table 5 we compare the performance of ***RE*** and $\boldsymbol{M_{RE}}$ for the 5 different selections of REs for weak labeling. It can be observed that RE1 is the weakest individual RE in the group with F1 = 4.83, while RE4 is the strongest with F1= 41.86. Using all 25 REs gives the highest accuracy of F1= 76.77. We can see that $\boldsymbol{M_{RE}}$ closely follows the performance of ***RE*** and it is interesting to observe that $\boldsymbol{M_{RE}}$ becomes visibly superior only with good REs.

In Figure 3, we plot the 4 accuracy metrics for model $\boldsymbol{M_{RE+human}}$, which was pretrained on weakly labeled data generated by 5 different choices of REs, with varying initial RE sets and sizes of human annotations. We observe a significant influence of REs on accuracy. We can also observe that as the number of strong labels grows, the impact of RE choice decreases. When the number

Initial Set	***RE***				M_{RE}

RE4: (20[0-9][0-9])-(0[1-9]|1[0-2])-(\d{2})T([01][0-9]|2[0-3]):([0-5][0-9]):([0-5][0-9])\.([0-9]{1,10})Z
```

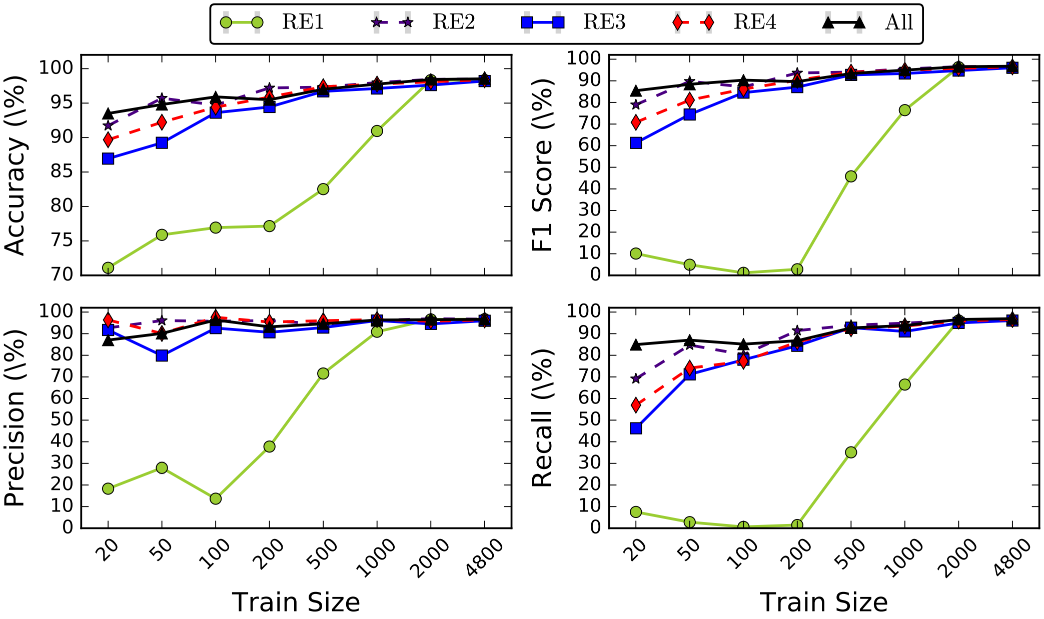

Figure 3: Performance of $M_{RE+human}$ for different initial sets of REs and sizes of D_{human}.

of strong labels exceeds $1,000$, the impact of the RE choice becomes negligible.

In summary, to answer **Q3**, there is a trade-off between creating more REs and creating more strong labels: (1) If designing a comprehensive RE takes a lot of time, a good strategy may be to take some time to construct one moderately good RE and spend more time on data labeling. (2) If the pattern is easy to describe by an RE, it may be a good strategy to spend time on creating a better set of REs and spend less time on labeling.

6 Conclusions

The main premise of this work is that it is practically impossible to create REs capable of identifying entities with perfect precision and recall at web scale. This paper explores ways to combine the expressive power of REs, ability of deep learning, and human-in-the loop into a novel integrated framework for entity recognition in web data. The framework starts by creating or collecting the existing REs for a particular type of an entity type (e.g., emails). Those REs are then used over a large document corpus to collect weak labels for the entity mentions and an NN is trained to predict those RE-generated weak labels. Finally, a human expert is asked to label a small set of documents and the neural network is fine tuned on those documents. The experimental evaluation on several entity identification problems shows that the proposed framework achieves impressive accuracy, while requiring very modest human effort.

Web sources often change in ways that prevent the induced REs from extracting data correctly. At the web scale, we require automated tools to maintain them. One direction of future work is to use our framework to diagnose when a RE is broken over a text stream.

Abstract

Knowledge Graph (KG) embedding has emerged as an active area of research resulting in the development of several KG embedding methods. Relational facts in KG often show temporal dynamics, e.g., the fact *(Cristiano_Ronaldo, playsFor, Manchester_United)* is valid only from 2003 to 2009. Most of the existing KG embedding methods ignore this temporal dimension while learning embeddings of the KG elements. In this paper, we propose HyTE, a temporally aware KG embedding method which explicitly incorporates time in the entity-relation space by associating each timestamp with a corresponding hyperplane. HyTE not only performs KG inference using temporal guidance, but also predicts temporal scopes for relational facts with missing time annotations. Through extensive experimentation on temporal datasets extracted from real-world KGs, we demonstrate the effectiveness of our model over both traditional as well as temporal KG embedding methods.

1 Introduction

Knowledge Graphs (KGs) are large multi-relational graphs where nodes correspond to entities, and typed edges represent relationships among them. KGs encode factual beliefs in the form of triple (entity, relation, entity), e.g., *(Brussels, isCapitalOf, Belgium)*. Examples of a few KGs include NELL (Mitchell et al., 2018), YAGO (Suchanek et al., 2007), and Freebase (Bollacker et al., 2008). KGs have been found to be useful for a variety of tasks, viz., Information Retrieval (Kotov and Zhai, 2012; Xiong and Callan, 2015), Question Answering (Dong et al., 2015; Bordes et al., 2015; Yao and Durme, 2014), among others.

KG embedding has emerged as a very active area of research over the last few years, resulting in the development of several techniques (Bordes et al., 2013; Nickel et al., 2016b; Yang et al., 2014; Lin et al., 2015; Trouillon et al., 2016; Dettmers et al., 2018; Guo et al., 2018). These methods learn high-dimensional vectorial representations for nodes and relations in the KG, while preserving various graph and knowledge constraints.

We note that KG beliefs are not universally true, as they tend to be valid only in a specific time period. For example, *(Bill Clinton, presidentOf, USA)* was true only from 1993 to 2001. KG beliefs with such temporal validity marked are called as temporally scoped. These temporal scopes are increasingly available on several large KGs, e.g., YAGO (Suchanek et al., 2007), Wikidata (Erxleben et al., 2014). The mainstream KG embedding methods ignore the availability or importance of such temporal scopes while learning embeddings of nodes and relations in the KGs. These methods treat the KG as a static graph with the assumption that the beliefs contained in them are universally true. This is clearly inadequate and it is quite conceivable that incorporating temporal scopes during representation learning is likely to yield better KG embeddings. In spite of its importance, temporally aware KG embeddings is a relatively unexplored area. Recently, a KG embedding method which utilizes temporal scopes was proposed in (Jiang et al., 2016). However, instead of directly incorporating time in the learned embeddings, the method proposed in (Jiang et al., 2016) first learns temporal order among relations (e.g., *wasBorIn* → *wonPrize* → *diedIn*). These relation orders are then incorporated as constraints during the KG embedding stage. Thus, the embedding learned by (Jiang et al., 2016) is not explicitly temporally aware.

In order to overcome this challenge, in this paper, we propose *Hyperplane-based Temporally aware KG Embedding (HyTE)*, a novel KG em-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2001–2011
Brussels, Belgium, October 31 - November 4, 2018.

bedding technique which directly incorporates temporal information in the learned embeddings. HyTE fragments a temporally-scoped input KG into multiple static subgraphs with each subgraph corresponding to a timestamp. HyTE then projects the entities and the relations of each subgraph onto timestamp specific hyperplanes. We learn the hyperplane (normal) vectors and the representation of the KG elements distributed over time jointly. Our contributions are as follows.

- We draw attention to the important but relatively unexplored problem of temporally aware Knowledge Graph (KG) embedding. In particular, we propose HyTE, a temporally aware method for learning Knowledge Graph (KG) embedding.
- In contrast to previous time-sensitive KG embedding methods, HyTE encodes temporal information directly in the learned embeddings. This enables us to predict temporal scopes for previously unscoped KG beliefs.
- Through extensive experiments on multiple real-world datasets, we demonstrate HyTE's effectiveness.

We have made HyTE's source code and datasets used in the paper available at https://github.com/malllabiisc/HyTE

2 Related Work

Temporal fact and event extraction: Time, apart from being an information, also introduces a separate dimension to knowledge. Thus temporal scoping of relational facts is an imperative part of automatic knowledge graph construction and completion. T-YAGO (Wang et al., 2010) extracts temporal facts from semi-structured data like Wikipedia Infoboxes, and categories using only regular expressions. On the other hand, systems like PRAVDA harvests temporal information from free text sources using label propagation. CoTS (Talukdar et al., 2012b) uses integer linear program based approach to model temporal constraints and proposes joint inference framework with few seed examples.

A method for discovering temporal ordering among factual relations was proposed in (Talukdar et al., 2012a). The task of extracting temporally rich events and time expressions and ordering between them is introduced in TempEval challenge (UzZaman et al., 2013; Verhagen et al., 2010). Various approaches (McDowell et al., 2017; Mirza and Tonelli, 2016) made for solving the task proved to be effective in other temporal reasoning tasks. Although we try to attend to a similar problem, the method proposed in this paper is more related to relational embedding learning paradigm than scoping temporal facts from the web.

Relational embedding learning methods: An enormous amount of research has been done in this field, especially for KG completion or link prediction task (Bordes et al., 2013). (Nickel et al., 2016a) provides a detailed review of the recent KG embedding learning methods. These can be broadly categorized into two different paradigms. TransE(Bordes et al., 2013), TransH(Wang et al., 2014), TransR (Lin et al., 2015), TransD (Ji et al., 2015) are the translational distance-based models. Here the main theme is to minimize the distance between two entity vectors where one of them is translated by a relation vector. The realm of matrix factorization based methods includes bilinear model RESCAL (Nickel et al., 2011), DistMult (Yang et al., 2014), HolE (Nickel et al., 2016b). Some of the other notable models are Neural Tensor Networks(NTN) (Socher et al., 2013). We also provide some background on the traditional methods in section 3. However, the temporal dimension remains silent in all of these inference methods.

Link prediction through embeddings of the graph nodes and edges, are not only useful for inference over KG but also important for predicting incomplete pieces of the KG itself. Learning temporally steered embeddings is an important but proportionately less explored problem. Only some handful of methods have been proposed for this purpose. t-TransE (Jiang et al., 2016) learns time aware embedding by learning relation ordering jointly with TransE. They try to inflict temporal order on time-sensitive relations e.g. $wasBornIn \rightarrow wonPrize \rightarrow diedIn$. t-TransE does not use the time information directly, whereas we incorporate time directly in our learning algorithm. Another approach Know-Evolve (Trivedi et al., 2017) models the non-linear temporal evolution of KG elements using bilinear embedding learning method. They deploy recurrent neural network to capture non-linear dynamical characteristics of the embeddings. However, they restrict their domain to event-based interac-

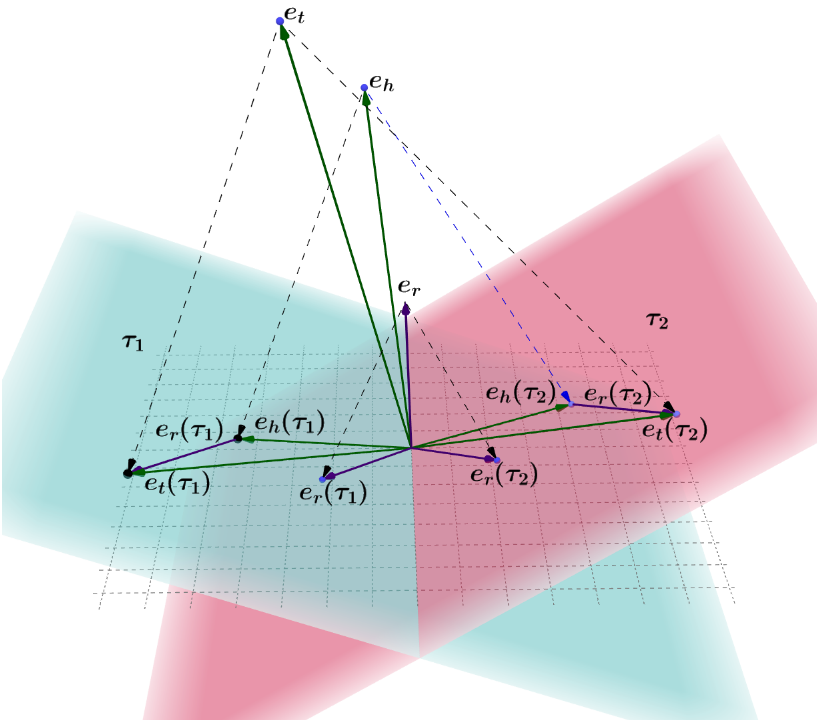

Figure 1: In the figure, the vectors e_h, e_r and e_t correspond to the triple (h, r, t) that is valid at time τ_1 and τ_2. $e_h(\tau_1), e_r(\tau_1)$ and $e_t(\tau_1)$ are the projections of this triple on the hyperplane corresponding to time τ_1 (similarly for time τ_2). Our method HyTE minimizes the translational distance, $\sum_i \|e_t(\tau_i) + e_r(\tau_i) - e_t(\tau_i)\|_1$, in order to learn the temporally aware representations of entities and relations in this triple.

tion type of datasets which are fairly dense in nature. Leblay and Chekol (2018) propose a method for temporal embedding learning using side information from the atemporal part of the graph. However, we use purely temporal KG to learn the temporally aware embedding.

3 Background: KG Embedding

In this section, we provide an overview of the existing methods for knowledge graph representation learning (Bordes et al., 2013), (Wang et al., 2014). Consider a KG $\mathcal{G}$ with a set of entities $\mathcal{E}$. The set of directed edges, $\mathcal{D}^+$ consists of triples (h, r, t), where the edge direction is from h to t and the edge label (also popularly known as relation) is r.

3.1 TransE and TransH

TransE (Bordes et al., 2013) is a simple and efficient translational distance model. It interprets the relation as a translation vector between head and tail entity vectors. Given two entity vectors e_h, e_t $\in \mathbb{R}^n$, it tries to map the relation as a translation vector $e_r \in \mathbb{R}^n$, i.e., $e_h + e_r \approx e_t$ for observed triple (h, r, t). So the distance based scoring function used for plausible triples is hereby,

$$f(h, r, t) = \|e_h + e_r - e_t\|_{l_1/l_2},$$

where, $\|\cdot\|_{l_1/l_2}$ is the l_1 or l_2-norm of the difference vector. $f(h, r, t)$ will be minimized for observed or correct triples. In order to differentiate between correct and incorrect triples, their TransE score difference is minimized using margin based pairwise ranking loss. More formally, we optimize

$$\sum_{x \in \mathcal{D}^+} \sum_{y \in \mathcal{D}^-} \max(0, f(x) - f(y) + \gamma),$$

with respect to the entity and relation vectors. γ is a margin separating correct and incorrect triples. $\mathcal{D}^+$ is the set of all positive triples, i.e., observed triples in KG. The negative samples are drawn randomly from the set -

$$\mathcal{D}^- = \{(h', r, t) | h' \in \mathcal{E}, (h', r, t) \notin \mathcal{D}^+\}$$
$$\cup \{(h, r, t') | t' \in \mathcal{E}, (h, r, t') \notin \mathcal{D}^+\}.$$

TransE fails to model the many-to-one, one-to-many, many-to-many type of relations as it does not learn a distributed representation of entities when it is involved with many relations. In order to tackle these situations, TransH was proposed. TransH (Wang et al., 2014) models a relation r as a vector on a relation specific hyperplane and project entities associated with it on that particular hyperplane in order to learn distributed representation of the entities.

We notice that not only the role of the entities changes with time, but also the relationship between them changes. In this paper, we intend to capture this temporal behavior of the entities and relations and try to learn their embeddings accordingly. As discussed above, TransH (Wang et al., 2014) uses relation specific hyperplanes in order to prevent an entity from exhibiting identical characteristic when it is involved with different relations. Taking inspiration from the objective of TransH, we propose a hyperplane based method for learning KG representation distributed in time.

4 Proposed Method: HyTE

In this section, we present a detailed description of HyTE (Figure 1) which not only exploits the relational properties among entities but also uses the temporal meta-data associated with them.

4.1 Temporal Knowledge Graph

Usually knowledge graphs are treated as a static graph consisting of triples in form of (h, r, t). Adding a separate time dimension to the triple makes the KG dynamic. Consider the quadruple $(h, r, t, [\tau_s, \tau_e])$, where τ_s and τ_e denote the start and end time during which the triple (h, r, t) is valid. Unlike (Jiang et al., 2016), we incorporate this time meta-fact directly into our learning algorithm to learn temporal embeddings of the KG elements. Given the timestamps, the graph can be dismantled into several static graphs consisting of triples that are valid in the respective time steps, e.g., knowledge graph G can be expressed as $\mathbb{G} = \mathbb{G}_{\tau_1} \cup \mathbb{G}_{\tau_2} \cup \cdots \cup \mathbb{G}_{\tau_T}$, where τ_i, $i \in 1, 2, \cdots, T$ are the discrete time points.

We constructed this temporal component-graphs ($\mathbb{G}_\tau$) from the quadruples by considering (h, r, t) to be a positive triple at each time point between τ_s and τ_e. Now, given a quadruple $(h, r, t, [\tau_s, \tau_e])$, we consider it to be a positive triple for each time point between τ_s and τ_e. So, we include (h, r, t) in each $\mathbb{G}_\tau$, where $\tau_s \leq \tau \leq \tau_e$. The set of positive triple corresponding to time τ is denoted as $\mathcal{D}^+_\tau$.

4.2 Projected-Time Translation

TransE considers entity and relation vectors in the same semantic space for a static graph. We observe that time is the main source of different many-to-one, one-to-many or many-to-many relations, e.g., (h, r) pair can be associated with different tail entity t at different points of time. Thus traditional methods fail to disambiguate them directly. In our time guided model, we want the entity to have a distributed representation associated with different time points.

We represent time as a hyperplane i.e., for T number of time steps in the KG, we will have T different hyperplanes represented by normal vectors $w_{t_1}, w_{t_2}, \cdots, w_{t_T}$. Thus, we try to segregate the space into different time zones with the help of the hyperplanes. Now, triples valid at time τ (i.e., the sub graph $\mathbb{G}_\tau$) are projected onto time specific hyperplane w_τ, where their translational distance (TransE Section 3 our case) is minimized. To illustrate, in Figure 1, the triple (h, r, t) is valid for both time frame τ_1 and τ_2. Hence they are projected on hyperplanes corresponding to those times.

Now we compute the projected representation on w_τ as,

$$P_\tau(e_h) = e_h - (w_\tau^\top e_h) w_\tau,$$

$$P_\tau(e_t) = e_t - (w_\tau^\top e_t) w_\tau,$$

$$P_\tau(e_r) = e_r - (w_\tau^\top e_r) w_\tau,$$

where we restrict $\|w_\tau\|_2 = 1$.

We expect that a positive triple, valid at time τ, will have the mapping as $P_\tau(e_h) + P_\tau(e_r) \approx P_\tau(e_t)$. Thus, we use the following scoring function.

$$f_\tau(h, r, t) = \|P_\tau(e_h) + P_\tau(e_r) - P_\tau(e_t)\|_{l_1/l_2}.$$

We learn $\{w_\tau\}_{\tau=1}^T$ for each time stamp τ, along with the entity and relation embeddings. So, by projecting the triple into its time hyperplane, we incorporate temporal knowledge into the relation and entity embeddings, i.e., the same distributed representation will have a different role in different points in time.

Optimization : As mentioned in section 3.1 , we minimize the margin-based ranking loss.

$$\mathcal{L} = \sum_{\tau \in [T]} \sum_{x \in \mathcal{D}^+_\tau} \sum_{y \in \mathcal{D}^-_\tau} \max(0, f_\tau(x) - f_\tau(y) + \gamma),$$

where, $\mathcal{D}_{\tau}^{+}$ is the set of valid triples with timestamp τ. The negative samples are drawn from the set of all negative samples, $\mathcal{D}_{\tau}^{-}$. We explored two different types of negative sampling:

- **Time agnostic negative sampling(TANS)** considers the set of all the triples that does not belong to the KG, irrespective of timestamps. More formally, for time step τ the negative samples are drawn from the set,

$$\mathcal{D}_{\tau}^{-} = \{(h^{'}, r, t, \tau) | h^{'} \in \mathcal{E}, (h^{'}, r, t) \notin \mathcal{D}^{+} \} \cup \{(h, r, t^{'}, \tau) | \, t^{'} \in \mathcal{E}, (h, r, t^{'}) \notin \mathcal{D}^{+} \}. \quad (1)$$

- **Time dependent negative sampling(TDNS)** emphasizes on time. Along with the time agnostic negative sample, we add extra negative samples which are present in the KG but do not exist in the subgraph for a particular time stamp. Thus we draw negative samples from the set,

$$\mathcal{D}_{\tau}^{-} = \{(h^{'}, r, t, \tau) | h^{'} \in \mathcal{E}, (h^{'}, r, t) \in \mathcal{D}^{+}, (h^{'}, r, t, \tau) \notin \mathcal{D}_{\tau}^{+} \} \cup \{(h, r, t^{'}, \tau) | \, t^{'} \in \mathcal{E}, (h, r, t^{'}) \in \mathcal{D}^{+}, (h, r, t^{'}, \tau) \notin \mathcal{D}_{\tau}^{+} \}. \quad (2)$$

The above mentioned loss $\mathcal{L}$ is minimized subjected to the constraints.

$$\|e_p\|_2 \leq 1, \forall \, p \in \mathcal{E}, \quad \|w_\tau\|_2 = 1, \forall \, \tau \in [T]$$

We enforce the first one by adding l_2- regularization of entity vectors with $\mathcal{L}$. We take care of the second constraint by normalizing the time embeddings viz., the hyperplane normal vectors after each update of stochastic gradient descent.

We perform link prediction as well as temporal scoping in order to show the effectiveness of HyTE. For link prediction, we train the model using the optimization procedure as described with time agnostic negative sampling (TANS, Equation 1). The temporal scoping task (Section 5.5) requires the time hyperplanes to be well structured in the embedding space. The time-dependent negative sampling (TDNS Equation 2) is more suitable in case of the temporal scoping problem.

Datasets	#Entity	#Relations	Train/Valid/Test
Wikidata12K	12,554	24	32.5k/4k/4k
YAGO11K	10,623	10	16.4k/2k/2k

Table 1: Details of datasets used. Please see Section 5.1 for details.

5 Experiments

We evaluate our model and compare with different state-of-the-art baselines based on Link prediction(Section 5.3,5.4) and Temporal scoping (Section 5.5). Evaluation metrics used are same as that of the traditional KG embedding method (Bordes et al., 2013) for link prediction task. For temporal scoping task, we present an evaluation criteria as none of the baselines are applicable for this task.

5.1 Datasets

Knowledge Graphs such as Wikidata (Erxleben et al., 2014) and YAGO (Suchanek et al., 2007) have time annotations on a subset of the facts. We extracted the temporally rich subgraph from them for testing our algorithm as well as the baselines.

YAGO11k: In the YAGO3 knowledge graph (Mahdisoltani et al., 2013), some temporally associated facts have meta-facts as *(#factID, occurSince, t_s), (#factID, occurUntil, t_e)*. The total number of time annotated facts containing both occursSince and occursUntil are 722,494. Out of them, we selected top 10 most frequent temporally rich relations. In order to handle sparsity, we recursively remove edges containing entity with only a single mention in the subgraph. This ensures a healthy connectivity within the graph. Finally, we obtain a purely temporal graph of 20.5k triples and 10,623 entities by following this procedure.

Wikidata12k: We extracted this temporal Knowledge Graph from a preprocessed dataset of Wikidata proposed by (Leblay and Chekol, 2018)[1]. We followed a similar procedure as described in YAGO11k. Here also, we distill out the subgraph with time mentions for both start and end. We ensure that no entity has only a single edge connected to it. We select top 24 frequent temporally rich relations for this case, which resulted in 40k triples with 12.5k entities. The dataset is almost double in size with respect to YAGO11k.

---

5.2 Method Compared

For evaluating the performance of our algorithm, we compare against the following methods:

- **t-TransE** (Jiang et al., 2016): This method uses a temporal ordering of relations to model knowledge evolution in the temporal dimension. They regularize the traditional embedding score function with observed relation ordering with respect to head entities.
- **HolE** (Nickel et al., 2016b): We consider this method as a representative of the state-of-the-art in non-temporal KG representation learning.
- **TransE** (Bordes et al., 2013): This is a simple but effective translation based model. We build HyTE on top of TransE and demonstrate the gains over this method.
- **TransH** (Wang et al., 2014): This method models each relation as different hyperplanes on which the translation operations are carried out. Our proposed method, HyTE also modifies TransE in a similar fashion by treating the timestamps as hyperplanes.
- **HyTE** : Our proposed method. Please see Section 4 for more details.

5.3 Entity Prediction

The task here is to predict the missing entity, given an incomplete relational fact with its time. We experimented with both YAGO11K and Wikidata12k dataset. Training is done in perspective of both head and tail prediction. More formally, for generation of negative sample from a correct triple (h, r, t, τ), we split them in two parts - $(h, r, ?, \tau)$ (for tail entity prediction) and $(?, r, t, \tau)$ (for head entity prediction). In this task, we follow the TANS (Equation 1) procedure for generating negative samples, i.e., for each of tail and head query terms we randomly replace an entity such that newly generated triple is not observed in the graph, for eg, we sample t' such that $t' \in \mathscr{E} \setminus t$ and $(h, r, t^{'}, \tau) \notin D_{\tau}^{+}$.

Ranking Protocol: For a test triple (h, r, t, τ), we generate corrupted triples by replacing tail entity (for tail prediction) or head entity (for head prediction) with all possible entities. Filtered protocol, proposed by (Bordes et al., 2013), says that the corrupted triples must not be a part of the graph itself. To illustrate, given a test triple (h, r, t) for tail prediction task, we compute scores for the candidate set $C(h, r) = \{(h, r, t^{'} : \forall t^{'} \in \mathscr{E})\} \setminus (Train \cup Test \cup Valid) \cup (h, r, t)$. We rank all the triples in $C(h, r)$ in the increasing order of their score and find the rank of the actual triple (h, r, t). We report the mean rank over all the test queries (MR) and proportion of correct entities in top 10 rank (Hits@10).

5.4 Relation Prediction

The aim of this task is to predict the relation between two entities, i.e, for a given time-stamped triple with missing relation $(h, ?, t, \tau)$, we predict the relation r. For evaluation, we corrupt the triples with all possible relations and report the rank of the actual relation. We report Hits@1 for this task as the number of relations are quite less in numbers for both the datasets, 10 and 24 for YAGO11k and Wikidata12k respectively. Please note that we do not train our model separately for this task, rather we report the values obtained by the exact same model used for head and tail entity prediction.

The main motivation for this task is to deal with the relational conflict between two entities at a particular time-scope. For example, given the year 1992, a person 'X' and a city 'Y', one would like to know if he/she was $bornIn$ or $diedIn$ that city in that year. Through the explicit use of temporal information during training, we find that our method HyTE outperforms the baseline methods in both the datasets (as shown in 6.1)

5.5 Temporal Scope Prediction

Given the scarcity of time annotations of the KG facts, predicting time for atemporal part of the KG is an important problem. Unlike the previous baseline methods, our model can predict the time scope for a given triple. In order to perform better in this task, we want the hyperplanes to be well separated even after maintaining consistency with the positive triples. To incorporate this nature during training, we use the time-dependent negative sampling technique (TDNS Equation 2). Rest of the training procedure remains the same as the link prediction task. The model is trained on the same train split used for link prediction. In this task, we predict the time interval or the time instance τ for a given test triple $(h, r, t, ?)$. We project the relation and the entities of the triple on all the time hyperplanes and check the plausibility of that test triple on each

Dataset	YAGO11K				Wikidata12K			
Metric	Mean Rank		Hits@10(%)		Mean Rank		Hits@10(%)	
	tail	head	tail	head	tail	head	tail	head
Trans-E (Bordes et al., 2013)	504	2020	4.4	1.2	520	740	11.0	6.0
TransH (Wang et al., 2014)	354	1808	5.8	1.5	423	648	23.7	11.8
HolE (Nickel et al., 2016b)	1828	1953	29.4	13.7	734	808	25.0	12.3
t-TransE (Jiang et al., 2016)	292	1692	6.2	1.3	283	413	24.5	14.5
HyTE	**107**	**1069**	**38.4**	**16.0**	**179**	**237**	**41.6**	**25.0**

Table 2: Mean Rank (lower the better) and Hits@10(higher the better) for different methods for Entity Prediction task. Proposed method HyTE outperforms all the traditional approaches. The better performance of HyTE over t-TransE can be attributed to the fact that it incorporates time directly. Please see Section 6.1 for details.

Dataset	YAGO11K		Wikidata12K	
Metric	Mean Rank	Hits@1(%)	Mean Rank	Hits@1(%)
Trans-E (Bordes et al., 2013)	1.7	78.4	1.35	88.4
TransH (Wang et al., 2014)	1.53	76.1	1.4	88.1
HolE (Nickel et al., 2016b)	2.57	69.3	2.23	83.96
t-TransE (Jiang et al., 2016)	1.66	75.5	1.97	74.2
HyTE	**1.23**	**81.2**	**1.13**	**92.6**

Table 3: Mean Rank (lower the better) and Hits@1 (higher the better) for different methods for Relation Prediction Task. Proposed method HyTE outperforms all the traditional approaches. Even though t-TransE imposes implicit relation ordering, HyTE beats it with a high margin. Please see Section 6.1 for details.

Negative Sampling	YAGO11K	Wikidata12k
TANS (Equation 1)	14.0	29.3
TDNS (Equation 2)	**9.88**	**17.6**

Table 4: The predicted Mean Rank (lower the better) for temporal Scoping. The number of classes are 61 and 78 for YAGO11K and Wiki-data12k respectively. The results depict the effectiveness of TDNS. Please see Section 6.2

of them. For evaluation, we order the time frames in increasing order of their plausibility score for that particular triple. Now, we select the rank of the time(τ) associated with the test triple. If the associated time is an interval, we consider the lowest rank among the times in between the interval.

6 Results

Implementation details: For all the methods, we have kept batch size b = 50k on both the datasets. The dimensions of the embeddings (d) are varied in the range $\{64, 128, 256\}$. The margins(η) for all the methods are chosen from the set $\{1, 2, 5, 10\}$. Learning rate used for SGD, $lr \in \{0.01, 0.001, 0.0001\}$.

The best configuration is chosen by corresponding lowest MR on the validation set. For both YAGO11k and Wikidata12k, we obtained $d = 128$, $\eta = 10$, $lr = 0.0001$ using ℓ_1-norm in the scoring function.

Both YAGO11k and Wikidata12k contain time annotations to the granularity of days. For the temporal scoping task, we only deal with year level granularity by dropping the month and date information. Timestamps are then treated as 61 and 78 different intervals for YAGO and Wikidata respectively. The main motive behind having time classes is to distribute the time annotations in the KG uniformly. For example, less frequent year mentions are clubbed into same time class but years with high frequency forms individual classes. We take care of the unbalance that may occur in terms of number of triples in a particular interval by applying a minimum threshold of 300 triples per interval during construction. To illustrate, in Wikidata there are classes like 1596-1777, 1791-1815 with a large span as the events occurring on those points of time are quite less in KG. The years like 2013, 2014 being highly frequent are self-contained.

6.1 Performance analysis & comparison

The obtained results for different tasks are based on the above mentioned hyperparameters.

Link Prediction: The results reported in Table 2 demonstrate the efficacy of HyTE. We observe that our model outperforms the traditional state-of-the-art link prediction model HolE (Nickel et al., 2016b) by a significant margin in both the datasets. We also show a large boost in performance over TransE (Bordes et al., 2013). This significant gain empirically validates our claim that including temporal information in a principled

Table 5: Example of Qualitative Results on relation prediction. The order of prediction is in descending order. Correct one is in **bold**. Please refer Section 6.2 for details.

fashion helps to learn richer embeddings of the KG elements. We notice that HolE is performing significantly poor in terms of MR but it exceeds the other baselines in Hits@10 by a large margin.

Again, in comparison with the temporal model t-TransE (Jiang et al., 2016), HyTE proves to be effective. t-TransE performs better than TransE and HolE due to its implicit time incorporation through relation ordering. HyTE with its direct inclusion of time in the relation-entity semantic space outperforms all of them.

Relation prediction: Again, in this scenario, we show improvement over baselines. We hypothesize that time scope information helps to disambiguate among relations e.g. traditional methods like TransE or HolE will confuse between relations like wasBornIN, diedIn. Where time information surely helps to resolve that conflict. From Table 3, we validate this claim. In Section 6.2, we also demonstrate some qualitative result in favor of our assertion.

Temporal scoping of facts: We report the rank of correct time instance of the triple. If the triple scope is an interval of time, we consider the lowest rank that corresponds to the time within that interval. The ranks are reported in table 4 for both the datasets. The baseline model t-TransE (Jiang et al., 2016) is not applicable here as it does not use the time meta-facts directly. We also observe that the HyTE hyperplanes form a sequential map in the space. We discuss it with details in subsection 6.2.

6.2 Qualitative results

Table 5 contains some of the qualitative analyses for the relation prediction task. We mention some of the cases where transE is confusing between the temporal relations like *wasBornIn* and *diedIn*. Consider the second example in Table 5, where transE wrongly predicts *wasBornIn* . HyTE predicts *diedIn* as it has a prior knowledge that S.Laubenthal "was born in 1943", "created Excalibur on 1973" from the training data. As the query year is 2002, our method comes to such a conclusion through its relative temporal ordering. We see many examples of this kind, where HyTE is naturally learning some relation ordering in parallel with the temporal direction. We observe many type inconsistency in relation prediction for our model, e.g., for this fact *(Lauren Miller, wasBornIn, Lakeland,Florida,[1982,1982])*, our model predicts *isMarriedTo*. This can be attributed to the fact that we do not impose any type related constraints in our model. We will look forward to incorporating type and temporal constraints within our model as future work.

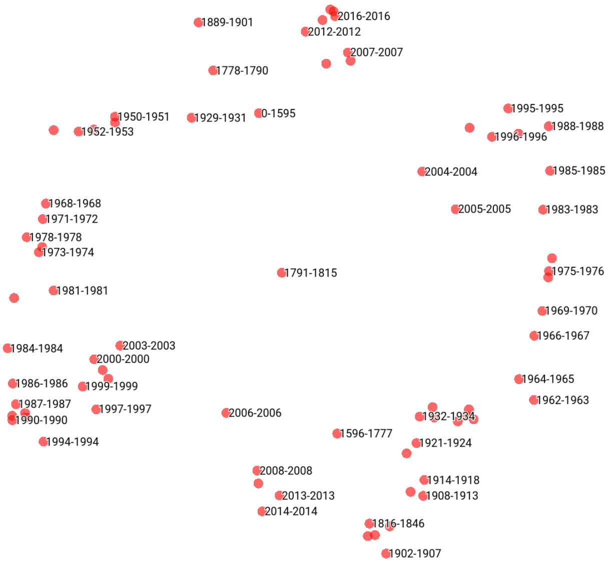

Figure 2: The figure illustrates 2-d PCA projection of the 128 dimensional time embeddings which are obtained after training HyTE for temporal scoping task. We observe that the trained time representations are forming natural clusters and ordering. Please ref Section 6.2

In Figure 2, we show a 2-d PCA projection of the 128-dimensional normal vectors of the hyperplanes. These vectors are trained for the temporal scoping task with time-dependent negative sampling (Equation 2). This figure demonstrates the ability of HyTE to structure the hyperplanes in the entity-relation space according to the data. Also, note that we do not regularize the model with any ordering constraint, but it learns the temporal ordering as well as the clustering from the data itself. We hypothesize that this phenomenon emerges due to TDNS (Equation 2). However, in case of link prediction, we notice that the extra samples are affecting performance as they originate from the KG itself.

7 Conclusion

We propose HyTE, a hyperplane-based method for learning temporally aware knowledge graph embeddings. Our method exploits temporally scoped facts of KG to perform link prediction as well as prediction of time scopes for unannotated temporal facts. Through extensive experiments on real-world datasets, we demonstrate effectiveness of HyTE over both traditional and time aware embedding methods. In future, we would like to incorporate type consistency information to further improve our model and also integrate HyTE with open-world knowledge graph completion (Shi and Weninger, 2018). We are hopeful that our proposed temporal representation learning algorithm will motivate further research on temporal KG embedding learning.

Abstract

Recent research efforts have shown that neural architectures can be effective in conventional information extraction tasks such as named entity recognition, yielding state-of-the-art results on standard newswire datasets. However, despite significant resources required for training such models, the performance of a model trained on one domain typically degrades dramatically when applied to a different domain, yet extracting entities from new emerging domains such as social media can be of significant interest. In this paper, we empirically investigate effective methods for conveniently adapting an existing, well-trained neural NER model for a new domain. Unlike existing approaches, we propose lightweight yet effective methods for performing domain adaptation for neural models. Specifically, we introduce adaptation layers on top of existing neural architectures, where no re-training using the source domain data is required. We conduct extensive empirical studies and show that our approach significantly outperforms state-of-the-art methods.

1 Introduction

Named entity recognition (NER) focuses on extracting named entities in a given text while identifying their underlying semantic types. Most earlier approaches to NER are based on conventional structured prediction models such as conditional random fields (CRF) (Lafferty et al., 2001; Sarawagi and Cohen, 2004), relying on hand-crafted features which can be designed based on domain-specific knowledge (Yang and Cardie, 2012; Passos et al., 2014; Luo et al., 2015). Recently, neural architectures have been shown effective in such a task, whereby minimal feature engineering is required (Lample et al., 2016; Ma and Hovy, 2016; Peters et al., 2017; Liu et al., 2018). Domain adaptation, as a special case for transfer learning, aims to exploit the abundant data of well-studied source domains to improve the performance in target domains of interest (Pan and Yang, 2010; Weiss et al., 2016). There is a growing interest in investigating the transferability of neural models for NLP. Two notable approaches, namely INIT (parameter initialization) and MULT (multitask learning), have been proposed for studying the transferrability of neural networks under tasks such as sentence (pair) classification (Mou et al., 2016) and sequence labeling (Yang et al., 2017b).

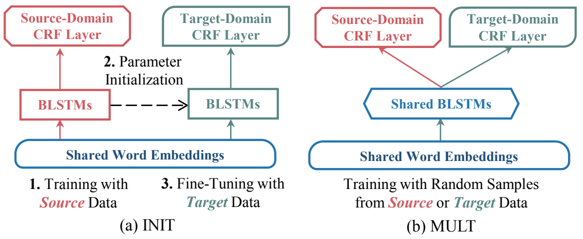

Figure 1: Two existing adaptation approaches for NER.

The INIT method first trains a model using labeled data from the source domain; next, it initializes a target model with the learned parameters; finally, it fine-tunes the initialized target model using labeled data from the target domain. The MULT method, on the other hand, simultaneously trains two models using both source and target data respectively, where some parameters are shared across the two models during the learning process. Figure 1 illustrates the two approaches based on the BLSTM-CRF (bidirectional LSTM augmented with a CRF layer) architecture for NER. While such approaches make intuitive senses, they also come with some limitations.

First, these methods utilize shared domain-general word embeddings when performing learning from both source and target domains. This essentially assumes there is no domain shift of input feature spaces. However, cases when the two domains are distinct (words may contain different se-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2012–2022

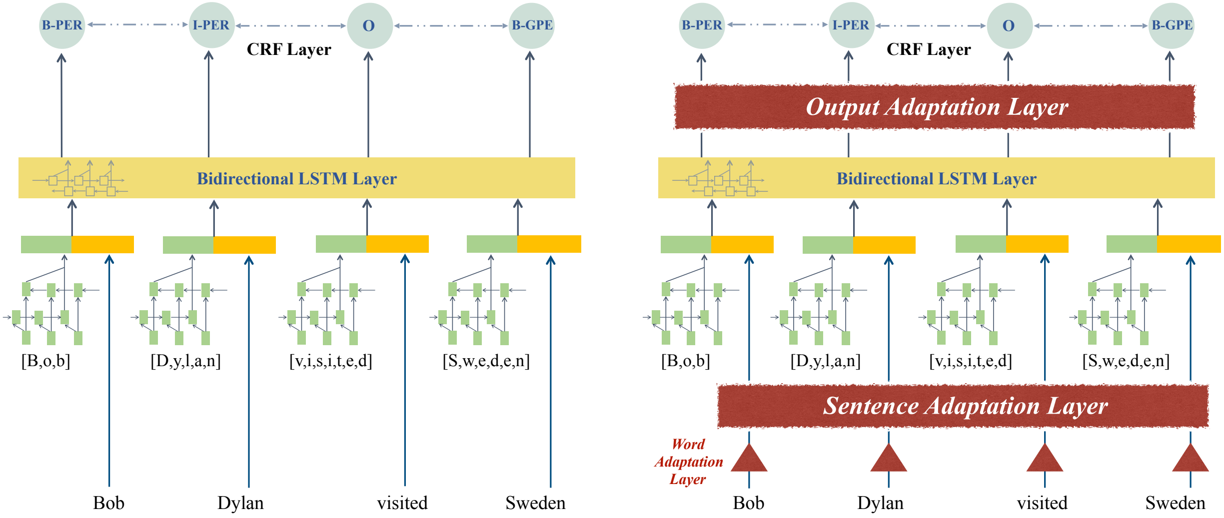

Figure 2: Our base model (left) and target model (right) where we insert new adaptation layers (highlighted in red).

mantics across two domains), we believe such an assumption can be weak.

Second, existing approaches such as INIT directly augment the LSTM layer with a new output CRF layer when learning models for the target domain. One basic assumption involved here is that the model would be able to re-construct a new CRF layer that can capture not only the variation of the input features (or hidden states outputted from LSTM) to the final CRF layer across two domains, but also the structural dependencies between output nodes in the target output space. We believe this overly restrictive assumption may prevent the model from capturing rich, complex cross-domain information due to the inherent linear nature of the CRF model.

Third, most methods involving cross-domain embedding often require highly time-consuming retraining word embeddings on domain-specific corpora. This makes it less realistic in scenarios where source corpora are huge or even inaccessible. Also, MULT-based methods need retraining on the source-domain data for different target domains. We think this disadvantage of existing methods hinders the neural domain adaptation methods for NER to be practical in real scenarios.

In this work, we propose solutions to address the above-mentioned issues. Specifically, we address the first issue at both the word and sentence level by introducing a *word adaptation layer* and *a sentence adaptation layer* respectively, bridging the gap between the two input spaces. Similarly, an *output adaptation layer* is also introduced between the LSTM and the final CRF layer, capturing the variations in the two output spaces. Furthermore, we introduce a single hyper-parameter that controls how much information we would like to preserve from the model trained on the source domain. These approaches are lightweight, without requiring re-training on data from the source domain. We show through extensive empirical analysis as well as ablation study that our proposed approach can significantly improve the performance of cross-domain NER over existing transfer approaches.

2 Base Model

We briefly introduce the BLSTM-CRF architecture for NER, which serves as our *base model* throughout this paper. Our base model is the combination of two recently proposed popular works for named entity recognition by Lample et al. (2016) and Ma and Hovy (2016). Figure 2 illustrates the BLSTM-CRF architecture.

Following Lample et al. (2016), we develop the comprehensive word representations by concatenating pre-trained word embeddings and character-level word representations, which are constructed by running a BLSTM over sequences of character embeddings. The middle BLSTM layer takes a sequence of comprehensive word representations and produces a sequence of hidden states, representing the contextual information of each token. Finally, following Ma and Hovy (2016), we build the final CRF layer by utilizing potential functions describing local structures to define the conditional probabilities of complete predictions for the given input sentence.

This architecture is selected as our base model due to its generality and representativeness. We note that several recently proposed models (Peters et al., 2017; Liu et al., 2018) are built based on it. As our focus is on how to better transfer such architectures for NER, we include further discussions of the model and training details in our supplementary material.

3 Our Approach

We first introduce our proposed three adaptation layers and describe the overall learning process.

3.1 Word Adaptation Layer

Most existing transfer approaches use the same domain-general word embeddings for training both source and target models. Assuming that there is little domain shift of input feature spaces, they simplify the problem as *homogeneous transfer learning* (Weiss et al., 2016). However, this simplified assumption becomes weak when two domains have apparently different language styles and involve considerable domain-specific terms that may not share the same semantics across the domains; for example, the term "*cell*" has different meaning in biomedical articles and product reviews. Furthermore, some important domain-specific words may not be present in the vocabulary of domain-general embeddings. As a result, we have to regard such words as out-of-vacabulary (OOV) words, which may be harmful to the transfer learning process.

Stenetorp et al. (2012) show that domain-specific word embeddings tend to perform better when used in supervised learning tasks.[1] However, maintaining such an improvement in the transfer learning process is very challenging. This is because two domain-specific embeddings are trained separately on source and target datasets, and therefore the two embedding spaces are *heterogeneous*. Thus, model parameters trained in each model are heterogeneous as well, which hinders the transfer process. How can we address such challenges while maintaining the improvement by using domain-specific embeddings?

We address this issue by developing a word adaptation layer, bridging the gap between the source and target embedding spaces, so that both input features and model parameters become homogeneous across domains. Popular pre-trained word embeddings are usually trained on very large corpora, and thus methods requiring re-training them can be extremely costly and time-consuming. We propose a straightforward, lightweight yet effective method to construct the word adaptation layer that projects the learned embeddings from the target embedding space into the source space. This method only requires some corpus-level statistics from the datasets (used for learning embeddings) to build the *pivot lexicon* for constructing the adaptation layer.

3.1.1 Pivot Lexicon

A *pivot word pair* is denoted as (w_s, w_t), where $w_s \in \mathcal{X}_S$ and $w_t \in \mathcal{X}_T$. Here, $\mathcal{X}_S$ and $\mathcal{X}_T$ are source and target vocabularies. A *pivot lexicon* $\mathcal{P}$ is a set of such word pairs.

To construct a pivot lexicon, first, motivated by Tan et al. (2015), we define $\mathcal{P}_1$, which consists of the ordinary words that have high relative frequency in both source and target domain corpora: $\mathcal{P}_1 = \{(w_s, w_t) | w_s = w_t, f(w_s) \geq \phi_s, f(w_t) \geq \phi_t\}$, where $f(w)$ is the frequency function that returns the number of occorrence of the word w in the dataset, and ϕ_s and ϕ_t are word frequency thresholds[2]. Optionally, we can utilize a customized word-pair list $\mathcal{P}_2$, which gives mappings between domain-specific words across domains, such as normalization lexicons (Han and Baldwin, 2011; Liu et al., 2012). The final lexicon is thus defined as $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2$.

3.1.2 Projection Learning

Mathematically, given the pre-trained domain-specific word embeddings $\mathbf{V_S}$ and $\mathbf{V_T}$ as well as a pivot lexicon $\mathcal{P}$, we would like to learn a linear projection transforming word vectors from $\mathbf{V_T}$ into $\mathbf{V_S}$. This idea is based on a bilingual word embedding model (Mikolov et al., 2013), but we adapt it to this domain adaptation task.

We first construct two matrices $\mathbf{V_S^*}$ and $\mathbf{V_T^*}$, where the i-th rows of these two matrices are the vector representations for the words in the i-th entry of $\mathcal{P}$: $\mathcal{P}^{(i)} = (w_s^i, w_t^i)$. We use $\mathbf{V_S^{*i}}$ to denote the vector representation of the word w_s^i, and similarly for $\mathbf{V_T^{*i}}$ and w_t^i.

Next, we learn a transformation matrix $\mathbf{Z}$ minimizing the distances between $\mathbf{V_S^*}$ and $\mathbf{V_T^*Z}$ with

---

[1] We also confirm this claim with experiments presented in supplementary materials.

[2] A simple way of setting them is to choose the frequency of the k-th word in the word lists sorted by frequencies.

the following loss function, where c_i is the confidence coefficient for the entry $\mathcal{P}^{(i)}$, highlighting the significance of the entry:

$$\underset{\mathbf{Z}}{\operatorname{argmin}} \sum_{i=1}^{|\mathcal{P}|} c_i \left\| \mathbf{V}_{\mathbf{T}}^{*\mathbf{i}} \mathbf{Z} - \mathbf{V}_{\mathbf{S}}^{*\mathbf{i}} \right\|^2 ,$$

We use normalized frequency ($\bar{f}$) and Sørensen-Dice coefficient (Sørensen, 1948) to describe the significance of each word pair:

$$\bar{f}(w_s) = \frac{f(w_s)}{\max_{w' \in \mathcal{X}_S} f(w')}, \quad \bar{f}(w_t) = \frac{f(w_t)}{\max_{w' \in \mathcal{X}_T} f(w')}$$

$$c_i = \frac{2 \cdot \bar{f}(w_s^i) \cdot \bar{f}(w_t^i)}{\bar{f}(w_s^i) + \bar{f}(w_t^i)}$$

The intuition behind this scoring method is that a word pair is more important when both words have high relative frequency in both domains. This is because such words are likely more domain-independent, conveying identical or similar semantics across these two different domains.

Now, the matrix $\mathbf{Z}$ exactly gives the weights to the word adaptation layer, which takes in the target domain word embeddings and returns the transformed embeddings in the new space. We learn $\mathbf{Z}$ with stochastic gradient descent. After learning, the projected new embeddings would be $\mathbf{V_T Z}$, which would be used in the subsequent steps as illustrated in Figure 2 and Figure 3. With such a word-level input-space transformation, the parameters of the pre-trained source models based on $\mathbf{V_S}$ can still be relevant, which can be used in subsequent steps.

We would like to highlight that, unlike many previous approaches to learning cross-domain word embeddings (Bollegala et al., 2015; Yang et al., 2017a), the learning of our word adaptation layer involves no modifications to the source-domain embedding spaces. It also requires no re-training of the embeddings based on the target-domain data. Such a distinctive advantage of our approach comes with some important practical implications: it essentially enables the transfer learning process to work directly on top of a well-trained model by performing adaptation without involving significant re-training efforts. For example, the existing model could be one that has already gone through extensive training, tuning and testing for months based on large datasets with embeddings learned from a particular domain (which may be different from the target domain).

3.2 Sentence Adaptation Layer

The word adaptation layer serves as a way to bridge the gap of heterogeneous input spaces, but it does so only at the word level and is context independent. We can still take a step further to address the input space mismatch issue at the sentence level, capturing the contextual information in the learning process of such a mapping based on labeled data from the target domain. To this end, we augment a BLSTM layer right after the word adaptation layer (see Figure 2), and we name it the *sentence adaptation layer*.

This layer pre-encodes the sequence of projected word embeddings for each target instance, before they serve as inputs to the LSTM layer inside the base model. The hidden states for each word generated from this layer can be seen as the further transformed word embeddings capturing target-domain specific contextual information, where such a further transformation is learned in a supervised manner based on target-domain annotations. We also believe that with such a sentence adaptation layer, the OOV issue mentioned above may also be partially alleviated. This is because without such a layer, OOV words would all be mapped to a single fixed vector representation – which is not desirable; whereas with such a sentence adaptation layer, each OOV word would be assigned their "transformed" embeddings based on its respective contextual information.

3.3 Output Adaptation Layer

We focus on the problem of performing domain adaptation for NER under a general setup, where we assume the set of output labels for the source and target domains could be different. Due to the heterogeneousness of output spaces, we have to reconstruct the final CRF layer in the target models.

However, we believe solely doing this may not be enough to address the *labeling difference* problem as highlighted in (Jiang, 2008) as the two output spaces may be very different. For example, in the sentence "***Taylor*** *released her new* ***songs***", "*Taylor*" should be labeled as "MUSIC-ARTIST" instead of "PERSON" in some social media NER datasets; this suggests *re-classifying* with contextual information is necessary. In another example, where we have a tweet "*so...****#kktny*** *in 30 mins?*"; here we should recognize "*#kktny*" as a CREATIVE-WORK entity, but there is little similar instances in newswire data, indicating that

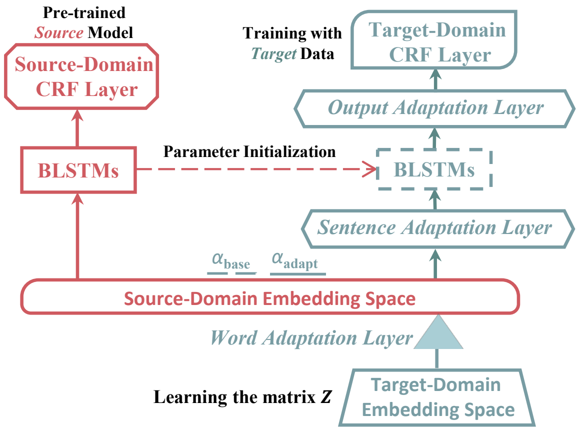

Figure 3: Overview of our transfer learning process.

context-aware *re-recognition* is also needed.

How can we perform re-classification and re-recognition with contextual information in the target model? We answer this question by inserting a BLSTM *output adaptation layer* in the base model, right before the final CRF layer, to capture variations in outputs with contextual information. This output adaption layer takes the output hidden states from the BLSTM layer from the base model as its inputs, producing a sequence of new hidden states for the re-constructed CRF layer. Without this layer, the learning process directly updates the pre-trained parameters of the base model, which may lead to loss of knowledge that can be transferred from the source domain.

3.4 Overall Learning Process

Figure 3 depicts our overall learning process. We initialize the base model with the parameters from the pre-trained source model, and tune the weights for all layers — including layers from the base model, sentence and output adaptation layers, and the CRF layer. We use different learning rates when updating the weights in different layers using Adam (Kingma and Ba, 2014). In all our experiments, we fixed the weights to $\mathbf{Z}$ for the word adaptation layers to avoid over-fitting. This allows us to preserve the knowledge learned from the source domain while effectively leveraging the limited training data from the target domain.

Similar to Yang et al. (2017b), who utilizes a hyper-parameter λ for controlling the transferability, we also introduce a hyper-parameter ψ that serves a similar purpose — it captures the relation between the learning rate used for the base model (α_{base}) and the learning rate used for the adaptation layers plus the final CRF layer $\alpha_{\text{base}} = \psi \cdot \alpha_{\text{adapt}}$.

If $\psi = 0$, we fix the learned parameters (from source domain) of the base model completely (Ours-Frozen). If $\psi = 1$, we treat all the layers equally (Ours-FineTune).

4 Experimental Setup

In this section, we present the setup of our experiments. We show our choice for source and target domains, resources for embeddings, the datasets for evaluation and finally the baseline methods.

4.1 Source and Target Domains

We evaluate our approach with the setting that the source domain is *newswire* and the target domain is *social media*. We designed this experimental setup based on the following considerations:

- *Challenging*: Newswire is a well-studied domain for NER and existing neural models perform very well (around 90.0 F1-score (Ma and Hovy, 2016)). However, the performance drop dramatically in social media data (around 60.0 F-score (Strauss et al., 2016)).
- *Important*: Social media is a rich soil for text mining (Petrovic et al., 2010; Rosenthal and McKeown, 2015; Wang and Yang, 2015), and NER is of significant importance for other information extraction tasks in social media (Ritter et al., 2011a; Peng and Dredze, 2016; Chou et al., 2016).
- *Representative*: The noisy nature of user generated content as well as emerging entities with novel surface forms make the domain shift very salient (Finin et al., 2010; Han et al., 2016).

Nevertheless, the techniques developed in this paper are domain independent and thus can be used for other learning tasks across any two domains so long as we have the necessary resources.

4.2 Resources for Cross-domain Embeddings

We utilizes GloVe (Pennington et al., 2014) to train domain-specific and domain-general word embeddings from different corpora, denoted as follows: 1) *source_emb*, which is trained on the newswire domain corpus (*NewYorkTimes* and *DailyMail* articles); 2) *target_emb*, which is trained on a social media corpus (Archive Team's Twitter stream grab[3]); 3) *general_emb*, which is pre-trained on CommonCrawl containing both formal

Table 1: Statistics of the NER datasets.

and user-generated content.[4] We obtain the intersection of the top 5K words from source and target vocabularies sorted by frequency to build $\mathcal{P}_1$. For $\mathcal{P}_2$, we utilize an existing twitter normalization lexicon containing 3,802 word pairs(Liu et al., 2012). More details are in supplemental material.

4.3 NER Datasets for Evaluation

For the source newswire domain, we use the following two datasets: OntoNotes-nw – the newswire section of OntoNotes 5.0 release dataset (On) (Weischedel et al., 2013) that is publicly available[5], as well as the CoNLL03 NER dataset (Co) (Sang and Meulder, 2003). For the first dataset, we randomly split the dataset into three sets: 80% for training, 15% for development and 5% for testing. For the second dataset, we follow their provided standard train-dev-test split. For the target domain, we consider the following two datasets: Ritter11 (Ri) (Ritter et al., 2011b) and WNUT16 (Wn) (Strauss et al., 2016), both of which are publicly available. The statistics of the four datasets we used in the paper are shown in Table 1.

4.4 Baseline Transfer Approaches

We present the baseline approaches, which were originally investigated by Mou et al. (2016). Lee et al. (2017) explored the INIT method for NER, while Yang et al. (2017b) extended the MULT method for sequence labeling.

INIT: We first train a source model $\mathcal{M}_S$ using the source-domain training data $\mathcal{D}_S$. Next, we construct a target model $\mathcal{M}_T$ and reconstruct the final CRF layer to address the issue of different output spaces. We use the learned parameters of $\mathcal{M}_S$ to initialize $\mathcal{M}_T$ excluding the CRF layer. Finally, INIT-FineTune continues training $\mathcal{M}_T$ with the target-domain training data $\mathcal{D}_T$, while INIT-Frozen instead only updates the parameters of the newly constructed CRF layer.

MULT: Multi-task learning based transfer method simultaneously trains $\mathcal{M}_S$ and $\mathcal{M}_T$ using $\mathcal{D}_S$ and $\mathcal{D}_T$. The parameters of $\mathcal{M}_S$ and $\mathcal{M}_T$ excluding their CRF layers are shared during the training process. Both Mou et al. (2016) and Yang et al. (2017b) follow Collobert and Weston (2008) and use a hyper-parameter λ as the probability of choosing an instance from $\mathcal{D}_S$ instead of $\mathcal{D}_T$ to optimize the model parameters. By selecting the hyper-parameter λ, the multi-task learning process tends to perform better in target domains. Note that this method needs re-training of the source model with $\mathcal{D}_S$ every time we would like to build a new target model, which can be time-consuming especially when $\mathcal{D}_S$ is large.

MULT+INIT: This is a combination of the above two methods. We first use INIT to initialize the target model. Afterwards, we train the two models as what MULT does.

5 Results and Discussion

5.1 Main Results

We primarily focus on the discussion of experiments with a particular setup where $\mathcal{D}_S$ is set to OntoNotes-nw and $\mathcal{D}_T$ is Ritter11. In the experiments, "in-domain" means we only use $\mathcal{D}_T$ to train our base model without any transfer from the source domain. "Δ" represents the amount of improvement we can obtain (in terms of F measure) using transfer learning over "in-domain" for each transfer method. The hyper-parameters ψ and λ are tuned from $\{0.1, 0.2, ..., 1.0\}$ on the development set, and we show the results based on the developed hyper-parameters.

We first conduct the first set of experiments to evaluate performance of different transfer methods under the assumption of homogeneous input spaces. Thus, we utilize the same word embeddings (general_emb) for training both source and target models. Consequently we remove the word adaptation layer (cd_emb) in our approach under this setting. The results are listed in Table 2. As we can observe, the INIT-Frozen method leads to a slight "negative transfer", which is also reported in the experiments of Mou et al. (2016). This indicates that solely updating the parameters of the final CRF layer is not enough for performing re-classification and re-recognition of the named entities for the new target domain. The INIT-FineTune method yields better results for it also updates the parameters of the middle LSTM

layers in the base model to mitigate the heterogeneousness. The MULT and MULT+INIT methods yield higher results, partly due to the fact that they can better control the amount of transfer through tuning the hyper-parameter. Our proposed transfer approach outperforms all these baseline approaches. It not only controls the amount of transfer across the two domains but also explicitly captures variations in the input and output spaces when there is significant domain shift.

We use the second set of experiments to understand the effectiveness of each method when dealing with heterogeneous input spaces. We use source_emb for training source models and target_emb for learning the target models. From the results shown in Table 3, we can find that all the baseline methods degrade when the two word embeddings used for training source models and learning target models are different from each other. The heterogeneousness of input feature space hinders them to better use the information from source domains. However, with the help of word and sentence adaptation layers, our method achieves better results. The experiment on learning without the word adaptation layer also confirms the importance of such a layer.[6]

Our results are also comparable to the results when the cross-lingual embedding method of Yang et al. (2017a) is used instead of the word adaptation layer. However, as we mentioned earlier, their method requires re-training the embeddings from target domain, and is more expensive.

5.2 Ablation Test

To investigate the effectiveness of each component of our method, we conduct ablation test based on our full model (F=66.40) reported in Table 3. We use Δ to denote the differences of the performance between each setting and our model. The results of ablation test are shown in Table 4. We first set ψ to 0 and 1 respectively to investigate the two special variant (Ours-Frozen, Ours-FineTune) of our method. We find they both perform worse than using the optimal ψ (0.6).

One natural concern is whether our performance gain is truly caused by the effective approach for cross-domain transfer learning, or is simply because we use a new architecture with more layers (that is built on top of the base model) for learning the target model. To understand this, we carry out an experiment named "w/o transfer" by setting ψ to 1, where we randomly initialize the parameters of the middle BLSTMs in the target model instead of using source model parameters. Results show that such a model does not perform well, confirming the effectiveness of transfer learning with our proposed adaptation layers. Results also confirm the importance of all the three adaptation layers that we introduced. Learning the confidence scores (c_i) and employing the optional $\mathcal{P}_2$ are also helpful but they appear to be playing less significant roles.

5.3 Additional Experiments

As shown in Table 5, we conduct some additional experiments to investigate the significance of our improvements on different source-target domains, and whether the improvement is simply because of the increased model expressiveness due to a larger number of parameters.[7]

We first set the hidden dimension to be the same as the dimension of source-domain word embeddings for the sentence adaptation layer, which is 200 (I/M-200). The dimension used for the output adaptation layer is just half of that of the base BLSTM model. Overall, our model roughly

---

[6] We use the approximate randomization test (Yeh, 2000) for statistical significance of the difference between "Ours" and "MULT+INIT". Our improvements are statistically significant with a p-value of 0.0033.

[7] In this table, I-200/300 and M-200/300 represent the best performance from {INIT-Frozen, INIT-FineTune} and {MULT, MULT+INIT} respectively after tuning; "in-do." here is the best score of our base model without transfer.

Settings		F	Δ
ψ=0.0	Ours-Frozen	63.95	-2.45
ψ=1.0	Ours-FineTune	63.40	-3.00
ψ=1.0	w/o transfer	63.26	-3.14

(ON, WN)	51.03	+0.89	+1.72	+0.88	+1.77	+3.16
(CO, WN)		+0.69	+1.04	+0.71	+1.13	+2.38

Table 5: Results of transfer learning methods on different datasets with different number of LSTM units in the base model. (I: INIT; M: MULT; 200/300: number of LSTM units).

involves 117.3% more parameters than the base model.[8] To understand the effect of a larger parameter size, we further experimented with hidden unit size as 300 (I/M-300), leading to a parameter size of $213,750$ that is comparable to "Ours" ($203,750$). As we can observe, our approach outperforms these approaches consistently in the four settings. More experiments with other settings can be found in the supplementary material.

5.4 Effect of Target-Domain Data Size

To assess the effectiveness of our approach when we have different amounts of training data from the target domain, we conduct additional experiments by gradually increasing the amount of the target training data from 10% to 100%. We again use the OntoNotes-nw and Ritter11 as $\mathcal{D}_S$ and $\mathcal{D}_T$, respectively. Results are shown in Figure 4. Experiments for INIT and MULT are based on the respective best settings used in Table 5. We find that the improvements of baseline methods tend to be smaller when the target training set becomes larger. This is partly because INIT and MULT do not explicitly preserve the parameters from source models in the constructed target models. Thus, the transferred information is diluted while we train the target model with more data. In contrast, our transfer method explicitly saves the transferred information in the base part of our target model, and we use separate learning rates to help the target model to preserve the transferred knowledge. Similar experiments on other datasets are shown in the supplementary material.

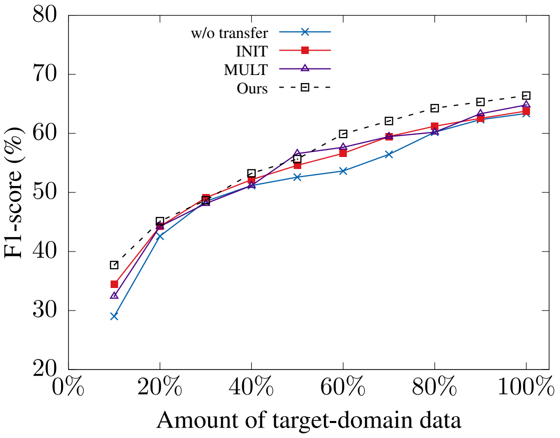

Figure 4: F1-score vs. amount of target-domain data.

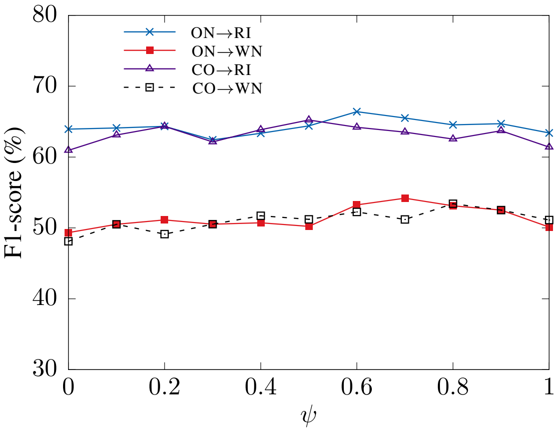

Figure 5: Performance at different ψ of our methods.

5.5 Effect of the Hyper-parameter ψ

We present a set of experiments around the hyper-parameter ψ in Figure 5. Such experiments over different datasets can shed some light on how to select this hyper-parameter. We find that when the target data set is small (Ritter11), the best ψ are 0.5 and 0.6 respectively for the two source domains, whereas when the target data set is larger (WNUT16), the best ψ becomes 0.7 and 0.8. The results suggest that the optimal ψ tends to be relatively larger when the target data set is larger.

6 Related Work

Domain adaptation and transfer learning has been a popular topic that has been extensively studied in the past few years (Pan and Yang, 2010). For well-studied conventional feature-based models in NLP, there are various classic transfer approaches, such as EasyAdapt (Daumé, 2007), instance weighting (Jiang and Zhai, 2007) and

---

[8] Base Model: $(25 \times 50 + 50^2) + (250 \times 200 + 200^2) = 93,750$; Ours: $(25 \times 50 + 50^2) + (200 \times 200 + 200^2) + (250 \times 200 + 200^2) + (200 \times 100 + 100^2) = 203,750$.

structural correspondence learning (Blitzer et al., 2006). Fewer works have been focused on transfer approaches for neural models in NLP. Mou et al. (2016) use intuitive transfer methods (INIT and MULT) to study the transferability of neural network models for the sentence (pair) classification problem; Lee et al. (2017) utilize the INIT method on highly related datasets of electronic health records to study their specific de-identification problem. Yang et al. (2017b) use the MULT approach in sequence tagging tasks including named entity recognition. Following the MULT scheme, Wang et al. (2018) introduce a label-aware mechanism into maximum mean discrepancy (MMD) to explicitly reduce domain shift between the same labels across domains in medical data. Their approach requires the output space to be the same in both source and target domains. Note that the scenario in our paper is that the output spaces are different in two domains.

All these existing works do not use domain-specific embeddings for different domains and they use the same neural model for source and target models. However, with our word adaptation layer, it opens the opportunity to use domain-specific embeddings. Our approach also addresses the domain shift problem at both input and output level by re-constructing target models with our specifically designed adaptation layers. The hyper-parameter ψ in our proposed methods and λ in MULT both control the knowledge transfer from source domain in the transfer learning process. While our method works on top of an existing pre-trained source model directly, MULT needs re-training with source domain data each time they train a target model.

Fang and Cohn (2017) add an "augmented layer" before their final prediction layer for cross-lingual POS tagging — which is a simple multilayer perceptron performing local adaptation for each token separately — ignoring contextual information. In contrast, we employ a BLSTM layer due to its ability in capturing contextual information, which was recently shown to be crucial for sequence labeling tasks such as NER (Ma and Hovy, 2016; Lample et al., 2016). We also notice that a similar idea to ours has been used in the recently proposed Deliberation Network (Xia et al., 2017) for the sequence generation task, where a second-pass decoder is added to a first-pass decoder to polish sequences generated by the latter.

We propose to learn the word adaptation layer in our task inspired by two prior studies. Fang and Cohn (2017) use the cross-lingual word embeddings to obtain distant supervision for target languages. Yang et al. (2017a) propose to re-train word embeddings on target domain by using regularization terms based on the source-domain embeddings, where some hyper-parameter tuning based on down-stream tasks is required. Our word adaptation layer serves as a linear-transformation (Mikolov et al., 2013), which is learned based on corpus level statistics. Although there are alternative methods that also learn a mapping between embeddings learned from different domains (Faruqui and Dyer, 2014; Artetxe et al., 2016; Smith et al., 2017), such methods usually involve modifying source domain embeddings, and thus re-training of the source model based on the modified source embeddings would be required for the subsequent transfer process.

7 Conclusion

We proposed a novel, lightweight transfer learning approach for cross-domain NER with neural networks. Our introduced transfer method performs adaptation across two domains using adaptation layers augmented on top of the existing neural model. Through extensive experiments, we demonstrated the effectiveness of our approach, reporting better results over existing transfer methods. Our approach is general, which can be potentially applied to other cross-domain structured prediction tasks. Future directions include investigations on employing alternative neural architectures such as convolutional neural networks (CNNs) as adaptation layers, as well as on how to learn the optimal value for ψ from the data automatically rather than regarding it as a hyper-parameter. Abstract

In this paper, we study a new entity linking problem where both the entity mentions and the target entities are within a same social media platform. Compared with traditional entity linking problems that link mentions to a knowledge base, this new problem have less information about the target entities. However, if we can successfully link mentions to entities within a social media platform, we can improve a lot of applications such as comparative study in business intelligence and opinion leader finding. To study this problem, we constructed a dataset called Yelp-EL, where the business mentions in Yelp reviews are linked to their corresponding businesses on the platform. We conducted comprehensive experiments and analysis on this dataset with a *learning to rank* model that takes different types of features as input, as well as a few state-of-the-art entity linking approaches. Our experimental results show that two types of features that are not available in traditional entity linking: social features and location features, can be very helpful for this task.

1 Introduction

Entity linking is the task of determining the identities of entities mentioned in texts. Most existing studies on entity linking have focused on linking entity mentions to their referred entities in a knowledge base (Cucerzan, 2007; Liu et al., 2013; Ling et al., 2015). However, on social media platforms such as Twitter, Instagram, Yelp, Facebook, etc., the texts produced on them may often mention entities that cannot be found in a knowledge base, but can be found on the platform itself. For example, consider Yelp, a platform where users can write reviews about businesses such as restaurants, hotels, etc., a restaurant review on Yelp may mention another restaurant to compare, which is also likely to be on Yelp but cannot be found in a knowledge base such as Wikipedia. As another example, when people post a photo on a social media platform, their friends may be mentioned in this post if they are also in the photo. Usually, their friends are not included in a knowledge base but may also have accounts on the same platform. Thus for such entity mentions, linking them to an account that is also on the platform is more practical than linking them to a knowledge base.

Performing this kind of entity linking can benefit many applications. For example, on Yelp, we can perform analysis on the comparative sentences in reviews after linking the business mentions in them. The results can be directly used to either provide recommendations for users or suggestions for business owners.

Thus, in this paper, we focus on a new entity linking problem where both the entity mentions and the target entities are within a social media platform. Specifically, the entity mentions are from the texts (which we will refer to as *mention texts*) produced by the users on a social media platform; and these mentions are linked to the accounts on this platform.

It is not straightforward to apply existing entity linking systems that link to a knowledge base to this problem, because they usually take advantage of the rich information knowledge bases provide for the entities. For example, they can use detailed text descriptions, varies kinds of attributes, etc., as features (Francis-Landau et al., 2016; Gupta et al., 2017; Tan et al., 2017), or even additional signals such as the anchor texts in Wikipedia articles (Guo and Barbosa, 2014; Globerson et al., 2016; Ganea et al., 2016). However, on social media platforms, most of these resources or information are either unavailable or of poor quality.

On the other hand, social media platforms also have some unique resources that can be exploited. One that commonly exists on all of them is social

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2023–2032
Brussels, Belgium, October 31 - November 4, 2018.

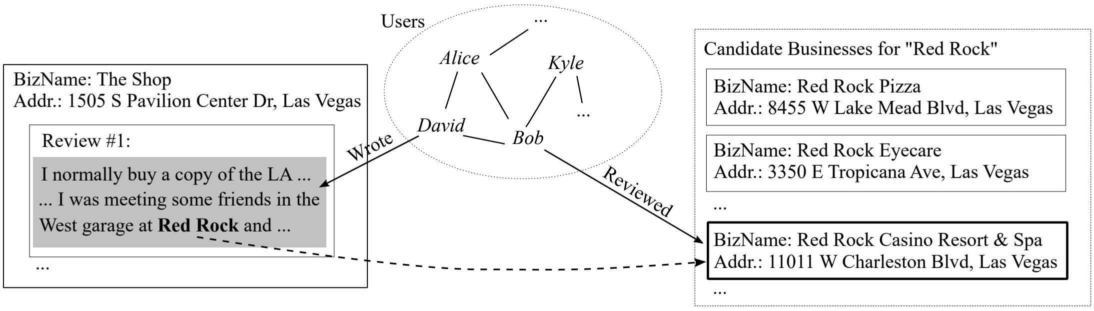

Figure 1: An example of entity linking within the Yelp social media platform. On Yelp, users can have friends which makes it a social network. Users can also write reviews about a business and compare with other businesses.

information, which can be intuitively used in our problem where *mention texts* and target entities may be directly connected by users and their social activities. Other than this, for location-based social media platforms such as Yelp and Foursquare, location information can also be helpful since people are more likely to mention and compare places close to each other.

To study this problem, we construct a dataset based on Yelp, which we name as Yelp-EL. As shown in Figure 1, on Yelp, users can write reviews for businesses and friend other users, and the reviews they write may mention businesses other than the reviewed ones. Thus, reviews, users, and businesses are connected and form a network through users' activities on the platform. In Yelp-EL, we link the business mentions in reviews to their corresponding businesses on the platform. We choose Yelp because other social media platforms such as Facebook and Instagram do not provide open dataset and there can be privacy issues related.

We then study the roles of three types of features in our entity linking problem: social features, location features, as well as conventional features that are also frequently used in traditional entity linking problems. We implemented a *learning to rank* model that takes the above features as input. We conducted comprehensive experiments and analysis on Yelp-EL with this model and also a few state-of-the-art entity linking approaches that we tailored to meet the requirements of Yelp-EL. Experimental results show that both social and location features can improve performance significantly.

Our contributions are summarized as follows.

- We are the first attempt to study the new entity linking problem where both entity mentions and target entities are within a same social media platform.
- We created a dataset based on Yelp to illustrate the usefulness of this problem and use it as a benchmark to compare different approaches.
- We studied both traditional entity linking features and social/location based features that are available from the social media platform, and show that they are indeed helpful for improving the entity linking performance.

The code and data are available at `https://github.com/HKUST-KnowComp/ELWSMP`.

2 Yelp-EL Dataset Construction

In this section we introduce how we create the dataset Yelp-EL based on the Yelp social media platform. We used the Round 9 version of the Yelp challenge dataset[1] to build Yelp-EL. There are 4,153,150 reviews, 144,072 businesses, and 1,029,432 users in this dataset. In order to build Yelp-EL, we first find possible entity mentions in Yelp reviews, and then ask people to manually link these mentions to Yelp businesses if possible.

Ideally, the mentions we need to extract from the reviews should be only those that refer the businesses in Yelp. Unfortunately, there is no existing method or tool that can accomplish this task. In fact, this problem itself is worth studying. Nonetheless, since we focus on entity linking in this paper, we only try to find as many mentions that may refer to Yelp businesses as we can, and then let the annotators decide whether to link this mention to a business. Thus, we use the following two ways to find mentions and then merge their results.

---

[1] https://www.yelp.com/dataset/challenge

#Mentions	#Linked	#NIL	#Disagreement1	#Disagreement2	Agreement%
7,731	1,749	5,117	842	23	88.8%

Table 1: Annotation statistics. “Linked” means the mentions that both annotators link to a same business. “NIL” means the mentions that both annotators think are “unlinkable.” “Disagreement1” means the mentions that are labeled by one annotator as “unlinkable,” but are linked to a business by the other annotator. “Disagreement2” means the mentions that are linked by two annotators to two different businesses.

(1) We use the Standford NER tool (Finkel et al., 2005) to find ordinary entity mentions and filter those that are unlikely to refer to businesses. To do the filtering, we first construct a dictionary which contains entity names that may occur in Yelp reviews frequently but are unlikely to refer to businesses, e.g., city names, country names, etc. Then we run through the mentions found with the NER tool and remove those whose mention strings matches one of the names in the dictionary.

(2) We find all the words/multi-word expressions in reviews that match the name of a business, and output them as mentions.

After extracting the mentions, we obtain the ground-truth by asking annotators to label them. Each time, we show the annotator one review with the mentions in this review highlighted, the annotator then needs to label each of the highlighted mentions. For each mention, we show several candidate businesses whose names match the mention string well. The annotator can also search the business by querying its name and/or location, in case the referred business is not included in the given candidates. We also ask the annotators to label the mention as “unlinkable” when its referred entity is not a Yelp business or it is not an entity mention.

An important issue to note is franchises. There are some mentions that refer to a franchise as a whole, e.g., the mention “Panda Express” in the sentence “If you want something different than the usual Panda Express this is the place to come.” There are also some mentions that refer to a specific location of a franchise. For example, the mention “Best Buy” in “Every store you could possibly need is no further than 3 miles from here, which at that distance is Best Buy” refers to a specific “Best Buy” shop. As a location based social network platform, Yelp only contains businesses for different locations of franchises, not franchises themselves. Thus in these cases, we ask the annotators to link the mentions when they refer to a specific location of a franchise, but label them as “unlinkable” when they refer to a franchise as a whole.

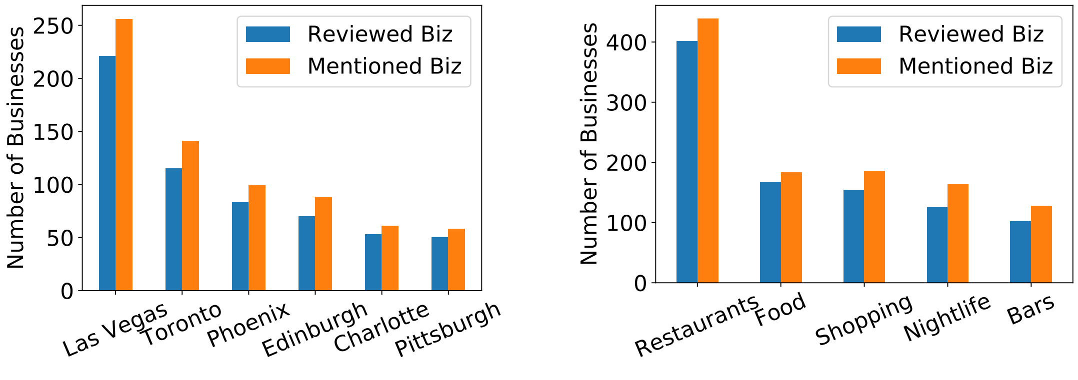
We asked 14 annotators who are all undergraduate or graduate students in an English environment university to perform the annotation. They were given a tutorial before starting to annotate, and the annotation supervisor answered questions during the procedure to ensure the annotation quality. Each review is assigned to two annotators.

The statistics of the annotation results are shown in Table 1. The total agree rate, calculated as $(\#\text{Linked} + \#\text{NIL})/\#\text{Mentions}$, is 88.8%. Most disagreements are on whether to link a mention or not. We checked the data and find that this happens mostly when: they disagree on whether the mention refers to a franchise as a whole or just one specific location; one of the annotators fails to find the referred business. However, when both annotators think the mention should be linked to a business, the disagree rate, calculated as $\#\text{Disagreement2}/(\#\text{Linked} + \#\text{Disagreement2})$, is very low (only 1.3%).

We only use the mentions that both annotators give the same labeling results to build the dataset. As a result, we obtain 1,749 mentions that are linked to a business. These mentions refer to 1,134 different businesses (mentioned businesses) and are from 1,110 reviews. The reviews that contain these mentions are for 967 different businesses (reviewed businesses).

The reviewed businesses are located in 96 different cities and belong to 419 different categories. Note that a business can only locate in one city but may have several different categories. The mentioned businesses are located in 98 different cities and belong to 425 different categories. Figure 2 shows the numbers of reviewed businesses and mentioned businesses in the most popular cities and categories, from where we can see that these mentions have an acceptable level of diversity.

The mentions that can be linked are our focus, but we also include the 5,117 unlinkable mentions in our dataset since they can be helpful for building a complete entity discovery and linking system (Ji et al., 2016).



(a) Top Cities

(b) Top Categories

Figure 2: Statistics of the related businesses in Yelp-EL. (a) The number of reviewed businesses in the six most popular cities. (b) The number of mentioned businesses in the five most popular categories. Here, “popular” means having the largest number of businesses in the dataset.

3 Entity Linking Algorithm

In this section, we introduce *LinkYelp*, an entity linking approach we design for Yelp-EL to investigate the new proposed problem. LinkYelp contains two main steps: candidate generation and candidate ranking. The candidate generation step finds a set of businesses that are plausible to be the target of a mention based on the mention string. Afterwards, the candidate ranking step ranks all the candidates and chooses the top ranked one as the target business.

3.1 Candidate Generation

For the first step, candidate generation, we score each business b with $g(m,b) = g_c(m,b) \cdot g_n(s_m, s_b)$ for a mention m, where s_m is the mention string of m, s_b is the name of b. $g_c(m,b)$ equals to a constant value that is larger than 1 (it is set to 1.3 in practice) when the review that contains m is for a business that is located in the same city with b; Otherwise, it equals to 0. g_n is defined as

$$g_n(s_m, s_b) = \begin{cases} 1 & \text{if } s_m \in A(s_b) \\ \text{sim}(s_m, s_b) & \text{Otherwise,} \end{cases} \quad (1)$$

where $A(s_b)$ is the set of possible acronyms for s_b, $\text{sim}(s_m, s_b)$ is the cosine similarity between the TF-IDF representations of s_m and s_b. In practice, $A(s_b)$ is empty when s_b contains less than two words; Otherwise, it contains one string: the concatenation of the first letter of each word in s_b. Then, we find the top 30 highest scored businesses as candidates. This approach has a recall of 0.955 on Yelp-EL.

3.2 Candidate Ranking

Let m be a mention and b be a candidate business of m. We use the following function to score how likely b is the correct business that m refers to:

$$f(m,b) = \boldsymbol{w} \cdot \boldsymbol{\phi}(m,b), \quad (2)$$

where $\boldsymbol{\phi}(m,b)$ is the feature vector for mention-candidate pair m and b, Section 4 describes how to obtain it in detail; $\boldsymbol{w}$ is a parameter vector.

We use a max-margin based loss function to train $\boldsymbol{w}$:

$$J = \frac{1}{|T|} \sum_{<m,b_t,b_c> \in T} \max[0, 1 - f(m,b_t) + f(m,b_c)] + \lambda \|\boldsymbol{w}\|^2, \quad (3)$$

where b_t is the true business mention m refers to; $b_c \neq b_t$ is a corrupted business sample randomly picked from the candidates of m; T is the set of training samples; $\|\cdot\|$ is the l_2-norm; λ is a hyperparameter that controls the regularization strength. We use stochastic gradient descent to train this model.

4 Feature Engineering

We study the effectiveness of three types of features: conventional features, social features, and location features. Among them, conventional features are those that can also be use in traditional entity linking tasks; social features and location features are unique in our problem.

4.1 Conventional Features

Lots of information used in traditional entity linking cannot be found for Yelp businesses, but we try our best to include all such features that can be used in our problem.

For Yelp-EL, we use the following conventional features for a mention m and its candidate business b:

u_1 : The cosine similarity between the TF-IDF representations of the mention string of m and the name of b.

u_2 : Whether the mention string of m is a possible acronym of b's name (i.e., whether it is an element of the set $A(s_b)$ in Equation 1).

u_3 : The popularity of b. Let the number of reviews received by b be n. Then this feature value equals to n/C if n is smaller than a parameter C that's used for normalization, otherwise it equals to 1.

u_4 : The cosine similarity between the TF-IDF representations of the review that contains m and combination of all reviews of b. This feature evaluates how well b fits m semantically.

u_5 : Whether b is the same as the reviewed business. This feature is actually not available in traditional EL, and it is usually not available on other social media platforms either. But it is obviously useful on Yelp-EL. Including it here helps us to see how beneficial social features and location features truly are.

4.2 Social Features

Through the activities of the users on the platform, the users, mentions, reviews and businesses in Yelp-EL form a network where there are different types of nodes and edges. Thus we use Heterogeneous Information Networks (HIN) to model it, and then design meta-path based features to capture the relations between mentions and their candidate businesses. We skip the formal definitions of HIN and meta-path here, readers can refer to (Sun et al., 2011) for detailed introduction. The HIN schema for Yelp-EL is shown in Figure 3.

The following meta-paths are used:

$$\begin{aligned} P1:&\quad M-R-U-R-B\\ P2:&\quad M-R-U-U-R-B\\ P3:&\quad M-R-U-R-B-R-U-R-B \end{aligned}$$

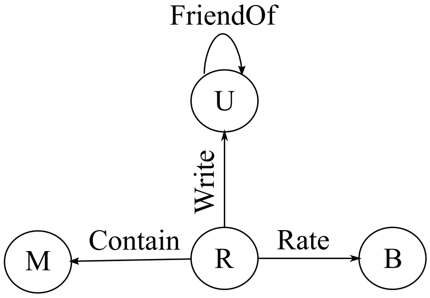


Figure 3: HIN schema of Yelp-EL. M: mention; R: Review; U: user; B: business.

where we denote M for mention, R for Review, U for user, and B for business.

Different meta-paths above capture different kinds of relations between a mention and its candidate entities that are induced by users' social activities. For example, if an instance of $P1$ exists between a mention m and a business b, then m is contained in a review that is written by a user who also reviewed business b. If many such instances of $P1$ exist, then we may assume that m and b are related, which makes it more possible for m to be referring to b.

With the meta-paths above, we use the *Path Count* feature defined in (Sun et al., 2011) to feed into the entity linking model described in Section 3. Given a meta-path P, for mention m and business b, *Path Count* is the number of path instances of P that start from m and end with b. In practice, we normalize this value based on global statistics before feeding it to a model.

4.3 Location Features

Location information commonly exists in location-based social media platforms such as Yelp and Foursquare. Users on platforms such as Twitter and Instagram may also be willing to provide their locations.

Here, we use the following two features for a mention m and its candidate business b:

v_1 : Whether the reviewed business is in the same city as b.

v_2 : The geographical distance between the reviewed business and b. This value is calculated based on the longitude and latitude coordinates of the businesses.

There are still some other location features that can be designed. For example, we can also consider the locations of the other businesses that are reviewed by the user. We only use the above two since we find in our experiments that including them already provides high performance boost.

5 Experiments

5.1 Compared Methods

We compare with a baseline method we name as DirectLink, as well as two existing entity linking methods including the method proposed by (Liu et al., 2013) (which we refer to as ELT) and SSRegu proposed by (Huang et al., 2014).

DirectLink simply links each mention to the corresponding reviewed business. Many business mentions in Yelp reviews actually refer to the business that is being reviewed. This baseline method tells us how many of these mentions there are in Yelp-EL.

ELT collectively links a set of mentions with an objective to maximize local compatibility and global consistence. It achieves this by integrating three types of similarities: mention-entity similarity, entity-entity similarity, and mention-mention similarity. To apply ELT to Yelp-EL, we use the conventional features introduced in Section 4.1 for mention-entity similarities. The path count feature of meta-path B–R–U–R–B is used as entity-entity similarity. For mention-mention similarity, we use two features that are both TF-IDF based cosine similarities, with one between the two mention strings and the other between the reviews that the two mentions belong to.

SSRegu is also a collective approach. It is a graph regularization model that incorporates both local and global evidence through three principals: local compatibility, coreference, and semantic relatedness. SSRegu computes a weight matrix for each of these three principals, and then forms a graph based on the weight matrices and performs graph regularization to rank candidate entities. To apply SSRegu, we need to compute three weight matrices. The weight matrix for local compatibility is based on features extracted from the mention and the candidate entity. In our case, the conventional features are used for computing this matrix. Computing the coreference weight matrix requires to determine whether two corresponding mentions are coreferential. Huang et al. (2014) assume two mentions to be coreferential if their mention strings are the same and there exists at least one meta-path instance of specific patterns between them. In our case, the meta-paths used are M–R–M and M–R–U–R–M. To compute the semantic relatedness weight matrix, we apply the entity-entity similarity used for ELT. Note that SSRegu is a semi-supervised approach and is capable of using unsupervised data, but for fair comparison we do not use this feature here.

Method	Accuracy (mean±std)
DirectLink	0.6684±0.008
ELT	0.8451±0.012
SSRegu	0.7970±0.013
LinkYelp	**0.9034±0.014**

Table 2: Entity linking performance of different methods on Yelp-EL.

ELT and SSRegu are originally proposed to tackle the problem of entity linking for tweets, but their linking target is Wikipedia. Evaluating the performance of these two methods on Yelp-EL shows the difference between their problem and ours.

5.2 Experimental Settings

Throughout our experiments, the hyperparameter λ in Equation (3) is set to 0.001. For each mention, three corrupted samples are random selected for the training with Equation (3). For ELT and SSRegu, the hyperparameters are tuned on the validation set with grid search. The candidate businesses for ELT and SSRegu are also obtained with the method describe in Section 3.1. We run five trials of random split of the linked mentions in the dataset, where each trail uses 60% of the linked mentions as training data and 40% as test data. In each of the training set, we further select 20% as validation set.

Note that we only use linked mentions to evaluate different methods since NIL detection is not our focus, but NIL mentions are utilized in Section 5.6 to build a complete entity linking system.

5.3 Comparison Results

Table 2 shows the entity linking performance of different methods on Yelp-EL. Here, all three types of features described in Section 4 are fed into LinkYelp. Within the compared methods, LinkYelp performs substantially better. This shows that methods carefully designed for traditional entity linking problems may not work so well when applied to entity linking within a social media platform, and this new problem we pro-

Features	All	Restaurants	Nightlife	Shopping	Food	A & E	Bars	E & S	H & T
C	84.05	86.80	79.18	83.15	81.15	71.67	83.49	68.79	63.70
S	79.65	82.92	75.09	82.05	77.69	66.95	80.66	72.25	67.41
L	80.05	85.71	72.70	81.32	85.77	50.21	82.55	49.13	37.78
C+S	86.45	89.29	84.98	85.71	85.00	78.54	87.26	**77.46**	**71.85**
C+L	89.42	93.32	84.98	90.48	88.46	76.39	88.21	72.83	66.67
S+L	85.19	89.29	79.86	87.91	87.31	72.10	85.38	72.25	67.41
C+S+L	**90.34**	**93.79**	**85.67**	**91.94**	**90.00**	**78.97**	**88.68**	76.30	71.11

Table 3: Entity linking accuracy (%) on different categories of businesses with different types of features as input. On the "Features" column, "C," "S," and "L" means conventional, social, and location features respectively. "All" means all the categories combined, i.e., the whole test set; "A & E" means Arts & Entertainment; "E & S" means Event Planning & Services; "H & T" means Hotels & Travel.

pose is worth studying differently from the traditional entity linking problem. The accuracy of DirectLink means that many mentions (about 67%) in Yelp-EL simply refer to the corresponding reviewed businesses. However, this does not mean that our problem is less challenging than traditional entity linking, since simply using the popularity measure of entities can achieve an accuracy of about 82% in the latter task (Pan et al., 2015).

5.4 Ablation Study

We further investigate how the three different types of features described in Section 4 contribute to the final performance of LinkYelp, and how they perform differently in linking mentions that refer to a specific category of Yelp businesses. The results are listed in Table 3. The categories in Table 3 are those that include the largest numbers of businesses in the dataset. Entries in the "All" column in Table 3 are the accuracies on all the categories combined. We can see from this column that both social features and location features are able to improve the performance when combined with conventional features. Location features are relatively more effective than social features, this is because people's activities are mainly restricted to a certain area, so they are more likely to mention businesses that are within this area. But social features are still helpful even when both conventional features and location features are already used, as the best performance is achieved with all the three types of features combined. Moreover, social features can become more important for other social media platforms that do not have location information available.

There are also some interesting findings if we consider the performance on different categories. For example, compared with only using conventional features (row C), incorporating social features (row C+S) provides the largest improvement for Event Planing & Services (e.g., wedding planning, party planning). This matches our intuition because for these kinds of businesses, people tend to be influenced more by their friends and make choices that are socially related. Table 3 also shows that on the categories Event Planning & Services and Hotels & Travel, incorporating location features is not that helpful as it does on other categories. We manually checked the mentions under these two categories that are linked correctly by C+S but incorrectly by C+L. We find that the reasons why incorporating location features fails on these mentions vary from case to case. Two possible reasons are: location information is not helpful to disambiguate a hotel and the shops in this hotel; it also does not work well in disambiguating different locations of a hotel chain that are all not far away from the reviewed business.

5.5 Error Examples

We also manually checked some of the errors made by LinkYelp with all the three types of features as input. A few examples are shown in Table 4. In the first case, since the reviewed business "Jean Philippe Patisserie" is a restaurant, our system tends to find a similar business instead of a hotel. Location features do not help here because Cafe Bellagio has the same location as Bellagio Hotel. The system is also incapable of identifying that "stay at" should be probably followed by a hotel instead of a Cafe. In the second case, the algorithm outputs the reviewed business because it is unable to understand what "the other Second Sole in Rock River" means. The above two examples show that there are still some errors caused by the failure of natural language understanding.

Reviewed Biz:	*Name*: Jean Philippe Patisserie *Addr.*: 3600 S Las Vegas Blvd, Las Vegas
Review:	... Even if you are not staying at the Bellagio, you have to stop by anyway to ...
True Referent:	*Name*: Bellagio Hotel *Addr.*: 3600 S Las Vegas Blvd, Las Vegas
System Prediction:	*Name*: Cafe Bellagio *Addr.*: 3600 S Las Vegas Blvd, Las Vegas
Reviewed Biz:	*Name*: Second Sole Athletic Footwear *Addr.*: 5114 Mayfield Rd, Cleveland
Review:	I did a review of the other Second Sole in Rocky River. This one is in Lyndhurst...
True Referent:	*Name*: Second Sole *Addr.*: 19341 Detroit Rd, Rocky River
System Prediction:	*Name*: Second Sole Athletic Footwear *Addr.*: 5114 Mayfield Rd, Cleveland
Reviewed Biz:	*Name*: Hoot Owl *Addr.*: 4361 W Bell Rd, Phoenix
Review:	This place is a really fun neighborhood bar ... Its tucked away in the Frys parking lot...
True Referent:	*Name*: Fry's Food and Drug *Addr.*: 4315 W Bell Road, Phoenix
System Prediction:	*Name*: Frys *Addr.*: 2626 S 83rd Ave, Phoenix

Table 4: Examples of errors made by LinkYelp. Business mentions are underlined.

Reviewed Biz	Sentence	Mentioned Biz
Name: Burger King *Addr.*: 1194 King St W, Toronto	When you compare it to the McDonald's across the street, the service is way better.	*Name*: McDonald's *Addr.*: 1221 King Street W, Toronto
Name: The Turf Public House *Addr.*: 705 N 1st St, Phoenix	I have to say I like the atmosphere and surroundings of the Turf better than Seamus.	*Name*: Seamus McCaffrey's *Addr.*: 18 W Monroe St, Phoenix

Table 5: Examples of comparative sentences and linked mentions.

Name	City	Stars	#Better
Bacchanal Buffet	Las Vegas	4.0	33
Wicked Spoon	Las Vegas	3.5	24
Cibo	Phoenix	4.5	9
Pizzeria Bianco	Phoenix	4.0	2
XS Nightclub	Las Vegas	4.0	8
Marquee	Las Vegas	3.5	1

Table 6: Comparative study using texts and average ratings. Each row is a pair of two frequently compared businesses. #Better means the number of sentences that claim the corresponding business to be better than the other one.

In the third case, "Fry's Food and Drug" is located at "4315 W Bell Road, Phoenix" which is nearer to the reviewed business "Hoot Owl" located at "4361 W Bell Rd, Phoenix." However, although location information favors the correct business, the others features may contribute more for the system output "Frys" since "Frys" has an exact match of the candidate mention name.

5.6 Comparative Study

In this study, we provide some insight on the possible applications of our task by checking the comparative sentences in Yelp reviews.

First, we find comparative sentences from the whole Yelp review dataset with a simple pattern matching method: we retrieve the sentences that contain one of eight predefined comparison phrases such as "is better," "not as good as," etc. Then we extract the named entity mentions within these sentences and link them to Yelp businesses. A threshold based approach is used to detect NIL mentions (Dalton and Dietz, 2013).

As a result, we get 12,149 comparative sentences from the total 4,153,150 reviews that contains at least one linked mention. Some of the results are shown in Table 5. We can successfully identify both the entity names and their locations on Yelp. We also selected the top three frequently compared pairs and compare with the stars provided by Yelp dataset. From Table 6 we can see that the text comparison is consistent with star ratings.

6 Related Work

The traditional entity linking task of mapping mentions in articles to their corresponding entities in a knowledge base has been studied extensively (Shen et al., 2015; Ling et al., 2015). Various kinds of methods have been studied, e.g., neural network models (Sun et al., 2015; He et al., 2013), generative models (Li et al., 2013), etc. A large group of the existing entity linking approaches are called collective approaches, which are based on the observation that the entities mentioned in a same context are usually related with each other. Thus they usually form entity linking as an optimization problem that tries to maximizes both local mention-entity compatibility and global entity-entity coherence (Han et al., 2011; Nguyen et al., 2016). LinkYelp does not consider global entity-entity coherence as it is not the focus of this paper, but it can be applied to our problem too.

The prevalence of on-line social networks has also motivated researchers to study entity linking in such environments. (Huang et al., 2014; Shen et al., 2013; Liu et al., 2013) proposed methods that are specially designed for linking named entities in tweets. They mainly address the problem that tweets are usually short and informal, while taking advantage of some of the extra information that tweets may provide. For example, (Shen et al., 2013) assumed that each user's tweets have an underlying interest distribution and proposed a graph based interest propagation algorithm to rank the entities. (Huang et al., 2014) also used meta-path on HIN in their entity linking approach, but they only used it to get an indication of whether two mentions are related. Finally, although these studies focused on entity linking for tweets, they still use entities in knowledge bases as the target.

There are a few entity linking studies that do not link mentions to knowledge bases. (Shen et al., 2017) proposed to link entity mentions to an HIN such as DBLP and IMDB. However, their articles are collected from the Internet through searching and thus are not related to the target entities. They also used an HIN based method, but their use is restricted to get the relatedness between different entities. (Lin et al., 2017) studied the entity linking problem where the entities are included in different lists and entities of the same type belong to the same list. They only used this information along with the name of each entity to perform entity linking. Thus their focus is very different from ours.

7 Conclusions

In this paper, we propose a new entity linking problem where both entity mentions and target entities are in a same social media platform. To study this problem, we first create a dataset called Yelp-EL, and then conduct extensive experiments and analysis on it with a learning to rank model that takes three different types of features as input. Through the experimental results, we find that traditional entity linking approaches may not work so well on our problem. The two types of features that are usually not available for traditional entity linking tasks – social features and location features – can both improve the performance significantly on Yelp-EL. Our work can also motivate and enable a lot of downstream applications such as comparative analysis of location based businesses. In the future, we plan to extract more patterns to obtain more comparative sentences, so that we may more accurately demonstrate how useful performing comparative analysis after linking the business mentions can be.

Abstract

Having an entity annotated corpus of the clinical domain is one of the basic requirements for detection of clinical entities using machine learning (ML) approaches. Past researches have shown the superiority of statistical/ML approaches over the rule based approaches. But in order to take full advantage of the ML approaches, an accurately annotated corpus becomes an essential requirement. Though there are a few annotated corpora available either on a small data set, or covering a narrower domain (like cancer patients records, lab reports), annotation of a large data set representing the entire clinical domain has not been created yet. In this paper, we have described in detail the annotation guidelines, annotation process and our approaches in creating a CER (clinical entity recognition) corpus of 5,160 clinical documents from forty different clinical specialities. The clinical entities range across various types such as diseases, procedures, medications, medical devices and so on. We have classified them into eleven categories for annotation. Our annotation also reflects the relations among the group of entities that constitute larger concepts altogether.

1 Introduction

Corpus annotation is a process of adding interpretive linguistic information to a corpus (Leech, 2004). In the era of increasing trend of machine learning in NLP, annotated data drives the progress of NLP systems in many ways. Fields of NLP like Machine Translation, Information Extraction/Retrieval, Relationship Detection among the entities, depends heavily on an annotated corpus. In the past, many traditional NLP engines have used rule based dictionary lookup methods, with Unified Medical Language System (UMLS) (Lindberg et al., 1993) as a base dictionary, to detect clinical entities. However, these approaches fetch very low recall, due to the fact that the dictionary lookup can never capture all the lexical and linguistic variants of a medical term, and also due to the fact that the clinical documents depend upon a physician's writing style (Pathak et al., 2014).

Over the last few decades, Electronic Medical Records (EMR) have been an integral part of health care. Most of the data consists of a patient's symptoms, procedures being conducted and the medications prescribed to them. This data is mostly available in free text form or semi-structured form and may contain different level of difficulties in parsing this natural text and getting meaningful information. The extensive linguistic study is not available for a clinical domain to the extent it is for the general domain. Therefore, ML approaches are preferred over rule based approaches in the clinical domain. So a resource of the annotated corpus became a necessity to take full advantage of ML approaches. In the recent past, a few attempts have been made to annotate clinical texts. One of the first such attempt was made by (Wang, 2009) on 311 clinical notes from an Intensive Care Unit (ICU) department of the single hospital - Royal Prince Alfred Hospital (RPAH). However, no specific guidelines on how that data were annotated are available. Shared tasks like i2b2 in 2010 (Uzuner et al., 2011) (more than 800 documents), ShARe/CLEF (Suominen et al., 2013) (around 300 documents) in 2013 and SemEval 2014 (Pradhan et al., 2014), 2015 (Elhadad et al., 2015) (around 300 documents) have contributed a lot in increasing the availability of annotated clinical corpora. However, these corpora are focused only on certain type of entities. For example, i2b2 2010 data set has the annotation of three entity types, including test, treatment and disease.

There are other contributions to annotating clin-

ical corpora, but depending on the purpose of the clinical research, most of the corpora generated in this domain are very specific to a disease or a disease category or some specialities of hospitals. For example, (Fiszman et al., 2000) annotated chest x-ray reports for automatic identification of acute bacterial pneumonia; (South et al., 2009) manually annotated clinical records to identify phenotypic information for inflammatory bowel disease; (Koeling et al., 2011) have annotated oncology reports on ovarian cancer for symptoms; (Xia and Yetisgen-Yildiz, 2012) have manually annotated the corpus for three different categories - Pneumonia (PNA), Critical Pulmonary Infection Score (CPIS) and critical recommendation on Radiology and ICU Reports; Clinical E-Science Framework (CLEF) corpus (Roberts et al., 2009) have annotated various types of clinical records from a single hospital, Royal Marsden Hospital, Oncology Center. This corpus is restricted to diagnosis, and only considers documents from the patients with neoplasms, that is only a primary diagnosis code in one of the top level sub-categories of ICD-10 Chapter II (neoplasms). As none of the above corpora cover the clinical domain in entirety, we have started building our own CER corpus.

In this paper, we demonstrate our approach of creating the corpus, deciding on annotation guidelines, annotation processes, annotation error analysis and improving the annotation quality with a corpus of 5,160 de-identified clinical documents for 11 different entity types varying from 40 different domains.

2 Corpus Creation

The success of many healthcare IT applications like computer assisted coding (CAC), clinical document improvement (CDI), core/quality measure monitoring are directly proportional to the accuracy of entity recognition and relations among the group of entities. Our aim of creating this corpus was to encapsulate as many entity types as possible, keeping in mind many of such future applications. We have annotated 5,160 de-identified clinical documents for 11 different entity types varying from 40 different domains. All the documents were de-identified using simple rule based approaches which follow safe harbour guidelines before any further use.

Clinical documents are very peculiar. Type of text in the document depends heavily on work types (like admit notes, discharge notes, operative notes, progress notes, etc.), associated medical domains (cardiology, oncology, endocrinology etc.) and varies considerably from physician to physician. So it was very important for us to make sure that we include as many different domains, work types and physicians as we could. So the first step towards corpus creation was to classify documents into different domains. We took around 700,000 documents, from 119 providers (hospitals and specialty clinics), unfortunately not all of these documents had the information regarding its domain and work type. We used a semi-automatic way to find domain related information and were able to classify 236,850 documents from all the documents into 40 different domains. We were also able to capture information regarding sub-specialities and physician expertise for these documents. Table 1 represents a sample domain classification.

Domain	**Docu- -ment Count**	**Sub specialty**	**Physician**
Radiology	84635	2	16
Internal Medicine	15751	3	56
Emergency Medicine	12742	5	28
Cardiology	11555	6	40
Oncology	8325	4	11
Orthopedics	5480	2	19

Table 1: Domain wise classification of the documents

Work Type	**Document Count**
Consultation Reports	18
Operative Report	20
Progress Notes	40
History and Physical	15
Discharge Summary	30
Total	123

Table 2: Sample Document selection of gastroenterology domain

Based on this classification, our domain team prepared a list of important domain and worktype pairs from the whole corpus and on the basis of document distribution over these pairs, we filtered 5,160 documents to annotate which represent 40 different domains and more than 100 worktypes.

For example, Table 2 shows a sample selection of gastroenterology domain.

3 Annotation Guidelines

The first step towards preparing the annotation guideline was to decide on what has to be annotated. The best resource available to make this decision for the clinical domain was UMLS semantic group. The UMLS classifies the bio-medical entities into 133 semantic groups defined as Term Unique Identifiers (TUIs). These semantic groups are very fine-grained. We grouped multiple of these TUIs into different bucket to come up with 11 different types of medical entities. For the purpose of clinical information extraction, it is not necessary to use this much of detail as they would not be of much use in the clinical NLP applications, for example, clinical coding etc.

3.1 Clinical Entity Types

The clinical domain includes medical records like consultation reports, progress notes, history and physical, discharge summary, operative notes. These medical records comprise information about patient's diseases, affected anatomical area, procedures performed to treat the condition, devices used during the procedures and list of medications. It mainly covers the important entity types such as Problem, Anatomical structure, Procedure, Medical device and Medicine respectively. Apart from such information, the medical record also consists of the patient's normal functions, vital signs, lab examination and status of the patient. To cover this information, we have added other entity types Body function, Body measurement, Laboratory data and Finding respectively. Most of the times, entity type like Body measurement is mentioned with its values and to cover these values we have added an entity type named Measurement value which acts like a numerical modifier to add meaning to the entity type. Just a numerical entity has no meaning, so it is necessary that this entity type is always used in relation to an entity type named Body measurement. There are some words used in the clinical domain to add specificity to an entity. Such type of words are mostly adjectives and need a head word without which they have no contextual meaning and cannot be annotated alone. For example the word acute. The word acute alone has no specific meaning, but when it is relates to a head word entity like pain then it adds meaning to the word pain. To cover such information and to maintain the entities as simple and unique as possible, we have added an entity type named Modifier as a separate enhancing entity type. So in all, the gist of the medical record is captured by annotating the documents in our classified entity types.

Problem: The disease conditions which include major problem, disease, symptoms and disorders.

e.g.: Complication of **bleeding, infection, arterial puncture, DVT.**

Finding: Concepts apart from major problem, including abnormal conditions and the minor alteration in the regular condition.

e.g.: This is a 27-year-old female **gravida 4 para 1,** feeling **weak** and **lethargic.**

Procedure: Surgery or other procedures performed to cure or diagnose.

e.g.: This is an 82-year-old female with the history of **appendectomy,** status post **open reduction internal fixation.**

Anatomical Structure: Anatomical sites, cells and organs of the human body.

e.g.: The patient continued to have mild colitis throughout into the **cecum.**

Body Function: Activities carried out by the body to maintain the normal functioning.

e.g.: The patient's **breathing** was normal.

Lab Data: The type of analysis performed on blood, urine, other body substances or tissues to help diagnose or monitor the patient's condition.

e.g.: **AFB test** is negative, **TSH** is 1.1.

Body Measurement: The normal measurement of the body obtained without performing a complex procedure or test.

e.g.: The **weight** is up a couple pounds at 157 pounds, **pulse** is 74.

Measurement Value: Numerical value with its unit, associated with body measurement.

e.g.: The patient's heart rate was **90** and the BP was **140/90.**

Medical Device: Instruments used for the treatment, operation and various medical purposes.

e.g.: **Arterial line catheter** was placed over the **guidewire** without any resistance.

Medicine: A drug used for the treatment or prevention of a disease.

e.g.: Completed antibiotic course of **ceftriaxone.**

Modifier: Any word that adds some specific meaning to an Entity.

e.g.: **Chronic** skin excoriation due to known neurodermatitis.

We have classified our entity types in such a way that the meaning of the medical record is captured properly. Medical terminology is vast in nature, so other entity types except the 11 mentioned types are possible, like gene/variants, lipids, cells, cell lines, steroids, etc. and no doubt they are important entity types, but we do not need to annotate them separately because some of these entities can be classified in the existing entity types and others do not occur frequently in our medical records.

For example, an entity type like Lipid, documented only in laboratory data section is covered by our entity type Laboratory data.

e.g.: Cholesterol levels are high.

In this example, cholesterol is an organic lipid molecule present in the body and generally should be labelled under entity type Lipid. But in the medical records, it is mostly present in the form of a laboratory test. So there is no need to create a new entity type as it would be easily covered under our classified entity type named Laboratory data. We encounter such cases in our data and so entity type like Lipid is not used and if we use, it alters the meaning, which in this case, the system won't understand that it is a lab report and not an organic lipid molecule present in the body.

Another example is an entity type like Steroid, it is documented only in the medicine section which is covered by our entity type Medicine.

e.g.: The patient was prescribed corticosteroids.

"Corticosteroid" is a type of steroid hormone present in the body. But in this case, "corticosteroids" is a medicine which is prescribed and it is annotated under Medicine type. We encounter such cases in our data and entity type like Steroid is covered by our classified Medicine type.

So we have categorized these groups into broader categories of entity types like Problem, Procedure etc. These categories are as mentioned in Table 3 with relevant TUIs from UMLS.

Primary annotation guidelines were prepared by a linguist and an experienced medical coder. Both linguists and medical coder finalized entity types and created its initial descriptive definition with some complex examples. After that, both linguists and coder annotated the same set of documents separately and on the basis of conflicting annotations they sat together and solved the conflicts, then they updated the annotation guidelines to cover these conflict patterns. During this process, we have covered all possible domains and their existing document types in order to cover all the prominent entity patterns. After a few iterations, a well-defined annotation guideline was prepared and we started the actual annotation work. Note that the documents annotated during this process were not included in the corpus.

Entity Type	**Related TUI**
Problem	T046,T047,T048,T049, T050,T191,T037,T019,T184
Finding	T033,T034,T041,T084,T032, T201,T053,T054,T069,T068, T070,T067
Procedure	T059,T060,T061,T065,T058
Medicine	T200,T120,T110,T195,T131
Medical Device	T073,T074,T075,T203,T072, T071
Lab Data	T196,T119
Anatomical Structure	T017,T021,T023,T024, T025,T026,T029,T030
Body Function	T038,T039,T040,T042, T043, T044,T045

Table 3: Entity types with their mappings to TUIs

3.2 Inter-Conceptual Relationships

Relationships may exist between two or more concepts. In such instances, we considered inter-conceptual relationships between limited and frequently used terminologies. Relationships are marked only when relations occur in the same sentence and less frequent relationships like Lab data and problem, Medicine and Problem are rarely mentioned in a single sentence and hence we do not annotate those relations. We have not covered some relations like medicine with its attributes because it unnecessarily increases the complexity of the annotation task and these relations are easy to extract using finite state automata or regex based tools like cTAKES (Savova et al., 2010, 2011). Currently, the relationships are marked for the anatomical structure, measurement value and modifier with their related entities. Anatomical structures get related with three categories like problem, finding and procedure; measurement value gets related to only body measurement and modifier gets related to all other concepts except measurement value.

3.2.1 Relationships with Anatomical Structures

Anatomical structure can be related to problem, procedure and finding. A relationship adds specificity to the concept.

Anatomical structure and problem relationship

This type of relationship helps to understand which part of the anatomical structure is affected by the particular problem. It simplifies the understanding of the problem and its area of effect.

For *e.g.*: she had severe pain in the left ankle.

Here pain is the problem and ankle is the anatomical structure. A relationship can be formed between these two concepts and it makes it easy to understand that pain is in the ankle.

Anatomical structure and finding relationship

This relation helps to understand to which anatomical structure is the finding related.

For *e.g.*: He noted he had felt some tingling and numbness in the left upper chest area.

Here tingling is the finding and chest is the anatomical structure. By linking these two concepts in a relationship we explain that tingling is occurring in the chest.

Anatomical structure and procedure relationship

This relationship explains that the procedure is being done at the given anatomical structure. It is usually used to relate any operation, test, and other such procedures to the organ or body site at which it is being performed.

e.g.: The patient had a CT of the brain.

Here CT is a procedure named Computed Tomography and brain is the anatomical structure. Relating these two concepts simplifies the understanding that CT of the brain was performed.

3.2.2 Relationships of Measurement Values

Measurement values cannot stand alone as only some numerical values do not provide any useful information. So these values need to be related to the concept where they belong to.

Body measurement and Measurement Value relationship

Body measurement is the measurement of basic body parameters like temperature, height, weight, pulse rate, etc. These parameters often have values that can be linked to the measurement in order to provide a complete meaning.

e.g.: Pulse: 80. BP: 110/70. Respirations: 16.

Here, pulse, BP, and respiration are the body measurements and 80, 110/70, and 16 are the measurement values of these respectively. So, forming the relationship between pulse and 80 signifies that the pulse rate is 80 per min, and similarly for all such concepts.

3.2.3 Relationships of Modifier

All the concepts except modifier itself and measurement values can be related to the modifier to add specific meaning to these concepts. Modifiers can never stand alone.

So after classifying the entity types to be annotated and the possible relationships between those entity types as mentioned above, a set of definite principles were documented. Annotators followed these principles while annotating the data. Some directive principles from the guideline are mentioned below.

3.2.4 Directive Principles

Consistency in the annotation is very important to get the good accuracy of systems using ML approaches. Therefore, to achieve good consistency, following simple rules were prescribed for the annotators:

- The entities should be annotated based on the above given entity types and also generate relationship as mentioned above.
- Modifiers and measurement values should not be annotated without any relationship with other entity types.
- Entities from section headers should not be annotated.
- Adjective should be annotated as a modifier only if it is not a part of an abbreviated term instead of the selected text. For example, in “Chronic Hypertension”, ‘Chronic’ should be annotated as Modifier and ‘Hypertension’ should be annotated as Problem but in “Chronic Obstructive Pulmonary Disease” the whole phrase must be marked as Problem, as the phrase has a universally accepted abbreviation COPD. We refer to the UMLS dictionary for the abbreviated terms.
- Mark normal alternation in condition as a finding and abnormal alteration as a problem. i.e. “ST wave changes” is marked as a finding while “ST wave abnormality” as a problem.

- The entities should be annotated depending on the meaning and the context of the sentences because there might be some cases in which the type of an entity changes based on the sentence structure. For example: There was an evidence of “drainage” of pus and “drainage” was carried out. In this case, the word drainage appears twice, in the first half it means the pus is oozing out, so it is tagged as an entity type finding and in the second half it means a procedure named drainage was carried out and so tagged under entity type Procedure.
- There are instances where there are disjoint entities present in the sentence which have a relationship with other entities too. For example “The patient suffered from chest and abdominal pain.” In this case, the word pain is a disjoint entity but it also has a relationship with the chest. So in such cases, we mark chest and abdominal as an anatomical structure respectively and pain as a problem and then generate a relationship between these entities.

4 Annotation Process

There are different ways to annotate a medical corpus, but we embarked on two pre-eminent approaches. The first approach is semi-automated annotation, in this approach, we can choose any pre-existing tools like MetaMap (Aronson, 2001), for CER task and thereafter annotator uses initial annotated results of tool to add, update or delete annotations as required and give the final annotated result. This approach definitely saves some human efforts and takes less time to annotate, however it is difficult to find an efficient and accurate tool. In addition, there is another issue with semi-automated annotation approach, that is, the annotator’s decision may alter after viewing the output of the tool for ambiguous entities. The Second approach is to annotate the document based on just annotation guidelines and based on annotator’s medical knowledge without looking at pre-annotated labels. As quality of annotation is more important than quantity of annotation specifically in medical domain, so we decided to go ahead with second approach.

Protégé (Noy et al., 2001) is an open source annotation and ontology editing tool. This tool was developed by Stanford Center for Biomedical Informatics Research. It allows us to add entity types with a description and assign color. Using this tool we can generate relationships between different entity types. The tool supports plain text, CSV and TSV format and so it is easy to load a medical document. The annotated data can be exported to a structured XML file format which makes the data widely accepted, machine readable and easy to use for any system.

Four annotators with a background in microbiology and biochemistry were involved in the annotation process. The medical document consists of major entities like the problem, procedure, anatomical structure and lab data which the annotators are well aware of because microbiology and biochemistry experts have a good knowledge about the anatomy and physiology as well as information about many ailments and procedures and laboratory tests. The queries were solved using UMLS dictionary and internal discussion with experienced medical experts and AAPC certified coders. The annotators are initially given a brief introduction about the importance of annotation and its applications and the impact of the annotated data on the clinical NLP. After that, the linguist and medical coders walk them through the set of guidelines which should be followed while annotating the corpus and present a demo of the annotating tool so that they get a brief knowledge of the tool. Initially, some documents were annotated in front of them so they become familiar with the process of annotation and tool. For the first few sets of documents (one set contains 30 documents), we divided the team of annotators into two pairs and made them annotate the same documents together. After completion of these sets, we changed the pairs of annotators. After 3 such iterations, each annotator had worked with all other annotators. This process was performed to make sure that all the annotators have the same level of understanding towards the task. The annotators are instructed to keep a note of problems faced while annotating data and discuss it with the medical coders regarding the medical annotation and with engineers regarding the technical difficulties and the functioning of the tool. While annotating ambiguous entity, UMLS metathesaurus was used as a reference. However, annotators found many inconsistencies in the UMLS. So in case of any disagreement among the annotators, the final decision about what to be annotated was taken by a mutual consensus arrived after a discussion with the whole team. Note that the documents annotated during this process were not included in the corpus. After that, all the annotators were given a distinct set of documents in which 20% of the documents were the same between two annotators. We chose these same documents considering the distribution of worktypes over the corpus. These documents were used to calculate the kappa score (inter-annotator agreement). After annotation, the kappa score is calculated. The errors are discussed and solved by the annotators and then the data becomes useful. It took one year for the annotators to complete this task, in which the initial one month was spent on the training process.

4.1 Inter-annotator Agreement Calculation

Annotation is a mentally taxing task, and so annotators occasionally miss to annotate some of the medical entities, especially when a document contains a large number of them. The annotators are free to mark the entities according to their medical knowledge and as a result of that, some disagreement arises. An inter-annotator agreement is an important quality measure. The Cohen's kappa coefficient is used to estimate the agreement between the annotators. The Cohen's kappa equation is calculated with the following formula:

$$K = \frac{p_o - p_e}{1 - p_e} = 1 - \frac{1 - p_o}{1 - p_e} \tag{1}$$

where, p_o is the relative observed agreement among annotators, and p_e is the hypothetical probability of chance agreement, using the observed data to calculate the probabilities of each observer randomly saying each category. If the annotators are in complete agreement then = 1. If there is no agreement among the raters other than what would be expected by chance (as given by pe), $K \leq 0$ (Koeling et al., 2011). The initial kappa score was 68.01% calculated on the set of 30 documents. The aim was to achieve good kappa score up to 95% to minimize the conception gap between the annotators. The kappa score is obtained after each set of annotation and the annotators are made to sit together and review the whole document with their own annotation results. They internally discuss why some entities are annotated and missed or ambiguously annotated. After discussion, they come to a conclusion and make a note of the changes which helps to decrease the conception gap. Using these notes, they are clear about what to annotate and what not to. Using structured guidelines and proper classification of entity types and relations, we achieved a 96.89% kappa score for the entity and relationship annotation.

5 Corpus Statistics

Using the mentioned process, we have created a large annotated corpus of the medical domain for clinical entity and relationships which covers 5,160 clinical documents with 398,568 sentences. Out of these sentences, 190,188 sentences contained one or more medical entities which were annotated as concepts in the corpus, hence concept density over sentences is 47.72%. These 398,568 sentences vary in length from 1 token to 150+ tokens as shown in Figure 3. The corpus has average 9.59 tokens per sentence with total 3,825,465 tokens across the corpus. Out of these 3,825,465 tokens, 600,550 tokens annotated as concepts in the corpus, hence concept density over token is 15.70%. An EMR record consists of a gist of the patient's conditions, procedure and tests carried out, medications prescribed etc. But, along with that, there is a lot of insignificant information present in the record like hospital name and address, patient's demographics which are not healthcare entities. Apart from all these, an EMR contains information documented using definite templates and so a lot of sentence are generally not important and common in every medical record and they reflect in annotated token density. The frequency of annotation for each relation and entity type are detailed in Figure 1 and 2 respectively. There are in total 443,328 annotated concepts in the corpus. These annotated concepts result in an average length of 1.35 tokens per concept. The highest frequency concepts are Problem, Procedure, Medication, Anatomical Structure and Modifier which account for 78.81% of the data. The remaining 21.19% concepts are distributed into 6 rare categories. For the relation annotation, the corpus contains total 119,968 relations, out of which modifier - anatomical structure cover 30,018 relations, modifier with other entity types except anatomical structure cover 49,677 relations, anatomical structure with other entity types except modifier cover 35,401 relations and body measurement - measurement value cover 4,872 relations.

5.1 Initial Experiment with CRF

Initially, we used Conditional Random Fields (CRF) which is a well-known and a proven approach to detect continuous entities using CRF++ (Kudo, 2010) toolkit. Feature selection is the key task for accurate CRF model. We used feature sets as mentioned below (Pathak et al., 2015)

- Bag of words features, prefix, suffix
- Orthographic features, binary (true/false) like whole word capital, first char capital, numeric values, dates, words contains hyphen or slash, medical units (mg, gram, ltr, etc)
- Grammatical features like
  - Parts of Speech (PoS) (Choudhary et al., 2014), chunk, consistency parser (Oinam et al., 2018); all developed and designed in-house for clinical NLP
  - Head of the phrases
  - Stemming of the words
- Dictionary features, binary (true/false) was used to check whether the word is present in the medical dictionary or not.
- Stop words and word embedding id from word2vec trained on 2 lakh clinical documents
- Section header and document type information and sentence cluster id

Table 4 shows the initial accuracy, calculated using the Perl script provided by the CoNLL 2000 task (Tjong Kim Sang and Buchholz, 2000), on CRF using a BIO format with the combination of different features on 5-fold validation. We are able

Feature Set	Precision	Recall	F-Measure
Token	92.32	86.00	89.05
Orthographic	92.22	86.26	89.30
POS and Chunk	91.92	87.94	89.89
Dictionary	91.91	87.43	89.61
Consistency Parse	92.04	87.32	89.62
POS-Chunk and Orthographic	91.91	88.04	89.93
POS-Chunk and Dictionary	91.82	88.77	90.27
POS-Chunk, Consistency Parse and Dictionary	91.65	88.90	90.25
Above + Stemmer, Word Embedding Id	92.00	90.26	91.12
All	92.12	91.05	91.58

Table 4: CER task accuracy using CRF with different feature set

to get 91.58% f-measure with 92.12% precision and 91.05% recall using all features. We obtained a good performance using CRF which shows the quality of the annotation over the definite corpus.

6 Conclusion

In the domain of clinical NLP, there is a paucity of good and large annotated corpus. Research shows that some amount of data has been annotated according to different purposes and applications. Available annotated corpora are not found covering the clinical domain in entirety. In this paper, we have described the creation of a corpus of the clinical domain annotated with clinical entities and their inter-conceptual relationships. We have manually annotated the clinical corpus comprising of 5,160 documents, 398,568 sentences according to the guidelines created in-house.

Acknowledgements

We acknowledge the contribution of former annotators namely Meera Panchal, Namrata Srivastava, Yvonne Christian and Pranita Joshi, who provided insight and expertise that greatly helped in building the corpus. We would also like to thank Sagar Soni for his assistance with the functioning of the protégé tool.

Abstract

We challenge a common assumption in active learning, that a list-based interface populated by informative samples provides for efficient and effective data annotation. We show how a *2D scatterplot* populated with *diverse* and *representative* samples can yield improved models given the same time budget. We consider this for bootstrapping-based information extraction, in particular named entity classification, where human and machine jointly label data. To enable effective data annotation in a scatterplot, we have developed an embedding-based bootstrapping model that learns the distributional similarity of entities through the patterns that match them in a large data corpus, while being discriminative with respect to human-labeled and machine-promoted entities. We conducted a user study to assess the effectiveness of these different interfaces, and analyze bootstrapping performance in terms of human labeling accuracy, label quantity, and labeling consensus across multiple users. Our results suggest that supervision acquired from the scatterplot interface, despite being noisier, yields improvements in classification performance compared with the list interface, due to a larger quantity of supervision acquired.

1 Introduction

One strategy for mitigating the cost of supervised learning in information extraction (IE) is to bootstrap extractors with light supervision from a few provided examples (or seeds). Most typical bootstrapping methods (Yarowsky, 1995; Collins and Singer, 1999; Abney, 2007; Carlson et al., 2010; Gupta and Manning, 2014, 2015, inter alia) are iterative in nature, and suffer from semantic drift: as the learning advances, the task often drifts semantically into a related but different space, e.g., from learning women names into learning flower names (Komachi et al., 2008; Yangarber, 2003). In such cases, a human-in-the-loop to help guide bootstrapping through active learning (AL) (Settles, 2012) can be highly beneficial.

In this work, we challenge the common assumption made for AL methods in the context of IE: a visual interface that shows a *list* of samples ranked by their *informativeness* to the classifier is effective for building classifiers that minimize human annotator time (Dalvi et al., 2016; He and Grishman, 2015). We argue that this is an inefficient form of acquiring supervision from humans. Instead, we propose a *two-dimensional (2D) scatterplot* interface (rather than the one-dimensional (1D) list), where the examples to be annotated are selected by their capacity to *cluster together* (rather than by their informativeness to the classifier). We demonstrate that our approach leads to more data being annotated, and better overall performance for the model being learned.

In particular, we focus on the task of bootstrapped named entity classification (NEC), where a classifier is trained to label named entities with their corresponding category. For example, such an algorithm starts with a few examples of labeled names, e.g., "Barack Obama" as `PERSON`, from which it learns representative patterns, e.g., the pattern "`@ENTITY , former president`", which are then used to label other names in future iterations. Unlike traditional bootstrapping, our approach receives supervision in two ways: from the seed examples (as shown above), but also from human labels through an active learning step that is inserted after each bootstrapping iteration. To facilitate the clustering of examples in the annotation interface, we propose a semi-supervised NEC approach that learns custom embeddings for the entities being classified (§4). We select entities that are *diverse* and *representative* of the embedding's data distribution, and project them into a 2D visual encoding of the data via a scatterplot using

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2043–2053
Brussels, Belgium, October 31 - November 4, 2018.

dimensionality reduction (§5).

The resulting scatterplot interface enables the user to label a larger quantity of entities, at the expense of label noise from mixed-category clusters and a potentially less-informative sampling criterion. To better understand this space, we conducted a user study to compare the effectiveness of the scatterplot interface compared to the traditional list that contains examples selected by informativeness (§7). Through our study, we arrive at the following takeaways:

- We observe that in configurations that used the scatterplot interface, annotators indeed labeled considerably more examples, but at an accuracy slightly lower than in the list interface. Despite the lower accuracy, the scatterplot interface generally yields better classifiers. In other words, the volume of annotations matters just as much as quality for the classifier performance.
- We find that a consensus model of users can mitigate noise, but must preserve a certain quantity of annotated data. A consensus model for the list interface that conservatively estimates labels *reduces* performance despite highly accurate labels due to the small amount of annotations. In contrast, the same model for the scatterplot interface yields higher label noise, but more annotations within the same budget of time and gives the best performance.

2 Related Work

Information extraction (IE) techniques commonly assume that the human supervision comes in the form of knowledge bases of facts disconnected from supporting text, as in the case of distant supervision (Mintz et al., 2009), or provides a light amount of supervision up front, as in the case of bootstrapping (Angeli et al., 2015). Common techniques for bootstrapping are to use rules for incrementally classifying entities (Collins and Singer, 1999) or to use syntactic (He and Grishman, 2015) and semantic (Gupta and Manning, 2014, 2015) contextual features. However, such approaches suffer from semantic drift, as previously discussed.

Considering a human-in-the-loop for IE has the potential to mitigate drift and greatly benefit performance, yet the challenge lies in minimizing human effort. The work of Angeli et al. (2014) show how to use active learning to improve distantly supervised relation extraction techniques (Surdeanu et al., 2012) through humans labeling informative relations. Werling et al. (2015) use Bayesian decision theory to minimize human cost and maximize accuracy for named entity recognition. For certain IE tasks, however, human supervision can be very noisy and thus counterproductive, especially from crowds, thus previous work has shown the importance of how to pose tasks for humans in providing labels (Liu et al., 2016), as well as automatically distinguishing simple labeling tasks from expert tasks in crowd-based task assignments (Wang et al., 2017). Our work shares a similar view of human supervision for IE, yet we instead study the impact of the annotation interface on the overall performance.

The role of the human-in-the-loop for topic modeling has also been extensively explored. For instance Smith et al. (2018) consider the types of modifications that one can provide to a built topic model (Hu et al., 2014) to make the topics more meaningful, while also studying the downstream human factor implications. Furthermore, prior work has also considered how different visual representations of topics impact a human's understanding of topic semantics (Smith et al., 2017). Closely related is the technique of Poursabzi-Sangdeh et al. (2016), where they highlight how different visual representations can have an impact on the effectiveness and efficiency of human labeling for document classification, comparing standard list interfaces with topic-grouped lists. Our method instead considers how 2D scatterplot interfaces, via embedding-based techniques, capture semantics for the purposes of providing labels in an IE task.

The visual analytics community has also investigated the role of visual interfaces and interaction tools for annotating data in supervised learning. For instance Heimerl et al. (2012) enable interactive labeling for document classification by visualizing unlabeled documents based on classifier uncertainty and document diversity. The technique of Höferlin et al. (2012) jointly visualizes unlabeled data and the classifier model, and allows the user to both label data points and directly modify model parameters. Closely related to our method is the work of Bernard et al. (2018) which compares active learning, via list interfaces, with in-

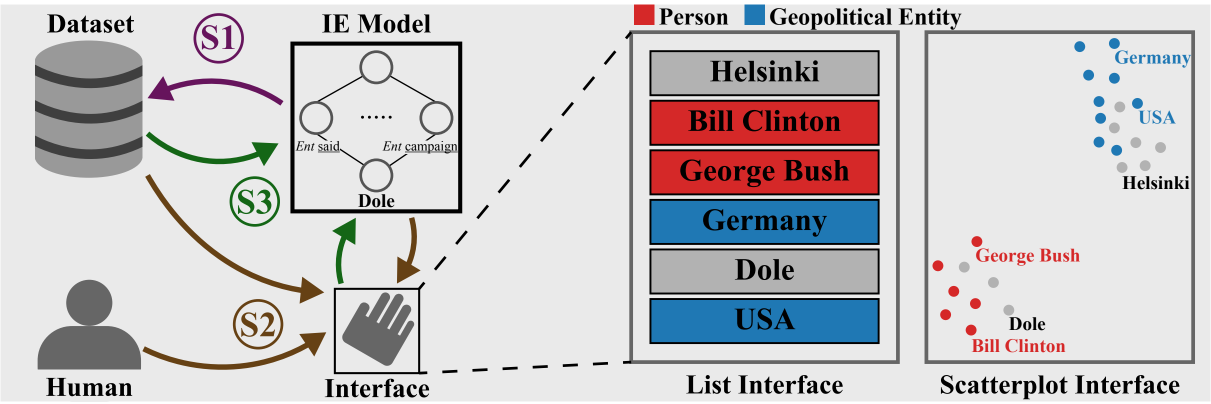

Figure 1: We show the workflow of our study (left): **(S1)** the Information Extraction model first automatically labels entities and updates its parameters, **(S2)** the human then labels entities through a given visual interface, and **(S3)** the model is updated based on the provided set of human labels. We study the effectiveness of two different interfaces (right): a list, and a 2D scatterplot of entities.

teractive visual labeling. However, their method is focused on acquiring labels solely from humans, whereas our method studies the interplay between self-labeling and human labels in a visualization context.

3 Human-Machine Workflow for Bootstrapping

We first describe the general workflow on which our study is based. We consider bootstrapping where both the human and the machine label entities *in tandem*, following the setup described in Fu and Grishman (2013) . More specifically, we consider the following iterative process (c.f. Fig. 1):

- (**S1**) The model automatically classifies entities, adds them as labeled data, and updates its parameters, as detailed in §4.
- (**S2**) The human interacts with a visual interface, driven by the model and the current set of labeled and unlabeled entities. The result of this step is a set of entities labeled by the human. We define this step a **round of labeling**, or just **round**.
- (**S3**) The model then updates its parameters given the human-labeled entities.

In contrast with typical bootstrapping, which interleaves entity promotion with model updates, here the human has the opportunity to label data. The intent is to *guide bootstrapping*: human annotations should steer bootstrapping towards learning the proper concepts, and away from semantic drift.

Yet, in this process we would like to *minimize human effort* while *maximizing bootstrapping performance*, where we define *effort* as the total time spent annotating data. In particular, the primary focus of our study is on step (**S2**), and how the user's interactions with the interface impacts these considerations. We consider two different types of interfaces for this purpose, shown on the right side of Fig. 1: list interfaces, and scatterplot interfaces. In particular, both interfaces utilize the state of the model to decide on what to show to the user. In the case of the list-based interface, we perform *uncertainty sampling* with respect to the model, as a way to maximize the information obtained from the user. For the scatterplot interface, the user interacts with a subset of *diverse* and *representative* entities through a 2D projection. Here we wish to see if more efficient *groupwise labeling* of perceived clusters in the scatterplot results in a more efficient and effective labeling process.

Of course, a critical piece to our study is the bootstrapping model itself. There exists a large body of work in bootstrapping, as previously discussed, and one possibility is to use an existing technique for our work. For our learning scenario, a bootstrapping technique should satisfy several criteria:

- Be efficient to update, in order to minimize user latency with the interface;
- Incorporate user supervision to ensure a discriminative representation;
- Be suitable for visual exploration.

Please note that traditional bootstrapping techniques such as rule-based methods (Collins and Singer, 1999) fail to meet all criteria. In particular, they are not suitable for visual exploration because there is no clear way to represent the semantic proximity of rules or of the concepts being learned. We next describe how to address these challenges through embedding-based bootstrapping.

4 Embedding-Based Bootstrapping

Our bootstrapping technique is based on neural language models (Mikolov et al., 2013), in particular, semi-supervised embedding-based bootstrapping techniques (Valenzuela-Escárcega et al., 2018). Unlike other word embedding algorithms, our approach measures distributional similarity of *entities* (rather than words) with respect to *patterns* (rather than context words). We define a pattern as a small sequence of words that surround an entity, up to ±4 words to the left/right of the entity under consideration. For instance, in the phrases "**John** <u>said</u> <u>on</u> <u>Saturday</u>" and "**John** <u>told</u> <u>reporters</u>" the patterns "<u>said</u> <u>on</u> <u>Saturday</u>" and "<u>told</u> <u>reporters</u>" are suggestive of the category Person for entity **John**.[1] We observe that entities of a given category, e.g. Person, are likely to have common pattern distributions. This observation drives our method for learning entity and pattern embeddings. Furthermore, as we will see, this method permits efficient updates, and it is suitable for visualization due to the geometric representation of entities and patterns.

More specifically, assume that we have extracted a set of entities E and patterns P in a given text corpus C. We associate each entity $e \in E$ and pattern $p \in P$ with *embeddings* $\mathbf{x}_e$ and $\mathbf{x}_p$, respectively, with $\mathbf{x}_e, \mathbf{x}_p \in \mathbb{R}^d$. To satisfy the above form of distributional similarity, we utilize the Skip Gram model (Mikolov et al., 2013) and seek entity embeddings to be close to their embeddings of observed patterns through maximizing:

$$SG = \sum_{(e,p) \in C_p} [\log(\sigma(\mathbf{x}_e^\top \mathbf{x}_p)) + \sum_{n \in N} \log(\sigma(-\mathbf{x}_e^\top \mathbf{x}_n))], \tag{1}$$

where (e, p) corresponds to an entity-pattern occurrence from the corpus set C_p, n represents a *negative* pattern, sampled from the unigram distribution of all patterns N (Levy and Goldberg, 2014) [2], and σ is the sigmoid function. Intuitively, this forces an entity's embedding to be similar to embeddings of its matched patterns from the corpus, and dissimilar to random pattern embeddings.

A disadvantage with the Skip Gram model is that it might fail to be discriminative, since it does not utilize category labels. Thus, we introduce an objective term that seeks to bring entities that belong to the same category to have similar embeddings, and entities that belong to different categories to be far apart in their embeddings. We realize this using large-margin metric learning (Cui et al., 2016; Sohn, 2016), minimizing:

$$LM = \sum_{(a,b,c) \in E_l} \lfloor s(\mathbf{x}_a, \mathbf{x}_c) - s(\mathbf{x}_a, \mathbf{x}_b) + M \rfloor_+, \tag{2}$$

where (a, b, c) represents a triplet of entities, such that a and b belong to the same category, while c belongs to a different category, and the function s is the cosine similarity between entity embeddings. The set E_l is a subset of entities from E that have been assigned categories so far, as provided by the bootstrapper (**S1**) or the human (**S2**). Intuitively, entities from dissimilar categories should be positioned in the embedding space such that their cosine similarity is at least a margin M from any pair of entities of the same category.

We combine the Skip Gram objective with the metric learning objective to obtain:

$$B = LM - SG. \tag{3}$$

The objective B can be viewed as a form of semi-supervised representation learning, where from a sparse set of labeled entities, we wish to learn entity representations that are similar should they have patterns in common (SG), while simultaneously ensuring that embeddings are discriminative with respect to categories (LM). Step (**S3**) minimizes this objective at every round of bootstrapping via stochastic gradient descent, given the current set of labeled entities E_l.

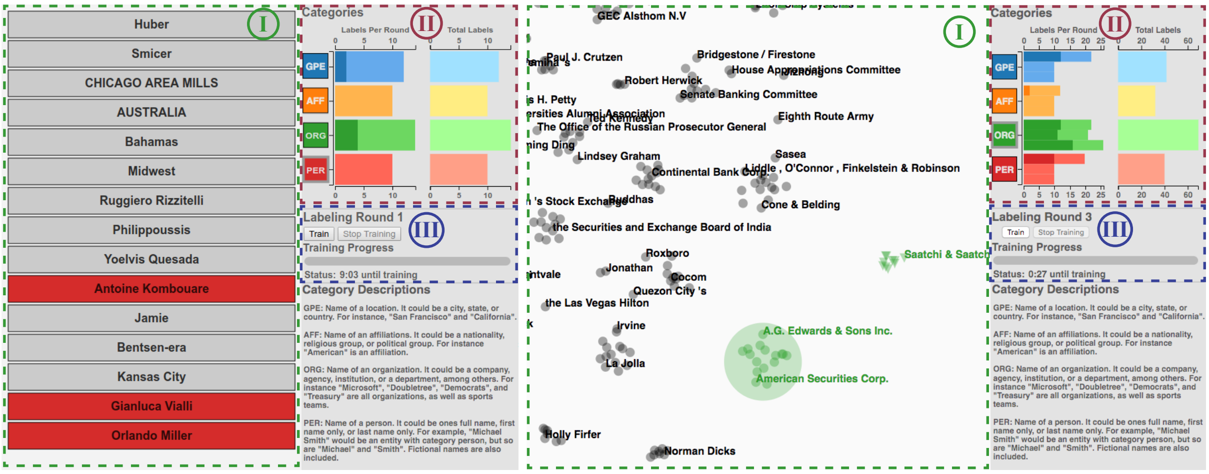
4.1 Promoting Entities

We use the learned embedding to automatically promote unlabeled entities to categories, as discussed in step (**S1**). We use the normalized entity embeddings as features, and build a multinomial

---

[1] In this work we use surface patterns, but the proposed algorithm is agnostic to the types of patterns used.

[2] In initial ablation studies, we found that this strategy was about as effective as negative sampling from *all* patterns, but significantly faster, which is necessary for interactivity.



GPE: Name of a location. It could be a city, state, or country. For instance, "San Francisco" and "California".

AFF: Name of an affiliations. It could be a nationality, religious group, or political group. For instance "American" is an affiliation.

ORG: Name of an organization. It could be a company, agency, institution, or a department, among others. For instance "Microsoft", "Doubletree", "Democrats", and "Treasury" are all organizations, as well as sports teams.

PER: Name of a person. It could be ones full name, first name only, or last name only. For example, "Michael Smith" would be an entity with category person, but so are "Michael" and "Smith". Fictional names are also included.

GPE: Name of a location. It could be a city, state, or country. For instance, "San Francisco" and "California".

AFF: Name of an affiliations. It could be a nationality, religious group, or political group. For instance "American" is an affiliation.

ORG: Name of an organization. It could be a company, agency, institution, or a department, among others. For instance "Microsoft", "Doubletree", "Democrats", and "Treasury" are all organizations, as well as sports teams.

PER: Name of a person. It could be ones full name, first name only, or last name only. For example, "Michael Smith" would be an entity with category person, but so are "Michael" and "Smith". Fictional names are also included.

(a) List Interface

(b) Scatterplot Interface

Figure 2: We study two different interfaces for humans to label entities, a list interface (a) and a 2D scatterplot interface (b). In both, the user selects entities in the main view (I), based on an assigned category (II), wherein we also show the total amount of labels the user, and the machine, has thus far labeled. In (III) we show the current status of training/labeling, and the option to initiate/stop training.

logistic regression model over the given set of labeled entities, trained to predict entity categories. For each category, we then promote the most confident entities to the category. To compute confidence, we treat the model's predictions as category probabilities, take the entropy over this distribution as a measure of unconfidence, and promote entities with the lowest entropy.

5 Supervision Interfaces

We now turn to the visual interface through which humans provide supervision (step **S2**). We distinguish the interfaces by how entities are *sampled*, *presented* to the user, and each interface's set of *interactions* for labeling.

5.1 List Interface

Sampling. We sample entities through sorting them by confidence, as defined in §4.1, and sample the most unconfident entities. This form of uncertainty sampling is common in list-based interfaces (Angeli et al., 2014; Poursabzi-Sangdeh et al., 2016), as a measure of informativeness for updating the model (Settles, 2012).

Presentation. We next show the 15 most uncertain entities in a 1D list-based visual interface (Fig. 2a **(I)**).

Interactions. The user labels entities by first selecting their desired category (Fig. 2a **(II)**), followed by clicking on the entity in the main display. We also allow the user to select multiple entities at once, for a given category. As the user labels entities, we repopulate the display with the next set of most unconfident entities.

5.2 Scatterplot Interface

Sampling. For the scatterplot interface, we aim to sample entities that are beneficial for the model, while also ensuring the user can efficiently label entities through groupwise selection. Uncertainty sampling, though potentially informative, can lead to projections that are challenging for the user in performing groupwise labeling, as we experimentally verified that entities with high classification uncertainty are unlikely to group together. To address this, we sample entities based on how they are distributed in the embedding space, to provide us a *diverse* and *representative* sampling (Xu et al., 2007). More specifically, we first perform k-means on the entities' normalized embeddings, with $k = 40$, and sample across clusters to give diversity. To ensure a representative sampling, kernel density estimation is performed within each cluster's entities, and the entity with highest density, along with its nearest neighbors in the embedding space, are selected. The number of neighbors sampled in each cluster is proportional to the cluster size, to ensure balance across clusters.

Presentation. We next perform a 2D projection of 500 sampled entities using t-SNE (Maaten and Hinton, 2008), visually encoding each entity by a filled circle (Fig. 2b **(I)**). To provide context with respect to entities labeled by the human or machine, we jointly project the unlabeled sampled entities, and a subset of the entities previously labeled (drawn as triangles), either by the human annotator or promoted with high-confidence by the machine.

Interactions. The user labels entities by first selecting a category (Fig. 2b **(II)**), followed by using a circular brush to label groups of entities. The user can adjust the brush's radius, as well as change the view through panning and zooming. We dynamically filter the text labels for entities based on the zoom level to reduce clutter, thus the user can observe a high-level overview of the space of entities when zoomed out, and observe more details upon zooming in. This gives the annotator the chance to perform groupwise annotations by jointly considering cluster structure and a sparse set of text labels from the cluster, and labeling all entities at once should the annotator decide the group of entities belongs to a single category.

5.3 Training

Common to both interfaces, user interactions are interleaved with model updates. During training, the list interface is refreshed with the top 15 most informative samples every 3 *training epochs*, or passes over the data, while for the scatterplot the samples and their 2D positions are updated. To ensure temporal coherence for those entities that persist between updates, we employ dynamic t-SNE (Rauber et al., 2016). The user can opt to stop training if they observe little change occurring between snapshots (Fig. 2 **(III)**).

6 User Study

We conducted a user study to investigate the effectiveness of the different interfaces. We recruited 10 participants for our study: the median age was 22, the minimum and maximum respectively 19 and 41, 5 participants self-reported as being "somewhat knowledgeable" of machine learning, 4 with "no knowledge", and 1 identifying as an "expert". We used a within-subject design, where the first interface presented to the participant was selected at random to mitigate potential priming effects. For each interface, a set of instructions was first presented, followed by a brief tutorial where the user must label a small set of seed entities – 10 per category. These seed entities, labeled with ground truth rather than user labels, initialize the bootstrapping model, so that participants start off with identical embeddings. After the instructions, the participant then performs 10 rounds of labeling, where they may label entities for up to 1 minute per round. After each round of labeling, the bootstrapper promotes 10 entities to each category, and then performs 30 epochs of training.

Dataset. We use the Ontonotes dataset (Weischedel et al., 2013), limited to the 4 categories that have the most frequently mentioned entities, in order to make the labeling task manageable, yet still nontrivial, for participants. These categories are people (PER), organizations (ORG), geopolitical entities (GPE), and nationalities as well as religious/political affiliations (AFF), resulting in 6,567, 6,199, 1,617, and 422 entities per category, respectively.

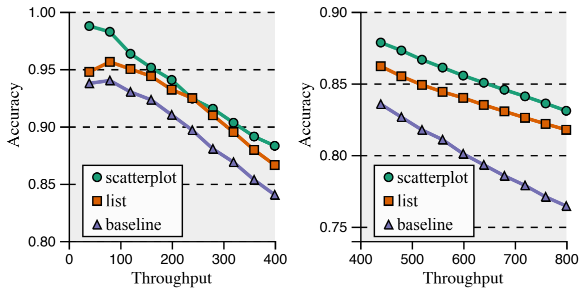
Bootstrapping Details. It is critical to ensure that bootstrapping training minimizes user latency, while not sacrificing performance (c.f. Eq. 3). To strike this balance, we set the number of negative patterns sampled for each entity to 10 (Levy and Goldberg, 2014), the embedding dimension d to 100, perform hard negative triplet mining (Cui et al., 2016) to form the loss on triplets likely to violate the margin, and set the margin M to 0.4. Experimentally, we found these settings allowed training to converge to a good solution after 30 training epochs, and that each epoch took no longer than 1 second on average.

7 Results

We analyze the results in terms of three forms of evaluation: *bootstrapping performance*, as determined by the entities promoted during the course of the user study, *extrapolation*, wherein we let bootstrapping proceed to promote entities after the joint human-machine labeling has completed, and *consensus*, where we combine the set of entities annotated by participants within the different interfaces. We also analyze a typical user's labeling, and corresponding machine performance.

7.1 Bootstrapping Performance

We first look at the effectiveness of promoted entities during the course of each participant's interactions. Fig. 3(a) shows bootstrapping accuracy averaged over all users for the list and scatterplot. We also compare to a baseline of traditional bootstrapping, where no human labels are considered, averaged over 10 trials. Note this is simi-

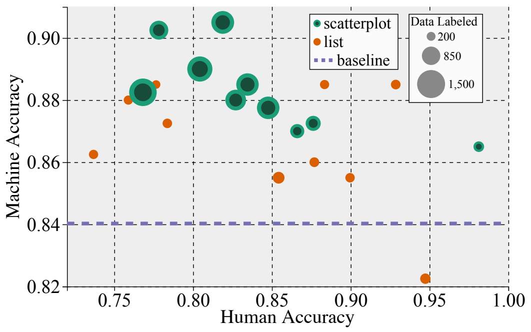


(a) Bootstrapping (b) Extrapolation

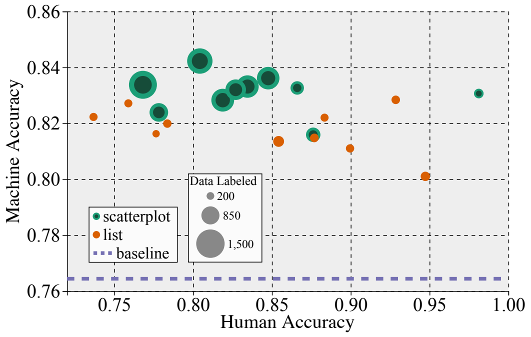
Figure 3: Performance averaged over all users for bootstrapping during user study (a) and extrapolation (b), for both interfaces and a baseline that does not use human labels. The green, orange, and purple plots are scatterplot, list, and baseline, respectively.

	scatterplot	list	baseline
bootstrapping	88.8	87.2	85.1
extrapolation	84.7	83.5	78.6

Table 1: We show performance in terms of recall, computed per-category and averaged across categories, for the baseline, list and scatterplot interfaces. This is shown for the last round of bootstrapping (c.f. Fig. 3a) and extrapolation (c.f. Fig. 3b).



(a) Bootstrapping



(b) Extrapolation

Figure 4: Bootstrapping performance for user study (a), and extrapolation (b) for individual participants, evaluated at throughputs (number of entities promoted) of 400 and 800, respectively. Each circle is a participant whose color indicates the interface (green, orange, and purple are scatterplot, list, and baseline, respectively); x-axis is participant labeling accuracy; y-axis is machine accuracy; and circle size encodes the number of annotated labels (large circle indicates large number of annotated labels).

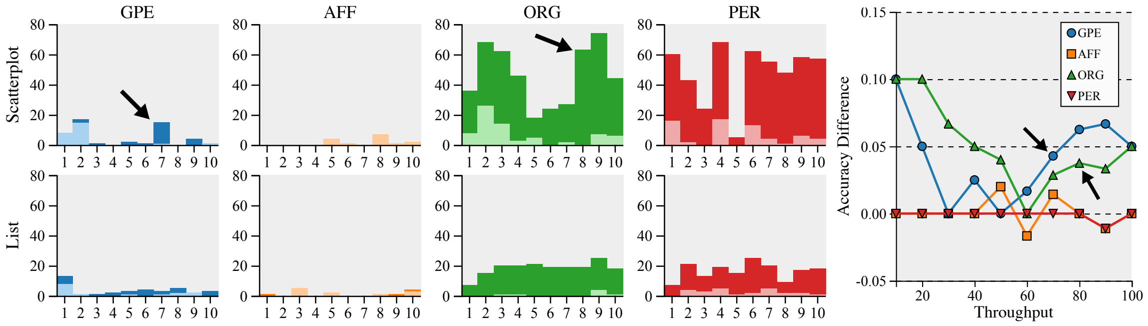
lar to Valenzuela-Escárcega et al. (2018), which demonstrates improved performance across a set of bootstrapping techniques, and thus represents a competitive baseline. We find that the performance of both interfaces outperform this baseline, and that the scatterplot outperforms the list: a two-sample Welch's t-test concludes statistical significance (p=0.05), as well as for a paired t-test measured within participants (p=0.03). In Table 1 we also show recall, computed per-category and averaged over categories, at the last round of bootstrapping and similarly find the scatterplot outperforms the list.

Better insight between the interfaces can be gained by looking at individual user performance. Fig. 4(a) shows a plot of each participant's performance (y-axis) for both interfaces, as a function of their labeling accuracy (x-axis) and the total number of labels provided (size of each circle). Note that the 3 best-performing models come from the scatterplot interface, *even at the expense of a lower labeling accuracy*. This suggests that the *number of labels* can counter the *noise in labeling*, compared to a list where we may have potentially more informative entities labeled more accurately, but much fewer entities annotated.

7.2 Extrapolation

We next look at how bootstrapping continues to learn, when starting from all of the annotations provided by the corresponding human annotator as well as the entities promoted by the machine. We term this configuration extrapolation. This analysis indirectly measures how much noise crept into the available annotations, by measuring the performance of the classifier trained on this data.

We repeated this experiment over 10 different trials, promoting 10 entities per category in each round, and take the average accuracy, see Fig. 3(b) for the performance averaged over all users for



(a) Human Labeling Accuracy

(b) Interface Accuracy

Figure 5: Labeling accuracy and bootstrapping performance for a typical participant. In (a) we show per-category annotations, where the x-axis is the round number and y-axis is the number of entities labeled. Colors of higher lightness indicate mislabeled entities. For example, approximately 40% of the user's annotations in round 2 for ORG in the scatterplot were incorrect. In (b) we show the difference in bootstrapping performance between the scatterplot and list interfaces. For instance, scatterplot yields a model 5% more accurate than list for GPE in round 10. Note the correlation between human labeling (left) and bootstrapping performance (right), highlighted by the arrows.

the interfaces, as well as the aforementioned baseline. Observe that the baseline performs progressively worse as a function of throughput, indicating that labels provided by the human annotators help to prevent drift. We also find the results to be stronger compared with §7.1; namely, a two-sample Welch's t-test concludes statistical significance (p=0.002) and similarly for a paired t-test within participants (p=0.007). The recall performance in Table 1 also confirms the performance gains of the scatterplot. Supporting these results, Fig. 4(b) shows that the scatterplot interface for users that labeled a large amount of entities generally outperform those where fewer entities were labeled. This experiment suggests that the best strategy to control for semantic drift is to aim for an interface that yields *many* annotations at *reasonable* accuracy, rather than few, higher-quality ones.

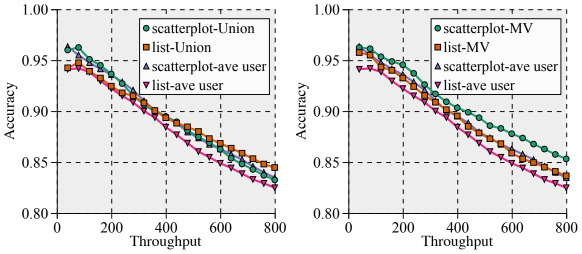
7.3 Individual User Labeling

We show labeling accuracy and bootstrapping accuracy for a participant that has similar performance to the average (c.f. Fig. 3(a)). In Fig. 5(a) we show the number of entities labeled across categories, where bars of higher color lightness encode the number of incorrect labels, and in (b) we plot the difference in bootstrapping performance between the scatterplot and the list. We observe that the class imbalance of the Ontonotes dataset tends to manifest in labeling as well, where ORG and PER are typically labeled the most. We also see a correlation between accurate human labeling and bootstrapping performance (e.g. the arrows pointing at GPE and ORG for rounds 7 and 8, respectively). This highlights an advantage of exploratory visual interfaces for labeling, such as a scatterplot, where the user can search for clusters of a particular category, e.g., in the case of GPE there may not exist many entities of this type in the list interface.

7.4 Consensus

Given the noise inherent in a single user's annotations, we last analyze whether techniques to *combine* labels across a set of users can help reduce label noise and improve performance. To this end, for the scatterplot and list interface we combine all annotations, and consider two different types of consensus methods: 1) **Union:** we take the union of all annotated entities, choosing an entity's label at random during conflicts; and 2) **Majority Vote (MV):** for conflicting entities we select the most voted category across users, discarding entities that have only been annotated once or have ties across users. We then seed bootstrapping with the resulting set of labels, run 20 rounds of promotion, and take the average performance of 10 trials.

Fig. 6(a-b) compares each method across the different interfaces, while Table 2 shows accuracy and total number of labels for the consensus methods. We also include performance, labeling accuracy, and label totals averaged across individual users, where for each user we seed bootstrapping



(a) Union (b) Majority Vote

Figure 6: Accuracy of different consensus methods, compared across the two interfaces, as well as average performance across individual users.

with their full set of annotations. For **Union**, we observe that despite the large number of labels, the scatterplot performance is comparable to average individual performance, suggesting that in this case, the volume of labels does not counter the noise in the data. For the list, we can see a gain in performance, which is likely attributed to the cleaner annotations from participants. For **MV**, however, we find that the scatterplot performs the best, whereas the list performs worse compared with its **Union** counterpart, now having approximately 3x less labels. This emphasizes the interplay between *accuracy* and *label quantity*, even despite the more informative labels provided through the list interface, and supports our previous observation that balancing the volume of annotations with their quality yields the best annotation strategy.

8 Discussion

We acknowledge some limitations in our technique and user study. A drawback to our sampling scheme for the scatterplot is that it does not utilize classifier informativeness. In initial experiments, we found that uncertainty sampling led to 2D projections that were challenging to groupwise label. This result is intuitive: data points classified with lowest confidence will naturally have low-quality embeddings, yielding poor clusters. Thus we can not perform a consistent comparison of the same sampling criterion used between the interfaces. For future work we will investigate active learning techniques that are relevant to the learning task, while still permitting efficient labeling.

Interface	Union		MV		Ave. User	
	Acc	Total	Acc	Total	Acc	Total
List	82.7	1463	95.4	543	85.1	217
Scatterplot	77.6	3503	92.5	1959	82.3	788

Table 2: Consensus accuracies and label amounts across the interfaces. The last column is average user accuracy and label amount.

In this work we restricted our study to entity classification, one of many types of IE tasks. Our approach should generalize to other IE tasks, however, provided these tasks exhibit certain structure. Specifically, user annotations in a task should amount to labeling of data instances, and the data instances defined by the task should be able to be perceived in a 2D scatterplot. For instance, coreference resolution and relationship extraction fit both criteria. Assessing the effectiveness of visual supervision for these tasks is outside of the scope of this paper, however, and we will consider these studies in future work.

Overall, our user study clearly highlights the importance of visual interfaces in acquiring supervision for semi-supervised information extraction. We demonstrated that, when compared to the traditional list interface, the scatterplot allows a larger volume of annotations to be created at reasonable accuracy, yielding better classifiers. We believe this finding will influence active learning, in terms of sampling criteria and the interplay between AL and visual interfaces.

Abstract

Recent advances in deep neural models allow us to build reliable named entity recognition (NER) systems without handcrafting features. However, such methods require large amounts of manually-labeled training data. There have been efforts on replacing human annotations with distant supervision (in conjunction with external dictionaries), but the generated noisy labels pose significant challenges on learning effective neural models. Here we propose two neural models to suit noisy distant supervision from the dictionary. First, under the traditional sequence labeling framework, we propose a revised fuzzy CRF layer to handle tokens with multiple possible labels. After identifying the nature of noisy labels in distant supervision, we go beyond the traditional framework and propose a novel, more effective neural model AutoNER with a new `Tie or Break` scheme. In addition, we discuss how to refine distant supervision for better NER performance. Extensive experiments on three benchmark datasets demonstrate that AutoNER achieves the best performance when only using dictionaries with no additional human effort, and delivers competitive results with state-of-the-art supervised benchmarks.

1 Introduction

Recently, extensive efforts have been made on building reliable named entity recognition (NER) models without handcrafting features (Liu et al., 2018; Ma and Hovy, 2016; Lample et al., 2016). However, most existing methods require large amounts of manually annotated sentences for training supervised models (e.g., neural sequence models) (Liu et al., 2018; Ma and Hovy, 2016; Lample et al., 2016; Finkel et al., 2005). This is particularly challenging in specific domains, where domain-expert annotation is expensive and/or slow to obtain.

To alleviate human effort, distant supervision has been applied to automatically generate labeled data, and has gained successes in various natural language processing tasks, including phrase mining (Shang et al., 2018), entity recognition (Ren et al., 2015; Fries et al., 2017; He, 2017), aspect term extraction (Giannakopoulos et al., 2017), and relation extraction (Mintz et al., 2009). Meanwhile, open knowledge bases (or dictionaries) are becoming increasingly popular, such as WikiData and YAGO in the general domain, as well as MeSH and CTD in the biomedical domain. The existence of such dictionaries makes it possible to generate training data for NER at a large scale without additional human effort.

Existing distantly supervised NER models usually tackle the entity span detection problem by heuristic matching rules, such as POS tag-based regular expressions (Ren et al., 2015; Fries et al., 2017) and exact string matching (Giannakopoulos et al., 2017; He, 2017). In these models, every unmatched token will be tagged as non-entity. However, as most existing dictionaries have limited coverage on entities, simply ignoring unmatched tokens may introduce false-negative labels (e.g., "prostaglandin synthesis" in Fig. 1). Therefore, we propose to extract high-quality out-of-dictionary phrases from the corpus, and mark them as potential entities with a special "unknown" type. Moreover, every entity span in a sentence can be tagged with multiple types, since two entities of different types may share the same surface name in the dictionary. To address these challenges, we propose and compare two neural architectures with customized tagging schemes.

We start with adjusting models under the traditional sequence labeling framework. Typically, NER models are built upon conditional random

Brussels, Belgium, October 31 - November 4, 2018.

fields (CRF) with the `IOB` or `IOBES` tagging scheme (Liu et al., 2018; Ma and Hovy, 2016; Lample et al., 2016; Ratinov and Roth, 2009; Finkel et al., 2005). However, such design cannot deal with multi-label tokens. Therefore, we customize the conventional CRF layer in LSTM-CRF (Lample et al., 2016) into a Fuzzy CRF layer, which allows each token to have multiple labels without sacrificing computing efficiency.

To adapt to imperfect labels generated by distant supervision, we go beyond the traditional sequence labeling framework and propose a new prediction model. Specifically, instead of predicting the label of each single token, we propose to predict whether two adjacent tokens are tied in the same entity mention or not (i.e., broken). The key motivation is that, even the boundaries of an entity mention are mismatched by distant supervision, most of its inner ties are not affected, and thus more robust to noise. Therefore, we design a new `Tie or Break` tagging scheme to better exploit the noisy distant supervision. Accordingly, we design a novel neural architecture that first forms all possible entity spans by detecting such ties, then identifies the entity type for each span. The new scheme and neural architecture form our new model, AutoNER, which proves to work better than the Fuzzy CRF model in our experiments.

We summarize our major contributions as

- We propose AutoNER, a novel neural model with the new `Tie or Break` scheme for the distantly supervised NER task.
- We revise the traditional NER model to the Fuzzy-LSTM-CRF model, which serves as a strong distantly supervised baseline.
- We explore to refine distant supervision for better NER performance, such as incorporating high-quality phrases to reduce false-negative labels, and conduct ablation experiments to verify the effectiveness.
- Experiments on three benchmark datasets demonstrate that AutoNER achieves the best performance when only using dictionaries with no additional human effort and is even competitive with the supervised benchmarks.

We release all code and data for future studies[1]. Related open tools can serve as the NER module of various domain-specific systems in a plug-in-and-play manner.

2 Overview

Our goal, in this paper, is to learn a named entity tagger using, and only using dictionaries. Each dictionary entry consists of 1) the surface names of the entity, including a canonical name and a list of synonyms; and 2) the entity type. Considering the limited coverage of dictionaries, we extend existing dictionaries by adding high-quality phrases as potential entities with unknown type. More details on refining distant supervision for better NER performance will be presented in Sec. 4.

Given a raw corpus and a dictionary, we first generate entity labels (including unknown labels) by exact string matching, where conflicted matches are resolved by maximizing the total number of matched tokens (Etzioni et al., 2005; Hanisch et al., 2005; Lin et al., 2012; He, 2017).

Based on the result of dictionary matching, each token falls into one of three categories: 1) it belongs to an entity mention with one or more known types; 2) it belongs to an entity mention with unknown type; and 3) It is marked as non-entity.

Accordingly, we design and explore two neural models, Fuzzy-LSTM-CRF with the modified `IOBES` scheme and AutoNER with the `Tie or Break` scheme, to learn named entity taggers based on such labels with unknown and multiple types. We will discuss the details in Sec. 3.

3 Neural Models

In this section, we introduce two prediction models for the distantly supervised NER task, one under the traditional sequence labeling framework and another with a new labeling scheme.

3.1 Fuzzy-LSTM-CRF with Modified IOBES

State-of-the-art named entity taggers follow the sequence labeling framework using `IOB` or `IOBES` scheme (Ratinov and Roth, 2009), thus requiring a conditional random field (CRF) layer to capture the dependency between labels. However, both the original scheme and the conventional CRF layer cannot handle multi-typed or unknown-typed tokens. Therefore, we propose the modified `IOBES` scheme and Fuzzy CRF layer accordingly, as illustrated in Figure 1.

Modified IOBES. We define the labels according to the three token categories. 1) For a token

---

[1] `https://github.com/shangjingbo1226/AutoNER`

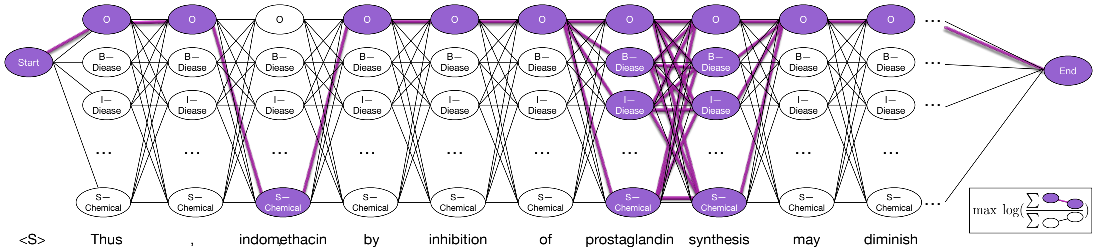

Figure 1: The illustration of the Fuzzy CRF layer with modified `IOBES` tagging scheme. The named entity types are {`Chemical`, `Disease`}. "indomethacin" is a matched `Chemical` entity and "prostaglandin synthesis" is an unknown-typed high-quality phrase. Paths from `Start` to `End` marked as purple form all possible label sequences given the distant supervision.

marked as one or more types, it is labeled with all these types and one of {`I`, `B`, `E`, `S`} according to its positions in the matched entity mention. 2) For a token with unknown type, all five {`I`, `O`, `B`, `E`, `S`} tags are possible. Meanwhile, all available types are assigned. For example, when there are only two available types (e.g., Chemical and Disease), it has nine (i.e., $4 \times 2 + 1$) possible labels in total. 3) For a token that is annotated as non-entity, it is labeled as `O`.

As demonstrated in Fig. 1, based on the dictionary matching results, "indomethacin" is a singleton `Chemical` entity and "prostaglandin synthesis" is an unknown-typed high-quality phrase. Therefore, "indomethacin" is labeled as `S-Chemical`, while both "prostaglandin" and "synthesis" are labeled as `O`, `B-Disease`, `I-Disease`, . . ., and `S-Chemical` because the available entity types are {`Chemical`, `Disease`}. The non-entity tokens, such as "Thus" and "by", are labeled as `O`.

Fuzzy-LSTM-CRF. We revise the LSTM-CRF model (Lample et al., 2016) to the Fuzzy-LSTM-CRF model to support the modified `IOBES` labels.

Given a word sequence $(X_1, X_2, \ldots, X_n)$, it is first passed through a word-level BiLSTM (Hochreiter and Schmidhuber, 1997) (i.e., forward and backward LSTMs). After concatenating the representations from both directions, the model makes independent tagging decisions for each output label. In this step, the model estimates the score P_{i,y_j} for the word X_i being the label y_j.

We follow previous works (Liu et al., 2018; Ma and Hovy, 2016; Lample et al., 2016) to define the score of the predicted sequence, the score of the predicted sequence $(y_1, y_2, \ldots, y_n)$ is defined as:

$$s(X, y) = \sum_{i=0}^{n} \Phi_{y_i,y_{i+1}} + \sum_{i=1}^{n} P_{i,y_i} \qquad (1)$$

where, $\Phi_{y_i,y_{i+1}}$ is the transition probability from a label y_i to its next label y_{i+1}. Φ is a $(k + 2) \times (k + 2)$ matrix, where k is the number of distinct labels. Two additional labels `start` and `end` are used (only used in the CRF layer) to represent the beginning and end of a sequence, respectively.

The conventional CRF layer maximizes the probability of the only valid label sequence. However, in the modified `IOBES` scheme, one sentence may have multiple valid label sequences, as shown in Fig. 1. Therefore, we extend the conventional CRF layer to a fuzzy CRF model. Instead, it maximizes the total probability of all possible label sequences by enumerating both the `IOBES` tags and all matched entity types. Mathematically, we define the optimization goal as Eq. 2.

$$p(y|X) = \frac{\sum_{\tilde{y} \in Y_{possible}} e^{s(X,\tilde{y})}}{\sum_{\tilde{y} \in Y_X} e^{s(X,\tilde{y})}} \qquad (2)$$

where Y_X means all the possible label sequences for sequence X, and $Y_{possible}$ contains all the possible label sequences given the labels of modified `IOBES` scheme. Note that, when all labels and types are known and unique, the fuzzy CRF model is equivalent to the conventional CRF.

During the training process, we maximize the log-likelihood function of Eq. 2. For inference, we apply the Viterbi algorithm to maximize the score of Eq. 1 for each input sequence.

3.2 AutoNER with "Tie or Break"

Identifying the nature of the distant supervision, we go beyond the sequence labeling framework and propose a new tagging scheme, `Tie or Break`. It focuses on the ties between adjacent tokens, i.e., whether they are tied in the same entity mentions or broken into two parts. Accordingly, we design a novel neural model for this scheme.

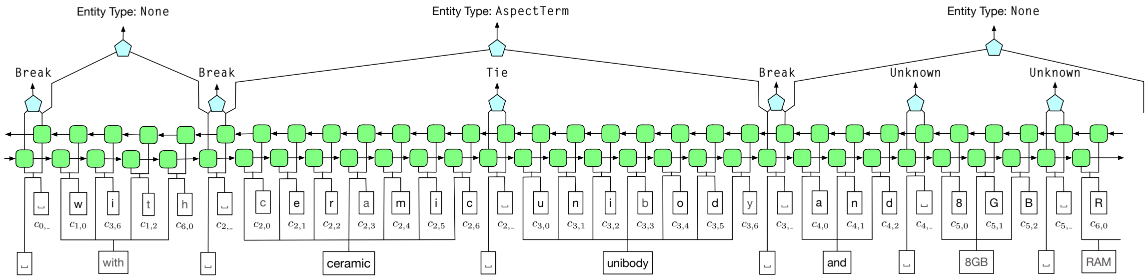

Figure 2: The illustration of AutoNER with `Tie or Break` tagging scheme. The named entity type is {`AspectTerm`}. “ceramic unibody” is a matched `AspectTerm` entity and “8GB RAM” is an unknown-typed high-quality phrase. `Unknown` labels will be skipped during the model training.

“Tie or Break” Tagging Scheme. Specifically, for every two adjacent tokens, the connection between them is labeled as (1) `Tie`, when the two tokens are matched to the same entity; (2) `Unknown`, if at least one of the tokens belongs to an unknown-typed high-quality phrase; (3) `Break`, otherwise.

An example can be found in Fig. 2. The distant supervision shows that “ceramic unibody” is a matched `AspectTerm` and “8GB RAM” is an unknown-typed high-quality phrase. Therefore, a `Tie` is labeled between “ceramic” and “unibody”, while `Unknown` labels are put before “8GB”, between “8GB” and “RAM”, and after “RAM”.

Tokens between every two consecutive `Break` form a token span. Each token span is associated with all its matched types, the same as for the modified `IOBES` scheme. For those token spans without any associated types, such as “with” in the example, we assign them the additional type `None`.

We believe this new scheme can better exploit the knowledge from dictionary according to the following two observations. First, even though the boundaries of an entity mention are mismatched by distant supervision, most of its inner ties are not affected. More interestingly, compared to multi-word entity mentions, matched unigram entity mentions are more likely to be false-positive labels. However, such false-positive labels will not introduce incorrect labels with the `Tie or Break` scheme, since either the unigram is a true entity mention or a false positive, it always brings two `Break` labels around.

AutoNER. In the `Tie or Break` scheme, entity spans and entity types are encoded into two folds. Therefore, we separate the entity span detection and entity type prediction into two steps.

For entity span detection, we build a binary classifier to distinguish `Break` from `Tie`, while `Unknown` positions will be skipped. Specifically, as shown in Fig. 2, for the prediction between i-th token and its previous token, we concatenate the output of the BiLSTM as a new feature vector, $\mathbf{u}_i$. $\mathbf{u}_i$ is then fed into a sigmoid layer, which estimates the probability that there is a `Break` as

$$p(y_i = \texttt{Break}|\mathbf{u}_i) = \sigma(\mathbf{w}^T\mathbf{u}_i)$$

where y_i is the label between the i-th and its previous tokens, σ is the sigmoid function, and $\mathbf{w}$ is the sigmoid layer’s parameter. The entity span detection loss is then computed as follows.

$$\mathcal{L}_{\text{span}} = \sum_{i|y_i \neq \texttt{Unknown}} l\big(y_i, p(y_i = \texttt{Break}|\mathbf{u}_i)\big)$$

Here, $l(\cdot,\cdot)$ is the logistic loss. Note that those `Unknown` positions are skipped.

After obtaining candidate entity spans, we further identify their entity types, including the `None` type for non-entity spans. As shown in Fig. 2, the output of the BiLSTM will be re-aligned to form a new feature vector, which is referred as $\mathbf{v}_i$ for i-th span candidate. $\mathbf{v}_i$ will be further fed into a softmax layer, which estimates the entity type distribution as

$$p(t_j|\mathbf{v}_i) = \frac{e^{\mathbf{t}_j^T\mathbf{v}_i}}{\sum_{t_k \in L} e^{\mathbf{t}_k^T\mathbf{v}_i}}$$

where t_j is an entity type and L is the set of all entity types including `None`.

Since one span can be labeled as multiple types, we mark the possible set of types for i-th entity span candidate as L_i. Accordingly, we modify the cross-entropy loss as follows.

$$\mathcal{L}_{\text{type}} = H(\hat{p}(\cdot|\mathbf{v}_i, L_i), p(\cdot|\mathbf{v}_i))$$

Here, $H(p, q)$ is the cross entropy between p and q, and $\hat{p}(t_j|\mathbf{v}_i, L_i)$ is the soft supervision distribution. Specifically, it is defined as:

$$\hat{p}(t_j|\mathbf{v}_i, L_i) = \frac{\delta(t_j \in L_i) \cdot e^{\mathbf{t}_j^T \mathbf{v}_i}}{\sum_{t_k \in L} \delta(t_k \in L_i) \cdot e^{\mathbf{t}_k^T \mathbf{v}_i}}$$

where $\delta(t_j \in L_i)$ is the boolean function of checking whether the i-th span candidate is labeled as the type t_j in the distant supervision.

It's worth mentioning that AutoNER has no CRF layer and Viterbi decoding, thus being more efficient than Fuzzy-LSTM-CRF for inference.

3.3 Remarks on "Unknown" Entities

"Unknown" entity mentions are not the entities of other types, but the tokens that we are less confident about their boundaries and/or cannot identify their types based on the distant supervision. For example, in Figure 1, "prostaglandin synthesis" is an "unknown" token span. The distant supervision cannot decide whether it is a `Chemical`, a `Disease`, an entity of other types, two separate single-token entities, or (partially) not an entity. Therefore, in the FuzzyCRF model, we assign all possible labels for these tokens.

In our AutoNER model, these "unknown" positions have undefined boundary and type losses, because (1) they make the boundary labels unclear; and (2) they have no type labels. Therefore, they are skipped.

4 Distant Supervision Refinement

In this section, we present two techniques to refine the distant supervision for better named entity taggers. Ablation experiments in Sec. 5.4 verify their effectiveness empirically.

4.1 Corpus-Aware Dictionary Tailoring

In dictionary matching, blindly using the full dictionary may introduce false-positive labels, as there exist many entities beyond the scope of the given corpus but their aliases can be matched. For example, when the dictionary has a non-related character name "Wednesday Addams"[2] and its alias "Wednesday", many Wednesday's will be wrongly marked as persons. In an ideal case, the dictionary should cover, and only cover entities occurring in the given corpus to ensure a high precision while retaining a reasonable coverage.

As an approximation, we tailor the original dictionary to a corpus-related subset by excluding entities whose canonical names never appear in the given corpus. The intuition behind is that to avoid ambiguities, people will likely mention the canonical name of the entity at least once. For example, in the biomedical domain, this is true for 88.12%, 95.07% of entity mentions on the BC5CDR and NCBI datasets respectively. We expect the NER model trained on such tailored dictionary will have a higher precision and a reasonable recall compared to that trained on the original dictionary.

4.2 Unknown-Typed High-Quality Phrases

Another issue of the distant supervision is about the false-negative labels. When a token span cannot be matched to any entity surface names in the dictionary, because of the limited coverage of dictionaries, it is still difficult to claim it as non-entity (i.e., negative labels) for sure. Specifically, some high-quality phrases out of the dictionary may also be potential entities.

We utilize the state-of-the-art distantly supervised phrase mining method, AutoPhrase (Shang et al., 2018), with the corpus and dictionary in the given domain as input. AutoPhrase only requires unlabeled text and a dictionary of high-quality phrases. We obtain quality multi-word and single-word phrases by posing thresholds (e.g., 0.5 and 0.9 respectively). In practice, one can find more unlabeled texts from the same domain (e.g., PubMed papers and Amazon laptop reviews) and use the same domain-specific dictionary for the NER task. In our experiments, for the biomedical domain, we use the titles and abstracts of 686,568 PubMed papers (about 4%) uniformly sampled from the whole PubTator database as the training corpus. For the laptop review domain, we use the Amazon laptop review dataset[3], which is designed for the aspect-based sentiment analysis (Wang et al., 2011).

We treat out-of-dictionary phrases as potential entities with "unknown" type and incorporate them as new dictionary entries. After this, only token spans that cannot be matched in this extended dictionary will be labeled as non-entity. Being aware of these high-quality phrases, we expect the trained NER tagger should be more accurate.

---

Table 1: Dataset Overview.

Dataset	BC5CDR	NCBI-Disease	LaptopReview
Domain	Biomedical	Biomedical	Technical Review
Entity Types	`Disease`, `Chemical`	`Disease`	`AspectTerm`
Dictionary	MeSH + CTD	MeSH + CTD	Computer Terms
Raw Sent. #	20,217	7,286	3,845

5 Experiments

We conduct experiments on three benchmark datasets to evaluate and compare our proposed Fuzzy-LSTM-CRF and AutoNER with many other methods. We further investigate the effectiveness of our proposed refinements for the distant supervision and the impact of the number of distantly supervised sentences.

5.1 Experimental Settings

Datasets are briefly summarized in Table 1. More details as as follows.

- **BC5CDR** is from the most recent BioCreative V Chemical and Disease Mention Recognition task. It has 1,500 articles containing 15,935 `Chemical` and 12,852 `Disease` mentions.
- **NCBI-Disease** focuses on Disease Name Recognition. It contains 793 abstracts and 6,881 `Disease` mentions.
- **LaptopReview** is from the SemEval 2014 Challenge, Task 4 Subtask 1 (Pontiki et al., 2014) focusing on laptop aspect term (e.g., “disk drive”) Recognition. It consists of 3,845 review sentences and 3,012 `AspectTerm` mentions.

All datasets are publicly available. The first two datasets are already partitioned into three subsets: a training set, a development set, and a testing set. For the LaptopReview dataset, we follow (Giannakopoulos et al., 2017) and randomly select 20% from the training set as the development set. Only raw texts are provided as the input of distantly supervised models, while the gold training set is used for supervised models.

Domain-Specific Dictionary. For the biomedical datasets, the dictionary is a combination of both the MeSH database[4] and the CTD Chemical and Disease vocabularies[5]. The dictionary contains 322,882 `Chemical` and `Disease` entity surfaces. For the laptop review dataset, the dictionary has 13,457 computer terms crawled from a public website[6].

Metric. We use the micro-averaged F_1 score as the evaluation metric. Meanwhile, precision and recall are presented. The reported scores are the mean across five different runs.

Parameters and Model Training. Based on the analysis conducted in the development set, we conduct optimization with the stochastic gradient descent with momentum. We set the batch size and the momentum to 10 and 0.9. The learning rate is initially set to 0.05 and will be shrunk by 40% if there is no better development F_1 in the recent 5 rounds. Dropout of a ratio 0.5 is applied in our model. For a better stability, we use gradient clipping of 5.0. Furthermore, we employ the early stopping in the development set.

Pre-trained Word Embeddings. For the biomedical datasets, we use the pre-trained 200-dimension word vectors [7] from (Pyysalo et al., 2013), which are trained on the whole PubMed abstracts, all the full-text articles from PubMed Central (PMC), and English Wikipedia. For the laptop review dataset, we use the GloVe 100-dimension pre-trained word vectors[8] instead, which are trained on the Wikipedia and GigaWord.

5.2 Compared Methods

Dictionary Match is our proposed distant supervision generation method. Specifically, we apply it to the testing set directly to obtain entity mentions with exactly the same surface name as in the dictionary. The type is assigned through a majority voting. By comparing with it, we can check the improvements of neural models over the distant supervision itself.

SwellShark, in the biomedical domain, is arguably the best distantly supervised model, especially on the BC5CDR and NCBI-Disease datasets (Fries et al., 2017). It needs no human annotated data, however, it requires extra expert effort for entity span detection on building POS tagger, designing effective regular expressions, and hand-tuning for special cases.

Distant-LSTM-CRF achieved the best performance on the LaptopReview dataset without annotated training data using a distantly supervised

AutoNER		88.96	81.00	**84.8**	79.42	71.98	**75.52**

Table 3: [Technical Review Domain] NER Performance Comparison. The supervised benchmark refers to the challenge winner.

Method	LaptopReview		
	Pre	Rec	F1
Supervised Benchmark	84.80	66.51	**74.55**
Distant-LSTM-CRF	74.03	31.59	53.93
Dictionary Match	90.68	44.65	59.84
Fuzzy-LSTM-CRF	85.08	47.09	60.63
AutoNER	72.27	59.79	**65.44**

LSTM-CRF model (Giannakopoulos et al., 2017).

Supervised benchmarks on each dataset are listed to check whether AutoNER can deliver competitive performance. On the BC5CDR and NCBI-Disease datasets, LM-LSTM-CRF (Liu et al., 2018) and LSTM-CRF (Lample et al., 2016) achieve the state-of-the-art F_1 scores without external resources, respectively (Wang et al., 2018). On the LaptopReview dataset, we present the scores of the Winner in the SemEval2014 Challenge Task 4 Subtask 1 (Pontiki et al., 2014).

5.3 NER Performance Comparison

We present F_1, precision, and recall scores on all datasets in Table 2 and Table 3. From both tables, one can find the AutoNER achieves the best performance when there is no extra human effort. Fuzzy-LSTM-CRF does have some improvements over the Dictionary Match, but it is always worse than AutoNER.

Even though SwellShark is designed for the biomedical domain and utilizes much more expert effort, AutoNER outperforms it in almost all cases. The only outlier happens on the NCBI-disease dataset when the entity span matcher in SwellShark is carefully tuned by experts for many special cases.

It is worth mentioning that AutoNER beats Distant-LSTM-CRF, which is the previous state-of-the-art distantly supervised model on the LaptopReview dataset.

Moreover, AutoNER's performance is competitive to the supervised benchmarks. For example, on the BC5CDR dataset, its F_1 score is only 2.16% away from the supervised benchmark.

5.4 Distant Supervision Explorations

We investigate the effectiveness of the two techniques that we proposed in Sec. 4 via ablation experiments. As shown in Table 4, using the tailored dictionary always achieves better F_1 scores than using the original dictionary. By using the tailored dictionary, the precision of the AutoNER model will be higher, while the recall will be retained similarly. For example, on the NCBI-Disease dataset, it significantly boosts the precision from 53.14% to 77.30% with an acceptable recall loss from 63.54% to 58.54%. Moreover, incorporating unknown-typed high-quality phrases in the dictionary enhances every score of AutoNER models significantly, especially the recall. These results match our expectations well.

5.5 Test F_1 Scores vs. Size of Raw Corpus

Furthermore, we explore the change of test F_1 scores when we have different sizes of distantly supervised texts. We sample sentences uniformly random from the given raw corpus and then evaluate AutoNER models trained on the selected sentences. We also study what will happen when the gold training set is available. The curves can be found in Figure 3. The X-axis is the number of

Table 4: Ablation Experiments for Dictionary Refinement. The dictionary for the LaptopReview dataset contains no alias, so the corpus-aware dictionary tailoring is not applicable.

Method	BC5CDR			NCBI-Disease			LaptopReview		
	Pre	Rec	F1	Pre	Rec	F1	Pre	Rec	F1

Figure 3: AutoNER: Test F_1 score vs. the number of distantly supervised sentences.

distantly supervised training sentences while the Y-axis is the F_1 score on the testing set.

When using distant supervision only, one can observe a significant growing trend of test F_1 score in the beginning, but later the increasing rate slows down when there are more and more raw texts.

When the gold training set is available, the distant supervision is still helpful to AutoNER. In the beginning, AutoNER works worse than the supervised benchmarks. Later, with enough distantly supervised sentences, AutoNER outperforms the supervised benchmarks. We think there are two possible reasons: (1) The distant supervision puts emphasis on those matchable entity mentions; and (2) The gold annotation may miss some good but matchable entity mentions. These may guide the training of AutoNER to a more generalized model, and thus have a higher test F_1 score.

5.6 Comparison with Gold Supervision

To demonstrate the effectiveness of distant supervision, we try to compare our method with gold annotations provided by human experts.

Specifically, we conduct experiments on the BC5CDR dataset by sampling different amounts of annotated articles for model training. As shown in Figure 4, we found that our method outperforms the supervised method by a large margin when less training examples are available. For example, when there are only 50 annotated articles available, the test F1 score drops substantially to 74.29%. To achieve a similar test F1 score (e.g., 83.91%) as our AutoNER models (i.e., 84.8%), the supervised benchmark model requires at least 300 annotated articles. Such results indicate the effectiveness and usefulness of AutoNER on the scenario without sufficient human annotations.

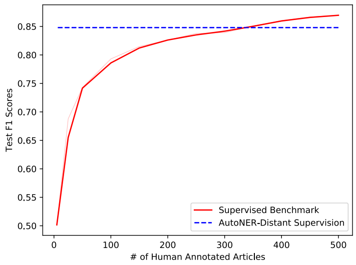

Figure 4: AutoNER: Test F_1 score vs. the number of human annotated articles.

Still, we observe that, when the supervised benchmark is trained with all annotations, it achieves the performance better than AutoNER. We conjugate that this is because AutoNER lacks more advanced techniques to handle distant supervision, and we leave further improvements of AutoNER to the future work.

6 Related Work

The task of supervised named entity recognition (NER) is typically embodied as a sequence labeling problem. Conditional random fields (CRF) models built upon human annotations and handcrafted features are the standard (Finkel et al., 2005; Settles, 2004; Leaman and Gonzalez, 2008). Recent advances in neural models have freed domain experts from handcrafting features for NER tasks. (Lample et al., 2016; Ma and Hovy, 2016; Liu et al., 2018). Such neural models are increasingly common in the domain-specific NER tasks (Sahu and Anand, 2016; Dernoncourt et al., 2017; Wang et al., 2018). Semi-supervised methods have been explored to further improve the accuracy by either augmenting labeled datasets with word embeddings or bootstrapping techniques in tasks like gene name recognition (Kuksa and Qi, 2010; Tang et al., 2014; Vlachos and Gasperin, 2006). Unlike these existing approaches, our study focuses on the distantly supervised setting without any expert-curated training data.

Distant supervision has attracted many attentions to alleviate human efforts. Originally, it was proposed to leverage knowledge bases to supervise relation extraction tasks (Craven et al., 1999; Mintz et al., 2009). AutoPhrase has demonstrated powers in extracting high-quality phrases from domain-specific corpora like scientific papers and business reviews (Shang et al., 2018) but it cannot categorize phrases into typed entities in a context-aware manner. We incorporate the high-quality phrases to enrich the domain-specific dictionary.

There are attempts on the distantly supervised NER task recently (Ren et al., 2015; Fries et al., 2017; He, 2017; Giannakopoulos et al., 2017). For example, SwellShark (Fries et al., 2017), specifically designed for biomedical NER, leverages a generative model to unify and model noise across different supervision sources for named entity typing. However, it leaves the named entity span detection to a heuristic combination of dictionary matching and part-of-speech tag-based regular expressions, which require extensive expert effort to cover many special cases. Other methods (Ren et al., 2015; He, 2017) also utilize similar approaches to extract entity span candidates before entity typing. Distant-LSTM-CRF (Giannakopoulos et al., 2017) has been proposed for the distantly supervised aspect term extraction, which can be viewed as an entity recognition task of a single type for business reviews. As shown in our experiments, our models can outperform Distant-LSTM-CRF significantly on the laptop review dataset.

To the best of our knowledge, AutoNER is the most effective model that can learn NER models by using, and only using dictionaries without any additional human effort.

7 Conclusion and Future Work

In this paper, we explore how to learn an effective NER model by using, and only using dictionaries. We design two neural architectures, Fuzzy-LSTM-CRF model with a modified `IOBES` tagging scheme and AutoNER with a new `Tie or Break` scheme. In experiments on three benchmark datasets, AutoNER achieves the best F_1 scores without additional human efforts. Its performance is even competitive to the supervised benchmarks with full human annotation. In addition, we discuss how to refine the distant supervision for better NER performance, including incorporating high-quality phrases mined from the corpus as well as tailoring dictionary according to the given corpus, and demonstrate their effectiveness in ablation experiments.

In future, we plan to further investigate the power and potentials of the AutoNER model with `Tie or Break` scheme in different languages and domains. Also, the proposed framework can be further extended to other sequence labeling tasks, such as noun phrase chunking. Moreover, going beyond the classical NER setting in this paper, it is interesting to further explore distant supervised methods for the nested and multiple typed entity recognitions in the future.

Zero-Shot Open Entity Typing as Type-Compatible Grounding

Abstract

The problem of entity-typing has been studied predominantly in supervised learning fashion, mostly with task-specific annotations (for coarse types) and sometimes with distant supervision (for fine types). While such approaches have strong performance within datasets, they often lack the flexibility to transfer across text genres and to generalize to new type taxonomies. In this work we propose a *zero-shot* entity typing approach that requires no annotated data and can flexibly identify newly defined types.

Given a *type taxonomy* defined as Boolean functions of FREEBASE "types", we ground a given mention to a set of *type-compatible* Wikipedia entries and then infer the target mention's types using an inference algorithm that makes use of the types of these entries. We evaluate our system on a broad range of datasets, including standard fine-grained and coarse-grained entity typing datasets, and also a dataset in the biological domain. Our system is shown to be competitive with state-of-the-art supervised NER systems and outperforms them on out-of-domain datasets. We also show that our system significantly outperforms other zero-shot fine typing systems.

1 Introduction

Entity type classification is the task of connecting an entity mention to a given set of semantic types. The commonly used type sets range in size and level of granularity, from a small number of coarse-grained types (Tjong Kim Sang and De Meulder, 2003) to over a hundred fine-grained types (Ling and Weld, 2012). It is understood that semantic typing is a key component in many natural language understanding tasks, including Question Answering (Toral et al., 2005; Li and Roth, 2005) and Textual Entailment (Dagan et al., 2010, 2013). Consequently, the ability to type mentions semantically across domains and text genres, and to use a flexible type hierarchy, is essential for solving many important challenges.

Nevertheless, most commonly used approaches and systems for semantic typing (e.g., CORENLP (Manning et al., 2014), COGCOMPNLP (Khashabi et al., 2018), NLTK (Loper and Bird, 2002), SPACY) are trained in a supervised fashion and rely on high quality, task-specific annotation. Scaling such systems to other domains and to a larger set of entity types faces fundamental restrictions.

Coarse typing systems, which are mostly fully supervised, are known to fit a single dataset very well. However, their performance drops significantly on different text genres and even new data sets. Moreover, adding a new coarse type requires manual annotation and retraining. For fine-typing systems, people have adopted a distant-supervision approach. Nevertheless, the number of types used is small: the distantly-supervised FIGER dataset covers only 113 types, a small fraction of most-conservative estimates of the number of types in the English language (the FREEBASE (Bollacker et al., 2008) and WORDNET (Miller, 1995) hierarchies consist of more than $1k$ and $1.5k$ unique types, respectively). More importantly, adapting these systems, once trained, to new type taxonomies cannot be done flexibly.

As was argued in Roth (2017), there is a need to develop new training paradigms that support scalable semantic processing; specifically, there is a need to scale semantic typing to flexible type taxonomies and to multiple domains.

In this work, we introduce ZOE, a *zero-shot* entity typing system, with *open* type definitions. Given a mention in a sentence and a taxonomy of entity types with their definitions, ZOE identifies a set of types that are appropriate for the mention

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2065–2076
Brussels, Belgium, October 31 - November 4, 2018.

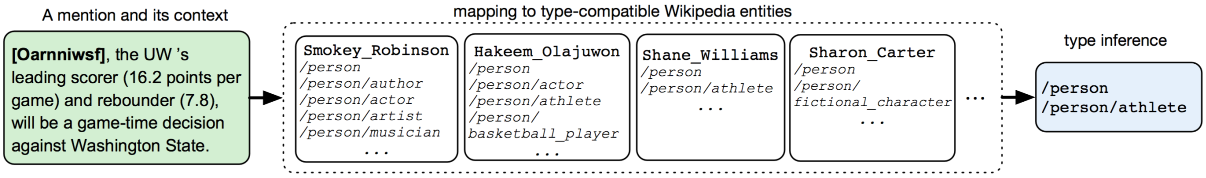

Figure 1: ZOE maps a given mention to its type-compatible entities in Wikipedia and infers a collection of types using this set of entities. While the mention "Oarnniwsf," a football player in the U. of Washington, does not exist in Wikipedia, we ground it to other entities with approximately the same types (§3).

in this context. ZOE does not require any training, and it makes use of existing data resources (e.g., Wikipedia) and tools developed without any task-specific annotation. The key idea is to ground each mention to a set of *type-compatible* Wikipedia entities. The benefit of using a set of Wikipedia titles as an intermediate representation for a mention is that there is much human-curated information in Wikipedia – categories associated with each page, FREEBASE types, and DBpedia types. These were put there independently of the task at hand and can be harnessed for many tasks: in particular, for determining the semantic types of a given mention in its context. In this grounding step, the guiding principle is that type-compatible entities often appear in similar contexts. We rely on contextual signals and, when available, surface forms, to rank Wikipedia titles and choose those that are more compatible with a given mention.

Importantly, our algorithm does not require a given mention to be in Wikipedia; in fact, in many cases (such as nominal mentions) the mentions are not available in Wikipedia. We hypothesize that any entity possible in English corresponds to some type-compatible entities in Wikipedia. We can then rely mostly on the context to reveal a *set* of *compatible titles*, those that are likely to share semantic types with the target mention. The fact that our system is not required to ground to the exact concept is a key difference between our grounding and "standard" Wikification approaches (Mihalcea and Csomai, 2007; Ratinov et al., 2011). As a consequence, while entity linking approaches rely heavily on priors associated with the surface forms and do not consider those that do not link to Wikipedia titles, our system mostly relies on context, regardless of whether the grounding actually exists or not.

Figure 1 shows a high-level visualization of our system. Given a mention, our system grounds it into type-compatible entries in Wikipedia. The target mention "Oarnniwsf," is not in Wikipedia, yet it is grounded to entities with approximately correct types. In addition, while some of the grounded Wikipedia entries are inaccurate in terms of entity types, the resulting aggregated decision is correct.

ZOE is an *open* type system, since it is not restricted to a closed set of types. In our experiments, we build on FREEBASE types as *primitive* types and use them to define types across seven different datasets. Note, however, that our approach is not fundamentally restricted to FREEBASE types; in particular, we allow types to be defined as Boolean formulae over these primitives (considering a type to be a set of entities). Furthermore, we support other primitives, e.g., DBPedia or Wikipedia entries. Consequently, our system can be used across type taxonomies; there is no need to restrict to previously observed types or retrain with annotations of new types. If one wants to use types that are outside our current vocabulary, one only needs to define the target type taxonomy in terms of the primitives used in this work.

In summary, our contributions are as follows:

- We propose a zero-shot open entity typing framework[1] that does not require training on entity-typing-specific supervised data.
- The proposed system outperforms existing zero-shot entity typing systems.
- Our system is competitive with fully-supervised systems in their respective domains across a broad range of coarse- and fine-grained typing datasets, and it outperforms these systems in out-of-domain settings.

2 Related Work

Named Entity Recognition (NER), for which the goal is to discover mention-boundaries in addition to typing, often using a small set of mutu-

---

[1] https://github.com/CogComp/zoe

ally exclusive types, has a considerable amount of work (Grishman and Sundheim, 1996; Mikheev et al., 1999; Tjong Kim Sang and De Meulder, 2003; Florian et al., 2003; Ratinov and Roth, 2009).

There have been many proposals to scale the systems to support a bigger type space (Fleischman and Hovy, 2002; Sekine et al., 2002). This direction was followed by the introduction of datasets with large label-sets, either manually annotated like BBN (Weischedel and Brunstein, 2005) or distantly supervised like FIGER (Ling and Weld, 2012). With larger datasets available, supervised-learning systems were proposed to learn from the data (Yosef et al., 2012; Abhishek et al., 2017; Shimaoka et al., 2017; Xu and Barbosa, 2018; Choi et al., 2018). Such systems have achieved remarkable success, mostly when restricted to their observed domain and labels.

There is a handful of works aiming to pave the road towards zero-shot typing by addressing ways to extract cheap signals, often to help the supervised algorithms: e.g., by generating gazetteers (Nadeau et al., 2006), or using the anchor texts in Wikipedia (Nothman et al., 2008, 2009). Ren et al. (2016) project labels in high-dimensional space and use label correlations to suppress noise and better model their relations. In our work, we choose not to use the supervised-learning paradigm and instead merely rely on a general entity linking corpus and the signals in Wikipedia. Prior work has already shown the importance of Wikipedia information for NER. Tsai et al. (2016a) use a cross-lingual WIKIFIER to facilitate cross-lingual NER. However, they do not explicitly address the case where the target entity does not exist in Wikipedia.

The zero-shot paradigm for entity typing has only recently been studied. Yogatama et al. (2015) proposed an embedding representation for user-defined features and labels, which facilitates information sharing among labels and reduces the dependence on the labels observed in the training set. The work of Yuan and Downey (2018) can also be seen in the same spirit, i.e., systems that rely on a form of representation of the labels. In a broader sense, such works–including ours–are part of a more general line of work on *zero-shot learning* (Chang et al., 2008; Palatucci et al., 2009; Norouzi et al., 2013; Romera-Paredes and Torr, 2015; Song and Roth, 2014). Our work can be thought of as the continuation of the same research direction.

Approach	Zero-shot?	Use labeled data?
ATTENTIVE (Shimaoka et al., 2017)	No	Yes
AAA (Abhishek et al., 2017)	No	Yes
NFETC-HIER(R) (Xu and Barbosa, 2018)	No	Yes
AFET (Ren et al., 2016)	No	Yes (partial)
PROTOLE (Ma et al., 2016)	**Yes** Prototype Embedding	Yes (partial)
OTYPER (Yuan and Downey, 2018)	**Yes** Word Embedding	Yes (partial)
(Huang et al., 2016)	**Yes** Concept-embedding Clustering	**No**
ZOE (ours)	**Yes** Type-Compatible Concepts	**No**

Table 1: Comparison of recent work on entity typing. Our system does not require any labeled data for entity typing; therefore it works on new datasets without retraining.

A critical step in the design of zero-shot systems is the characterization of the output space. For supervised systems, the output representations are trivial, as they are just indices. For zero-shot systems, the output space is often represented in a high-dimensional space that encodes the semantics of the labels. In OTYPER (Yuan and Downey, 2018), each type embedding is computed by averaging the word embeddings of the words comprising the type. The same idea is also used in PROTOLE (Ma et al., 2016), except that averaging is done only for a few prototypical instances of each type. In our work, we choose to define types using information in Wikipedia. This flexibility allows our system to perform well across several datasets without retraining. On a conceptual level, the work of Lin et al. (2012) and Huang et al. (2016) are close to our approach. The governing idea in these works is to cluster mentions, followed by propagating type information from representative mentions.

Table 1 compares our proposed system with several recently proposed models.

3 Zero-Shot Open Entity Typing

Types are conceptual containers that bind entities together to form a coherent group. Among the entities of the same type, *type-compatibility* creates a network of loosely connected entities:

Definition 1 (Weak Type Compatibility) *Two entities are type-compatible if they share at least one type with respect to a type taxonomy and the contexts in which they appear.*

In our approach, given a mention in a sentence, we aim to discover type-compatible entities in Wikipedia and then infer the mention's types using all the type-compatible entities together. The advantage of using Wikipedia entries is that the rich information associated with them allows us to infer the types more easily. Note that this problem is different from the standard entity linking or Wikification problem in which the goal is to find the corresponding entity in Wikipedia. Wikipedia does not contain all entities in the world, but an entity is likely to have at least one type-compatible entity in Wikipedia.

In order to find the type-compatible entities, we use the context of mentions as a proxy. Defining it formally:

Definition 2 (Context Consistency) *A mention m (in a context sentence s) is* context-consistent *with another well-defined mention m', if m can be replaced by m' in the context s, and the new sentence still makes logical sense.*

Hypothesis 1 *Context consistency is a strong proxy for type compatibility.*

Based on this hypothesis, given a mention m in a sentence s, we find other context-compatible mentions in a Wikified corpus. Since the mentions in the Wikified corpus are linked to the corresponding Wikipedia entries, we can infer m's types by aggregating information associated with these Wikipedia entries.

Figure 2 shows the high-level architecture of our proposed system. The inputs to the system are a mention m in a sentence s, and a type definition T. The output of the system is a set of types $\{t_{\text{Target}}\} \subseteq T$ in the target taxonomy that best represents the given mention. The type definitions characterize the target entity-type space. In our experiments, we choose to use FREEBASE types to define the types across 7 datasets; that is, T is a mapping from the set of FREEBASE types to the set of target types: $T : \{t_{\text{FB}}\} \rightarrow \{t_{\text{Target}}\}$. This definition comprises many atomic definitions; for example, we can define the type `location` as the disjunction of FREEBASE types like `FB.location` and `FB.geography`:

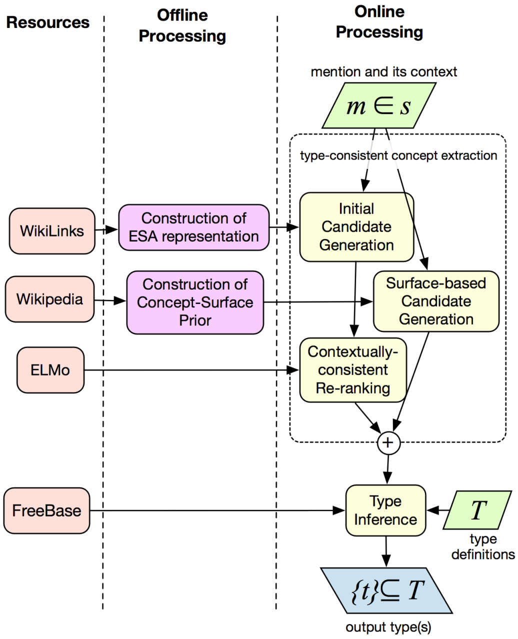

Figure 2: A high-level view of our approach. The inputs to the system are a mention m in a context s, and type definitions T. The output is set of types $\{t\}$ in the type definition. The figure also highlights the input resources, as well as offline and online processes.

```
T (Type Definitions)

- Target.company := FB.business &&
                    !(FB.education || FB.government)
- Target.location := FB.location || FB.geography ||
                     FB.casino || FB.court
- ...
```

The type definitions of a dataset reflect the understanding of a domain expert and the assumptions made in dataset design. Such definitions are often much cheaper to define, than to annotate full-fledged supervised datasets. It is important to emphasize that, to use our system on different datasets, one does not need to retrain it; there is one single system used across different datasets, working with different type definitions.

For notational simplicity, we define a few conventions for the rest of the paper. The notation $t \in T$, simply means t is a member of the image of the map T (i.e., t is a member of the target types). For a fixed concept c, the notation $T(c)$ is the application of $T(.)$ on the FREEBASE types attached to the concept c. For a collection of concepts C, $T(C)$ is defined as $\bigcup_{c \in C} T(c)$. We use $T_{\text{coarse}}(.)$ to refer to the subset of coarse types of $T(.)$, while $T_{\text{fine}}(.)$ defines the fine type subset.

Components in Figure 2 are described in the following sections.

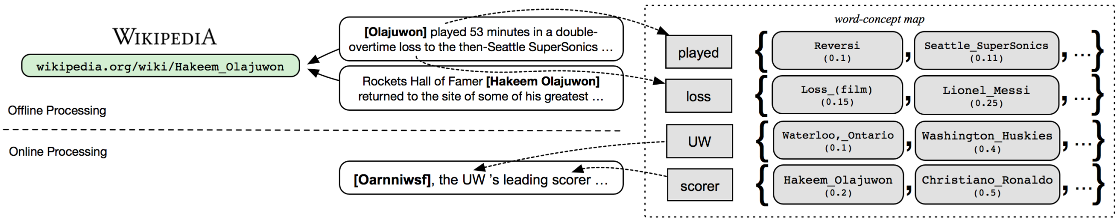

Figure 3: Extraction of topically relevant concepts. Word-concept map is pre-computed using WIKILINKS and used to retrieve the most relevant concepts for a given mention (see §3.1).

3.1 Initial Concept Candidate Generation

Given a mention, the goal of this step is to quickly generate a set of Wikipedia entries based on other words in the sentence. Since there are millions of entries in Wikipedia, it is extremely inefficient to go through all entries for each mention. We adopt ideas from explicit semantic analysis (ESA) (Gabrilovich and Markovitch, 2007), an approach to representing words with a vector of Wikipedia *concepts*, and to providing fast retrieval of the relevant Wikipedia concepts via inverted indexing.

In our construction we use the WIKILINKS (Singh et al., 2012) corpus, which contains a total of 40 million mentions over 3 million concepts. Each mention in WIKILINKS is associated with a Wikipedia concept. To characterize it formally, in the WIKILINKS corpus, for each concept c, there are example sentences $\mathsf{sent}(c) = \{s_i\}$.

Offline computation: The first step is to construct an ESA representation for each word in the WIKILINKS corpus. We create a mapping from each word in the corpus to the relevant concepts associated with it. The result is a map $\mathcal{S}$ from tokens to concepts: $\mathcal{S} : w \to \{c, \mathsf{score}(c|w)\}$ (see Figure 3), where $\mathsf{score}(c|w)$ denotes the association of the word w with concept c, calculated as the sum of the TF-IDF values of the word w in the sentences describing c:

$$\mathsf{score}(c|w) \triangleq \sum_{s \in \mathsf{sent}(c)} \sum_{w \in s} \text{tf-idf}(w, s).$$

That is, we treat each sentence as a document and compute TF-IDF scores for the words in it.

Online computation: For a given mention m and its sentence context s, we use our offline word-concept map $\mathcal{S}$ to find the concepts associated with each word, and aggregate them to create a single list of weighted concepts; i.e., $\sum_{w \in s} \mathcal{S}(w)$. The resulting concepts are sorted by the corresponding weights, and the top ℓ_{ESA} candidates form a set C_{ESA} which is passed to the next step.

3.2 Context-Consistent Re-Ranking

After quick retrieval of the initial concept candidates, we re-rank concepts in C_{ESA} based on context consistency between the input mention and concept mentions in WIKILINKS.

For this step, assume we have a representation that encodes the sentential information anchored on the mention. We denote this mention-aware context representation as $\mathsf{SentRep}(s|m)$. We define a measure of consistency between a concept c and a mention m in a sentence s:

$$\mathsf{Consistency}(c, s, m) = \mathsf{cosine}(\mathsf{SentRep}(s|m), \mathsf{ConceptRep}(c)), \quad (1)$$

where $\mathsf{ConceptRep}(c)$ is representation of a concept:

$$\mathsf{ConceptRep}(c) \triangleq \mathrm{avg}_s \left(\mathsf{SentRep}(s|c) \middle| s \in \text{WIKILINKS}, c \in s \right),$$

which is the average vector of the representation of all the sentences in WIKILINKS that describe the given concept.

We use pre-trained ELMO (Peters et al., 2018), a state-of-the-art contextual and mention-aware word representation. In order to generate $\mathsf{SentRep}(s|m)$, we run ELMO on sentence s, where the tokens of the mention m are concatenated with "_", and retrieve its ELMO vector as $\mathsf{SentRep}(s|m)$.

According to the consistency measure, we select the top ℓ_{ELMO} concepts for each mention. We call this set of concepts C_{ELMO}.

3.3 Surface-Based Concept Generation

While context often is a key signal for typing, one should not ignore the information included in the surface form of the mentions. If the corresponding concept or entity exists in Wikipedia, many mentions can be accurately grounded with only trivial prior probability $\mathbf{Pr}(\text{concept}|\text{surface})$. The prior distribution is pre-computed by calculating the frequency of the times a certain surface string refers to different concepts within Wikipedia.

In the test time, for a given mention, we use the pre-computed probability distribution to obtain the most likely concept, $c_{\text{surf}} = \arg\max_c \mathbf{Pr}(c|m)$, for the given mention m.

3.4 Type Inference

Our inference algorithm starts with selection of concepts, followed by inference of coarse and fine types. Our approach is outlined in Algorithm 1 and explained below.

Concept inference. To integrate surface-based and context-based concepts, we follow a simple rule: if the prior probability of the surface-based concept (c_{surf}) has confidence below a threshold λ, we ignore it; otherwise we include it among the concepts selected from context (C_{ELMo}), and only choose coarse and fine types from c_{surf}.

To map the selected concepts to the target entity types, we retrieve the FREEBASE-types of each concept and then apply the type definition T (defined just before §3.1). In Algorithm 1, the set of target types of a concept c is denoted as $T(c)$. This is followed by an aggregation step for selection of a coarse type $t_{\text{coarse}} \in T_{\text{coarse}}(.)$, and ends with the selection of a set of fine types $\{t_{\text{fine}}\} \subseteq T_{\text{fine}}(.)$.

Coarse type inference. Our type inference algorithm works in a relatively simple confidence analysis procedure. To this end, we define $\text{Count}(t; C)$ to be the number of occurrences of type t in the collection of concepts C:

$$\text{Count}(t; C) := |\{c : c \in C \text{ and } t \in T(c)\}|.$$

In theory, for a sensible type t, the count of context-consistent concepts that have this type should be higher than that of the initial concept candidates. In other words, $\frac{\text{Count}(t; C_{\text{ELMo}})/\ell_{\text{ELMo}}}{\text{Count}(t; C_{\text{ESA}})/\ell_{\text{ESA}}} > 1$. We select the first concept (in the C_{ELMo} ranking) which has some coarse type that matches this criterion. If there is no such concept, we use the coarse types of the highest scoring concept. To select one of the coarse types of the selected concept, we let each concept of C_{ELMo} vote based on its consistency score. We name this voting-based procedure $\text{SelectCoarse}(c)$, which selects one coarse type from a given concept:

$$\text{SelectCoarse}(c) \triangleq$$
$$\operatorname*{argmax}_{t} \sum_{\tilde{c} \in C_{\text{ELMo}}} \sum_{t \in T_{\text{coarse}}(\tilde{c})} \text{Consistency}(\tilde{c}, s, m),$$

where consistency is defined in Equation (1).

Algorithm 1: Type inference algorithm

```
Input mention $m$ in sentence $s$, retrieved concepts
  $C_{\text{ESA}}, C_{\text{ELMo}}, c_{\text{surf}}$, and type definition $T$
Output Inferred types $t_{\text{coarse}}$ and $\{t_{\text{fine}}\}$.
Define, $r(t, t'; C, C') := \frac{\text{Count}(t;C)/|C|}{\text{Count}(t';C')/|C'|}$,
  $r(t; C, C') := r(t, t; C, C')$,
  $r(t, t'; C, ) := r(t, t'; C, C)$.

$\tau_{\text{surf}} \leftarrow \{t | t \in T_{\text{coarse}}(c_{\text{surf}}), r(t; C_{\text{ELMo}}, C_{\text{ESA}}) > 1\}$
if $\mathbf{Pr}(c_{surf}|m) \geq \lambda$ and $\tau_{surf} \neq \emptyset$ then
    $t_{\text{coarse}} \leftarrow \text{SelectCoarse}(c_{\text{surf}})$
    $\tilde{C} \leftarrow \{c_{\text{surf}}\} \cup C_{\text{ELMo}}$
    $\{t_{\text{fine}}\} \leftarrow \left\{ t_f \middle| \begin{array}{l} t_f \in T_{\text{fine}}(c_{\text{surf}}), \\ \text{compatible w/ } t_{\text{coarse}} \text{ and,} \\ r(t_f, t_{\text{coarse}}; \tilde{C}) \geq \eta_s \end{array} \right\}$
else
    $\tilde{C}_{\text{ELMo}} \leftarrow \left\{ c \middle| \begin{array}{l} c \in C_{\text{ELMo}}, \exists t \in T_{\text{coarse}}(c) \\ r(t; C_{\text{ELMo}}, C_{\text{ESA}}) > 1 \end{array} \right\}$
    if $\tilde{C}_{\text{ELMo}} = \varnothing$ then
        $\tilde{c} \leftarrow \text{argmax}_{c \in C_{\text{ELMo}}} \text{Consistency}(c, s, m)$
    else
        $\tilde{c} \leftarrow \text{argmax}_{c \in \tilde{C}_{\text{ELMo}}} \text{Consistency}(c, s, m)$
    end
    $t_{\text{coarse}} \leftarrow \text{SelectCoarse}(\tilde{c})$
    $\{t_{\text{fine}}\} \leftarrow \left\{ t_f \middle| \begin{array}{l} t_f \in T_{\text{fine}}(C_{\text{ELMo}}), \\ \text{compatible w/ } t_{\text{coarse}} \text{ and,} \\ r(t_f, t_{\text{coarse}}; C_{\text{ELMo}}) \geq \eta_c \end{array} \right\}$
end
```

Fine type inference. With the selected coarse type, we take only the fine types that are compatible with the selected coarse type (e.g., the fine type `/people/athlete` and the coarse type `/people` are compatible).

Among the compatible fine types, we further filter the ones that have better support from the context. Therefore, we select the fine types t_f such that $\frac{\text{Count}(t_f; C_{\text{ELMo}})}{\text{Count}(t_c; C_{\text{ELMo}})} \geq \eta$, where t_c is the previously selected coarse type which is compatible with t_f. Intuitively, the fraction filters out the fine-grained candidate types that don't have enough support compared to the selected coarse type.

4 Experiments

Empirically, we study the behavior of our system compared to published results. All the results are reproduced except the ones indicated by $*$, which are directly cited from their corresponding papers.

Datasets. In our experiments, we use a wide range of typing datasets:

- For **coarse** entity typing, we use MUC (Grishman and Sundheim, 1996), CoNLL (Tjong Kim Sang and De Meulder, 2003), and OntoNotes (Hovy et al., 2006).

Table 2: Evaluation of fine-grained entity-typing: we compare our system with state-of-the-art systems (§4.1) For each column, the best zero-shot and overall results are **bold-faced** and underlined, respectively. Numbers are $F1$ in percentage. For supervised systems, we report their in-domain performances, since they do not transfer to other datasets with different labels. For OTYPER, cells with gray color indicate *in-domain* evaluation, which is the setting in which it has the best performance. Our system outperforms all the other zero-shot baselines, and achieves competitive results compared to the best supervised systems.

System	Trained on	OntoNotes PER	OntoNotes LOC	OntoNotes ORG	CoNLL PER	CoNLL LOC	CoNLL ORG	MUC PER	MUC LOC	MUC ORG
COGCOMPNLP	OntoNotes	98.4	91.9	97.7	83.7	70.1	68.3	82.5	76.9	86.7

Table 3: Evaluation of coarse entity-typing (§4.2): we compare two supervised entity-typers with our system. For the supervised systems, cells with gray color indicate *in-domain* evaluation. For each column, the best, out-of-domain and overall results are **bold-faced** and underlined, respectively. Numbers are $F1$ in percentage. In most of the out-of-domain settings our system outperforms the supervised system.

- For **fine** typing, we focus on FIGER (Ling and Weld, 2012), BBN (Weischedel and Brunstein, 2005), and $\text{OntoNotes}_{\text{fine}}$ (Gillick et al., 2014).
- In addition to the news NER, we use the BB3 dataset (Delėger et al., 2016), with contain mentions of *bacteria* or other notions, extracted from sentences of scientific papers.

ZOE's parameters. We use different type definitions for each dataset. In order to design type definitions for each dataset, we follow in the footsteps of Abhishek et al. (2017) and randomly sample 10% of the test set. For the experiments, we exclude the sampled set. For completeness, we have included the type definitions of the major experiments in Appendix D.

The parameters are set universally across different experiments. For parameters that determine the number of extracted concepts, we use $\ell_{\text{ESA}} = 300$ and $\ell_{\text{ELMo}} = 20$, which are based on the upper-bound analysis in Appendix A. For other parameters, we set $\lambda = 0.5$, $\eta_s = 0.8$ and $\eta_c = 0.3$, based on the FIGER dev set. We emphasize that these parameters are universal across our evaluations.

Evaluation metrics. Given a collection of mentions M, denote the set of gold types and predicted types of a mention $m \in M$ as $T_g(m)$ and $T_p(m)$ respectively. We define the following metrics for our evaluations:

- Strict Accuracy (Acc.): $\frac{|\{m|T_g(m)=T_p(m)\}|}{|M|}$.
- Macro F1 ($F1_{\text{ma}}$): Macro Precision is defined as $\frac{1}{|M|}\sum_{m\in M}\frac{|T_p(m)\cap T_g(m)|}{|T_p(m)|}$. With this, the definitions of Macro recall and F1 follow.
- Micro F1 ($F1_{\text{mi}}$): The precision is defined as $\frac{\sum_{m\in M}|T_p(m)\cap T_g(m)|}{\sum_{m\in M}|T_p(m)|}$, and the Micro recall and F1 follow the same pattern.

In the experiment in §4.3, to evaluate systems on unseen types we used modified versions of metrics. Let $G(t)$ be the number of mentions with gold type t, $P(t)$ be the number of mentions predicted to have type t, $C(t)$ be the number of mentions correctly predicted to have type t:

- The precision corresponding to $F1_{\text{ma}}^{\text{type}}$ is defined as $\sum_t \frac{C(t)}{P(t)}\frac{G(t)}{\sum_{t'}G(t')}$; recall follows the same pattern.
- The precision corresponding to $F1_{\text{mi}}^{\text{type}}$ is defined as $\frac{\sum_t C(t)}{\sum_t P(t)}$; recall follows the same pattern.

Approach	$F1^{\text{type}}_{\text{ma}}$	$F1^{\text{type}}_{\text{mi}}$
ELMoNN	63.1	53.8
WikifierTyper	53.0	43.9
OTyper (Yuan and Downey, 2018)	50.6	23.4
Zoe (ours)	**71.7**	**71.1**

Table 4: Comparing systems where no labels (types) are seen a priori (§4.3).

System	Bacteria	not-Bacteria	Overall
WikifierTyper	54.8	**86.2**	70.5
ELMoNN	67.6	81.2	74.4
Zoe (ours)	**68.1**	84.2	**76.2**

Table 5: Results of the system classifying mentions to "*bacteria*" or something else (§4.4). Numbers are $F1$ in percentage.

Baselines. To add to the best published results on each dataset, we create two simple and effective baselines. The first baseline, ELMoNN, selects the nearest neighbor types to a given mention, where *mentions* and *types* are represented by ELMo vectors. To create a representation for each type t, we average the representation of the WikiLinks sentences that contain mentions of type t (as explained in §3.2). Our other baseline, WikifierTyper, uses Wikifier (Tsai et al., 2016b) to map the mention to a Wikipedia concept, followed by mapping to FreeBase types, and finally projecting them to the target types, via type definition function $T(.)$. Additionally, to compare with published zero-shot systems, we compare our system to OTyper, a recently published *open*-typing system. Unfortunately, to the best of our knowledge, the systems proposed by Ma et al.; Huang et al. (2016; 2016) are not available online for empirical comparison.

4.1 Fine-Grained Entity Typing

We evaluate our system for *fine-grained* named-entity typing. Table 2 shows the evaluation result for three datasets, FIGER, BBN, and $\text{OntoNotes}_{\text{fine}}$. We report our system's performance, our zero-shot baselines, and two supervised systems (AFET, plus the-state-of-the-art), for each dataset. There is no easy way to transfer the supervised systems across datasets, hence no out-of-domain numbers for such systems. For each dataset, we train OTyper and evaluate on the test sets of all the three datasets. In order to run OTyper on different datasets, we disabled original dataset-specific entity and type features. As a result, among the *open* typing systems, our system has significantly better results. In addition, our system has competitive scores compared to the supervised systems.

4.2 Coarse Entity Typing

In Table 3 we study entity typing for the coarse types on three datasets. We focus on three types that are shared among the datasets: *PER*, *LOC*, *ORG*. In coarse-entity typing, the best available systems are heavily supervised. In this evaluation, we use gold mention spans; i.e., we force the decoding algorithm of the supervised systems to select the best of the three classes for each gold mention. As expected, the supervised systems have strong in-domain performance. However, they suffer a significant drop when evaluated in a different domain. Our system, while not trained on any supervised data, achieves better or comparable performance compared to other supervised baselines in the out-of-domain evaluations.

4.3 Typing of Unseen Types within Domain

We compare the quality of *open* typing, in which the target type(s) have not been seen before. We compare our system to OTyper, which relies on supervised data to create representations for each type; however, it is not restricted to the *observed types*. We follow a similar setting to Yuan and Downey (2018) and split the FIGER test in folds (one fold per type) and do cross-validations. For each fold, mentions of only one type are used for evaluation, and the rest are used for training OTyper. To be able to evaluate on *unseen* types (only for this experiment), we use modified metrics $F1^{\text{type}}_{\text{ma}}$ and $F1^{\text{type}}_{\text{mi}}$ that measure *per type* quality of the system (§4). In this experiment, we focus on a within-domain setting, and show the results of transfer across genres in the next experiments. The results are summarized in Table 4. We observe a significant margin between Zoe and other systems, including OTyper.

4.4 Biology Entity Typing

We go beyond the scope of popular entity-typing tasks, and evaluate the quality of our system on a dataset that contains sentences from scientific papers (Delėger et al., 2016), which makes it different from other entity-typing datasets. The mentions refer to either "*bacteria*", or some miscellaneous class (two class typing). As indicated in Ta-

	FIGER			BBN			OntoNotes$_{\text{fine}}$		
Approach	Acc.	$F1_{\text{ma}}$	$F1_{\text{mi}}$	Acc.	$F1_{\text{ma}}$	$F1_{\text{mi}}$	Acc.	$F1_{\text{ma}}$	$F1_{\text{mi}}$
ZOE (ours)	58.8	74.8	71.3	61.8	74.6	74.9	50.7	66.9	60.8
no surface-based concepts	-8.8	-7.5	-9.2	-12.9	-7.0	-8.6	-1.8	-1.2	-0.1
no context-based concepts	-39.3	-42.1	-25.4	-36.4	-31.0	-13.9	-10.0	-12.3	-7.4

Table 6: Ablation study of different ways in which concepts are generated in our system (§4.5). The first row shows performance of our system on each dataset, followed by the *change* in the performance upon dropping a component. While both signals are crucial, contextual information is playing more important role than the mention-surface signal.

ble 5, our system's overall scores are higher than our baselines.

4.5 Ablation Study

We carry out ablation studies that quantify the contribution of surface information (§3.3) and context information (§3.2). As Table 6 shows, both factors are crucial and complementary for the system. However, the contextual information seems to have a bigger role overall.

We complement our qualitative analysis with the quantitative share of each component. In 69.3%, 54.6%, and 69.7% of mentions, our system uses the context information (and ignores the surface), in FIGER, BBN, and OntoNotes$_{\text{fine}}$ datasets, respectively, underscoring the importance of contextual information.

4.6 Error Analysis

We provide insights into specific reasons for the mistakes made by the system. For our analysis, we use the erroneous decisions in the FIGER dev set. Two independent annotators label the cause(s) of the mistakes, resulting in 83% agreement between the annotators. The disagreements are later reconciled by an adjudication step.

1. *Incompatible concept, due to context information:* Ambiguous contexts, or short ones, often contribute to the inaccurate mapping to concepts. In our manual annotations, 23.3% of errors are caused, at least partly, by this issue.
2. *Incompatible concept, due to surface information:* Although the prior probability is high, the surface-based concept could be wrong. About 26% of the errors are partly due to the surface signal errors.
3. *Incorrect type, due to type inference:* Even when the system is able to find several type-compatible concepts, it can fail due to inference errors. This could happen if the types attached to the type-compatible concepts are not the majority among other types attached to other concepts. This is the major reason behind 56.6% of errors.
4. *Incorrect type, due to type definition:* Some errors are caused by the inaccurate definition of the type mapping function T. About 23% of the mistakes are partly caused by this issue.

Note that each mistake could be caused by multiple factors; in other words, the above categories are not mutually disjoint events. A slightly more detailed analysis is included in Appendix C.

5 Conclusion

Moving beyond a fully supervised paradigm and scaling entity-typing systems to support bigger type sets is a crucial challenge for NLP. In this work, we have presented ZOE, a zero-shot open entity typing framework. The significance of this work is threefold. First, the proposed system does not require task-specific labeled data. Our system relies on type definitions, which are much cheaper to obtain than annotating thousands of examples. Second, our system outperforms existing state-of-the-art zero-shot systems by a significant margin. Third, we show that without reliance on task-specific supervision, one can achieve relatively robust transfer across datasets.

Abstract

Despite that current reading comprehension systems have achieved significant advancements, their promising performances are often obtained at the cost of making an ensemble of numerous models. Besides, existing approaches are also vulnerable to adversarial attacks. This paper tackles these problems by leveraging *knowledge distillation*, which aims to transfer knowledge from an ensemble model to a single model. We first demonstrate that vanilla knowledge distillation applied to answer span prediction is effective for reading comprehension systems. We then propose two novel approaches that not only penalize the prediction on confusing answers but also guide the training with alignment information distilled from the ensemble. Experiments show that our best student model has only a slight drop of 0.4% F1 on the SQuAD test set compared to the ensemble teacher, while running 12× faster during inference. It even outperforms the teacher on adversarial SQuAD datasets and NarrativeQA benchmark.

1 Introduction

Machine reading comprehension (MRC), which aims to answer questions about a given passage or document, is a long-term goal of natural language processing. Recent years have witnessed rapid progress from early cloze-style test (Hermann et al., 2015; Hill et al., 2016) to latest answer extraction test (Rajpurkar et al., 2016; Joshi et al., 2017). Several end-to-end neural networks based approaches even outperform the human performance in terms of exact match accuracy on the SQuAD dataset (Wang et al., 2017, 2018; Yu et al., 2018).

Despite of the advancements, there are still two problems that impedes the deployment of real-world MRC applications. First, although effective, current approaches are *not efficient* because superior performances are usually achieved by ensembling multiple trained models. For example, Seo et al. (2017) submit an ensemble model consisting of 12 training runs and Huang et al. (2018) boost the result with 31 models. The ensemble system, however, has two major drawbacks: the inference time is slow and a huge amount of resource is needed. Second, existing models are *not robust* since they are vulnerable to adversarial attacks. Jia and Liang (2017) show that the models are easily fooled by appending an adversarial sentence into the passage. Such fragility on adversarial examples severely diminishes the practicality of current MRC systems.

One promising direction to address these problems is model compression (Bucilu et al., 2006), which attempts to compress the ensemble model into a single model that has comparable performances. Particularly, the *knowledge distillation* approach (Hinton et al., 2014) has been proposed to train a student model with the supervision of a teacher model. Such idea is further explored to enhance the generalizability and robustness of image recognition systems (Papernot et al., 2016). Some subsequent works attempt to transfer teacher's intermediate representation, such as feature map (Romero et al., 2015; Zagoruyko and Komodakis, 2017), neuron selectivity (Huang and Wang, 2017) and so on, to provide additional supervisions.

In this paper, we present the first work to investigate knowledge distillation in the context of MRC, to improve efficiency and robustness simultaneously. We first apply the standard knowledge disillation to MRC models, by mimicking output distributions of answer boundaries from an ensemble model, and observe consistent improvements upon a strong baseline. We then propose two novel

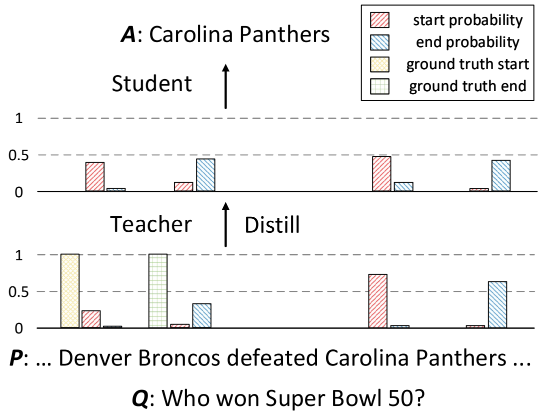
Brussels, Belgium, October 31 - November 4, 2018.

Passage: Super Bowl 50 was an American football game to determine the champion of the National Football League (NFL) for the 2015 season. The American Football Conference (AFC) champion Denver Broncos defeated the National Football Conference (NFC) champion Carolina Panthers 24–10 to earn their third Super Bowl title. The game was played on February 7, 2016, at Levi's Stadium in the San Francisco Bay Area at Santa Clara, California. The Champ Bowl 40 took place in Chicago.

Question1: Who won Super Bowl 50?
Question2: Where did Super Bowl 50 take place?

(a) Gold answers (red) versus confusing answers (blue) in the SQuAD and adversarial SQuAD datasets.



(b) The knowledge biased towards the confusing answer is distilled from the teacher to the student.

Figure 1: An illustration of confusing answer and biased distillation in machine reading comprehension.

distillation approaches to further transfer knowledge between the teacher and the student.

First, we introduce *answer distillation*, which penalizes the most confusing answer with a margin loss, to deal with the problem that biased knowledge misleads the student into incorrect predictions. We find that in MRC datasets there exists many confusing answers (Figure 1(a)), which match the category of true answers but are semantically-contradicted to the question, and an extreme case is the adversarial example. Once the teacher produces biased probabilities towards these distractors, inaccurate distributions will be distilled and later used to supervise the student. As a result, the student could produce over-confident wrong predictions. We refer to this problem as *biased distillation*, and Figure 1(b) gives an example. To address this problem, our approach distilles the boundary of the strongest distractor from the teacher, and explicitly informs the student to decrease its confidence score. This forces the student to produce comparable and unbiased distributions between candidate answers.

Second, we present *attention distillation* that aims to match the attention distribution between the teacher and the student. We notice that neural attention plays an important role in MRC tasks by enabling the model to capture complex interactions between the question and the passage. Compared to other forms of intermediate representation such as feature map and neuron selectivity, attention distribution is more compressed and more informative in reflecting semantic similarities of input text pairs. Hence, by mimicking the word alignments from an ensemble model, we expect that the student can learn to attend more precisely with better compression efficiencies.

We evaluate our approach on the Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016), the adversarial SQuAD dataset (Jia and Liang, 2017) and the NarrativeQA benchmark (Kočiskỳ et al., 2017). Compared to the ensemble teacher, the single student model trained with our approach has a slight drop of 0.4% F1 on the SQuAD test set, while running 12× faster during inference. The student even outperforms the teacher on the adversarial SQuAD dataset, and surpasses the teacher in terms of Bleu-1 score on the NarrativeQA benchmark.

2 Background

2.1 Machine Reading Comprehension

In the extractive MRC task, the question and the passage are described as sequences of word tokens, denoted as $Q = \{q_i\}_{i=1}^{n}$ and $P = \{p_j\}_{j=1}^{m}$ respectively. The task is to predict an answer A, which is constrained as a segment of text in the passage: $A = \{p_j\}_{j=k}^{l}$.

To model complicated interactions between the question and the passage, the attention mechanism (Bahdanau et al., 2015) has been widely used. Let $V = \{v_i\}_{i=1}^{n}$ and $U = \{u_j\}_{j=1}^{m}$ denote the encoded question/passage representations, where v_i and u_j are both dense vectors. A similarity matrix $E \in \mathbb{R}^{n \times m}$ can be computed as:

$$E_{ij} = f(v_i, u_j)$$

where f is a scalar function producing the similarity between two inputs. Let $\mathrm{softmax}(x)$ denote the softmax function that normalizes the vec-

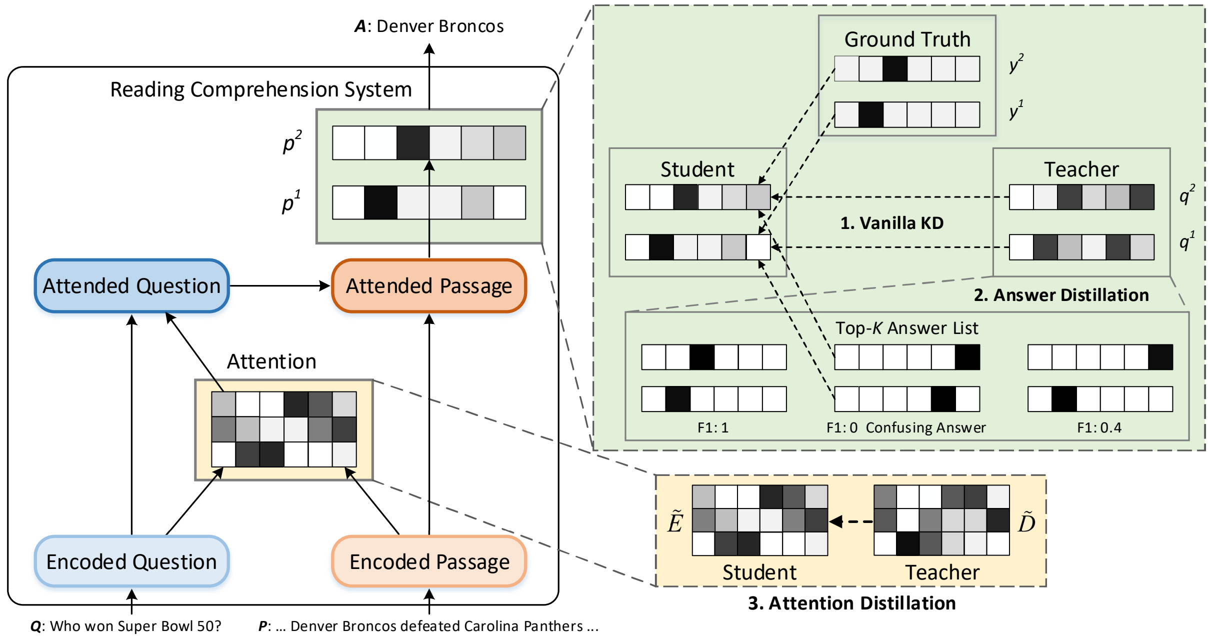


Figure 2: Overview of our approaches. In vanilla knowledge distillation (green), the cross entropy is minimized between the student/teacher distributions of answer positions. In answer distillation (green), the student is trained to penalize the most confusing answer distilled from the teacher. In attention distillation (yellow), mean-squared error is minimized between the student/teacher attention distributions. Darker color denotes higher probability.

tor x. Then the attention distribution across the question for the j-th passage word is computed as $\tilde{E}_j = \text{softmax}(E_{:j})$. This attentive information is commonly used to summarize the entire question as a single vector that is later fused back into the j-th passage word (Seo et al., 2017), resulting in an attended passage representation.

Finally, based on the attended passage, previous works usually apply a pointer network (Vinyals et al., 2015) to produce two probabilities p^1 and p^2 that indicate the answer start and end positions:

$$p(A|Q,P) = p^1(k|Q,P)p^2(l|k,Q,P)$$

where p is the model distribution.

2.2 Knowledge Distillation

The knowledge distillation framework (Hinton et al., 2014) consists of two networks: a *teacher* T, which is a pre-trained large model or an ensemble of multiple models, and a *student* S, which is a smaller network that learns from the teacher. The idea is to supervise the student with not only ground truth labels but also output distributions of the teacher. Concretely, given a data set of examples of the form (X, Y), the cross-entropy loss can be minimized to learn a multi-class classifier:

$$\mathcal{L}_{CE}(\theta) = -\sum_{k=1}^{m} Y_k \log p(k|X;\theta)$$

where p is the model distribution that is parameterized by θ, and m indicates the number of classes. The standard knowledge distillation is to replace ground truth Y with a soft probability distribution q generated by the teacher as:

$$q = \text{softmax}(\frac{\alpha}{\tau}), \quad p = \text{softmax}(\frac{\beta}{\tau})$$

$$\mathcal{L}_{KD}(\theta_S) = -\sum_{k=1}^{m} q(k|X;\theta_T)\log p(k|X;\theta_S)$$

where α and β are pre-softmax logits for teacher and student respectively, and τ is a temperature coefficient that is normally set to 1. A higher τ produces a softer probability distribution, and thus, provides more information about the relative similarity between classes. As Hinton et al. (2014) suggested, the above losses can be jointly optimized as follows:

$$\mathcal{L}(\theta_S) = \mathcal{L}_{CE}(\theta_S) + \lambda\mathcal{L}_{KD}(\theta_S)$$

where λ is usually set as τ^2 since the magnitudes of gradients produced by $\mathcal{L}_{KD}$ scale as $1/\tau^2$.

3 Attention-guided Answer Distillation

Figure 2 gives an overview of our distillation framework, which mainly consists of three approaches including vanilla knowledge distillation, answer distillation and attention distillation. First, we explore standard knowledge distillation in the context of MRC by replacing one-hot labels with soft output distributions extracted from the teacher. We then distill the span of the most confusing answer from the teacher, so that the student can learn to distinguish gold answers from the distractor. Next, we utilize teacher's attention distributions to guide the student's training process for forcing the student to attend more precisely. Finally, the student is jointly trained with the above distilled knowledge.

3.1 Vanilla Knowledge Distillation

The standard training method for MRC models is to minimize the cross entropies on two answer positions (Wang and Jiang, 2017):

$$\mathcal{L}_{CE} = -\sum_{k=1}^{m}\sum_{l=1}^{m} y_k^1 \log p^1(k) + y_l^2 \log p^2(l|k)$$

where y^1 and y^2 are one-hot labels for the answer start and end positions respectively, and m refers to the passage length. We denote $p^1(k|Q,P)$ as $p^1(k)$ and $p^2(l|k,Q,P)$ as $p^2(l|k)$ for abbreviation.

Following the standard procedure of knowledge distillation in Section 2.2, we can replace one-hot labels with output distributions of answer start and end positions predicted by the teacher as:

$$\mathcal{L}_{KD} = -\sum_{k=1}^{m}\sum_{l=1}^{m} q^1(k) \log p^1(k) + q^2(l|k) \log p^2(l|k)$$

Here, we first consider the teacher as a single model, and later extend it to the ensemble scenario in Section 3.4.

3.2 Answer Distillation

Vanilla knowledge distillation allows the student to learn relative similarities between answer candidates at position level. However, the student can suffer from the biased distillation problem once the teacher makes wrong predictions towards confusing answers. As a result, the model may be over-confident on the distractors during inference. Therefore, it is necessary to produce confidence scores that are comparable and unbiased between candidate answers. Since there usually exists one most confusing candidate answer, we hence consider explicitly informing the student about its boundary so as to relatively decrease the corresponding confidence.

Specifically, we perform inference with the teacher network to get a top-K answer list $\mathcal{A}_{\mathcal{K}}$ for each example, and measure the word overlap between the ground truth A^* and each answer candidate A_i from the list. The one that shares no overlap with gold answers and has the highest confidence score is chosen as the *confusing answer*. We use the F1 scoring function $F_1(A^*, A_i)$ as the measurement of word overlap and use the probability $q(A_i)$ as the confidence score. If the F1 scores of all top-K answers are larger than 0, then we argue that the teacher makes a good prediction and therefore do not distill the confusing answer for this example. The above process is performed on the entire training set to annotate all potential confusing answers.

Once the process is finished, we force the student to produce confidence scores of gold answers that are distinguishable from the score of confusing answer, by minimizing a margin ranking loss (Bai et al., 2010) as:

$$\begin{aligned}\mathcal{L}_{ANS} = &\max(0, 1 - \beta_k^1 + \beta_i^1) + \\ &\max(0, 1 - \beta_l^2 + \beta_j^2)\end{aligned}$$

where β is the student's pre-softmax logit, k and l indicate the boundary of gold span while i and j refer to the confusing boundary. With this loss, we penalize the strongest distractor on which the model is over-confident, and encourage the true answer that is underestimated by the student.

3.3 Attention Distillation

The above distillation approaches allow knowledge to be transferred through teacher's outputs. However, we would like to distill not only the final outputs but also some intermediate representations (Romero et al., 2015), in order to provide additional supervised signals for training the student network. The standard approach is to regress the student's intermediate passage representation to the teacher's corresponding representation as a pre-training step. Nevertheless, this approach is cumbersome in that the dimension of passage representation, denoted as $h \times m$ where h is the hidden size, is quite large, leading to a huge amount of resource consumption as we need to distill all training examples. Since neural attention is more compressed and contains rich informantion about where to attend, we hence propose to match the attention distribution between the teacher and the student instead.

Following the notation in Section 2.1, let $\tilde{D}_j$ and $\tilde{E}_j$ denote the attention distribution across the question for the j-th passage word in teacher and student repectively. We define a mean-squared loss as:

$$\mathcal{L}_{ATT} = \frac{1}{2}\sum_{j=1}^{m}||\tilde{D}_j - \tilde{E}_j||^2$$

Compared to regressing the hidden representation, attention distillation brings in two benefits: 1) the dimension of similarity matrix is $n \times m$, where the question length n is significantly smaller than the hidden size h, resulting in a better compression efficiency; 2) the student can learn to attend more precisely as neural attention directly reflects semantic similarities between input text pairs.

3.4 Joint Training

So far, we define three losses to transfer knowledge between MRC models. Next we consider using a joint objective to train the student network as:

$$\mathcal{L} = \mathcal{L}_{CE} + \lambda\mathcal{L}_{KD} + \gamma\mathcal{L}_{ANS} + \delta\mathcal{L}_{ATT} \qquad (1)$$

where λ is set as τ^2 to scale gradients, γ and δ are two hyper-parameters that control the task-specific weights.

In addition, since the knowledge is distilled from an ensemble model, we need to integrate multiple outputs into an unified label. For vanilla knowledge distillation and attention distillation, we use an arithmetic mean of their individual predicted distributions as the final soft label. As for answer distillation, we choose the confusing answer that has the highest confidence score among all models.

In summary, the entire training procedure is: 1) train an ensemble teacher model; 2) distill knowledge using the teacher on the training set; 3) integrate multiple types of knowledge to build a new training set; 4) train a single student model with Equation 1 on the new dataset.

4 Experiments

4.1 Datasets and Metrics

We conduct experiments on the following three datasets.

SQuAD (Stanford Question Answering Dataset) (Rajpurkar et al., 2016) is a machine comprehension dataset containing $100,000$+ questions that are annotated by crowd workers on 536 Wikipedia articles. The answer to each question is always a span in the corresponding passage.

Adversarial SQuAD (Jia and Liang, 2017) is a dataset aiming to test whether the model truely understands the text by appending an adversarial sentence to the passage. A strong confusing answer is constructed in the adversarial sentence to distract the answer prediction.

NarrativeQA (Kočiskỳ et al., 2017) is a benchmark proposed for story-based reading comprehension. The answers in this dataset are handwritten by human annotators based on a short summary. Following Tay et al. (2018), we compete on the summary setting to compare with reported baselines. We choose the span that achieves the highest Rouge-L score with respect to the gold answers as labels for training.

We use the official metrics to perform the evaluation. Specifically, for both SQuAD and adversarial SQuAD datasets, we report exact match (EM) and F1 scores. As for the NarrativeQA benchmark, the metrics are Blue-1, Bleu-4 and Rouge-L.

4.2 Implementation Details

We implement the Reinforced Mnemonic Reader (RMR) (Hu et al., 2018) as our base model, which contains the standard attention mechanism and the two-step answer prediction described in Section 2.1. Therefore, our distillation approaches can be seamlessly used, and the improvement of our approaches can be directly compared to the baseline. We use slightly different network architectures and hyper-parameters for different datasets. More specifically, we use the original configuration for SQuAD and adversarial SQuAD datasets. As for the NarrativeQA benchmark, we truncate the passage to the first 800 words and use a batch size of 32. Besides, we also remove ELMo embeddings (Peters et al., 2018) and reduce the number of aligning layer to 2 to avoid out-of-memory problem.

We run 12 single models with the identical architecture but different initial parameters to obtain the ensemble model. The student has the same network architecture as the teacher. We reuse the models trained on the SQuAD dataset to test on

(2017)[4], Wang et al. (2018)[5], Yu et al. (2018)[6] and Hu et al. (2018)[7]. BiSAE refers to BiDAF + Self Attention + ELMo. (E: ensemble model)

adversarial SQuAD datasets, but we retrain another pair of teacher and student models for the NarrativeQA benchmark. The temperature τ is tuned among $[1, 2, 3, 5]$ and is set as 2 by default. The weight γ is set to 0.3 and δ is 0.1. K is set to 4 for generating the top-K answer list. All experiments and runtime benchmarks are tested on a single Nvidia Tesla P100 GPU. Our approach is denoted as A2D for abbreviation.

4.3 Main Results

In this section we report main results on three MRC datasets[1]. Since our main purpose is to compress the ensemble model into a single model that possesses better efficiency and robustness, we focus on comparing our approach with the ensemble baseline.

We present the results on the test set of SQuAD in Table 1. We can see that the student network is able to compete with the ensemble model with only a slight drop of 0.4% on F1. Moreover, nearly 80% of the improvement in terms of F1 achieved by the ensemble model is successfully transferred to the distilled model, which indicates the effectiveness of our approach.

To validate the effect of our approach on enhancing robustness, we show the results on two adversarial SQuAD datasets, namely AddOneSent and AddSent, in Table 2. As we can see, the improvement on adversarial data is much higher than the one on original SQuAD dataset: the student network successfully surpasses the teacher. The significant improvement comes from the fact that there exists much more confusing answers in adversarial datasets, and hence the baseline is more likely to be over-confident on distractors. Our approach, however, explicitly decreases distractor's confidence, thus yielding more robust predictions against adversarial examples.

Model	AddSent		AddOneSent	
	EM	F1	EM	F1

Table 3: Comparison of different approaches on the NarrativeQA test set using summaries: Kadlec et al. (2016)[1], Seo et al. (2017)[2] and Tay et al. (2018)[3]. (E: ensemble model)

To verify the generalizability of our approach among various datasets, we further detail the results on the test set of NarrativeQA in Table 3, Despite that both of our single baseline and ensemble model have already achieved top results, the student's performance can still be boosted using our approach, even outperforming the teacher in terms of Bleu-1 score.

4.4 Speedup over Ensemble Model

Next, in order to show the improvement on efficiency brought by our approach, we compare

---

	Params	Time	Speedup
RMR (E)	6.9m×12	118.2	-
RMR + A2D	6.9m	**9.6**	**12.3×**

Table 4: Comparison between the ensemble teacher and the single student on the SQuAD dev set. Time denotes number of minutes needed to perform the entire inference. (E: ensemble model)

the inference speedup of the student against the teacher in Table 4. Since we use 12 single models to make the ensemble, we can easily see that the student is nearly 12× faster than the teacher. Besides, compared to the baseline, the student has nearly the same number of parameters, demonstrating that our approach does not introduce additional computation complexity.

4.5 Ablation Study

To get better insights of our distillation approaches, we conduct in-depth ablation study on both the development set of SQuAD and the AddSent set of adversarial SQuAD. We mainly focus on the F1 score since it is used as the main metric on the SQuAD leaderboard.

Table 5 shows the ablation results. First, we evaluate the vanilla knowledge distillation by removing the KD loss. We find that this loss contributes a lot on both datasets, implying that standard knowledge distillation is helpful for MRC models. Next we ablate the attention loss (ATT), and observe a smaller performance degradation on both datasets, which suggests that matching attention distributions is also beneficial but less effective. We then test the effect of removing answer distillation (ANS), and discover that although the impact on the SQuAD dev set is relatively small, the influence on the AddSent dataset is quite large. We argue that this is because the model trained with answer distillation can better handle the biased distillation problem, which is more severe in the adversarial dataset. Finally, we replace the joint training process with a stage-wise fashion proposed by Romero et al. (2015). Concretely, we first warm up the student by matching the attention distribution as a pre-training step, and then minimize the rest of losses to train the model. The result, however, shows that this strategy does harm to the performance. We think the reason may be that the pre-training step leads the model into a local minima.

	Dev		AddSent

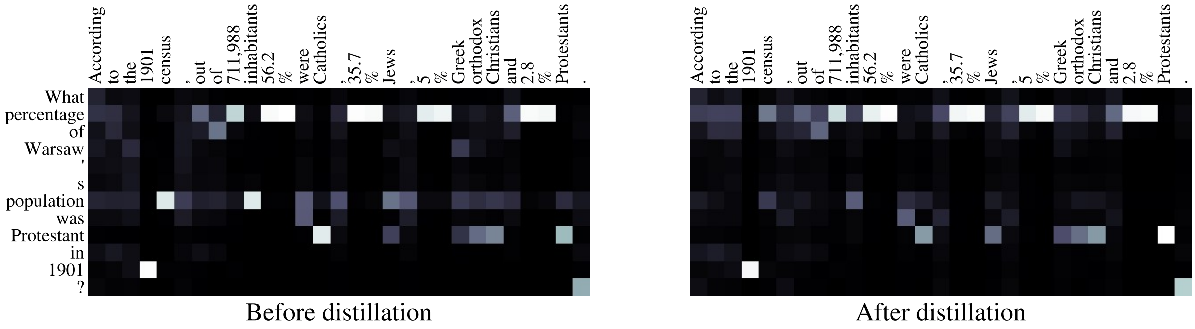
4.6 Analysis and Discussion

We now give a qualitative analysis on our approach by visualizing attention distributions and output probabilities for both of the baseline and the distilled model. From Figure 3(a) we can see that, both models are good at finding candidate answers, such as "*56.2%*" and "*2.8%*", according to the key question word "percentage". Nevertheless, the base model pays more attention on question-passage word pairs around the confusing answer "*56.2%*". As a result, the model is more likely to produce a high confidence score on "*56.2%*", as shown in Figure 3(b). Using our approach, however, leads to less concentrations on superfical clues around the confusing answer. Instead, the distilled model is able to focus more on the critical alignments (e.g., "*Protestant*" to "*Protestants*"), and therefore predicts the correct answer "*2.8%*".

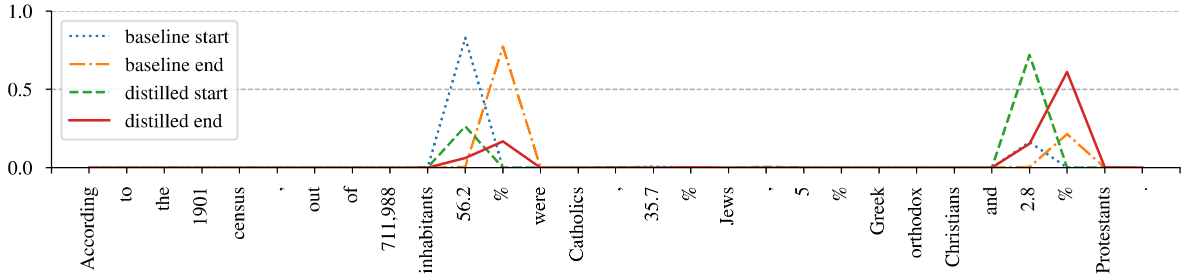
To show on which type of questions our approach is doing better, we report the results in Figure 4. We can see that our approach yields consistent performance gain over the baseline across different question types on various datasets. Particularly, A2D provides an obvious advantage for question types such as "*what*", "*who*", "*which*", "*how*", "*why*" and so on.

5 Related Work

Machine Reading Comprehension. Benefiting from large-scale machine reading comprehension (MRC) datasets (Hermann et al., 2015; Hill et al., 2016; Rajpurkar et al., 2016; Joshi et al., 2017), end-to-end neural networks have achieved promising results (Wang et al., 2018; Yu et al., 2018). Wang and Jiang (2017) combine the match-LSTM with pointer networks to predict the answer boundary. Wang et al. (2017) match the context aginst itself to refine the passage representation. Later, a variety of attention mechanisms have been



(a) Alignments before/after distillation. Using A2D, the attention distributions concentrate less on superfical clues around the confusing answer "*56.2%*" (e.g., "*population*" to "*inhabitants*", "*Protestant*" to "*Catholics*" and so on.).



(b) The base model points to the confusing answer ("*56.2%*"), while the distilled model predicts the correct one ("*2.8%*").

proposed, such as bi-attention (Seo et al., 2017), coattention (Xiong et al., 2018), fully-aware attention (Huang et al., 2018) and reattention (Hu et al., 2018). Among these works, two common traits can be summarized as: 1) compute a similary matrix between the question and the passage; 2) sequentially predict the answer start and end positions. Our proposed approach is a simple and effective adaptation to existing models by taking advantage of these traits, and do not complicate previous works more than necessary.

Efficiency and Robustness in MRC. Improving efficiency and robustness for reading comprehension system has attracted a lot of interest in recent years. For efficiency, previous works mostly concentrate on how to scale passage-level models to large corpora such as a document without increasing computation complexity. Existing approaches (Chen et al., 2017; Clark and Gardner, 2018) usually first retrieve relevant passages with a ranking model and then return an answer with a reading model. As for robustness, Wang and Bansal (2018) train the model with an adversarial data augmentation method. Min et al. (2018) propose to selectively read salient sentences rather than the entire passage, so as to avoid looking at the adversarial sentence. Our approach, however, focuses on improving efficiency and robustness by transferring knowledge from a cumbersome ensemble model to a single model.

Knowledge Distillation. Knowledge distillation is first explored by Bucilu et al. (2006) and Hinton et al. (2014), which attempts to transfer knowledge defined as soft output distributions from a teacher to a student. Later works have been proposed to distill not only the final output but also intermediate representation from the teacher (Romero et al., 2015; Zagoruyko and Komodakis, 2017; Huang and Wang, 2017). Papernot et al. (2016) show that knowledge distillation can be used to prevent the network from adversarial attacks in image recognition. Radosavovic et al. (2017) introduce data distillation that annotates large-scale unlabelled data for omni-supervised learning.

In natural language processing (NLP), Mou et al. (2016) distill task-specific knowledge from word embeddings. Kuncoro et al. (2016) propose to learn a single parser from an ensemble of parsers. Kim and Rush (2016) investigate knowledge distillation for neural machine translation by approximately matching the sequence-level distribution of the teacher. Nakashole and Flauger (2017) propose to learn bilingual mapping functions through a distilled training objective. Xu and Yang (2017) distill discriminative knowledge across languages for cross-lingual text classifica-

tion. Our work shows that the standard knowledge distillation and its novel variants can be successfully applied to the MRC task.

6 Conclusion

In this paper, we investigate knowledge distillation for machine reading comprehension. We first explore vanilla knowledge distillation to transfer knowledge of answer positions, and then propose two variant approaches including answer distillation for penalizing student's predictions on confusing answer spans, and attention distillation for transferring teacher's attentive information. Experiments show that the ensemble model has been successfully compressed into a single model that possesses better efficiency and robustness.

In future work, we will explore new distillation methods that have better compression capabilities for MRC tasks, such as distilling knowledge from a single model instead of the ensemble without lossing performances, adding weights on knowledge based on the distilling quality and so on. We also plan to further study the biased distillation problem and explore the compatibility of our approach in other NLP tasks such as natural language inference (Bowman et al., 2015), answer sentence selection (Yang et al., 2015) and so on.

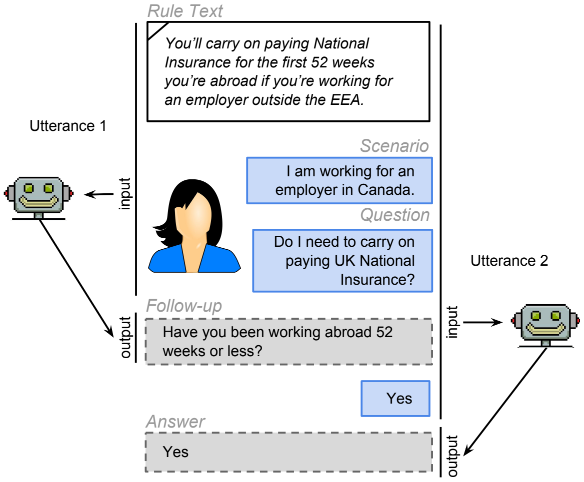
Abstract

Most work in machine reading focuses on question answering problems where the answer is directly expressed in the text to read. However, many real-world question answering problems require the reading of text not because it contains the literal answer, but because it contains a recipe to derive an answer together with the reader's background knowledge. One example is the task of interpreting regulations to answer "Can I...?" or "Do I have to...?" questions such as "I am working in Canada. Do I have to carry on paying UK National Insurance?" after reading a UK government website about this topic. This task requires both the interpretation of rules and the application of background knowledge. It is further complicated due to the fact that, in practice, most questions are underspecified, and a human assistant will regularly have to ask clarification questions such as "How long have you been working abroad?" when the answer cannot be directly derived from the question and text. In this paper, we formalise this task and develop a crowd-sourcing strategy to collect 32k task instances based on real-world rules and crowd-generated questions and scenarios. We analyse the challenges of this task and assess its difficulty by evaluating the performance of rule-based and machine-learning baselines. We observe promising results when no background knowledge is necessary, and substantial room for improvement whenever background knowledge is needed.

1 Introduction

There has been significant progress in teaching machines to read text and answer questions when the answer is directly expressed in the text (Rajpurkar et al., 2016; Joshi et al., 2017; Welbl et al., 2018; Hermann et al., 2015). However, in many settings, the text contains rules expressed in natural language that can be used to infer the answer when combined with background knowledge, rather than the literal answer. For example, to answer someone's question "I am working for an employer in Canada. Do I need to carry on paying National Insurance?" with "Yes", one needs to read that "You'll carry on paying National Insurance if you're working for an employer outside the EEA" and understand how the rule and question determine the answer.



You'll carry on paying National Insurance for the first 52 weeks you're abroad if you're working for an employer outside the EEA.

I am working for an employer in Canada.

Do I need to carry on paying UK National Insurance?

Have you been working abroad 52 weeks or less?

Yes

Yes

Figure 1: An example of two utterances for rule interpretation. In the first utterance, a follow-up question is generated. In the second, the scenario, history and background knowledge (Canada is not in the EEA) is used to arrive at the answer "Yes".

Answering questions that require rule interpretation is often further complicated due to missing information in the question. For example, as illustrated in Figure 1 (Utterance 1), the actual rule also mentions that National Insurance only needs to be paid for the first 52 weeks when abroad. This means that we cannot answer the original question without knowing how long the user has already

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2087–2097
Brussels, Belgium, October 31 - November 4, 2018.

been working abroad. Hence, the correct response in this conversational context is to issue another query such as "Have you been working abroad 52 weeks or less?"

To capture the fact that question answering in the above scenario requires a dialog, we hence consider the following *conversational machine reading* (CMR) problem as displayed in Figure 1: Given an input question, a context scenario of the question, a snippet of supporting rule text containing a rule, and a history of previous follow-up questions and answers, predict the answer to the question ("Yes"or "No") or, if needed, generate a follow-up question whose answer is necessary to answer the original question. Our goal in this paper is to create a corpus for this task, understand its challenges, and develop initial models that can address it.

To collect a dataset for this task, we could give a textual rule to an annotator and ask them to provide an input question, scenario, and dialog in one go. This poses two problems. First, this setup would give us very little control. For example, users would decide which follow-up questions become part of the scenario and which are answered with "Yes" or "No". Ultimately, this can lead to bias because annotators might tend to answer "Yes", or focus on the first condition. Second, the more complex the task, the more likely crowd annotators are to make mistakes. To mitigate these effects, we aim to break up the utterance annotation as much as possible.

We hence develop an annotation protocol in which annotators collaborate with virtual users—agents that give system-produced answers to follow-up questions—to incrementally construct a dialog based on a snippet of rule text and a simple underspecified initial question (e.g., "Do I need to ...?"), and then produce a more elaborate question based on this dialog (e.g., "I am ... Do I need to...?"). By controlling the answers of the virtual user, we control the ratio of "Yes" and "No" answers. And by showing only subsets of the dialog to the annotator that produces the scenario, we can control what the scenario is capturing. The question, rule text and dialogs are then used to produce utterances of the kind we see in Figure 1. Annotators show substantial agreement when constructing dialogs with a three-way annotator agreement at a Fleiss' Kappa level of 0.71.[1] Likewise, we find that our crowd-annotators produce questions that are coherent with the given dialogs with high accuracy.

In theory, the task could be addressed by an end-to-end neural network that encodes the question, history and previous dialog, and then decodes a Yes/No answer or question. In practice, we test this hypothesis using a seq2seq model (Sutskever et al., 2014; Cho et al., 2014), with and without copy mechanisms (Gu et al., 2016) to reflect how follow-up questions often use lexical content from the rule text. We find that despite a training set size of 21,890 training utterances, successful models for this task need a stronger inductive bias due to the inherent challenges of the task: interpreting natural language rules, generating questions, and reasoning with background knowledge. We develop heuristics that can work better in terms of identifying what questions to ask, but they still fail to interpret scenarios correctly. To further motivate the task, we also show in oracle experiments that a CMR system can help humans to answer questions faster and more accurately.

This paper makes the following contributions:

1. We introduce the task of conversational machine reading and provide evaluation metrics.
2. We develop an annotation protocol to collect annotations for conversational machine reading, suitable for use in crowd-sourcing platforms such as Amazon Mechanical Turk.
3. We provide a corpus of over 32k conversational machine reading utterances, from domains such as grant descriptions, traffic laws and benefit programs, and include an analysis of the challenges the corpus poses.
4. We develop and compare several baseline models for the task and subtasks.

2 Task Definition

Figure 1 shows an example of a conversational machine reading problem. A user has a question that relates to a specific rule or part of a regulation, such as "Do I need to carry on paying National Insurance?". In addition, a natural language description of the context or *scenario*, such as "I am working for an employer in Canada", is provided. The question will need to be answered using a small snippet of supporting *rule text*. Akin to machine reading problems in previous work (Rajpurkar et al., 2016; Hermann et al., 2015), we assume that this snippet is pre-identified. We generally assume that the question is *underspecified*, in the sense that the

---

[1] This is well within the range of what is considered as substantial agreement (Artstein and Poesio, 2008).

question often does not provide enough information to be answered directly. However, an agent can use the supporting rule text to infer what needs to be asked in order to determine the final answer. In Figure 1, for example, a reasonable follow-up question is “Have you been working abroad 52 weeks or less?”.

We formalise the above task on a per-utterance basis. A given dialog corresponds to a sequence of prediction problems, one for each utterance the system needs to produce. Let W be a vocabulary. Let $q = w_1 \dots w_{n_q}$ be an *input question* and $r = w_1 \dots w_{n_r}$ an input *support* rule text, where $w_i \in W$ is a word from a vocabulary. Furthermore, let $h = (f_1, a_1) \dots (f_{n_h}, a_{n_h})$ be a dialog *history* where each $f_i \in W^*$ is a *follow-up question*, and each $a_i \in \{\text{YES}, \text{NO}\}$ is a *follow-up answer*. Let s be a scenario describing the context of the question. We will refer to $x = (q, r, h, s)$ as the *input*. Given an input x, our task is to predict an *answer* $y \in \{\text{YES}, \text{NO}, \text{IRRELEVANT}\} \cup W^*$ that specifies whether the answer to the input question, in the context of the rule text and the previous follow-up question dialog, is either YES, NO, IRRELEVANT or another follow-up question in W^*. Here IRRELEVANT is the target answer whenever a rule text is not related to the question q.

3 Annotation Protocol

Our annotation protocol is depicted in Figure 2 and has four high-level stages: Rule Text Extraction, Question Generation, Dialog Generation and Scenario Annotation. We present these stages below, together with discussion of our quality-assurance mechanisms and method to generate negative data. For more details, such as annotation interfaces, we refer the reader to Appendix A.

3.1 Rule Text Extraction Stage

First, we identify the source documents that contain the rules we would like to annotate. Source documents can be found in Appendix C. We then convert each document to a set of *rule texts* using a heuristic which identifies and groups paragraphs and bulleted lists. To preserve readability during the annotation, we also split by a maximum rule text length and a maximum number of bullets.

3.2 Question Generation Stage

For each rule text we ask annotators to come up with an input question. Annotators are instructed to ask questions that cannot be answered directly but instead require follow-up questions. This means that the question should a) match the topic of the support rule text, and b) be underspecified. At present, this part of the annotation is done by expert annotators, but in future work we plan to crowdsource this step as well.

3.3 Dialog Generation Stage

In this stage, we view human annotators as assistants that help users reach the answer to the input question. Because the question was designed to be broad and to omit important information, human annotators will have to ask for this information using the rule text to figure out which question to ask. The follow-up question is then sent to a *virtual user*, *i.e.*, a program that simply generates a random YES or NO answer. If the input question can be answered with this new information, the annotator should enter the respective answer. If not, the annotator should provide the next follow-up question and the process is repeated.

When the virtual user is providing random YES and NO answers in the dialog generation stage, we are traversing a specific branch of a decision tree. We want the corpus to reflect all possible dialogs for each question and rule text. Hence, we ask annotators to label additional branches. For example, if the first annotator received a YES as the answer to the second follow-up question in Figure 3, the second annotator (orange) receives a NO.

3.4 Scenario Annotation Stage

In the final stage, we choose parts of the dialogs created in the previous stage and present this to an annotator. For example, the annotator sees “Are you working or preparing for work?” and NO. They are then asked to write a scenario that is consistent with this dialog such as “I am currently out of work after being laid off from my last job, but am not able to look for any yet.”. The number of questions and answers that the annotator is presented with for generating a scenario can vary from one to the full length of a dialog. Users are encouraged to paraphrase the questions and not to use many words from the dialog.

In an attempt to make these scenarios closer to the real-world situations where a user may provide a lot of unnecessary information to an operator, not only do we present users with one or more questions and answers from a specific dialog but

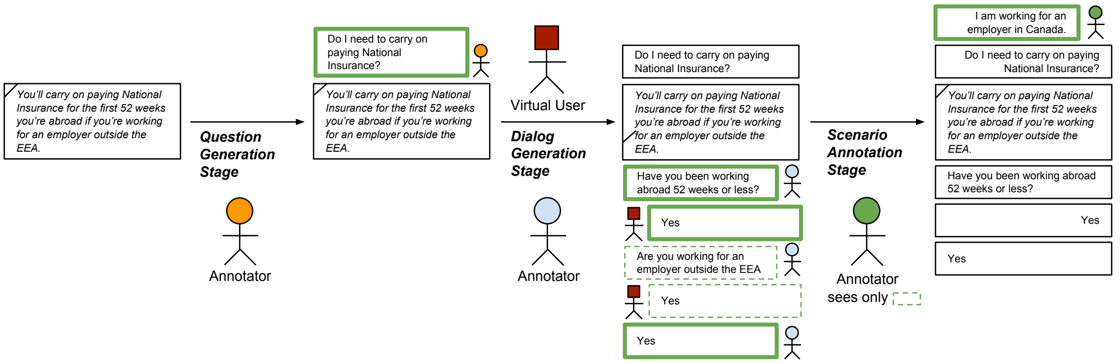

Figure 2: The different stages of the annotation process (excluding the rule text extraction stage). First a human annotator generates an underspecified input question (question generation). Then, a virtual user and a human annotator collaborate to produce a dialog of follow-up questions and answers (dialog generation). Finally, a scenario is generated from parts of the dialog, and these parts are omitted in the final result.

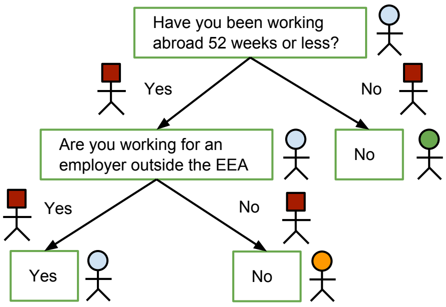

Figure 3: We use different annotators (indicated by different colors) to create the complete dialog tree.

also with one question from a random dialog. The annotators are asked to come up with a scenario that fits all the questions and answers.

Finally, a dialog is produced by combining the scenario with the input question and rule text from the previous stages. In addition, all dialog utterances that were *not* shown to the final annotator are included as well as they complement the information in the scenario. Given a dialog of this form, we can create utterances that are described in Section 2.

As a result of this stage of annotation, we create a corpus of scenarios and questions where the correct answers (YES, NO or IRRELEVANT) to questions can be derived from the related scenarios. This corpus and its challenges will be discussed in Section 4.2.2.

3.5 Negative Examples

To facilitate the future application of the models to large-scale rule-based documents instead of rule text, we deem it to be imperative for the data to contain negative examples of both questions and scenarios.

We define a *negative question* as a question that is not relevant to the rule text. In this case, we expect models to produce the answer IRRELEVANT. For a given rule text and question pair, a negative example is generated by sampling a random question from the set of all possible questions, excluding the question itself and questions sourced from the same document using a methodology similar to the work of Levy et al. (2017).

The data created so far is biased in the sense that when a scenario is given, at least one of the follow-up questions in a dialog can be answered. In practice, we expect users to also provide background scenarios that are completely irrelevant to the input question. Therefore, we sample a *negative scenario* for each input question and rule text pair, (q, r) in our data. We uniformly sample from the scenarios created in Section 3.4 for all question and rule text pairs (q', r') unequal to (q, r). For more details, we point the reader to Appendix D.

3.6 Quality Control

We employ a range of quality control measures throughout the process. In particular, we:

1. Re-annotate pre-terminal nodes in the dialog trees if they have identical YES and NO branches.
2. Ask annotators to validate the previous dialog in case previous utterances where created by different annotators.
3. Assess a sample of annotations for each an-

notator and keep only those annotators with quality scores higher than a certain threshold.

4. We require annotators to pass a qualification test before selecting them for our tasks. We also require high approval rates and restrict location to the UK, US, or Canada.

Further details are provided in Appendix B.

3.7 Cost, Duration and Scalability

The cost of different stages of annotation is as follows. An annotator was paid \$0.15 for an initial question (948 questions), \$0.11 for a dialog part (3000 dialog parts) and \$0.20 for a scenario (6,600 scenarios). It takes in total 2 weeks to complete the annotation process. Considering that all the annotation stages can be done through crowdsourcing and in a relatively short time period and at a reasonable cost using established validation procedures, the dataset can be scaled up without major bottlenecks or an impact on the quality.

4 ShARC

In this section, we present the *SHaping Answers with Rules and Conversation (ShARC)* dataset.[2]

4.1 Dataset Size and Quality

The dataset is built up from of 948 distinct snippets of rule text. Each has an input question and a "dialog tree". At each step in the dialog, there is a followup question posed and the tree branches depending on the answer to the followup question (yes/no). The ShARC dataset is comprised of all individual "utterances" from every tree, i.e. every possible point/node in any dialog tree. There are 6058 of these utterances. In addition, there are 6637 scenarios that provide more information, allowing some questions in the dialog tree to be "skipped" as the answers can be inferred from the scenario. Scenarios therefore modify the dialog trees, which creates new trees. When combined with scenarios and negative sampled scenarios, the total number of distinct utterances became 37087. As a final step, utterances were removed where the scenario referred to a portion of the dialog tree that was unreachable for that utterance, leaving a final dataset size of 32436 utterances.[3]

We break these into train, development and test sets such that each dataset contains approximately the same proportion of sources from each domain, targeting a 70%/10%/20% split.

To evaluate the quality of dialog generation HITs, we sample a subset of 200 rule texts and questions and allow each HIT to be annotated by three distinct workers. In terms of deciding whether the answer is a YES, NO or some follow-up question, the three annotators reach an answer agreement of 72.3%. We also calculate Cohen's Kappa, a measure designed for situations with two annotators. We randomly select two out of the three annotations and compute the unweighted kappa values, repeated for 100 times and averaged to give a value of 0.82.

The above metrics measure whether annotators agree in terms of deciding between YES, NO or some follow-up question, but not whether the follow-up questions are equivalent. To approximate this, we calculate BLEU scores between pairs of annotators when they both predict follow-up questions Generally, we find high agreement: Annotators reach average BLEU scores of 0.71, 0.63, 0.58 and 0.58 for maximum orders of 1, 2, 3 and 4 respectively.

To get an indication of human performance on the sub-task of classifying whether a response should be a YES, NO or FOLLOW-UP QUESTION, we use a similar methodology to (Rajpurkar et al., 2016) by considering the second answer to each question as the human prediction and taking the majority vote as ground truth. The resulting human accuracy is 93.9%.

To evaluate the quality of the scenarios, we sample 100 scenarios randomly and ask two expert annotators to validate them. We perform validation for two cases: 1) scenarios generated by turkers who did not attempt the qualification test and were not filtered by our validation process, 2) scenarios that are generated by turkers who have passed the qualification test and validation process. In the second case, annotators approved an average of 89 of the scenarios whereas in the first case, they only approved an average of 38. This shows that the qualification test and the validation process im-

---

[2] The dataset and its Codalab challenge can be found at `https://sharc-data.github.io`.

[3] One may argue that the the size of the dataset is not sufficient for training end-to-end neural models. While we believe that the availability of large datasets such as SNLI or SQuAD has helped drive the state-of-the-art forward on related tasks, relying solely on large datasets to push the boundaries of AI cannot be as practical as developing better models for incorporating common sense and external knowledge which we believe ShARC is a good test-bed for. Furthermore, the proposed annotation protocol and evaluation procedure can be used to reliably extend the dataset or create datasets for new domains.

proved the quality of the generated scenarios by more than double. In both cases, the annotators agreed on the validity of 91-92 of the scenarios. For further details on dataset quality, the reader if referred to Appendix B.

4.2 Challenges

We analyse the challenges involved in solving conversational machine reading in ShARC. We divide these into two parts: challenges that arise when interpreting rules, and challenges that arise when interpreting scenarios.

4.2.1 Interpreting Rules

When no scenarios are available, the task reduces to a) identifying the follow-up questions within the rule text, b) understanding whether a follow-up question has already been answered in the history, and c) determining the logical structure of the rule (*e.g.*disjunction vs. conjunction vs. conjunction of disjunctions) .

To illustrate the challenges that these sub-tasks involve, we manually categorise a random sample of 100 (q_i, r_i) pairs. We identify 9 phenomena of interest, and estimate their frequency within the corpus. Here we briefly highlight some categories of interest, but full details, including examples, can be found in Appendix G.

A large fraction of problems involve the identification of at least two conditions, and approximately 41% and 27% of the cases involve logical disjunctions and conjunctions respectively. These can appear in linguistic coordination structures as well as bullet points. Often, differentiating between conjunctions and disjunctions is easy when considering bullets—key phrases such as "if all of the following hold" can give this away. However, in 13% of the cases, no such cues are given and we have to rely on language understanding to differentiate. For example:

Q: Do I qualify for Statutory Maternity Leave?
R: You qualify for Statutory Maternity Leave if - you're an employee not a "worker" - you give your employer the correct notice

4.2.2 Interpreting Scenarios

Scenario interpretation can be considered as a multi-sentence entailment task. Given a scenario (premise) of (usually) several sentences, and a question (hypothesis), a system should output YES (ENTAILMENT), NO (CONTRADICTION) or IRRELEVANT (NEUTRAL). In this context, IRRELEVANT indicates that the answer to the question cannot be inferred from the scenario.

Different types of reasoning are required to interpret the scenarios. Examples include numerical reasoning, temporal reasoning and implication (common sense and external knowledge). We manually label 100 scenarios with the type of reasoning required to answer their questions. Table 1 shows examples of different types of reasoning and their percentages. Note that these percentages do not add up to 100% as interpreting a scenario may require more than one type of reasoning.

5 Experiments

To assess the difficulty of ShARC as a machine learning problem, we investigate a set of baseline approaches on the end-to-end task as well as the important sub-tasks we identified. The baselines are chosen to assess and demonstrate both feasibility and difficulty of the tasks.

Metrics For all following classification tasks, we use micro- and macro- averaged accuracies. For the follow-up generation task, we compute the BLEU scores at orders 1, 2, 3 and 4 computed between the gold follow-up questions, y_i and follow-up question $\hat{y}_i = w_{\hat{y}_i,1}, w_{\hat{y}_i,2} \ldots w_{\hat{y}_i,n}$ for all utterances i in the evaluation dataset.

5.1 Classification (excluding Scenarios)

On each turn, a CMR system needs to decide, either explicitly or implicitly, whether the answer is YES or NO, whether the question is not relevant to the rule text (IRRELEVANT), or whether a follow-up question is necessary—an outcome we label as MORE. In the following experiments, we will test whether one can learn to make this decision using the ShARC training data.

When a non-empty scenario is given, this task also requires an understanding of how scenarios answer follow-up questions. In order to focus on the challenges of rule interpretation, here we only consider empty scenarios.

Formally, for an utterance $x = (q, r, h, s)$, we require models to predict an answer y where $y \in \{\text{YES}, \text{NO}, \text{IRRELEVANT}, \text{MORE}\}$. Since we consider only the classification task without scenario influence, we consider the subset of utterances such that $s = NULL$. This data subset consists of 4026 train, 431 dev and 1601 test utterances.

Category	Questions	Scenario	%
Explicit	Has your wife reached state pension age? <u>Yes</u>	My wife just recently reached the age for state pension	25%
Temporal	Did you own it before April 1982? <u>Yes</u>	I purchased the property on June 5, 1980.	10%
Geographic	Do you normally live in the UK? <u>No</u>	I'm a resident of Germany.	7%
Numeric	Do you work less than 24 hours a week between you? <u>No</u>	My wife and I work long hours and get between 90 - 110 hours per week between the two of us.	12%
Paraphrase	Are you working or preparing for work? <u>No</u>	I am currently out of work after being laid off from my last job, but am not able to look for any yet.	19%
Implication	Are you the baby's father? <u>No</u>	My girlfriend is having a baby by her ex.	51%

Table 1: Types of reasoning and their proportions in the dataset based on 100 samples. Implication includes reasoning beyond what is explicitly stated in the text, including common sense reasoning and external knowledge.

Model	Micro Acc.	Macro Acc.
Random	0.254	0.250
Surface LR	0.555	0.511
Heuristic	0.791	0.779
Random Forest	**0.808**	**0.797**
CNN	0.677	0.681

Table 2: Selected Results of the baseline models on the classification sub-task.

Baselines We evaluate various baselines including random, a surface logistic regression applied to a TFIDF representation of the rule text, question and history, a rule-based heuristic which makes predictions depending on the number of overlapping words between the rule text and question, detecting conjunctive or disjunctive rules, detecting negative mismatch between the rule text and the question and what the answer to the last follow-up history was, a feature-engineered Random Forest and a Convolutional Neural Network applied to the tokenised inputs of the concatenated rule text, question and history.

Results We find that, for this classification sub-task, Random Forest slightly outperforms the heuristic. All learnt models considerably outperform the random and majority baselines.

5.2 Follow-up Question Generation without Scenarios

When the target utterance is a follow-up question, we still have to determine what that follow-up question is. For an utterance $x = (q, r, h, s)$, we require models to predict an answer y where y is the next follow-up question, $y = w_{y,1}, w_{y,2} \dots w_{y,n} = f_{m+1}$ if x has history of length m. We therefore consider the subset of utterances such that $s = NULL$ and $y \notin \{\textsc{Yes}, \textsc{No}, \textsc{Irrelevant}\}$. This data subset consists of 1071 train, 112 dev and 424 test utterances.

Baselines We first consider several simple baselines to explore the relationship between our evaluation metric and the task. As annotators are encouraged to re-use the words from rule text when generating follow-up questions, a baseline that simply returns the final sentence of the rule text performs surprisingly well. We also implement a rule-based model that uses several heuristics.

If framed as a seq2seq task, a modified CopyNet is most promising (Gu et al., 2016). We also experiment with span extraction/sequence-tagging approaches to identify relevant spans from the rule text that correspond to the next follow-up questions. We find that Bidirectional Attention Flow (Seo et al., 2017) performed well.[4] Further implementation details can be found in Appendix H.

Results Our results, shown in Table 3 indicate that systems that return contiguous spans from the rule text perform better according to our BLEU metric. We speculate that the logical forms in the data are challenging for existing models to extract and manipulate, which may suggest why the explicit rule-based system performed best. We further note that only the rule-based and NMT-Copy models are capable of generating genuine questions rather than spans or sentences.

5.3 Scenario Interpretation

Many utterances require the interpretation of the scenario associated with a question. If the scenario

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4
First Sent.	0.221	0.144	0.119	0.106
NMT-Copy	0.339	0.206	0.139	0.102
BiDAF	0.450	0.375	0.338	0.312
Rule-based	**0.533**	**0.437**	**0.379**	**0.344**

Table 3: Selected Results of the baseline models on follow-up question generation.

Model	Micro Acc.	Macro Acc.
Random	0.330	0.326
Surface LR	**0.682**	0.333
DAM (SNLI)	0.479	**0.362**
DAM (ShARC)	0.492	0.322

Table 4: Results of entailment models on ShARC.

is understood, certain follow-up questions can be skipped because they are answered within the scenario. In this section, we investigate how difficult scenario interpretation is by training models to answer follow-up questions based on scenarios.

Baselines We use a random baseline and also implement a surface logistic regression applied to a TFIDF representation of the combined scenario and the question. For neural models, we use Decomposed Attention Model (DAM) (Parikh et al., 2016) trained on each the SNLI and ShARC corpora using ELMO embeddings (Peters et al., 2018).[4]

Results Table 4 shows the result of our baseline models on the entailment corpus of ShARC test set. Results show poor performance especially for the macro accuracy metric of both simple baselines and neural state-of-the-art entailment models. This performance highlights the challenges that the scenario interpretation task of ShARC presents, many of which are discussed in Section 4.2.2.

5.4 Conversational Machine Reading

The CMR task requires all of the above abilities. To understand its core challenges, we compare baselines that are trained end-to-end vs. baselines that reuse solutions for the above subtasks.

Baselines We present a Combined Model (CM) which is a pipeline of the best performing Random Forest classification model, rule-based follow-up question generation model and Surface LR entailment model. We first run the classification model to predict YES, NO, MORE or IRRELEVANT. If MORE is predicted, the Follow-up Question Generation model is used to produce a follow-up question, f_1. The rule text and produced follow-up question are then passed as inputs to the Scenario Interpretation model. If the output of this is IRRELEVANT, then the CM predicts f_1, otherwise, these steps are repeated recursively until the classification model no longer predicts MORE or the entailment model predicts IRRELEVANT, in which case the model produces a final answer. We also investigate an extension of the NMT-copy model on the end-to-end task. Input sequences are encoded as a concatenation of the rule text, question, scenario and history. The model consists of a shared encoder LSTM, a 4-class classification head with attention, and a decoder GRU to generate followup questions. The model was trained by alternating training the classifier via standard softmax-cross entropy loss and the followup generator via seq2seq. At test time, the input is first classified, and if the predicted class is MORE, the follow-up generator is used to generate a followup question, f_1. A simpler model without the separate classification head failed to produce predictive results.

Model	**Micro Acc**	**Macro Acc**	**BLEU-1**	**BLEU-4**
CM	0.619	0.689	0.544	0.344
NMT	0.448	0.428	0.340	0.078

Table 5: Results of the models on the CMR task.

Results We find that the combined model outperforms the neural end-to-end model on the CMR task, however, the fact that the neural model has learned to classify better than random and also predict follow-up questions is encouraging for designing more sophisticated neural models for this task.

User Study In order to evaluate the utility of conversational machine reading, we run a user study that compares CMR to when such an agent is not available, i.e. the user has to read the rule text and determine themselves the answer to the question. On the other hand, with the agent, the user does not read the rule text, instead only responds to follow-up questions. Our results show that users using the conversational agent reach conclusions > 2 times faster than ones that are not, but more importantly, they are also much more accurate (93% as compared to 68%). Details of the experiments and the results are included in Appendix I.

6 Related Work

This work relates to several areas of active research.

Machine Reading In our task, systems answer questions about units of texts. In this sense, it is most related to work in Machine Reading (Rajpurkar et al., 2016; Seo et al., 2017; Weissenborn et al., 2017). The core difference lies in the conversational nature of our task: in traditional Machine Reading the questions can be answered right away; in our setting, clarification questions are often needed. The domain of text we consider is also different (regulatory vs Wikipedia, books, newswire).

Dialog The task we propose is, at its heart, about conducting a dialog (Weizenbaum, 1966; Serban et al., 2018; Bordes and Weston, 2016). Within this scope, our work is closest to work in dialog-based QA where complex information needs are addressed using a series of questions. In this space, previous approaches have been looking primarily at QA dialogs about images (Das et al., 2017) and knowledge graphs (Saha et al., 2018; Iyyer et al., 2017). In parallel to our work, both Choi et al. (2018) and Reddy et al. (2018) have to began to investigate QA dialogs with background text. Our work not only differs in the domain covered (regulatory text vs wikipedia), but also in the fact that our task requires the interpretation of complex rules, application of background knowledge, and the formulation of free-form clarification questions. Rao and Daume III (2018) does investigate how to generate clarification questions but this does not require the understanding of explicit natural language rules.

Rule Extraction From Text There is a long line of work in the automatic extraction of rules from text (Silvestro, 1988; Moulin and Rousseau, 1992; Delisle et al., 1994; Hassanpour et al., 2011; Moulin and Rousseau, 1992). The work tackles a similar problem—interpretation of rules and regulatory text—but frames it as a text-to-structure task as opposed to end-to-end question-answering. For example, Delisle et al. (1994) maps text to horn clauses. This can be very effective, and good results are reported, but suffers from the general problem of such approaches: they require careful ontology building, layers of error-prone linguistic preprocessing, and are difficult for non-experts to create annotations for.

Question Generation Our task involves the automatic generation of natural language questions. Previous work in question generation has focussed on producing questions for a given text, such that the questions can be answered using this text (Vanderwende, 2008; M. Olney et al., 2012; Rus et al., 2011). In our case, the questions to generate are *derived* from the background text but cannot be answered by them. Mostafazadeh et al. (2016) investigate how to generate natural follow-up questions based on the content of an image. Besides not working in a visual context, our task is also different because we see question generation as a sub-task of question answering.

7 Conclusion

In this paper we present a new task as well as an annotation protocol, a dataset, and a set of baselines. The task is challenging and requires models to generate language, copy tokens, and make logical inferences. Through the use of an interactive and dialog-based annotation interface, we achieve good agreement rates at a low cost. Initial baseline results suggest that substantial improvements are possible and require sophisticated integration of entailment-like reasoning and question generation.

A State-transition Framework to Answer Complex Questions over Knowledge Base

Sen Hu[1], **Lei Zou**[1,2], **Xinbo Zhang**[1]

{husen,zoulei,zhangxinbo}@pku.edu.cn

Abstract

Although natural language question answering over knowledge graphs have been studied in the literature, existing methods have some limitations in answering complex questions. To address that, in this paper, we propose a *State Transition*-based approach to translate a complex natural language question N to a *semantic query graph* (SQG) Q^S, which is used to match the underlying knowledge graph to find the answers to question N. In order to generate Q^S, we propose four primitive operations (expand, fold, connect and merge) and a learning-based state transition approach. Extensive experiments on several benchmarks (such as QALD, WebQuestions and ComplexQuestions) with two knowledge bases (DBpedia and Freebase) confirm the superiority of our approach compared with state-of-the-arts.

1 Introduction

Complex Question Answering, in which the question corresponds to multiple triples in knowledge base, has attracted researchers' attentions recently (Bao et al., 2014; Xu et al., 2016; Berant and Liang, 2014; Bast and Haussmann, 2015; Yih et al., 2015). However, most of existing solutions employ the predefined patterns or templates in understanding complex questions. For example, (Bao et al., 2014; Xu et al., 2016) use dependency tree patterns to decompose a complex question to several simple questions. (Berant and Liang, 2014; Bast and Haussmann, 2015) rely on templates to translate natural language sentences to predefined logical forms. Obviously, it is impossible to cover all real-world cases using those handcrafted templates. The recent work STAGG (Yih et al., 2015) proposes a state transition strategy to tackle complex questions. However, the generated query graph's structure in STAGG is limited, as shown in Figure 1. Generally, the structure is formed by linking the topic entity e and the answer node t through a core relation. It only allows entity constraints (such as c) and one variable (the answer node t), the expressivity is quite limited. It cannot cover all types of complex questions such as the question in Figure 2, whose query graph contains variable constraint (v_4) and multi-edges (between v_1 and v_4). Therefore, in this paper, we propose a more flexible strategy to answer complex questions without handcrafted templates or restricting the query graph's structure.

1.1 Properties and Challenges of Complex Questions

We first analyze the inherent challenges for complex question answering, which has not been well studied in existing literatures.

Multi or Implicit relations. A complex question has multiple relations and some relations may be multi-hop or implicit. Consider the question N_1 = "*Which Russian astronauts died in the same place they were born in?*". Obviously there are two explicit relations represented by the two phrases "died in" and "born in", but many traditional methods only extract a single relation between topic entity and the answer node. On the other hand, there is an implicit relation between "Russian" and "astronauts" (i.e., ⟨Nationality⟩), which lacks a corresponding relation phrase.

Multi or No entities. Different from simple (one-hop) questions that only contain a single *topic entity* in the question sentence N, complex questions may have multiple entities. For example, "Which Russian astronauts were died in Moscow and born in Soviet Union". There are three entities "Russian", "Moscow" and "Soviet Union". In some cases, the question sentence does not include any entity, such as "Who died in the same place they were born in". Therefore, existing methods that

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2098–2108
Brussels, Belgium, October 31 - November 4, 2018.

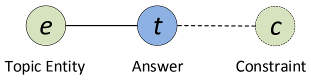

Figure 1: The query graph structure of STAGG. Node *e* is the "topic entity", path *e-t* is the "core inferential chain" and *c* represents "augmenting constraints". Notice we omit the CVT node as it is a virtual node only existed in Freebase.

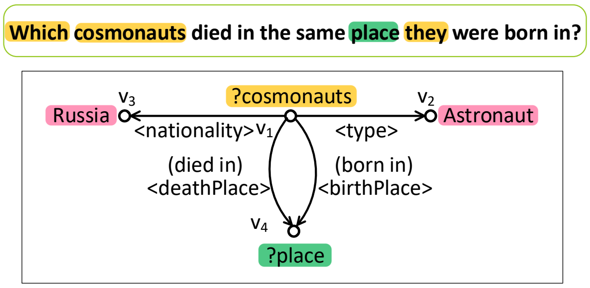

Figure 2: The example of complex questions with semantic query graph

only care about a single topic entity cannot work for such types of complex questions.

Variables and Co-reference. Existing solutions assume that there is a single variable in the question N, i.e., the wh-word, which is focus of the question (representing the answer node). However, complex questions may have other variables. Consider the question in Figure 2, there are four variables "Which", "cosmonauts", "place" and "they" recognized. While the three in yellow grid ("Which", "cosmonaut", "they") refer to the same thing, which is the co-reference phenomenon.

Composition. In the simple questions, the query graph's structure is determinate (one-hop edge). For complex questions, even when all entities, variables and relations are recognized, how to assemble them to logical forms or executable queries (query graphs) is still a challenge. As mentioned earlier, existing solutions that depend on predefined templates (such as (Xu et al., 2016; Bast and Haussmann, 2015)) or query graph structure patterns (such as (Yih et al., 2015)) may not be suitable due to the diversity of complex questions.

1.2 Our Solution

Considering the above challenges, we propose a *state transition* based framework to translate users' question N into a semantic query graph (SQG) Q^S, further the answers of N can be found by matching Q^S over the knowledge graph G. Specifically, we first recognize nodes (such as entities and variables) from N as the initial state (Section 2.1). Then, to enable and speed up the state transition process, we propose four primitive operations with corresponding conditions (Section 2.2). The entity/relation candidates are extracted using existing entity linking algorithms and our proposed MCCNN model (Section 2.3). To guide the state transition, we learn a reward function using SVM ranking algorithm (Section 3) to greedily select a subsequent state.

Compared with existing solutions, our framework has stronger expressivity to solve more types of complex questions (considering the challenges introduced in Section 1.1) and does not rely on handcrafted templates.

2 Semantic Query Graph Generation

This section outlines the whole framework of our system. Given a natural language question N, we aim to translate N into a *semantic query graph* (SQG) (see Definition 1).

Definition 1 ***(Semantic Query Graph).*** *A semantic query graph (denoted as* Q^S*) is a connected graph, in which each vertex* v_i *corresponds a phrase in the question sentence* N *and associated with a list of entity/type/literal candidates; and each edge* $\overline{v_iv_j}$ *is associated with a list of relation candidates,* $1 \leq i, j \leq |V(Q^S)|$.

Given a question sentence N_1 = "Which cosmonauts died in the same place they were born in?", the corresponding semantic query graph Q^S_1 is given in Figure 2. In Q^S_1, the subgraph $\{v_1$, v_2 and $v_3\}$ corresponds "cosmonauts", v_4 corresponds "place". The relation phrases "born in" and "died in" denote two relations between v_1 and v_4. Each edge in Q^S has a list of relation(predicate) candidates with confidence probabilities. In this paper, we only draw one relation candidate of each edge for simplicity. Notice that the edge $\overline{v_1v_3}$ and $\overline{v_1v_2}$ have no relation phrases, however, they still have corresponding relation candidates $\langle$nationality$\rangle$ and $\langle$type$\rangle$.

After obtaining semantic query graph Q^S, we find matches of Q^S over the underlying knowledge graph G to find answers to the original question N. This stage is identical to gAnswer (Zou et al., 2014) and NFF (Hu et al., 2018). Thus, in this paper, we concentrate ourselves on discussing how to generate semantic query graph Q^S, which is different from NFF that relies on the paraphrasing dictionaries and heuristic rules to build Q^S.

2.1 Node Recognition

The first step is to detect the "nodes" (for building SQG Q^S) in users' question sentences. According to Definition 1, each node in the semantic query graph is a phrase corresponding to a subject or object in the SPARQL query. Generally, constant nodes (e.g., *Titanic*) can be divided into three categories according to their roles (entity, type, literal) in knowledge graph. Besides, a variable node (e.g., *?place*) has the potential to map any vertices in knowledge graph.

Generally, the node recognition task is regarded as a sequence labeling problem and we adopt a BLSTM-CRF model (Huang et al., 2015) to realize it. However, this model doesn't work very well on recognizing entity/type nodes as the entity phrases may be too long or too complex. Therefore, we first detect entity and type nodes by utilize existing entity linking algorithms of specific knowledge bases (see section 2.3), and then detect variable/literal nodes by the BLSTM-CRF model. A phrase w_{ij}, which contains the words from i to j in the question, is recognized as entity/type node if we can find entity/type mappings of w_{ij} through the entity linking algorithm. We check all possible phrases and select the longer one if two candidate nodes share any words. The detected entity/type nodes will be replaced by special tokens $\langle E\rangle$ or $\langle T\rangle$ before calling the BLSTM-CRF model.

In practice, we find that some nodes have hidden information, which can be expanded to a subgraph (i.e, one or multiple triples). For example, the hidden information of "?cosmonauts" in question N_1 in Figure 2 can extends two triples: ⟨?cosmonauts rdf:type dbo:Astronaut⟩ and ⟨?cosmonauts dbo:nationality dbr:Russia⟩. Such information can help us to reduce the matching space and make the answers more accurate.

We mine those nodes with hidden information from several QA benchmarks[1] and build a translation dictionary D^T in offline. Given a question N with the gold query graph Q^G, we try to match Q^G to the SQG Q^S generated by our approach. Each unmatched connected subgraph in Q^G is regarded as hidden information of the nearest matched node v. For the benchmarks only have gold question-answers pairs, we utilize the method in (Zhang and Zou, 2017) to mine the gold query graph first.

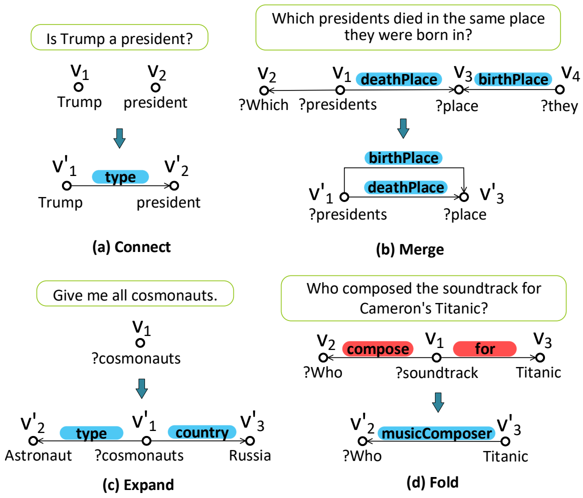

Figure 3: Samples of Operations

2.2 SQG's Structure Construction

As mentioned earlier, our SQG's structure is generated in a state-transition paradigm. Initially, the state only contains several *isolated* nodes that are recognized in the first step. To enable the state transition, we propose four primitive operations as follows.

1. **Connect**. Given two operate nodes u_1 and u_2, we introduce an edge $\overline{u_1u_2}$ between them by the connect operation. Note that the relation mention and candidate relations (predicates) of the edge $\overline{u_1u_2}$ can be found through relation extraction model (see section 2.3).

2. **Merge**. Given a SQG $Q^S = \{V, E\}$ and two operate nodes u,v, this operation is to merge the node u into v. The new SQG $Q'^S = \{V \setminus \{u\}, (E \setminus E^d) \cup E^a\}$, $E^d = \{\overline{uw} \in E\}$ and $E^a = \{\overline{vw} | \overline{uw} \in E \wedge w \neq v\}$. Notice that v also inherits the properties of u. The merge operation is designed to support co-reference resolution. The Figure 3(b) gives an example. For the question "Which presidents died in the same place they were born in?", the node v_2("which") is redundant and can be merged into v_1("presidents"). The node v_4("they") and v_1("presidents") are co-reference, we can merge v_4 to v_1. The edge $\overline{v_3v_4}$(birthPlace) is replaced by edge $\overline{v_3'v_1'}$(birthPlace).

3. **Expand**. Given a SQG $Q^S = \{V, E\}$ and the operate node $u \in V$, this operation is to expand u to a subgraph $Q_u^S = \{V_u, E_u\}$. The new SQG $Q'^S = \{V \cup V_u, E \cup E_u\}$. The expand operation is designed to those

---

[1] QALD, WebQuestions and ComplexQuestions, only the training sets are used to build the translation dictionary D^T.

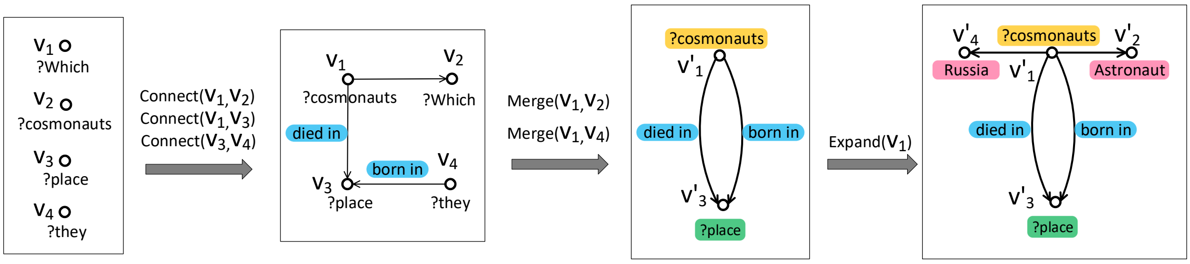

Figure 4: Semantic Query Graph Generation

nodes that have hidden information. Let us see Figure 3(c). The word "cosmonauts"(v_1) means "Russia astronauts", but it cannot be mapped to a certain entity or type in the knowledge base directly. To match "cosmonauts", we can expand it to an equivalent subgraph $\{v_1^{'}, v_2^{'}, v_3^{'}\}$ (according to the transition dictionary D^T) that can match the underlying knowledge base.

4. **Fold**. Given a SQG $Q^S = \{V, E\}$ and an operate node $u \in V$, this operation is to delete u and merge the associated relations. Formally, the new SQG $Q'^S = \{V \setminus \{u\}, (E \setminus E^d) \cup E^a\}$, in which $E^d = \{\overline{uv_i} \in E\}$ and $E^a = \{\overline{v_i v_j} | \overline{uv_i} \in E \wedge \overline{uv_j} \in E \wedge i \neq j\}$. The fold operation is designed to eliminate those nodes which are useless or mis-recognized. Figure 3(d) gives an example. For the question "Who composed the soundtrack for Cameron's Titanic?", SQG $\{v_1, v_2, v_3\}$ cannot find matches in knowledge base because there are no correct relations of $\overline{v_1 v_2}$ and $\overline{v_1 v_3}$. By applying a fold operation, these two edges with the redundant node v_1 are removed, while the new edge $\overline{v'_1 v'_2}$ can be matched to the correct relation $\langle$musicComposer$\rangle$ (according to the relation extraction model).

We focus on generating the correct SQG with the above operations. Obviously, it is impossible to enumerate all possible transitions in each step due to exponential search space. Therefore, we propose a greedy search algorithm[2] inspired by (Yih et al., 2015). The intention is that an better intermediate state should have more opportunities to be visited and produce subsequent states. As each state can be seen as a partial SQG, we propose a reward function using a log-linear model (see Section 3) to estimate the likelihood of each state. A priority queue is utilized to maintain the order of unvisited states. Each turn we choose the state with maximum correctness likelihood and try all possible transitions by each operation. Specifically, the connect and merge operations try every pair of nodes in current state as the two operate nodes, while the expand and fold operations try each node as the operate node. The newly generated states are estimated by the learning model and pushed into the priority queue. Note that reduplicated states will not be added. The algorithm ends when a complete SQG Q^S is found and Q^S can not generates any better subsequent states.

To reduce the search space of the state-transition process, we also propose several constraints for each operation. Only when the conditions are satisfied, the corresponding operation can be executed. Experiments show that those conditions not only speeds up the QA process but also improves the precision (see Section 4.4). The conditions are listed as follows.

Condition 1 (**Condition for Connect**) *Two nodes v_1 and v_2 can be connected if and only if there exists* no *other node v^* that occurs in the shortest path between v_1 and v_2 of the dependency parse tree*[3] *of question sentence N.*

Condition 2 (**Condition for Merge**) *For the merge operation, there should be at least one variable v in the two operate nodes. And v should be a wh-word or pronoun, which may co-reference*[3] *with an other node.*

Condition 3 (**Condition for Expand**) *For the expand operation, the operate node u should be a variable, and we need to be able to find u and its hidden information in the transition dictionary D^T.*

Condition 4 (**Condition for Fold**) *For the fold operation, we require at least one of the connected edges with the operate node have no relation candidates or the confidence probabilities of the corresponding relations are less than a threshold τ.*

---

[2] The formal algorithm can be found in Appendix A.

[3] We utilize the Stanford CoreNLP dependency parser and coreference annotator (Manning et al., 2014)

The following example illustrates the process of SQG generation. Note that it can have other transition sequences to get the final state.

Example 1 *Consider Figure 4. Given a question* N_1 *= "Which cosmonauts died in the same place they were born in?", we first extract four nodes* v_1*,* v_2*,* v_3*,* v_4*, which are all variable nodes. According the condition 1, we connect (*v_1*,*v_2*), (*v_1*,*v_3*), and (*v_3*,*v_4*). The simple path between* v_1 *and* v_3 *in the dependency parse tree can be regarded as the relation phrase of* $\overline{v_1 v_3}$*, which is "died in". Similarly, the relation phrase of* $\overline{v_3 v_4}$ *is "born in". As* v_1 *and* v_2 *are neighbors in the dependency parse tree, the corresponding relation phrase is empty. Then we merge (*v_1*,*v_2*) as they are recognized co-reference. Similarly* v_1 *and* v_4 *are merged. Notice that the associated edge* $\overline{v_3 v_4}$ *have been reserved, then there are two edges between* v_1' *and* v_3' *in the new SQG. In the end, we expand* v_1' *to the subgraph* $\{v_1', v_4', v_2'\}$ *and get the final SQG.*

2.3 Finding entity/relation candidates and matches of SQG

During SQG construction, there are two subtasks: entity extraction and relation extraction. We briefly discuss the two steps as follows.

Given a node phrase in Q^S, we find the candidate entities/types with confidence probabilities by using existing entity linking approaches. Specifically, we use S-MART (Yang and Chang, 2015) for Freebase dataset and DBpeida Lookup[4] for DBpedia dataset.

Given two connected nodes v_i and v_j in Q^S, we need to find the relation candidates between them. Inspired by the recent success of neural relation extraction models in KBQA (Yih et al., 2015; Dong et al., 2015; Xu et al., 2016), we propose a Multi-Channel Convolutional Neural Network (MCCNN) to extract all relations in the question N exploiting both syntactic and sentential information. We use the simple path between v_i and v_j in the dependency tree $Y(N)$ as input to the first channel. The input of second channel is the whole question sentence excluded all nodes, which represents the context of the relation we want to predict. If v_i and v_j are neighbors in $Y(N)$, we need to extract an implicit relation. To tackle this task, we use v_i, v_j and their types as input to the third channel. For v_i = "Chinese" and v_j = "actor", the input is "Chinese-Country-actor-Actor".

Different from (Xu et al., 2016) which can only extract one explicit relation, our model can not only extract multiple relations from N by taking different node pairs, but also extract the implicit relation considering the embedded information in the two nodes v_i and v_j.

After generating the SQG Q^S, we employ the subgraph matching algorithm (Hu et al., 2018) to find matches of Q^S over the underlying RDF knowledge graph G. Once the matches are found, it is straightforward to derive the answers.

3 Learning the reward function

Given an intermediate state s during SQG generation process, we may transit to multiple subsequent states s' by applying different operations. Thus, we greedily select a subsequent state s' with the maximum $\gamma(s')$, where $\gamma()$ is a reward function taking the features and outputting the reward of corresponding state. In this work, the reward function $\gamma()$ is a linear model trained with the SVM ranking loss. Below we describe the features, learning process and how to generate the training data.

3.1 Features

Note that for any intermediate state s, we also regard it as a SQG $Q^S(s)$ even though it is a disconnected graph. For a given SQG Q^S, we extract the following features which are passed as an input vector to the SVM ranker.

Nodes. For each entity/type node v, we utilize entity linking systems to find the candidate entities or types and corresponding confidence probabilities. We use the largest confidence probability as the score of v, and use the average score of all entity nodes as the feature. In addition, the number of constant nodes and variable nodes in current Q^S are considered as features.

Edges. For each edge $\overline{v_i v_j}$, the relation extraction model returns a list of candidate predicates with the corresponding confidence probabilities. We use the largest confidence probability as the score of $\overline{v_i v_j}$, and use the average score of all edges as the feature. We also consider the total number of edges in Q^S, the number of edges which have relation phrase and which have no relation phrase.

Matches. We also consider the matching between Q^S and the knowledge graph G. A new state s would get a low score if its corresponding

---

[4] http://wiki.dbpedia.org/projects/dbpedia-lookup

SQG Q^S could not find any matches in G. We do not discard s directly from the search queue as we allow the fold operation of it. To speed up the matching process, we build the index of all entities and relations in offline. For a given SQG Q^S, we use the offline index to check whether it is valid.

Given a valid state s, if all of its possible subsequent states s' have smaller reward function value than that of s, we will terminate the state transition process and return s as the final state. The corresponding SQG $Q^S(s)$ is used to match the knowledge base to retrieve answers.

3.2 Learning

The task of reward function can be viewed as a ranking problem, in which the appropriate SQGs should be ranked in the front. In this work, we rank them using a SVM rank classifier (Joachims, 2006).

Given a SQG $Q^S = \{V, E\}$, the ranking score that we use to train our reward function $\gamma()$ is calculated by the following function.

$$R(Q^S) = \frac{|P(V)|}{|V'|} + \frac{|P(E)|}{|E'|} + \max(F(A_i, A')) \tag{1}$$

V' and E' are the gold node set and relation set extracted from the gold SPARQL query. $P(V)$ contains the nodes existing in both V and V'. $P(E)$ contains the relations existing in both E and E'. $F(A_i, A')$ is the F-1 measure where A' is the gold answer set and A_i is one of the subgraph matches between Q^S and knowledge graph G obtained by the executing method in (Hu et al., 2018). Notice that for the benchmark without gold SPARQL queries, $R(Q^S) = max(F(A_i, A'))$.

3.3 Generating Training Data

To generate the training data of the reward function, given a question $N = \{w_1, w_2, ..., w_n\}$, we first check all possible phrases w_{ij} by existing entity linking system and get the candidate entity list $C_{v_i} = \{e_1, e_2, ..., e_m\}$ for each entity node v_i. If two entity node v_i and v_j have conflict, i.e, v_i and v_j share one or more words, we reserve the longer one. We replace each entity node v_i with a special token to denote the type of entity e_j, where $e_j \in C_{v_i}$ and has the largest confidence possibility. Then the whole node set V can be predicted by the well-trained node recognition model. $Q^S = \{V, \phi\}$ is the initial state. Further we do state transition by applying the predefined operations using a BFS algorithm. Meanwhile, only the states satisfied with corresponding conditions are considered if enabling the condition mechanism. Once we get a new Q^S we call the well-trained relation extraction model to get the relation candidate list of each new edge $\overline{v_i v_j} \in E$, while the features are collected according Section 3.1 and the ranking score is calculated using Equation 1.

4 Evaluation

We evaluate our system on several benchmarks with two knowledge base DBpedia and Freebase. For DBpedia, we use the QALD-6 benchmark. We compare our method STF (State Transition Framework) with all systems in QALD-6 competition as well as Aqqu (Bast and Haussmann, 2015), gAnswer (Zou et al., 2014) and NFF (Hu et al., 2018). For Freebase, we use WebQuestions (Berant et al., 2013) and ComplexQuestions (Abujabal et al., 2017) as benchmarks and compare our method with corresponding state-of-art systems.

4.1 Setup

4.1.1 Knowledge Bases

DBpedia RDF repository is a knowledge base derived from Wikipedia (Bizer et al., 2009). We use the version of DBpedia 2014 and the statistics are given in Table 1.

Freebase is a collaboratively edited knowledge base. We use the version of Freebase 2013, which is same with (Berant and Liang, 2014). The statistics are given in Table 1.

4.1.2 Benchmarks

QALD is a series of open-domain question answering campaigns, which have several different tasks. We only consider the task of English question answering over DBpedia in QALD-6 (Unger et al., 2016), which has 350 training questions and 100 test questions, with gold SPARQL queries and answer sets.

WebQuestions (Berant et al., 2013) consists of 3778 training questions and 2032 test questions, which are collected using the Google Suggest API and crowdsourcing. It only provides the pairs of question and answer set.

ComplexQuestions (Abujabal et al., 2017) is composed of 150 test questions that exhibit compositionality through multiple clauses, which is constructed using the crawl of WikiAnswers (http://wiki.answers.com) and human annotator. It has no training questions and SPARQL queries.

Table 1: Statistics of Knowledge Bases

	DBpedia	Freebase
Number of Entities	5.4 million	41 million
Number of Triples	110 million	596 million
Number of Predicates	9708	19456
Size of KBs (in GB)	8.7	56.9

Table 2: The average F1 score of WebQuestions and ComplexQuestions benchmark

	WQ	CQ
STF (Our approach)	**53.6%**	**54.3%**
STAGG (Yih et al., 2015)	52.5%	-
QUINT (Abujabal et al., 2017)	51.0%	49.2%
NFF (Hu et al., 2018)	49.6%	-
Aqqu (Bast and Haussmann, 2015)	49.4%	27.8%
Aqqu++ (Bast and Haussmann, 2015)	49.4%	46.7%

4.2 Results on WebQuestions and ComplexQuestions

Table 2 shows the results on the test set of WebQuestions(WQ) and ComplexQuestions(CQ), which are based on the Freebase. We compare our system with STAGG (Yih et al., 2015), QUINT (Abujabal et al., 2017), NFF (Hu et al., 2018) and Aqqu(Bast and Haussmann, 2015). QUINT is the model used in the original ComplexQuestions paper and Aqqu is the best publicly available QA system on WebQuestions. The average F1 of our system (53.6% for WQ and 54.3% for CQ) are better than the other systems.

Aqqu defines three query templates for WebQuestions and try to match test questions to predefined templates. It has a poor performance (27.8%) on ComplexQuestions when answering the test questions directly. Aqqu++ shows the result (46.7%) by taking manually decomposed subquestions as input and getting the intersection of subquestions' answer sets. QUINT is a system that automatically learns utterance-query templates from the pairs of question and answer set. NFF builds a relation paraphrase dictionary and leverages it to extract relations from the questions. STAGG proposes a state-transition based query graph generation method. However, its query graph structure is limited as in the Figure 1, which is very similar with the templates of Aqqu.

To generate the training data of relation extraction model on the WebQuestions, for each two nodes u and v in the training question, we explore all simple relations between u and v in Freebase. Note that if u or v is the answer node, we will anchor the answer entity first and select the relation which can handle most of answer entities as the gold relation. Each entity will be replaced in text by a special token representing its type before training. As there are no training data in ComplexQuestions, we use the models trained on WebQuestions directly.

Table 3: Evaluating QALD-6 Testing Questions

	Processed	Right	Recall	Precision	F-1
Our approach	100	70	0.72	0.89	0.80
CANaLI	100	83	0.89	0.89	**0.89**
UTQA	100	63	0.69	0.82	0.75
KWGAnswer	100	52	0.59	0.85	0.70
SemGraphQA	100	20	0.25	0.70	0.37
UIQA1	44	21	0.63	0.54	0.25
UIQA2	36	14	0.53	0.43	0.17
NFF	100	68	0.70	0.89	0.78
gAnswer	100	40	0.43	0.77	0.55
Aqqu	100	36	0.37	0.39	0.38

Generally, WebQuestions benchmark has low diversity and contains some incorrect or incomplete labeled answers. Most of questions in WebQuestions are simple questions, which can be translated to a "one-triple" query. The results on WebQuestions benchmark prove our approach is able to obtain good performance on simple questions. ComplexQuestions benchmark is more complex than WebQuestions. The experiments results show that the two template based methods QUINT and Aqqu can solve a part of the complex questions. However, it still lack of the capacity to tackle all questions due to the error of dependency parse or the mismatch of the templates. On the other hand, our system outperforms them because we do not rely on templates and have better generalization ability to solve complex questions.

4.3 Results on QALD

Table 3 shows the evaluation results on the test set of QALD-6. We compare our system with all participants of QALD-6 as well as gAnswer (Zou et al., 2014), NFF (Hu et al., 2018) and Aqqu (Bast and Haussmann, 2015). To enable the comparison, we show the experiment results in the QALD competition report format. "Processed" denotes the number of questions can be processed and "Right" refers to the number of questions that were answered correctly. Our approach can answer 70 questions correctly, and get the 0.80 F-1 score.

The experiment results show that we can beat all systems in QALD-6 campaign in F-1 except for CANaLI (Mazzeo and Zaniolo). Note that CANaLI is not an automatic QA system, as it needs users to specify the precise entities and predicates in the question sentences. gAnswer (Zou et al., 2014) proposes a relation first framework to generate the semantic query graph while it can not detect implicit relations. NFF (Hu et al., 2018) proposes a node first framework which performs well on answering complex ques-

Table 4: The performance comparison of state transition with conditions or without conditions in QALD-6 test set

	Right	Recall	Precision	F-1
with condition	70	0.72	0.89	0.80
no condition	62	0.64	0.84	0.72

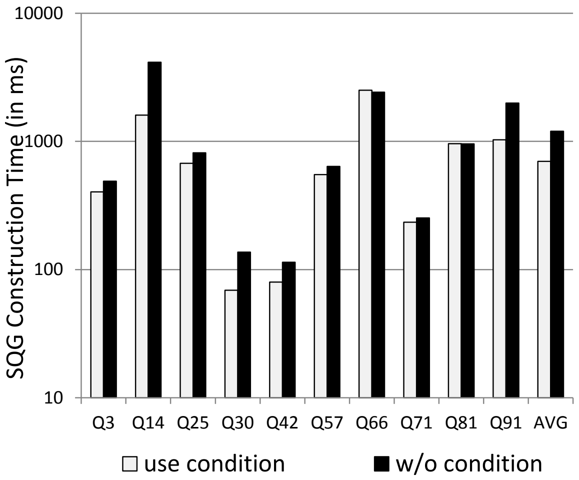

Figure 5: The elapsed time comparison of state transition with conditions or without conditions in QALD-6 test set

tions (0.78 F1 score on QALD-6). However it relies on the predefined paraphrasing dictionaries to extract relations and could not tackle with redundant nodes.

As QALD has the gold SPARQL queries, we can obtain the training data of node recognition and relation extraction model directly. Different from the WebQuestions and ComplexQuestions which have only special questions, the QALD benchmark also has general questions and imperative sentence. Besides, there are some questions that have no entities or multiple entities.

Generally, QALD benchmark has both high diversity and quality. The performance of Aqqu in QALD is worse than its performance in WebQuestions and ComplexQuestions as it has only designed the templates to WebQuestions. In contrast, our approach do not rely specific benchmark or knowledge base. The evaluation results show that our approach performs well on various types of complex questions.

4.4 Comparison experiments of the four conditions

We run experiments on QALD-6 test set to verify the effectiveness of the four conditions proposed in Section 2.2. We first compare the elapsed time of state transition with conditions or without conditions. Figure 5 shows the results of 10 questions selected randomly and AVG means the average time consumption among all 100 test questions. The average elapsed time with conditions is 700 ms while it rises to 1200 ms without the conditions. The results declare that using the conditions in the search process can avoid unnecessary searches and save SQG construction time. In some questions (such as Q66 and Q81), the gap of elapsed time are very little because the number of recognized nodes are less than three. In other words, those simple questions do not need the conditions to speed up the SQG construction process.

Table 5: Failure Analysis on QALD-6

Reason	**# (Ratio)**	**Sample question**
Structure Failure	6 (20%)	Q55: In which countries do people speak Japanese?
Entity Mapping	5 (17%)	Q88: What color expresses loyalty?
Relation Mapping	10 (33%)	Q44: What is the full name of Prince Charles?
Complex Aggregation	9 (30%)	Q80: How short is the shortest active NBA player?

On the other hand, using conditions can improve the evaluation performance (see Table 4). That because the conditions help system to reduce search space and avoid local optimum, especially the condition of connect operation. When the question has multiple nodes, if we do not use the condition of connect operation, it tries to connect each two nodes and enrolls too many mistaken states.

4.5 Error Analysis

We provide the error analysis of our approach on QALD-6 test set (100 questions), which contains gold SPARQL queries and more diversified questions. The ratio of each error type and the corresponding examples are given in Table 5.

There are mainly four reasons for the failure of some questions in our approach. The first reason is the structure failure, which means we generate a wrong SQG. That usually occurred when the correct SQG needs a fold operation. For example, the correct SQG of question "In which countries do people speak Japanese" has only two nodes "countries", "Japanese". However, we recognized the phrase "people" as a variable node by mistake and connected it to both "countries" and "Japanese" to generate a wrong SQG $Q^{S'}$. It should be eliminated by the fold operation to get the correct SQG Q^S. However, the score of $Q^{S'}$ that we get from the reward function is higher than the score of Q^S. The inherent reason is the lack of training data.

The second reason is the failure of entity linking, for example, we could not find the correct entity of the node “loyalty” in the question “What color expresses loyalty?”. It has smallest proportion as the existing entity linking algorithms already have high accuracy on QA task.

The third reason is the failure of relation extraction. For example, the correct relation between “What” and “Prince Charles” in the question ‘What is the full name of Prince Charles?” is ⟨alias⟩. However, we got a wrong relation ⟨name⟩. The relation extraction problem is very important to QA task, which can be improved by designing more elegant models and combining more useful information.

The last one is that our method cannot answer some complex aggregation questions, which need to detect the aggregation constraint first and then infer the related node and corresponding relation. Using predefined templates or utilizing textual evidence maybe works but not good enough.

5 Related Work

Generally, the solutions of KBQA can be divided into *information retrieval-based* and *semantic parsing-based* methods. The general process of *information retrieval-based* methods is to select candidate answers first and then rank them by various methods(Veyseh, 2016; Dong et al., 2015; Xu et al., 2016; Bordes et al., 2014; Yao and Durme, 2014). The main difference among *information retrieval-based* methods is how to rank the candidate answers. (Bordes et al., 2014) utilizes subgraph embedding to predict the confidence of candidate answers. (Dong et al., 2015) maximize the similarity between the distributed representation of a question and its answer candidates using Multi-Column Convolutional Neural Networks (MCCNN), while (Xu et al., 2016) aims to predicate the correct relations between topic entity and answer candidates with text evidence.

The *semantic parsing-based* methods try to translate the natural language question into semantic equivalent logical forms, such as simple λ-DCS (Berant et al., 2013; Berant and Liang, 2014), query graph (Yih et al., 2015; Zou et al., 2014), or executable queries such as SPARQL (Bast and Haussmann, 2015; Unger et al., 2012; Yahya et al., 2012). Then the logical forms are executed by corresponding technique and get the answers from knowledge base. For answering complex questions, the key is how to construct the logical form. Different from existing systems relying on the predefined templates, we build the query graph by state transition, which has stronger representation power and more robustness.

(Dong and Lapata, 2016) trains a sequence to tree model to translate natural language to logical forms directly, which needs a lot of training data. (Yu et al., 2017) uses deep bidirectional LSTMs to learn both relation-level and word-level question/relation representations and match the question to candidate relations. The pipeline of (Yu et al., 2017) is similar with (Yih et al., 2015), which detect topic entity and relation first and then recognize constraints by enumerating all connected entities of answer node or CVT node in knowledge base. The issue is they assume the question N only have one relation, which is from the topic entity to the answer. Different from (Yu et al., 2017), we consider the question can have many nodes (including entities and variables) and recognize them by a BLSTM model. We also allow multi relations between these nodes and extract them by the MCCNN model.

6 Conclusions

In this paper, we propose a state transition framework to utilize neural networks to answer complex questions, which generates semantic query graph based on four primitive operations. We train a BLSTM-CRF model to recognize nodes including entities and variables from the question sentence. To extract the relations between those nodes, we propose a MCCNN model which can tackle both explicit and implicit relations. Comparing with existing solutions, our framework do not rely on handcrafted templates and has the potential to generate all kinds of SQGs given enough training data. Extensive experiments on multi benchmark datasets confirm that our approach have the state-of-art performance.

Abstract

The task of machine reading comprehension (MRC) has evolved from answering simple questions from well-edited text to answering real questions from users out of web data. In the real-world setting, full-body text from multiple relevant documents in the top search results are provided as context for questions from user queries, including not only questions with a single, short, and factual answer, but also questions about reasons, procedures, and opinions. In this case, multiple answers could be equally valid for a single question and each answer may occur multiple times in the context, which should be taken into consideration when we build MRC system. We propose a multi-answer multi-task framework, in which different loss functions are used for multiple reference answers. Minimum Risk Training is applied to solve the multi-occurrence problem of a single answer. Combined with a simple heuristic passage extraction strategy for overlong documents, our model increases the ROUGE-L score on the DuReader dataset from 44.18, the previous state-of-the-art, to 51.09.

1 Introduction

Machine reading comprehension (MRC) or question answering (QA) has been a long-standing goal in Natural Language Processing. There is a surge of interest in this area due to new end-to-end modeling techniques and the release of several large-scale, open-domain datasets.

In earlier datasets (Hermann et al., 2015; Hill et al., 2016; Yang et al., 2015; Rajpurkar et al., 2016), the questions did not arise from actual end users. Instead, they were constructed in cloze style or created by crowdworkers given a short passage from well-edited sources such as Wikipedia and CNN/Daily Mail. As a consequence, the questions are usually well-formed and about simple facts, and the answers are guaranteed to exist as short spans in the given candidate passages.

In MS-MARCO (Nguyen et al., 2016), the questions were sampled from actual search queries, which may have typos and may not be phrased as questions.[1] Multiple short passages, which might have the answer to the query, were extracted from webpages by a separate information retrieval system.

He et al. (2017) made the DuReader dataset a more realistic reflection of the real-world problem by including not only questions with relatively short and factual answers, but also questions about complex descriptions, procedures, opinions, etc. which may have multiple, much longer answers, or no answer at all. Furthermore, full-body text from webpages listed in top search results are directly provided as context. These documents tend to be much noiser than Wikipedia and CNN. They are much longer (5 times longer than those in MS-MARCO on average) and contain many paragraphs that are irrelevant to the query.

New problems arise as we now consider the task of machine reading comprehension in a much more challenging real-world setting. First, multiple valid answers to a single question are not only possible but quite common. Figure 1 shows some examples of questions with multiple answers from the DuReader dataset. There could be multiple ways to perform the same task (Question 1), multiple opinions about the same subject (Question 2), or multiple explanations for the same observation (Question 3). However, few works have been done with multiple answers in machine reading comprehension. To address this problem, we propose a multi-answer multi-task scheme which incorporates multiple reference answers in the objective

[1] We use these two terms, question and query, interchangeably in the following content

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2109–2118
Brussels, Belgium, October 31 - November 4, 2018.

Question 1:
word字间距
character spacing in Word
Answers:
1. 选择要缩进的内容，点击右键选择字体，打开“字体”对话框，选择“字符间距”选项卡，勾选“为字体调整字间距”并输入数字，最后单击“确定”按钮。
2. 选中你要设置字符间距的文字后，单击鼠标右键，选择字体选项，在切换到字符间距。
3. 点击上部菜单栏上“格式”→“字体”→“字符间距”，调节间距的磅值即可。
1. Select the text you want to indent, and right-click on it to select Font, open the Font dialog box, and then select the Character Spacing tab, select the Kerning for fonts check box, and enter a number, at last click OK.
2. Select the text you want to set character spacing, and right-click on it to select Font, and then switch to Character Spacing.
3. click Format from the upper menu bar, select Font, select Character Spacing, and then change the point size.

Question 2:	
龙珠传奇好看吗	Is LONGZHU worth watching?
Answers:	
1. 好看的、节奏还可以、萌萌的甜甜的。	1. It is, the pace is good and it's adorable and sweet.
2. 不好看，个人不喜欢那种类型的电视剧。	2. It’s not, personally I don’t like that kind of TV series.
3. 还行，不纠结历史问题的话可追。	3. It’s ok, it’s fine to follow if you don’t care about the historical accuracy.

Question 3:	
响一声就说正在通话中	Got “User Busy” message after one ring
Answers:	
1. 别人对你设置了黑名单。	1. Your number is in that person’s blacklist.
2. 别人挂了你的电话。	2. The person you called hung up on you.

Figure 1: Examples of questions with multiple answers from the DuReader dataset

function (but still predicts a single answer in decoding time). We propose three different kinds of multi-answer loss functions and compare their performance through experiment.

Another problem is the multiple occurrences of the same answer. As rich context is provided for a single question, the same answer could occur more than one time in different passages, or even at different places of the same passage. In this case, using only one gold span for the answer could be problematic, as the model is forced to choose one span over others that contain the same content. To solve this problem, we propose to apply Minimum Risk Training (MRT), which uses the expected metric as the loss and gives reward to all spans that are similar with the gold answer.

In this paper, we present a multi-answer, multi-task objective function to train an end-to-end MRC/QA system. We experiment with various alternatives on the DuReader dataset and show that our model out-performs other competing systems and increases the state-of-the-art ROUGE-L score by about 7 points.

2 Related Work

Various datasets have been released in recent years, which fuel the research for reading comprehension and question answering. The CNN/Daily-Mail dataset (Hermann et al., 2015) and the Children’s Book Test (Hill et al., 2016) evaluate comprehension by filling in missing words from well-edited texts. SQuAD (Rajpurkar et al., 2016) is one of the most popular datasets for reading comprehension, where a span in a Wikipedia passage is to be extracted to answer questions generated by annotators. The WikiQA (Yang et al., 2015) is another dataset from Wikipedia, where one single sentence is to be selected to answer questions from search engine logs. Different from the above datasets, the MS-MARCO dataset (Nguyen et al., 2016) was built in a real-world setting. The questions were real anonymized Bing queries and multiple passages are extracted from related web pages by a separate system. The DuReader (He et al., 2017) is a Chinese dataset, similarly constructed from user queries as MS MACRCO, but in a more realistic setting using Baidu Web Search and Baidu Answers (Zhidao) data. While a small proportion of questions were labeled with multiple answers in MS MARCO (9.93%), more than half of the DuReader queries were annotated with multiple answers, which provides the perfect setup for our work.

Great effort has been put into the development of sophisticated neural models for machine reading comprehension. The attention mechanism was first introduced by Hermann et al. (2015) into reading comprehension and soon became the dominating model. Wang and Jiang (2017) proposed to solve machine comprehension using Match-LSTM and answer pointer. Seo et al. (2017) and Xiong et al. (2017) applied different ways to match the question and the context with bi-directional attention. Hu et al. (2017) used iterative aligner to match the question and the passage with feature-rich encoder. Cui et al. (2017) employed one more layer of attention over the bi-directional attention mechanism. Wang et al. (2017) applied a self-matching mechanism to aggregate evidence from the context. Tan et al. (2018) proposed to generate answer from extracted answer span. Yu et al. (2018) proposed to use convolution with self-attention instead of recurrent models in reading comprehension.

Recently there are some emerging works starting to touch the reading comprehension task from the answer side. Wang et al. (2018a) proposed to use evidence aggregation to re-rank answer candidates extracted from different passages, and Wang et al. (2018b) proposed Cross-Passage Answer Verification model for the same purpose. Neither of them involved multiple answers as in this work.

Minimum Risk Training (MRT) has been widely used in various tasks in NLP. Shen et al. (2016) introduced MRT into Neural Machine Translation, and Ayana et al. (2016) applied it in Text Summarization.

3 Our Approach

In this section we describe in details the architecture of our model which is depicted in Figure 2.

3.1 Passage Extraction

Unlike most other datasets where the source of answers is a short passage with a few hundred words, the DuReader dataset provides up to 5 full documents, which may contain up to 100K words. This incurs exorbitant demand on memory and training time. To deal with this issue, previous approaches select a single representative paragraph for each document, on which the answer extraction is performed. The original paper of DuReader (He et al., 2017) employed a simple heuristic strategy, and Wang et al. (2018b) trained a paragraph ranking model, while Clark and Gardner (2017) applied TF-IDF based method for the TriviaQA dataset (Joshi et al., 2017) which was in a similar situation. However, answers could come from more than one paragraph. We apply a simple yet effective method to extract contents from multiple paragraphs of the document, aiming to include as much information for the answer extraction as possible.

We concatenate the title and the whole document as the passage if it is shorter than a predefined maximum length. If not, we employ passage extraction in the following way:

- The title of the document is extracted. Whether a document is relevant to the question could be easily seen from the title.
- We compute BLEU-4 score of each paragraph relative to the question, and select the one that appears first in the document among paragraphs with top-k scores.
- We extract the full body of this selected paragraph and the next paragraph.
- For each of the following paragraphs, the first sentence is extracted as it probably contains the main point.
- We concatenate all the extracted contents to form the extracted passage, and it is truncated to the maximum length if it is longer than the predefined value.

We apply our model on the basis of the extracted passages.

3.2 Representation of Word

Given a word sequence of question $Q = \{w_t^q\}_{t=1}^m$, and a word sequence of extracted passage $P = \{w_t^p\}_{t=1}^n$, we combine different useful information to form the representation of each question word w_t^q and passage word w_t^p:

- Word-level embedding: each word w in the question and passage is mapped to its corresponding n-dimensional embedding we.
- POS tag embedding: we use a POS tagger to tag each word in the question and passage. Each POS tag is mapped to a m-dimensional embedding pe.
- Word-in-question feature: following Chen et al. (2017) and Weissenborn et al. (2017), we use one additional binary feature wiq for each passage word, indicating whether this word occurs in the question.

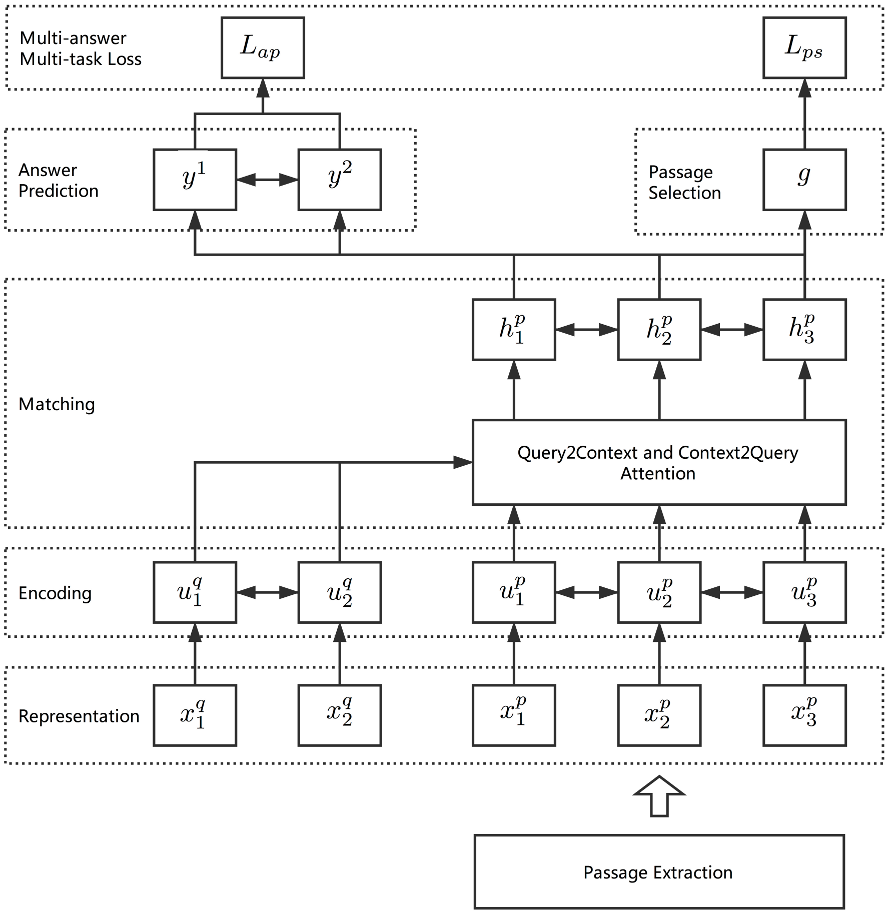

Figure 2: Model Architecture

Each question word is represented as the concatenation of the word embedding we, and the POS tag embedding pe, denoted as $x^q = [we; pe]$. Each passage word is additionally concatenated with the word-in-question feature wiq: $x^p = [we; pe; wiq]$.

It should be noted that, character-level embedding is an important part of word representation in English MRC models (Seo et al., 2017; Weissenborn et al., 2017; Wang et al., 2017; Tan et al., 2018). Character sequence would give information which helps to relieve the OOV problem, as many English words share the same stem and differ only in prefix or suffix. However, this is not the case in Chinese, and we observe no significant improvement incorporating character-level embedding into our system.

3.3 Encoding Layer

Following previous work, we use a bi-directional LSTM to obtain contextual encoding for each word in the question and passage respectively:

$$u_i^q = BiLSTM(u_{i-1}^q, x_i^q) \tag{1}$$

$$u_j^p = BiLSTM(u_{j-1}^p, x_j^p) \tag{2}$$

3.4 Match Layer

To fuse question encoding and passage encoding, we adopt the Attention Flow Layer (Seo et al., 2017) with a simpler similarity function. The similarity score between the contextual encoding for a query word u_i^q and that for a passage word u_j^p is defined as:

$$s_{ij} = u_i^{qT} \cdot u_j^p \tag{3}$$

The context-to-query attention vectors c_j^p are computed from the similarity scores:

$$a_{ij} = \frac{exp(s_{ij})}{\sum_{k=1}^{m} exp(s_{kj})} \tag{4}$$

$$c_j^p = \sum_{i=1}^{m} a_{ij} u_i^q \tag{5}$$

The query-to-context attention vector d^p is computed as:

$$z_j = \max_i s_{ij} \tag{6}$$

$$b_j = \frac{exp(z_j)}{\sum_{k=1}^{n} exp(z_k)} \tag{7}$$

$$d^p = \sum_{j=1}^{n} b_j u_j^p \tag{8}$$

Another BiLSTM is applied on top of them to get the question-aware passage representation:

$$h_j^p = BiLSTM(h_{j-1}^p, [u_j^p; c_j^p; u_j^p \circ c_j^p; u_j^p \circ d^p]) \tag{9}$$

3.5 Multi-answer multi-task loss function

3.5.1 Answer prediction with multi-answer

A reading comprehension model is typically trained as an extractor of an answer span from a candidate passage. In DuReader dataset, multiple reference answers are provided for a single question. For each of the reference answers, we add the span with the highest F1 score to the gold answer spans. For models considering only a single answer span (baseline model), the gold answer span is the one with the highest F1 score relative to any of the reference answers (He et al., 2017; Wang et al., 2018b).

In the boundary model with pointer network (Wang and Jiang, 2017; Wang et al., 2017; Tan et al., 2018), two probability distributions y_j^1 and y_j^2 $(j = 1 \ldots n)$, which denote the probability that position j is the beginning or the end of the answer span respectively, are computed as follows:

$$s_j^t = v^T tanh(W_h^p h_j^p + W_a^P h_{j-1}^a) \tag{10}$$

$$y_j^t = \frac{exp(s_j^t)}{\sum_{k=1}^{n} exp(s_k^t)} \tag{11}$$

$$c_t = \sum_{j=1}^{n} y_j^t h_j^p \tag{12}$$

$$h_t^a = BiLSTM(h_{t-1}^a, c_t) \tag{13}$$

where $t = 1, 2$, and the initial hidden state h_0^a is generated by an attention-pooling over the question representation following Wang et al. (2017):

$$s_i = v^T tanh(W_u^q u_i^q + b) \tag{14}$$

$$a_i = \frac{exp(s_i)}{\sum_{k=1}^{m} exp(s_k)} \tag{15}$$

$$h_0^a = \sum_{i=1}^{m} a_i u_i^q \tag{16}$$

Note that all passages for the same question are concatenated in order to predict one answer span. The loss is defined as the sum of negative log probabilities of the ground truth start and end position based on the predicted distributions:

$$L = -(\log y_{start}^1 + \log y_{end}^2) \tag{17}$$

We propose three different ways to incorporate multiple answers. A simple solution is to compute the average loss for multiple answer spans:

$$L_{avg} = -\frac{1}{A} \sum_{k=1}^{A} (\log y_{start_k}^1 + \log y_{end_k}^2) \tag{18}$$

L_{avg} treats all answer spans as equally good. However, some of them may be closer to human-generated answers than others. We therefore define the weighted average loss as follow:

$$L_{wavg} = -\sum_{k=1}^{A} w_k (\log y_{start_k}^1 + \log y_{end_k}^2) \tag{19}$$

where w_k is the F-score between the answer span and the corresponding human-generated answer, normalized by the sum of the scores of each answer.

Another solution is to use the minimal value of the loss from each span:

$$L_{min} = \min_k (-(\log y_{start_k}^1 + \log y_{end_k}^2)) \tag{20}$$

Instead of predicting all answer spans, this loss will encourage the model to predict only the easiest answer span for it.

The answer span prediction loss L_{ap} is defined as the average of any of the loss functions described above over the training set.

3.5.2 Passage selection with multi-answer

Tan et al. (2018) showed that their single-answer, multi-passage MRC model benefits from using multi-task learning by adding an auxiliary loss to predict the correct passage to extract the answer from. We adapt the idea to compute passage selection loss L_{ps} in multi-answer setting.

We first apply attention-pooling over the passage representation $\{h_j^p\}_{j=1}^n$, and then calculate a matching score g for each passage:

$$s_j = v^T tanh(W_u^p h_j^p + b) \tag{21}$$

$$a_j = \frac{exp(s_j)}{\sum_{k=1}^n exp(s_k)} \tag{22}$$

$$r^p = \sum_{j=1}^n a_j h_j^p \tag{23}$$

$$g = sigmoid(v_{sp}^T r^p) \tag{24}$$

Since multiple answers are provided in the DuReader dataset, multiple passages may contain correct answers. The match score g for different passages are not in competition against one another. We therefore used pointwise sigmoid function instead of the softmax function (as in Tan et al. (2018)) in the passage selection loss L_{ps}:

$$\begin{aligned} L_{ps} = -\frac{1}{K}\sum_{k=1}^K (y_k \log g_k \\ +(1-y_k)\log(1-g_k)) \end{aligned} \tag{25}$$

where $y_k = 1$ if one of the gold span comes from this passage, $y_k = 0$ otherwise.

3.5.3 Joint training

We train our model by jointly optimizing answer span prediction loss and passage selection loss:

$$L = L_{ap} + \lambda_{ps} L_{ps} \tag{26}$$

where λ_{ps} is a hyper-parameter tuned on the dev set.

3.6 Minimum Risk Training

Minimum Risk Training (MRT) has been widely used in various tasks in NLP. The basic idea is to directly optimize the evaluation metric instead of maximizing the log likelihood of training data using Maximum Likelihood Estimation (MLE) as described above. In MRT, the object is to minimize the expected loss with respect to the posterior distribution:

$$J_{MRT}(\theta) = \frac{1}{N}\sum_{i=1}^N \mathbb{E}_{y_i|x_i;\theta}[\Delta(y_i, y_i^*)] \tag{27}$$

where $\Delta(y_i, y_i^*)$ is a function which indicates the difference between the predicted result y_i and the label result y_i^*.

In this work, we apply MRT to solve the problem of multi-occurrence of answer in machine reading comprehension, directly using the metric (ROUGE-L) as Δ. As an answer occurs multiple times in the context, each span in which the answer occurs will have minimum difference with the answer, and is thus given a high score by a model trained with MRT.

In machine translation and many other tasks, to compute the expected metric with respect to the posterior distribution is often intractable. Thus sampling methods are commonly used in MRT training. However, in our span extraction model, we use all spans without sampling.

Formally, the MRT loss in our model is defined as:

$$J_{MRT}(\theta) = \frac{1}{N}\sum_{i=1}^N \sum_{k=1}^{|P|} \sum_{l=k+1}^{|P|} y_k^1 y_l^2 \Delta(P_{k,l}, A) \tag{28}$$

As in Hu et al. (2017), we minimize the linear combination of MLE and MRT loss:

$$J(\theta) = J_{MLE}(\theta) + \lambda J_{MRT}(\theta) \tag{29}$$

where $J_{MLE}(\theta)$ refers to L in equation 26 and λ is a hyper-parameter tuned on the development set.

4 Experiment

We conduct our experiment on the DuReader dataset (He et al., 2017), where multiple passages containing full-body text are provided for each question, and over half of the questions have multiple answers.

4.1 Dataset and Evaluation Metrics

The DuReader dataset consists of 201574 questions in total, with 181574 in the training set, 10000 in the development set, and 10000 in the test set. The questions are sampled from frequently occurring queries from Baidu search engines, and the full-body text of top-5 search results from the web are provided as the context.

BLEU-4 and ROUGE-L are used in evaluation on DuReader. However, the implementations for the two metrics are quite different in the official evaluation tool. As in MS-MARCO, the BLEU-4 score is normalized across all questions, essentially giving different weights to different questions, while the ROUGE-L is averaged across different questions. We mainly focus on ROUGE-L as each question in a reading comprehension

Model	**ROUGE-L**	**BLEU-4**
BiDAF baseline	37.68	35.51
+ passage extraction	44.57	38.03
+ rich feature	**48.93**	**42.17**

Table 1: The influence of passage extraction and rich-feature representation on the development set

Loss	**ROUGE-L**	Δ
single answer	48.93	-
L_{min}	49.05	+ 0.12
L_{avg}	49.67	+ 0.74
L_{wavg}	**49.77**	**+ 0.84**

Table 2: Comparison among different choices for the loss function with multiple answers on the development set

dataset should have equal weight in evaluation (Tan et al., 2018). For a single question with multiple reference answers, the maximum score with any reference answers is used, as implemented in the official tool for ROUGE-L. This is reasonable as providing one valid answer is good enough in many cases.

4.2 Implementation Details

4.2.1 Word and POS Tag Embedding

We train a segmentation model with one-layer BiLSTM using the DuReader dataset, and apply it to a subset of SogouT corpus[2], which contains a large amount of Chinese web pages(Liu et al., 2012). 256-dimension word embeddings are trained on this data with language model task using one-layer BiLSTM model.

As for POS tag, we use a POS tagger trained on the Chinese Treebank (CTB) data to tag each word in questions and passages in the DuReader dataset. 64-dimension POS tag embeddings are trained on this data using one-layer BiLSTM model.

We keep all word and POS tag embeddings fixed during training.

4.2.2 Training and Parameters

The maximum length of each passage is set to be 500. The batch size is set to be 32. The dimension of hidden vector is set to be 150 for all layers. Dropout (Srivastava et al., 2014) is applied between layers, with a dropout rate of 0.15. We use $\lambda_{ps} = 3$ for passage selection loss and $\lambda = 10$ for MRT. All parameters are tuned on the DuReader development set.

As MRT training is more time-consuming than MLE training, our MRT model is initialized with model trained with MLE. It usually obtains the best result in just one epoch, which results in feasible training time.

Our model is optimized with Adam algorithm (Kingma and Ba, 2014), and the learning rate is fixed to 0.001 during training.

Model	**ROUGE-L**	Δ
single-answer baseline	48.93	-
+ multi-answer loss	49.77	+ 0.84
+ passage selection loss	49.96	+ 1.03
+ MRT	**50.62**	**+ 1.69**

Table 3: Results with multi-answer multi-task loss and Minimum Risk Training on the development set

4.3 Results

4.3.1 Single-Answer Baseline

Table 1 shows the results for passage extraction and rich-feature representation (pre-trained word, POS, and word-in-query embeddings) on the development set. Both of them dramatically increase ROUGE-L and BLEU-4 score over the BiDAF baseline from the original DuReader paper. Together they form our single-answer baseline, on which we test the effectiveness of the multi-answer multi-task loss and Minimum Risk Training.

4.3.2 Different loss functions with multi-answer

Table 2 shows the experimental results with three different multi-answer loss functions introduced in Section 3.5.1. All of them offer improvement over the single-answer baseline, which shows the effectiveness of utilizing multiple answers. The average loss performs better than the min loss, which suggests that forcing the model to predict all possible answers is better than asking it to just find the easiest one. Not surprisingly, by taking into account the quality of different answer spans, the weighted average loss outperforms the average loss and achieves the best result among the three. All later experiments are conducted based on the weighted average loss.

Model	ROUGE-L	BLEU-4
BiDAF (He et al., 2017)	39.0	31.8
Match-LSTM (He et al., 2017)	39.2	31.9
PR+BiDAF (Wang et al., 2018b)	41.81	37.55
PE+BiDAF (ours)	45.93	38.86
V-Net (Wang et al., 2018b)	44.18	40.97
Our complete model	**51.09**	**43.76**
Human	57.4	56.1

Table 4: Performance of our model and competing models on the DuReader test set

Model	ROUGE-L	
	Q_s	Q_m
single-answer	38.01	53.8
multi-answer	**38.66**	**54.65**

Table 5: Results on Q_s and Q_m

4.3.3 Multi-task Loss and Minimum Risk Training

As we can see in Table 3, the ROUGE-L score on the DuReader development set increases to 49.77 by incorporating multi-answer into the loss function. Joint learning with passage selection loss yields an increase of 0.19. And with Minimum Risk Training, our model can reach a ROUGE-L score of 50.62, with a further increment of 0.66.

4.3.4 Comparison with State-of-the-art

Table 4 shows the performance of our model and other state-of-the-art models on the DuReader test set. First, we compare our passage extraction method with the paragraph ranking model from Wang et al. (2018b). Based on the same BiDAF model described in Section 3.4, our method (PE+BiDAF) significantly outperforms the trained model from Wang et al. (2018b) (PR+BiDAF) on the DuReader test set. As we can see, our complete model achieves the state-of-the-art performance in both ROUGE-L and BLEU-4, and greatly narrows the performance gap between MRC system and human in the challenging real-world setting.

4.3.5 Further Analysis

For further analysis, we construct two sets from the development set. Q_s contains 2787 questions with a single reference answer, and Q_m contains 6650 questions with more than one reference answer. 563 questions from the development set are labeled with no answer, and thus not included in Q_s or Q_m. Table 5 shows the performance of our model on Q_s and Q_m. It can be seen that even questions with single answer (Q_s) can benefit from using multiple answers in training. The improvement for Q_m is higher than that for Q_s.

5 Conclusion

In this paper, we focus on real-world machine reading comprehension. We propose a multi-answer multi-task framework to tackle the multi-answer problem which is common in everyday world. Minimum Risk Training is applied to solve the multi-occurrence problem of the answer. We also propose a simple method for passage extraction which solves the length issue of the passage. Experimental results indicate that our model achieves state-of-the-art performance in the challenging DuReader dataset.

Despite using multiple answers in training, our system only predicts a single answer in decoding time. However, in some cases (e.g. for questions about opinion), finding all possible answers may be desirable. In the future, we plan to design models which could generate all possible answers for a single question.

Abstract

We propose the task of Open-Domain Information Narration (OIN) as the reverse task of Open Information Extraction (OIE), to implement the dual structure between language and knowledge in the open domain. We then develop an agent, called Orator, to accomplish the OIN task, and assemble the Orator and the recently proposed OIE agent – Logician (Sun et al., 2018) into a dual system to utilize the duality structure with a reinforcement learning paradigm. Experimental results reveal the dual structure between OIE and OIN tasks helps to build better both OIE agents and OIN agents.

1 Introduction

The duality between language and knowledge is natural for human intelligence. The human can extract knowledge from natural language to learn or remember, and then narrate the knowledge back to natural language to communicate. Information extraction (IE) is a task to simulate the first part of the duality, which is a long-term hot spot for NLP research. Recently, the task that fulfills the last part of the duality, that is, assembling a set of relation instances/facts or database records into natural language sentences/documents, has also attracted many interests (Wiseman et al., 2017; Chisholm et al., 2017; Agarwal and Dymetman, 2017; Vougiouklis et al., 2017; Yin et al., 2016). In the literature, this task has been referred to as "data to document generation" (Wiseman et al., 2017) or "knowledge-to-text" (Chisholm et al., 2017). In this paper, we name the task as *information narration (IN)*, to emphasize the reverse relationship to the information extraction (IE) task.

The duality between language and knowledge (and thus between the IE and IN tasks) can be examined in closed-domain or open-domain. For the closed-domain problem, the closed-domain IE (CIE) task is often referred to as "relation extraction" or "relation classification", which identifies instances of a fixed and finite set of relations from natural language corpus, using supervised methods (Kambhatla, 2004; Zelenko et al., 2003; Miwa and Bansal, 2016; Zheng et al., 2017) or weakly supervised methods (Mintz et al., 2009; Lin et al., 2016). In the meantime, the close-domain IN (CIN) task (Wiseman et al., 2017; Chisholm et al., 2017; Agarwal and Dymetman, 2017; Vougiouklis et al., 2017; Yin et al., 2016) transforms a set of facts with a pre-defined schema or relation types (such as facts from Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), or database tables), into natural language sentences/documents. Furthermore, the dual structure between CIE and CIN tasks has been noticed and utilized in (Chisholm et al., 2017).

For the open-domain problem, the open-domain IE (OIE) task is to investigate how the natural language sentences express the facts, and then use the learned knowledge to extract entity and relation level intermediate structures from open-domain sentences (Christensen et al., 2011; Etzioni et al., 2011; Schmitz et al., 2012; Pal and Mausam, 2016). Although the OIE task has attracted much interests and obtained many applications (Christensen et al., 2013, 2014; Mausam, 2016; Stanovsky et al., 2015; Khot et al., 2017; Fader et al., 2014), the OIN task has not been stated, neither the duality between the language and knowledge in the open domain.

	Open-Domain	Closed-Domain
Extraction	OIE	CIE
Narration	OIN	CIN

Table 1: Taxonomy: Tasks between knowledge and natural language.

The tasks involved in the duality between language and knowledge is shown in Table 1, where

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2119–2130
Brussels, Belgium, October 31 - November 4, 2018.

the OIN task has not been stated. In this paper, we focus on the OIN task and the duality between the OIE and OIN tasks, for following reasons: 1) the OIN task is an essential component for open-domain information processing pipeline. For example, it is helpful for building natural and informative response for open-domain KBQA systems (Khot et al., 2017; Fader et al., 2014). 2) (as the results in this paper will illustrate) the duality between tasks can be valuable for building better agents for both tasks (Xia et al., 2017, 2016).

A major historical obstacle for investigating the duality between OIE and OIN tasks is the absence of parallel corpus between natural language sentence and open-domain facts. Recently, the SAOKE dataset (Sun et al., 2018) was released, which contains more than forty thousand of human-labeled open-domain sentence-facts pairs, and thus essentially eliminates the obstacle for our investigation.

The contribution of this paper lies in following aspects:

- We propose the concept of OIN task, which is potentially an important component for open-domain information pipeline. We develop the Orator agent to fulfill the task;
- We build a multi-agent system with Logician and Orator to exploit the dual structure between language and knowledge in open domain. Experimental results reveal that the dual information is beneficial for improving the performance of both agents.

The paper is organized as follows: Section 2 discusses the related work. Section 3 explains the Orator agent for OIN task. Section 4 describes the multi-agent system with Logician and Oration and its algorithm to learn from the duality between language and sentence. The experimental results of the fine tuned agents are shown and discussed in Section 5. We conclude our work and discuss the future direction in Section 6.

2 Related Work

2.1 Information Narration

The closed-domain information narration (CIN) task has been studied in (Wiseman et al., 2017; Chisholm et al., 2017; Agarwal and Dymetman, 2017; Vougiouklis et al., 2017). These CIN agents face problems from different problem domains, from people biographies to basketball game records, but most of them follow the same sequence-to-sequence pattern. First, the algorithm encodes a sequence of facts into a set of annotations and then decodes the annotations into a natural language text. Mechanisms such as attention (Bahdanau et al., 2014) and copying (Gu et al., 2016) are employed into the decoder to improve the performance. Then, the models are trained on a supervised dataset with back-propagation.

In this work, we adopt a similar sequence-to-sequence architecture to build our baseline Orator agent, but with following differences: 1) the Orator is proposed to narrate open domain facts, where the encoder must encode words rather than the entities and relations in the closed domain; 2) the baseline Orator will be fine tuned using the dual learning algorithm proposed in this paper.

2.2 Dual Learning Systems

For many natural language processing tasks, there exist corresponding reverse/dual tasks. One example of a pair of dual problems is the question answering (QA) and question generation (QG). In (Tang et al., 2017), the duality between QA problem and QG problem was considered as a constraint that both problems must share the same joint probability. Then, a loss function that implemented the constraint was involved in the supervised learning procedures for both agents. Furthermore, researchers (Tang et al., 2017; Duan et al., 2017; Sachan and Xing, 2018) use both the question-answering agent and the question-generation agent to identify extra high-confident question-answering pairs, which are further used to fine tune the pre-trained agents.

Back-and-forth translation (or round-trip translation) [1] is another example of duality, in the field of machine translation. It has been employed to evaluate the quality of machine translation systems (Van Zaanen and Zwarts, 2006), or to test the suitability of text for machine translation (Gaspari, 2006; Shigenobu, 2007). Recently, (Xia et al., 2016) implemented the duality in a neural-based dual learning system, in which the quality of each translation agent was improved on the unlabeled dataset using the rewards provided by its

---

	Chinese	English Translation
Sentence	他发明了有两个固定点（水的沸点和冰点）的100摄氏度计温尺，是世界大多数地区通用的摄氏温度计的前身。	He invented a 100 degree centimeter temperature scale with two fixed points (the boiling point of water and the freezing point), which is the precursor of the Celsius thermometer in most parts of the world.
Facts	(他,发明,100摄氏度计温尺)(100摄氏度计温尺,有,两个固定点)(水的[沸点|冰点],ISA,两个固定点)(100摄氏度计温尺,是X的前身,世界大多数地区通用的摄氏温度计)	(He, invented, the 100 degree Celsius temperature scale) (100 Celsius temperature scale, has, two fixed points) (water [boiling point | freezing point], ISA, two fixed points) (100 degrees Celsius temperature scale, is the predecessor of X, most Celsius thermometers in most parts of the world)

Table 2: An example sentence and the corresponding facts in the SAOKE dataset, where "ISA" is a symbol denoting the "is-a" relationship in the SAOKE format.

corresponding dual agent, using the reinforcement learning technique.

Parsing-reconstruction is also a pattern of duality. (Konstas et al., 2017) considered the AMR (Abstract Meaning Representation)(Banarescu et al., 2013) parsing problem (text to AMR) and AMR generation problem (AMR to text) in one system, in which the AMR parser generated extra text-AMR pair data to fine tune the AMR generator. The AMR generator, however, does not contribute to the performance improvement of the AMR parser. The CIE agent and CIN agent in (Chisholm et al., 2017) also follow this pattern, where both agents help each other to improve by sharing weights. Nevertheless, the sharing weight strategy cannot be applied to agents with different architecture, which is a typical situation in practice.

From these practices, it can be seen that the duality can be implemented with two major approaches: 1) by providing additional labeled samples via bootstrapping, and 2) by adding losses or rewards to the training procedure of the agents. In this paper, we follow the second approach. We design a set of rewards, among which some are related to OIE and OIN tasks respectively, and some are related to the duality of the problems. Then we optimize both agents using the reinforcement learning technique. The learning algorithm is similar to the dual-NMT algorithm described in (Xia et al., 2016), but with adaption for the OIE and OIN tasks, especially on the task related rewards. Compared to the approach of applying the regularization about sharing the same joint probability (Tang et al., 2017), our approach directly optimizes the task objective by introducing task related rewards. Furthermore, our approach is more adaptable than the weight sharing approach adopted in (Chisholm et al., 2017).

3 Orator

3.1 SAOKE Dataset

Symbolic Aided Open Knowledge Expression (SAOKE) is proposed in (Sun et al., 2018) as the form to honestly record the facts that humans can extract from sentences when humans read them. SAOKE uses a unified form - an n-ary tuple:

$$(subject, predicate, object_1, \cdots, object_N),$$

to express four categories of facts: 1) Relation: Verb/preposition-based n-ary relations between entity mentions; 2) Attribute: Nominal attributes for entity mentions; 3) Description: Descriptive phrases of entity mentions; 4) Concept: Hyponymy and synonymy relations among concepts and instances.

Using this SAOKE format, Sun et al. (2018) manually labeled the SAOKE dataset $\mathbb{D}_{\text{SAOKE}}$ by crowdsourcing, which includes more than forty thousand sentence-facts pairs $< \mathcal{S}, \mathcal{F} >$.[2] The labeling procedure is under the supervision of the "Completeness" criterion (Sun et al., 2018), so the facts recorded information in the sentence as much as possible (only auxiliary information and relation between facts are omitted (Sun et al., 2018)). As a result, the SAOKE dataset is a valid open-domain sentence-facts parallel dataset for both OIE and OIN tasks. Table 2 is an example from the SAOKE dataset for an easy understanding of the dual relationship between sentence and facts.

---

3.2 Model

The Orator is an agent $\mathfrak{O}$ that assembles a set of open-domain facts $\mathcal{F}$ into a sentence $\mathcal{S}$ with probability $P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F},\Theta_{\mathfrak{O}})$, where $\Theta_{\mathfrak{O}}$ is the set of parameters of $\mathfrak{O}$:

$$\text{Orator } \mathfrak{O}: \quad \mathcal{F} \quad \rightarrow \quad P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F},\Theta_{\mathfrak{O}}).$$

For each pair $< \mathcal{S},\mathcal{F} >\in \mathbb{D}_{\text{SAOKE}}$, the set of facts $\mathcal{F}$ is actually expressed as a sequence of facts, in the order of the labeler wrote them. So, the deep sequence to sequence paradigm is suitable to model the Orator. In this work, we build the base Orator model with the attention-based sequence to sequence model, together with copy and coverage mechanism, in a similar way of the implementation of the Logician in (Sun et al., 2018).

3.2.1 Attention based Sequence-to-sequence Learning

The attention-based sequence-to-sequence learning (Bahdanau et al., 2014) first encodes the input fact sequence $\mathcal{F}$ (actually the sequence of N_e-dimensional word embedding vectors) into a N_h-dimensional hidden states $H^{\mathcal{F}} = [h_1^{\mathcal{F}},\cdots,h_{N_S}^{\mathcal{F}}]$ using bi-directional GRU (Gated Recurrent Units) network (Cho et al., 2014). Then, when generating word w_t of the target sentence, the decoder computes the probability of generating w_t by $p(w_t|\{w_1,\cdots,w_{t-1}\},c_t) = g(h_{t-1},s_t,c_t)$, where s_t is the hidden state of the GRU decoder, g is the word generation model, and c_t is the dynamic context vector which focuses attention on specific location l in the input hidden states $H^{\mathcal{F}}$.

For the Orator, we use the copy mechanism to implement the word generation model g and use the coverage mechanism to compute the dynamic context vector c_t.

3.2.2 Copy Mechanism

In the SAOKE dataset, the words in the set of facts (excluding the external symbols) must be in the corresponding sentence, so the problem is suitable to be modeled via the copy mechanism (Gu et al., 2016). In the copy mechanism, when the decoder is considering generating a word w_t, it can either be copied from the source fact sequence $\mathcal{F}$ or select from a vocabulary V:

$$\begin{aligned} p(w_t|w_{t-1},s_t,c_t) \quad = \quad & p_{\mathcal{F}}(w_t|w_{t-1},s_t,c_t) + \\ & p_V(w_t|w_{t-1},s_t,c_t), \end{aligned}$$

where $p_{\mathcal{F}}$ is the probability of copying from $\mathcal{F}$ and p_V is the probability of selecting from V. The details can be found in (Gu et al., 2016).

3.2.3 Coverage Mechanism

To cope with the problem of information lost or redundancy in the generated sentence, the copied histories of previous generated words should be remembered to guide future generation. This could be done through the coverage mechanism (Tu et al., 2016), in which a coverage vector m_j^t is introduced for each word $w_j^{\mathcal{F}}$ in $\mathcal{F}$ and updated at each step t as a gated function of $h_j^{\mathcal{F}},\alpha_{tj},s_{t-1},m_j^{t-1}$. By this means, the coverage vectors remember the historical attentions over source sequence and can be incorporated in the alignment model to generate complete and non-redundant sentences. Detailed formulations can be found in (Tu et al., 2016) and (Sun et al., 2018).

4 Learning the Dual Structure between Knowledge and Natural Language

4.1 Dual Structure between Orator and Logician

In (Sun et al., 2018), an agent $\mathfrak{L}$, called Logician, was trained to convert a sentence $\mathcal{S}$ into a set of facts $\mathcal{F}$ with probability $P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S},\Theta_{\mathfrak{L}})$, where $\Theta_{\mathfrak{L}}$ is the set of parameters of $\mathfrak{L}$:

$$\text{Logician } \mathfrak{L}: \quad \mathcal{S} \quad \rightarrow \quad P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S},\Theta_{\mathfrak{L}}).$$

Obviously, the Logician and Orator can cooperate to supervise each other. Given $< \mathcal{S},\mathcal{F} >\in \mathbb{D}_{\text{SAOKE}}$, the Logician produces a predicted set of facts $\mathcal{F}^*$ for the sentence $\mathcal{S}$, and the Orator can calculate the probability $P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F}^*,\Theta_{\mathfrak{O}})$ of reconstruction $\mathcal{S}$ from $\mathcal{F}^*$. Intuitively, if $\mathcal{F}^*$ loses major information of $\mathcal{S}$, honestly reconstructing $\mathcal{S}$ from $\mathcal{F}^*$ would be impossible, and thus the probability $P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F}^*,\Theta_{\mathfrak{O}})$ would be small. Thus, it is a strong signal to evaluate the quality of $\mathcal{F}^*$. Similarly, when the Orator produces a sentence $\mathcal{S}^*$ for the set of facts $\mathcal{F}$, the probability $P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S}^*,\Theta_{\mathfrak{L}})$ provided by the Logician is a strong signal for evaluating the quality of $\mathcal{S}^*$. These signals are helpful to conquer several problems of the original agents, including information lost, information redundancy, and non-fluency.

Note that the supervision signals $P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F}^*,\Theta_{\mathfrak{O}})$ and $P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S}^*,\Theta_{\mathfrak{L}})$ do not rely on any supervised parallel corpus. Thus, similar to the application of dual learning paradigm on NMT task (Xia et al., 2016), it is theoretically possible to use unparalleled sentences and sets of facts to compute these signals. However, unsupervised collections of fact-groups that can be reasonably narrated in a sentence are not naturally available. Currently, the only available collection is the sets of facts provided by the SAOKE dataset, where the supervised information is available. As a result, we implement our dual learning system in a supervised approach, which uses the reinforcement learning algorithm to optimize the Orator and the Logician. The involved rewards are described in the next subsection, and then the algorithm is detailed in the last subsection.

4.2 Rewards

Given $< \mathcal{S}, \mathcal{F} > \in \mathbb{D}_{\text{SAOKE}}$, we sample a set of facts $\mathcal{F}^*$ from distribution $P_{\mathfrak{L}}(\cdot|\mathcal{S}, \varTheta_{\mathfrak{L}})$ and a sentence $\mathcal{S}^*$from distribution $P_{\mathfrak{O}}(\cdot|\mathcal{F}, \varTheta_{\mathfrak{O}})$. Following rewards are introduced into the proposed dual learning system, and the relationships between them are shown in Figure 1.

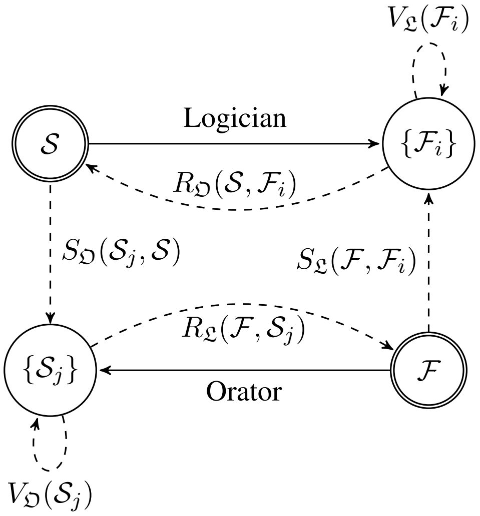

Figure 1: Illustration of the dual learning system of Logician and Orator.

4.2.1 Reconstruction Rewards

Following the idea described in above subsection, we design the reconstruction reward for the Orator as:

$$R_{\mathfrak{O}}(\mathcal{S}^*, \mathcal{F}) = \log P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S}^*, \varTheta_{\mathfrak{L}}),$$

and that for the Logician as:

$$R_{\mathfrak{L}}(\mathcal{F}^*, \mathcal{S}) = \log P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F}^*, \varTheta_{\mathfrak{O}}).$$

4.2.2 Similarity Rewards

Since the SAOKE dataset has label information, the similarities between the predicted results and the ground truths can be used as rewards.

For the Orator, since the $\mathcal{S}^*$ can be viewed as the summarization of $\mathcal{S}$, we use the widely used ROUGE-L (Lin, 2004) measure in the text summarization field to evaluate the quality of $\mathcal{S}^*$:

$$S_{\mathfrak{O}} = \text{ROUGE}_L(\mathcal{S}, \mathcal{S}^*).$$

For the Logician, we use following procedure to calculate the similarity between $\mathcal{F}$ and $\mathcal{F}^*$. First, we compute the similarity between each predicted fact $f^* \in \mathcal{F}^*$ and each ground truth fact $f \in \mathcal{F}$ with following measure:

$$SimFact(f^*, f) = \frac{\sum_{i=1}^{\min(|f^*|,|f|)} SimStr(f_i^*, f_i)}{\max(|f^*|, |f|)},$$

where f_i^* and f_i denote the i-th element of tuples of fact f^* and f, $SimStr(\cdot, \cdot)$ denotes the gestalt pattern matching (Ratcliff and Metzener, 1988) measure for two strings, and $|\cdot|$ is the cardinality function. Then, each predicted fact in $\mathcal{F}^*$ is aligned to its corresponding ground-truth fact in $\mathcal{F}$ by solving a linear assignment problem (Wikipedia, 2017) to maximize the sum of similarities between the aligned facts. Finally, the similarity reward for the Logician is calculated by:

$$S_{\mathfrak{L}}(\mathcal{F}^*, \mathcal{F}) = \frac{\sum SimFact(f*, f)}{\max(|\mathcal{F}^*|, |\mathcal{F}|)},$$

where $f^* \in \mathcal{F}^*, f \in \mathcal{F}$ are aligned pair of facts.

4.2.3 Validity Rewards

For the Orator, the output is expected as a valid natural language sentence, so the validity reward can be defined as:

$$V_{\mathfrak{O}}(\mathcal{S}^*) = LM(\mathcal{S}^*),$$

where the $LM(\cdot)$ is a language model.

For the Logician, the output should represent a valid collection of facts, which means: 1) the output can be parsed into a collection of facts; 2) there is no duplicated fact (identified by the $SimFact$ value larger than 0.85) in the parsed collection. The validity reward for Logician is defined as:

$$V_{\mathfrak{L}}(\mathcal{F}^*) = \begin{cases} 0 & \text{if } \mathcal{F}^* \text{is valid;} \\ -1 & \text{otherwise.} \end{cases}$$

Algorithm 1 A simple dual-learning algorithm for facts extraction and expression

```
Require:
    A set of sentence-facts pairs $\{< \mathcal{S}, \mathcal{F} >\}$;
    An initial Logician $\mathfrak{L}$ and an initial Orator $\mathfrak{O}$;
    Beam size $K$;
repeat
    Sample a sentence-facts pair $< \mathcal{S}, \mathcal{F} >$;
    Logician produces $K$ sets of facts $\mathcal{F}_1, \cdots, \mathcal{F}_K$ from $\mathcal{S}$ via beam search;
    for each set of facts $\mathcal{F}_i$ do
        Compute the reward for $\mathcal{F}_i$ as:
            $r_i^{\mathcal{F}} = \alpha_1 R_{\mathfrak{O}}(\mathcal{S}, \mathcal{F}_i) + \alpha_2 V_F(\mathcal{F}) + \alpha_3 S_F(\mathcal{F}, \mathcal{F}_i).$
    end for
    Compute the total reward $r = \frac{1}{K} \sum_{i=1}^{K} r_i^{\mathcal{F}}$;
    Compute the stochastic gradient of $\Theta_{\mathfrak{L}}$:
        $\nabla_{\Theta_{\mathfrak{L}}} \hat{E}[r] = \frac{1}{K} \sum_{i=1}^{K} r_i^{\mathcal{F}} \mathfrak{D}_{\Theta_{\mathfrak{L}}}(\mathcal{S}, \mathcal{F}_i)$
    Compute the stochastic gradient of $\Theta_{\mathfrak{O}}$:
        $\nabla_{\Theta_{\mathfrak{O}}} \hat{E}[r] = \frac{\alpha_1}{K} \sum_{i=1}^{K} \mathfrak{D}_{\Theta_{\mathfrak{O}}}(\mathcal{F}_i, \mathcal{S})$
    Model updates:
        $\Theta_{\mathfrak{L}} \leftarrow \Theta_{\mathfrak{L}} + \eta_{\mathfrak{L}} \cdot \nabla_{\Theta_{\mathfrak{L}}} \hat{E}[r],$
        $\Theta_{\mathfrak{O}} \leftarrow \Theta_{\mathfrak{O}} + \eta_{\mathfrak{O}} \cdot \nabla_{\Theta_{\mathfrak{O}}} \hat{E}[r].$

    Sample a sentence-facts pair $< \mathcal{S}, \mathcal{F} >$;
    Orator produces $K$ sentences $\mathcal{S}_1, \cdots, \mathcal{S}_K$ from $\mathcal{F}$ via beam search;
    for each sentence $\mathcal{S}_i$ do
        Compute the reward for $\mathcal{S}_i$ as:
            $r_i^{\mathcal{S}} = \beta_1 R_{\mathfrak{L}}(\mathcal{F}, \mathcal{S}_i) + \beta_2 V_S(\mathcal{S}_i) + \beta_3 S_S(\mathcal{S}, \mathcal{S}_i).$
    end for
    Compute the total reward $r = \frac{1}{K} \sum_{i=1}^{K} r_i^{\mathcal{S}}$;
    Compute the stochastic gradient of $\Theta_{\mathfrak{O}}$,
        $\nabla_{\Theta_{\mathfrak{O}}} \hat{E}[r] = \frac{1}{K} \sum_{i=1}^{K} r_i^{\mathcal{S}} \mathfrak{D}_{\Theta_{\mathfrak{O}}}(\mathcal{S}_i, \mathcal{F})$
    Compute the stochastic gradient of $\Theta_{\mathfrak{L}}$:
        $\nabla_{\Theta_{\mathfrak{L}}} \hat{E}[r] = \frac{\beta_1}{K} \sum_{i=1}^{K} \mathfrak{D}_{\Theta_{\mathfrak{L}}}(\mathcal{F}_i, \mathcal{S})$
    Model updates:
        $\Theta_{\mathfrak{O}} \leftarrow \Theta_{\mathfrak{O}} + \eta_{\mathfrak{O}} \cdot \nabla_{\Theta_{\mathfrak{O}}} \hat{E}[r],$
        $\Theta_{\mathfrak{L}} \leftarrow \Theta_{\mathfrak{L}} + \eta_{\mathfrak{L}} \cdot \nabla_{\Theta_{\mathfrak{L}}} \hat{E}[r].$
until convergence
```

4.3 Algorithm

For each pair $< \mathcal{S}, \mathcal{F} > \in \mathbb{D}_{\text{SAOKE}}$, the following procedures are performed respectively (details are shown in Algorithm 1):

4.3.1 Learning from Sentence to Facts

We sample $\mathcal{F}^*$ from the Logician $P_{\mathfrak{L}}(\cdot|\mathcal{S}, \Theta_{\mathfrak{L}})$ and calculate the total reward for $\mathcal{F}^*$ by

$$
\begin{aligned}
r_{\mathfrak{L}} = {} & \alpha_1 \cdot R_{\mathfrak{L}}(\mathcal{F}^*, \mathcal{S}) + \alpha_2 \cdot V_{\mathfrak{L}}(\mathcal{F}^*) + \\
& \alpha_3 \cdot S_{\mathfrak{L}}(\mathcal{F}^*, \mathcal{F}),
\end{aligned}
$$

where $\sum \alpha_i = 1$. The gradients of the expected reward $E[r_{\mathfrak{L}}]$ to the parameters of agents can be computed as follows, according to the policy gradient theorem (Sutton et al., 1999):

$$
\begin{aligned}
\nabla_{\Theta_{\mathfrak{L}}} E[r_{\mathfrak{L}}] &= E[r_{\mathfrak{L}} \mathfrak{D}_{\Theta_{\mathfrak{L}}}(\mathcal{F}^*, \mathcal{S})], \\
\nabla_{\Theta_{\mathfrak{O}}} E[r_{\mathfrak{L}}] &= E[\alpha_1 \mathfrak{D}_{\Theta_{\mathfrak{O}}}(\mathcal{S}, \mathcal{F}^*)].
\end{aligned}
$$

where $\mathfrak{D}_{\Theta_{\mathfrak{L}}}(\mathcal{F}, \mathcal{S}) = \nabla_{\Theta_{\mathfrak{L}}} \log P_{\mathfrak{L}}(\mathcal{F}|\mathcal{S}, \Theta_{\mathfrak{L}})$ and $\mathfrak{D}_{\Theta_{\mathfrak{O}}}(\mathcal{S}, \mathcal{F}) = \nabla_{\Theta_{\mathfrak{O}}} \log P_{\mathfrak{O}}(\mathcal{S}|\mathcal{F}, \Theta_{\mathfrak{O}})$.

4.3.2 Learning from Facts to Sentence

We sample $\mathcal{S}^*$ from the Logician $P_{\mathfrak{O}}(\cdot|\mathcal{F}, \Theta_{\mathfrak{O}})$ and define the total reward for $\mathcal{S}^*$ by:

$$
\begin{aligned}
r_{\mathfrak{O}} = {} & \beta_1 R_{\mathfrak{O}}(\mathcal{S}^*, \mathcal{F}) + \beta_2 V_{\mathfrak{O}}(\mathcal{S}^*) + \\
& \beta_3 S_{\mathfrak{O}}(\mathcal{S}^*, \mathcal{S}),
\end{aligned}
$$

where $\sum \beta_i = 1$. The gradients can be computed as follows:

$$
\begin{aligned}
\nabla_{\Theta_{\mathfrak{L}}} E[r_{\mathfrak{O}}] &= E[\beta_1 \mathfrak{D}_{\Theta_{\mathfrak{L}}}(\mathcal{F}, \mathcal{S}^*)], \\
\nabla_{\Theta_{\mathfrak{O}}} E[r_{\mathfrak{O}}] &= E[r_{\mathfrak{O}} \mathfrak{D}_{\Theta_{\mathfrak{O}}}(\mathcal{S}^*, \mathcal{F})].
\end{aligned}
$$

In practice, we use beam search (Sutskever et al., 2014) to obtain high-quality samples as $\mathcal{F}^*$ and $\mathcal{S}^*$, and estimate the true gradient with the empirical average of gradients over these samples.

5 Experimental Results

5.1 Experimental Design

First, we evaluate the performance of each agent fine-tuned by the dual learning procedure on the

SAOKE dataset. Then we evaluate the Orator on noisy facts, which accords with real OIN application scenarios. Last, we investigate the behavior of agents in the dual system.

In the experiments, the SAOKE dataset is split into the training set, validating set and testing set with ratios of 80%, 10%, 10%, respectively. For each algorithm involved in the experiments, we perform grid search to find the optimal super-parameters, and the model with the best performance on the validating set is chosen as the learnt model to be evaluated on the testing set.

5.1.1 Evaluation Metric

For the Orator, BLEU-4 and ROUGE-L are used to measure how well the output matches the ground truth sentence.

For the Logician, based on the fact-equivalence judgment proposed in (Sun et al., 2018), we compute the Precision(P), Recall (R) and F1-score over the testing set of the SAOKE dataset as the evaluation metric.

5.1.2 Agent Implementation

For the Orator, we make a vocabulary V with size 72,591 by collecting all web pages from Baidu Baike website[3] (a Chinese alternative to Wikipedia) and identifying the words occurred in more than 100 web pages. For the Orator, the dimension of embedding vectors is set to $N_e = 256$, and the dimension of hidden states is set to $N_h = 256$. We use a three-layer bi-directional GRU with dimension 128 as the encoder. All dimensions of hidden states in the decoder are set to 256.

For the Logician, we implement the model described in (Sun et al., 2018), including the shallow tag information and the gated dependency attention mechanism.

Furthermore, to provide an intuitive comprehension of the OIN task, we implement a rule-based method for OIN task. For each sequence of facts in the SAOKE dataset, the method first identifies the subsequences in which the facts share the same subject. Then it preserves the subject of the first fact in each subsequence and removes the subjects of following facts (by replacing it with an empty string). It is necessary since the SAOKE dataset requires the shared subject to be repeated for completeness of the related facts. At last, each fact is formatted into a string by filling the objects into the placeholders of the predicate and these strings are concatenated with commas to form the final sentence.

5.1.3 Reward Implementation

For the validity reward of the Orator, the language model is trained using an RNN based method (Mikolov et al., 2010) with the same vocabulary V and the web pages from Baidu Baike website.

For the reconstruction reward of the Orator, since the Logician needs the shallow tag and dependency information of $\mathcal{S}^*$ as inputs, the information is extracted using the LTP tool-set (Che et al., 2010) and then fed to the Logician.

5.1.4 Training

When training the base model for each agent, the batch size is set to 20. When training two agents in dual learning, the batch size is set to 12, and the beam size is set to 3. Both agents are trained using the stochastic gradient descent (SGD) with RMSPROP strategy (Hinton et al., 2012) and early-stop strategy on the validating set. In dual learning, the super-parameters, including α_i , β_i, is determined by grid-search.

5.2 Evaluation of Agents on the SAOKE dataset

First, we evaluate the performance of the agents optimized by the dual learning method. To identify the contribution of the dual structure, we train another pair of agents with $\alpha_1 = 0$ and $\beta_1 = 0$ in Algorithm 1 to exclude the dual information. Without the dual information, these two agents are trained independently to each other with reinforcement learning on their own supervised information. We name these two agents as R-Logician and R-Orator, where "R" means "Reinforced". In the experimental results of this paper, the symbol at the top mark means that the marked result is significantly different (with $p = 0.05$) with the corresponding result of the agent with the specific mark.

Methods	Precision	Recall	F1
Logician*	0.449	0.400	0.423
R-Logician$^{\mp}$	0.462*	0.432*	0.446*
Logician@Dual	0.494$^{*\mp}$	0.426*	0.457$^{*\mp}$

Table 3: Performance of the Logicians.

The experimental results for the Logician agents are shown in Table 3, from which we can observe a significant performance improvement

---

[3] http://baike.baidu.com

from Logician to R-Logician and also from R-Logician to Logician@Dual. The experimental results for the Orator agents are shown in Table 4. The neural based Orator agents significantly outperform the rule-based agent. For both evaluation metric, the R-Orator and Orator@Dual are both significantly outperform the original Orator. The Orator@Dual significantly outperforms the R-Orator on the BLEU-4 score, but is not significantly different on the ROUGE-L score.

Methods	BLEU-4	ROUGE-L
Rule*	0.257	0.434
Orator*	0.401*	0.556*
R-Orator$^{\mp}$	0.405$^{\star *}$	0.559$^{\star *}$
Orator@Dual	0.419$^{\star * \mp}$	0.559$^{\star *}$

Table 4: Performance of the Orators.

By comparing the performance of R-agents and the agents@Dual, we can observe that agents@Dual generally achieve better performance on precision, but may recall less information, resulting in smaller advances in the balanced evaluation metric (F1 and ROUGE-L). This may imply that the agents tend to provide easy input for each other for higher accuracy, by neglecting some difficult part of the problem which they currently cannot handle properly. This interesting phenomenon is the subject of our future research.

5.3 Evaluation of Orator on Noisy Facts

Experiments in the previous subsection show the performance of Orators to narrate a set of human-labeled facts. In practice, however, the input to the Orator might not be the human-labeled perfect facts, but some noisy facts automatically extracted by OIE algorithms. In this subsection, we make a collection of sets of noisy facts by feeding the sentences in the testing set of the SAOKE dataset to the base Logician model and collecting the outputs. Then we evaluate the series of Orator models on these noisy facts, and report their performance at Table 5, from which we can see the performance improvement from the Orator to Orator@Dual.

Methods	BLEU-4	ROUGE-L
Orator*	0.428	0.565
R-Orator$^{\mp}$	0.431*	0.567*
Orator@Dual	0.458$^{* \mp}$	0.572$^{* \mp}$

Table 5: Performance of the Orators on noisy facts.

5.4 Evaluation of the Dual System

In this section, we investigate the behavior of agents in the dual system. We first examine the procedure $\mathcal{F} \xrightarrow{Orator} \mathcal{S}^{*} \xrightarrow{Logician} \mathcal{F}^{**}$, that is, for each $\mathcal{F}$ in the testing set of the SAOKE dataset, let the Orator narrate it into a sentence $\mathcal{S}^{*}$, and then let the Logician to extract facts $\mathcal{F}^{**}$ from $\mathcal{S}^{*}$. Then the quality of $\mathcal{F}^{**}$ is measured by comparing it with $\mathcal{F}$. Then we examine $\mathcal{S} \xrightarrow{Logician} \mathcal{F}^{*} \xrightarrow{Orator} \mathcal{S}^{**}$, which is the reverse procedure. The comparison is made between the family of base agents and that of the dual-trained agents. The results are shown in Table 6, and two instance of these two experiments are shown in Table 7 and 8 respectively. From these results, we can observe large improvements of reconstruction quality on both directions.

	$\mathcal{F} \xrightarrow{Orator} \mathcal{S}^{*} \xrightarrow{Logician} \mathcal{F}^{**}$		
Methods	Precision	Recall	F1
Base*	0.574	0.488	0.527
Dual	0.657*	0.565*	0.608*

	$\mathcal{S} \xrightarrow{Logician} \mathcal{F}^{*} \xrightarrow{Orator} \mathcal{S}^{**}$	
Methods	BLEU-4	ROUGE-L
Base*	0.428	0.565
Dual	0.635*	0.635*

Table 6: Reconstruction performance for the Logicians and the Orators.

6 Conclusion

In this paper, we investigate the OIN task and its duality to the OIE task. The proposed Orator has shown its ability to fulfill the OIN task, that is, assembling open-domain facts into high quality sentences. Furthermore, our attempt to utilize the duality between OIN and OIE tasks for improving the performances for both OIN and OIE agents accomplishes a preliminary success.

Our work suggests at least three future research topics: Firstly, one can enrich the theoretical study of the duality between the OIE and OIN tasks. Secondly, one can investigate how to conquer the barrier of the absence of an extensive collection of reasonable sets of open-domain facts and incorporate unsupervised information into this Logician-Orator dual learning structures for further improvement. Lastly, one can also interested in developing task-oriented rewards for adapting the agent to a specific task, for example, the answer generation task for open-domain KBQA system.

$\mathcal{S}$	大综货物吞吐量均保持两位数增长，其中铁矿石吞吐量突破4500万吨，木材吞吐量突破600万立方，均创历史新高，成为全国进口木材第一大港。

Abstract

Machine reading comprehension helps machines learn to utilize most of the human knowledge written in the form of text. Existing approaches made a significant progress comparable to human-level performance, but they are still limited in understanding, up to a few paragraphs, failing to properly comprehend lengthy document. In this paper, we propose a novel deep neural network architecture to handle a long-range dependency in RC tasks. In detail, our method has two novel aspects: (1) an advanced memory-augmented architecture and (2) an expanded gated recurrent unit with dense connections that mitigate potential information distortion occurring in the memory. Our proposed architecture is widely applicable to other models. We have performed extensive experiments with well-known benchmark datasets such as TriviaQA, QUASAR-T, and SQuAD. The experimental results demonstrate that the proposed method outperforms existing methods, especially for lengthy documents.

1 Introduction

Most of the human knowledge has been stored in the form of text. Reading comprehension (RC) to understand this knowledge is a major challenge that can vastly increase the range of knowledge available to the machines. Many neural network-based methods have been proposed, pushing performance close to a human level. Nonetheless, there still exists room to improve the performance especially in comprehending lengthy documents that involve complicated reasoning processes. We identify the main bottleneck as the lack of the long-term memory and its improper controlling mechanism.

Previously, several memory-augmenting methods have been proposed to solve the long-term dependency problem. For example, in relatively simple tasks such as bAbI tasks (Weston et al., 2015), Graves et al. (2014, 2016); Henaff et al. (2017) proposed methods that handle the external memory to address long-term dependency. Inspired by these approaches, we develop a customized memory controller along with an external memory augmentation (Graves et al., 2016) for complicated RC tasks. However, we found that the memory controller is susceptible to information distortion as neural networks become deeper, this distortion can hinder the performance.

To overcome this issue, we propose two novel strategies that improve the memory-handling capability while mitigating the information distortion. We extend the memory controller with a residual connection to alleviate the information distortion occurring in it. We also expand the gated recurrent unit (GRU) (Cho et al., 2014) with a dense connection that conveys enriched features to the next layer containing the original as well as the transformed information. We conducted extensive experiments through several benchmark datasets such as TriviaQA, QUASAR-T, and SQuAD. The results show that the proposed model outperforms all the published results. We also integrated the proposed memory controller and the expanded GRU cell block with other existing methods to ensure that our proposed components are widely applicable. The results show that our components consistently bring performance improvement across various state-of-the-art architectures.

The main contributions of this work include the following: (1) We propose an extended memory controller module for RC tasks. (2) We propose a densely connected encoder block with self attention to provide rich representation of given data, reducing information loss due to deep layers of the network. (3) We present the state-of-the-art results

in lengthy-document RC tasks such as TriviaQA and QUASAR-T as well as relatively short document RC tasks such as SQuAD.

2 Proposed Method

This section presents two of our proposed components in detail, as depicted in Figure 1.

2.1 Memory Controller

Our first proposed component is an advanced external memory controller module for solving RC tasks. We modified the recently proposed memory controller (Graves et al., 2016) by using our new encoder block and layer-wise residual connections. These modifications enable the memory controller to reason over a lengthy document, leading to the overall performance improvement.

This layer takes input as a sequence of vector representations corresponding to individual tokens, $\mathbf{d}_t \in \mathbb{R}^l$, where l is the given vector dimension. For example, such input can be the output of the co-attention layer in Section 3. The operation of this layer is defined as

$$\mathbf{o}_t, \mathbf{i}_t = \text{Controller}(\mathbf{d}_t, M_{t-1}).$$

That is, at time step t, the controller generates an interface vector $\mathbf{i}_t$ for read and write operations and an output vector $\mathbf{o}_t$ based on the input vector $\mathbf{d}_t$ and the external memory content from the previous time step, $M_{t-1} \in \mathbb{R}^{p \times q}$, where p is the memory size and q is the vector dimension of each memory.

Through this controller, we encode an input $D = \{\mathbf{d}_t\}_{t=1}^n$ to $\{\mathbf{x}_t\}_{t=1}^n$ by using the encoder block, i.e.,

$$\{\mathbf{x}_t\}_{t=1}^n = \text{EncoderBlock}^x(D) \in \mathbb{R}^{n \times k},$$

where k is the output dimension of the encoder block. In general, this block is implemented as a recurrent unit, e.g., GRU (Cho et al., 2014). In our model, we replace it with our dense encoder block with self attention (DEBS), as will be discussed in Section 2.2.

To generate a memory-augmented vector $\mathbf{z}_t$, we concatenate $\mathbf{x}_t$ with the vectors read from the previous time step memory, M_{t-1}, i.e.,

$$\mathbf{z}_t = [\mathbf{x}_t; \mathbf{m}_{t-1}^1; \cdots; \mathbf{m}_{t-1}^s] \in \mathbb{R}^{k+sq},$$

where s represents the number of read heads in the memory interface. We then feed the vector $\mathbf{z}_t$ to the bi-directional GRU (BiGRU) layer and obtain the output vector $\mathbf{h}_t^m$ as

$$\mathbf{h}_t^m = \text{BiGRU}(\mathbf{z}_t, \mathbf{h}_{t-1}^m, \mathbf{h}_{t+1}^m) \in \mathbb{R}^{2l}.$$

Afterwards, we generate output vector $\mathbf{v}_t$ as the weighted sum of the BiGRU output and read vectors from the memory in the current step, i.e.,

$$\mathbf{v}_t = W_h \mathbf{h}_t^m + W_m [\mathbf{m}_t^1; \cdots; \mathbf{m}_t^s] \in \mathbb{R}^{2l}.$$

Finally, we add a residual connection between the input $\mathbf{d}_t$ and the output $\mathbf{v}_t$ to mitigate any possible information distortion that can occur while accessing the memory, resulting in a the output vector that can handle long-term dependency, i.e.,

$$\mathbf{o}_t = \text{ReLU}(W_v \mathbf{v}_t + \mathbf{d}_t) \in \mathbb{R}^l.$$

For further details on how the interface vector works, we refer the readers to Graves et al. (2016) as well as our supplemental material.

2.2 Dense Encoder Block with Self Attention

The second novel component we propose is a dense encoder block with self attention (DEBS), which further improves a GRU cell. Recently, Huang et al. (2017a) proposed that adding a connection between each layer to the other layers in convolution networks can help to properly convey the information across multiple layers. Inspired by this, we add such dense connections that concatenate the input to a particular layer to its output. We also add a self-attention module to this block, to properly address long-term dependency in a length document. In this manner, our encoder block maintains the necessary information not only along the vertical direction (across layers) through dense connections but also along the horizontal direction (across time steps) through self attention.

DEBS takes the input vector sequence with its length as n and transforms each vector to an l-dimensional vector $\mathbf{p}_t$ through the fully connected layer with ReLU as a nonlinear unit and generates a contextually encoded vector $\mathbf{r}_t$ as

$$\mathbf{r}_t = \text{BiGRU}(\mathbf{p}_t, \mathbf{r}_{t-1}, \mathbf{r}_{t+1}) \in \mathbb{R}^{2l}.$$

Then we concatenate each output vector $\mathbf{r}_t$ to the projected input $\mathbf{p}_t$ to obtain $\mathbf{g}_t = [\mathbf{r}_t; \mathbf{p}_t] \in \mathbb{R}^{3l}$ and pass it to the self-attention layer. The self-attention layer then calculates the similarity map $S^g \in \mathbb{R}^{n \times n}$ using the tri-linear function as

$$s_{ij}^g = \mathbf{w}_a \cdot \mathbf{g}_i + \mathbf{w}_b \cdot \mathbf{g}_j + \mathbf{w}_f \cdot (\mathbf{g}_i \odot \mathbf{g}_j),$$

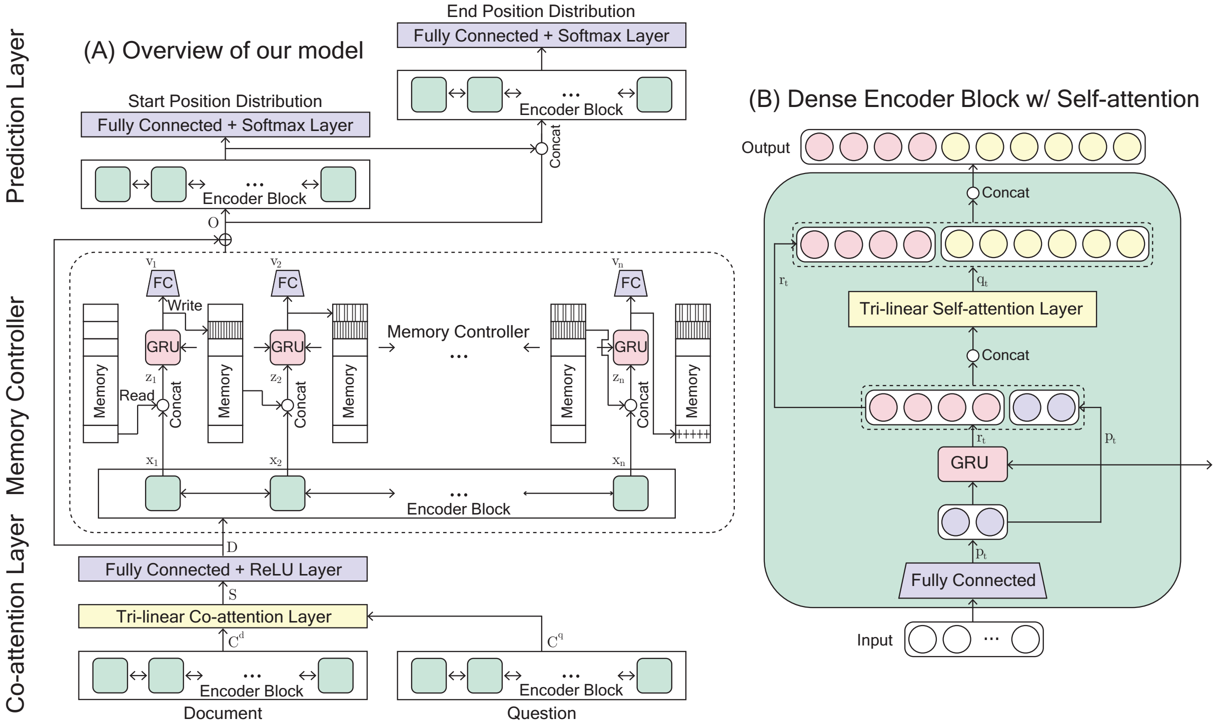

Figure 1: Overview of our model (A) and dense encoder block with self attention (B).

where $i, j = 1, \dots, n$. Finally, the self-attended representation $Q = \{\mathbf{q}_t\}_{t=1}^{n}$ is obtained by performing column-wise softmax on S^g to get the attention matrix A^g, which is further multiplied with $G = \{\mathbf{g}_t\}_{t=1}^{n}$, i.e.,

$$Q = A^g G \in \mathbb{R}^{n \times 3l}.$$

The final output is obtained as the concatenation of outputs from the recurrent layer (BiGRU) and the self-attention layer, i.e., $[\mathbf{r}_t; \mathbf{q}_t] \in \mathbb{R}^{5l}$.

3 Reading Comprehension Model with Proposed Components

We apply the proposed components to our model for RC tasks. As depicted in Figure 1, the model consists of three major layers: the co-attention layer, the memory controller, and the prediction layer. Given the embeddings of a question and a document, the co-attention layer generates query-aware contextual representations. The memory controller further refines these contextual representations using an external memory. Based on such representations, the prediction layer determines the start and the end token indices that form the answer span. In addition, we replace all the encoder block with DEBS in the three major layers.

Embedding. We incorporate both word- and character-level embedding methods to obtain the vector representation of each word in the input data. For word-level embedding $\mathbf{e}_w$, we utilize pre-trained, 300-dimensional embedding vectors from GloVe 6B (Pennington et al., 2014). The character-level word embedding $\mathbf{e}_c$ is obtained as a 100-dimensional vector by first applying a convolution layer with 100 filters to a sequence of 20-dimensional character embeddings learned during training and by further applying global max-pooling over the entire character-level sequence. Then we obtain the embedding vector of a given word token, $\mathbf{e}$, by concatenating these word- and character-level embeddings, i.e., $\mathbf{e} = [\mathbf{e}_w; \mathbf{e}_c] \in \mathbb{R}^{400}$.

Finally, we obtain the two sets of embedding vectors of question and document token sequences as $E^q = \{\mathbf{e}_u^q\}_{u=1}^{m} \in \mathbb{R}^{m \times 400}$ and $E^d = \{\mathbf{e}_t^d\}_{t=1}^{n} \in \mathbb{R}^{n \times 400}$, where m and n represent the sequence length of a question and a document, respectively.

Co-attention layer. Given E^q and E^d, we feed each of them into the encoder block and obtain their contextual representations as

$$C^q = \{\mathbf{c}_u^q\}_{u=1}^{m} = \text{EncoderBlock}^q(E^q) \in \mathbb{R}^{m \times k}$$
$$C^d = \{\mathbf{c}_t^d\}_{t=1}^{n} = \text{EncoderBlock}^d(E^d) \in \mathbb{R}^{n \times k}.$$

These representations are used to calculate the pairwise similarity matrix $S \in \mathbb{R}^{m \times n}$ between tokens in the question and those in the document by a tri-linear function (Seo et al., 2017), i.e.,

$$s_{ij} = \mathbf{w}_q \cdot \mathbf{c}_i^q + \mathbf{w}_d \cdot \mathbf{c}_j^d + \mathbf{w}_c \cdot (\mathbf{c}_i^q \odot \mathbf{c}_j^d),$$

where $i = 1, \ldots, m$, $j = (1, \ldots, n)$, and $\odot$ represents the element-wise multiplication and $\mathbf{w}_q$, $\mathbf{w}_d$, and $\mathbf{w}_c$ are trainable vectors. We apply column-wise softmax to S to obtain the document-to-question attention matrix A. Afterwards, a question-attended document representation $\tilde{C}^q$ is calculate as

$$\tilde{C}^q = \{\tilde{\mathbf{c}}_t^q\}_{t=1}^n = A^T C^q \in \mathbb{R}^{n \times k}.$$

In addition to this, we obtain vector $\tilde{\mathbf{a}} \in \mathbb{R}^n$, corresponding to the attention of a question to document tokens, by applying softmax to the column-wise max values of S. Then document-attended question vector is obtained by

$$\tilde{\mathbf{c}}^d = \sum_{t=1}^{n} \tilde{\mathbf{a}}_t \mathbf{c}_t^d \in \mathbb{R}^k.$$

The final co-attended representations $\{\mathbf{d}_t\}_{t=1}^n$ is obtained by fully connected layer with ReLU as a nonlinear unit, φ, as

$$\mathbf{d}_t = \varphi([\mathbf{c}_t^d; \tilde{\mathbf{c}}_t^q; \mathbf{c}_t^d \odot \tilde{\mathbf{c}}_t^q; \mathbf{c}_t^d \odot \tilde{\mathbf{c}}_t^d]) \in \mathbb{R}^l.$$

Memory controller. This layer takes the output of the co-attention layer $\{\mathbf{d}_t\}_{t=1}^n$ as input and refine their representations using our proposed memory controller (Section 2.1). Afterwards, the resulting output vector $\{\mathbf{o}_t\}_{t=1}^n$ are given as input to the prediction layer.

Prediction layer. We feed the output of the memory controller $\{\mathbf{o}_t\}_{t=1}^n$ to the prediction layer to predict the start and the end token indices of the answer span. First, it goes through the encoder block followed by the fully connected layer with softmax over the entire sequence to compute the probability distribution of a start index. The probability distribution of the end index is calculated by concatenating the output of the encoder block for the start index with the output of the memory controller and then by feeding them as input to another encoder block. These probability distributions are used as part of the negative log-likelihood objective function.

4 Experimental Setup

Datasets and preprocessing. We perform extensive experiments with well-known benchmarks such as TriviaQA, QUASAR-T, and SQuAD, as summarized in Table 1. In most of these datasets, a question q and a document d are represented as a sequence of words, and the answer span has to be selected from the document words based on the question. SQuAD consists of crowd-sourced questions and paragraphs from Wikipedia articles containing the answer to these questions. QUASAR-T is mostly based on factoid questions with their corresponding, large-sized corpus. TriviaQA is composed of question-answer pairs obtained from 14 trivia and quiz-league websites, along with the documents collected later that are likely to contain the answer from either web search or Wikipedia. In TriviaQA dataset, we truncate each document to 1,200 words. Even with such truncation, the average word count per document (AWC) of TriviaQA is approximately four times larger than that of SQuAD. In terms of the AWC, documents in TriviaQA, QUASAR-T, and SQuAD can be viewed as large-, medium-, and small-length documents, respectively.

Dataset	Total Train / Dev / Test	AWC
SQuAD	87,599 / 10,570 / UNK	142
QUASAR-T (Short)	25,465 / 2,043 / 2,068	221
QUASAR-T (Long)	26,318 / 2,129 / 2,102	392
TriviaQA (Web)	528,979 / 68,621 / 65,509	631
TriviaQA (Wikipedia)	110,648 / 14,229 / 13,661	955

Table 1: Statistics of datasets in terms of the average word count per document (AWC). In TriviaQA, AWC was calculated after truncating each document to 1,200 words.

In TriviaQA dataset, because a document is collected separately for an already collected question-answer pair, the document does not sometimes have the information to properly infer the answer to the question. In response, Clark and Gardner (2017) attempted to solve this problem by exposing both relevant and irrelevant paragraphs together separated based on TF-IDF scores. We follow this approach in TriviaQA. In QUASAR-T, we follow the same preprocessing steps done by Dhingra et al. (2017).

Implementation details. We use TensorFlow[1]

Table 2: Single model results on TriviaQA (Web and Wikipedia) dataset. All the results are gathered from their corresponding publications except for our models and 'BiDAF + DNC,' which we implemented on our own. 'Full' represents a complete dataset not guaranteed to contain relevant information to answer the question while 'Verified' corresponds to its subset annotated by humans so that the relevant information for the answer is guaranteed to exist. The last column indicates whether a model uses any additional feature augmentation (AF).

to build the model and Sonnet[2] to implement the memory interface. NLTK (Bird and Loper, 2004) is used for tokenizing words. In the memory controller, we use four read heads and one write head, and the memory size is set to 100×36, with all initialized as 0. The hidden vector dimension l is set to 200. We use AdaDelta (Zeiler, 2012) as an optimizer with a learning rate of 0.5. The batch size is set to 20 for TriviaQA (Joshi et al., 2017) and 30 for SQuAD (Rajpurkar et al., 2016) and QUASAR-T (Dhingra et al., 2017). We use an exponential moving average of weights with a decaying factor of 0.001. Our model does require more memory than existing methods, but a single GPU (e.g., M40 with 12GB memory) was enough to train model within a reasonable amount of time.

5 Quantitative Results

For our quantitative comparisons, we use BiDAF with self attention (Clark and Gardner, 2017) as a baseline, which maintains the best results published on both TriviaQA and SQuAD datasets. In TriviaQA and QUASAR-T dataset, we compare our model with BiDAF (Seo et al., 2017) as well as its variant called 'BiDAF + DNC,' which is augmented with an existing external memory architecture (Graves et al., 2016) just before the answer prediction layer in the BiDAF.

Overall, in lengthy-document cases such as TriviaQA and QUASAR-T, our model outperforms all the published results, as seen in Tables 2 and 3, while in the short-document case such as SQuAD, we mostly achieve the best results, as seen in Table 4. In the following, we present detailed analyses on each dataset.

TriviaQA. As shown in Table 2, our model, even without DEBS, outperforms the existing state-of-the-art method such as 'BiDAF + SA + SN' by a large margin in all the cases. Our model with DEBS, which replaces BiGRU encoder blocks, performs even better than that without it in all the cases except for the combination of the 'full' and 'Wikipedia' case, which involves documents containing no relevant information for the answer. Among those methods shown in Table 2, Reading Twice for NLU (Weissenborn, 2017) uses background knowledge from ConceptNet while both M-Reader (Hu et al., 2017) and MEMEN (Pan et al., 2017) use POS and NER in-

formation as additional features. We note that our method achieves these outstanding results without any additional features.

QUASAR-T. As shown in Table 3, our simple baseline 'BiDAF + DNC,' which involves an existing memory architecture, improves performance over BiDAF, indicating the efficacy of incorporating an external memory. Moreover, our model with the proposed memory controller achieves significantly better results compared to other models. Furthermore, another proposed component, DEBS, gives an additional performance boost to our model.

SQuAD. As shown in Table 4, most of the models, if not all, use additional features such as ELMo (Peters et al.), and the self-attention mechanism to further improve the performance. We also adopt these mechanisms one by one to show that our model can also benefit from these. First, we adopt ELMo to our model (without DEBS), which uses word embedding as the weighted sum of the hidden layers of a language model with regularization as an additional feature to our word embeddings. This improves the F1 score of our model up to 85.13 and EM to 77.44, showing the highest performances among all the methods without using self attention. Due to the relatively short document length in SQuAD compared to TriviaQA and QUASAR-T, our model without DEBS performs worse than the baseline 'BiDAF + Self Attention + ELMo.' However, after applying DEBS, our model outperforms the baseline, achieving 86.73 F1 and 79.69 EM.

Minimum anchor distance. Rajpurkar et al. (2016) proposed the difficulty measure called syntactic divergence, which is computed as the edit distance between syntactic parse trees of the question and the sentence containing the answer. However, this measure has limitations that the syntactic parser does not work properly on incomplete sentences, which are common in web text. It also becomes difficult to compute this measure if the

answer requires multi-sentence inference.

Instead, we develop our own metric called a minimum anchor distance, which is simple and robust to noisy text. To compute this metric, we first identify for all the co-occurring words (anchor words) between a document and a question while ignoring stop words. Then, we compute the number of words found between the answer and all the possible anchor words and select the minimum number from these.

In Figure 2, we show F1 scores of our model with DEBS and the baseline with respect to the minimum anchor distance. The scores are obtained from the development set of TriviaQA(Web) and SQuAD. The heat map at the bottom of the figure indicates the number of samples in each interval of the minimum anchor distance. One can see that our model performs increasingly better than the baseline as the minimum anchor distance gets larger. The examples shown in Table 5 indicate that documents with long dependencies tend to have a large minimum anchor distance. These examples show that our model predicts the remotely placed answer from the anchor word relatively well when anaphora resolution and negation are involved.

Ablation study with an encoder block. We assume that the concatenation of the layer outputs in DEBS helps the memory controller store contextual representations clearly. To see how DEBS affects the memory controller depending on different positions in the entire network, we conducted an ablation study by replacing the encoder block with DEBS on SQuAD. As can be seen in Table 6, using DEBS in all the places improves the performance most, and furthermore, the memory controller with DEBS gives the largest performance margin. This implies that DEBS can generally work as a better alternative to a BiGRU module, and DEBS is critical in maintaining the high performance of our proposed memory controller.

Adding our proposed modules to other models. To show the wide effectiveness of our proposed approaches, we choose two well-known baseline models in SQuAD: R-net (Wang et al., 2017) and 'BiDAF + Self Attention' (Clark and Gardner, 2017). These models have similar architectures where the model first pairs a given question and document pair using an attention and afterward applies a self-attention mechanism. We use the publicly available implementation of these models[3,4]. In Table 7, replacing all the recurrent units with DEBS and adding our memory controller between the question-document pairing

layer and the self-attention layer increases the F1 score by around 0.5 compared to the baseline.

6 Related Work

Numerous neural network-based methods have been proposed, pushing the performance nearly up to a human level. Although slight differences exist, (Wang et al., 2017; Seo et al., 2017; Xiong et al., 2017) mostly leverage the question-document co-attention based on their pairwise similarity of word-level vector representations. These models currently work as the backbone architecture for many other models. Furthermore, Wang et al. (2017) suggest utilizing a self attention mechanism between tokens within a document to refine contextual representations.

Salant and Berant (2017); Chen et al. (2016); Pan et al. (2017); Weissenborn (2017); Peters et al. focus on augmenting feature representations in the word embedding layer to provide rich information. Salant and Berant (2017); Weissenborn (2017); Peters et al. extract and use additional features from other neural models trained for another task or external resources. Chen et al. (2016); Pan et al. (2017) utilize additional syntactic or semantic features through part-of-speech tagging or named-entity recognition, etc.

Enriching the input representation from pre-trained external models has been shown to be useful in improving RC task performances. Yu et al. (2018a) have also improved the performance by leveraging self attention for context encoding based on convolutional neural networks. Hu et al. (2017) refine the contextual representation with multiple hops, and Pan et al. (2017) use the encoded query for refining the answer prediction as a memory, which are different from our work in terms of handling long-range dependency.

7 Conclusion

This paper proposed two novel, crucial components for deep neural network-based RC tasks, (1) an advanced memory controller architecture and (2) a densely connected encoder block with self attention. We showed the effectiveness of these approaches in handling long-range dependencies using three benchmark RC datasets such as TriviaQA, QUASAR-T, and SQuAD. Our proposed modules are widely applicable to other models to improve their performance. Future work includes developing a scalable read/write accessing mechanism to handle a large-scale external memory to reason over multiple documents.

Abstract

Sequence encoders are crucial components in many neural architectures for learning to read and comprehend. This paper presents a new compositional encoder for reading comprehension (RC). Our proposed encoder is not only aimed at being fast but also expressive. Specifically, the key novelty behind our encoder is that it explicitly models across multiple granularities using a new dilated composition mechanism. In our approach, gating functions are learned by modeling relationships and reasoning over multi-granular sequence information, enabling compositional learning that is aware of both long and short term information. We conduct experiments on three RC datasets, showing that our proposed encoder demonstrates very promising results both as a standalone encoder as well as a complementary building block. Empirical results show that simple Bi-Attentive architectures augmented with our proposed encoder not only achieves state-of-the-art / highly competitive results but is also considerably faster than other published works.

1 Introduction

Teaching machines to read, comprehend and reason lives at the heart of reading comprehension (RC) tasks (Rajpurkar et al., 2016; Lai et al., 2017; Dunn et al., 2017; Kočiskỳ et al., 2017). In these tasks, the goal is to answer questions based on a given passage, effectively testing the learner's capability to understand natural language. This has been an extremely productive area of research in the recent years, giving rise to many highly advanced neural network architectures (Xiong et al., 2016; Weissenborn et al., 2017; Seo et al., 2016; Hu et al., 2017; Shen et al., 2017; Wang and Jiang, 2016b; Wang et al., 2018). A common denominator in many of these models is the compositional encoder, i.e., usually a bidirectional recurrent-based (LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014)) encoder that sequentially parses the text sequence word-by-word. This helps to model compositionality of words, capturing rich and complex linguistic and syntactic structure in language.

While the usage of recurrent encoder is often regarded as indispensable in highly complex RC tasks, there are still several challenges and problems pertaining to its usage in modern RC tasks. Firstly, documents can be extremely long to the point where running a BiRNN model across a long document is computationally prohibitive[1]. This is aggravated since RC tasks can be easily extended to reasoning over multiple long documents. Secondly, recurrent encoders have limited access to long term context since each word is sequentially parsed. This restricts any form of multi-sentence and intra-document reasoning from happening within compositional encoder layer.

To this end, we propose a new compositional encoder that can either be used in place of standard RNN encoders or serve as a new module that is complementary to existing neural architectures. Our proposed encoder leverages *dilated compositions* to model relationships across multiple granularities. That is, for a given word in the target sequence, our encoder exploits both long-term (far) and short-term (near) information to decide how much information to retain for it. Intuitively, this can be interpreted as learning to compose based on modeling relationships between word-level, phrase-level, sentence-level, paragraph-level and so on. The output of the dilated composition mechanism acts as gating functions, which are then used to learn compositional representations of the input sequence.

---

[1] Many recent works tackle this issue (Yu et al., 2018; Choi et al., 2017). However, this work presents a complementary/orthogonal approach to many of these works.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2141–2151
Brussels, Belgium, October 31 - November 4, 2018.

A brief high-level overview to our proposed encoder is given as follows: Firstly, sequences are chunked into blocks based on user-defined (hyperparameter) block sizes. Block sizes are often dilated in nature, i.e., $1, 2, 4, 10, 25$, etc., in order to capture more long-term information. Our encoder takes the neural bag-of-words representation of each block size and compresses/folds all words (that reside in each block) into a single summed embedding. All blocks are then passed into fully-connected layers and re-expanded/unfolded to their original sequence lengths. For each word, the gating vectors are then constructed by modeling the relationships between all blocks that this word resides in. As such, this can be interpreted as a divide-and-conquer sequence encoding method.

This has several advantages. Firstly, we enable a major speedup by avoiding either costly step-by-step gate construction while still maintaining interactions between neighboring words. As such, our model belongs to a class of architectures which is inspired by QRNNs (Bradbury et al., 2016) and SRUs (Lei and Zhang, 2017). The key difference is that our gates are not constructed by convolution layers but explicit block-based matching across multiple ranges, both long and short. Secondly, modeling at a long range (e.g., 25 or 50) enables our model to look further ahead as opposed to only one step forward. As such, the learned gates not only possess information about nearby words but also a larger overview of the context. This is in similar[2] spirit to self-attention, albeit occuring within the encoder. Thirdly, the final gates are formed by modeling relationships between multi-range projections (n-gram blocks), allowing for fine-grained intra-document relationships to be captured. The overall contributions of our work are as follows:

- We propose DCU (Dilated Compositional Units[3]), a new compositional encoder for both fast and expressive sequence encoding. We propose an overall architecture that utilizes DCU within a Bi-Attentive framework for both multiple choice and span prediction RC tasks. DCU can be used as a standalone (without RNNs) for fast reading and/or together with RNN models (i.e., DCU-LSTM) for more expressive reading.
- We conduct extensive experiments on three large-scale and challenging RC datasets - RACE (Lai et al., 2017), SearchQA (Dunn et al., 2017) and NarrativeQA (Kočiský et al., 2017). Our model is lightweight, fast and efficient, achieving state-of-the-art or highly competitive performance on three datasets.
- Despite its simplicity, our model outperforms highly complex models such as Dynamic Fusion Networks (DFN) (Xu et al., 2017) on RACE. While DFN takes approximately a week to train, spending at least several hours per epoch, our model converges in less than 12 hours with only $4-5$ minutes per epoch. Moreover, our model outperforms DFN by $2\% - 6\%$ on the RACE benchmark and other strong baselines such as the Gated Attention Reader by 10%. On RACE, we outperform DFN without any recurrent and convolution layers. Ablation studies show an improvement of up to 6% when using DCU over a LSTM/GRU encoder.

2 Dilated Compositional Units (DCU)

In this section, we describe our proposed DCU encoder.

2.1 Dilated Composition Mechanism

The inputs to the DCU encoder are (1) a sequence $\{w_1, w_2 \cdots w_\ell\}$, and (2) list of ranges $\{r_1, r_2 \cdots r_k\}$ where k is the number of times the fold/unfold operation is executed. The final output of the encoder is a sequence of vectors which retains the same dimensionality as its inputs. Figure 1 provides an illustration of the overall encoder architecture.

2.1.1 Fold Operation

This section describes the operation for each r_j. For each r_j and the input sequence, the fold operation performs the summation of every r_j word. This is essentially the NBOW (neural bag-of-words) representation. This reduces the overall document length to ℓ/r_j where each item in the sequence is the sum of every r_j word. Given the new sequence of ℓ/r_j tokens, we then pass each token into a single layered feed-forward neural network:

$$\bar{w_t} = \sigma_r(\mathbf{W}_a(w_t)) + \mathbf{b}_a \qquad (1)$$

---

[2] It is good to note that our approach explicitdly compares across blocks of multi-granularities while self-attention compares on a word-level basis.

[3] This model was originally known as MRU (Multi-Range Reasoning Units) and was published on ArXiv on March 2018.

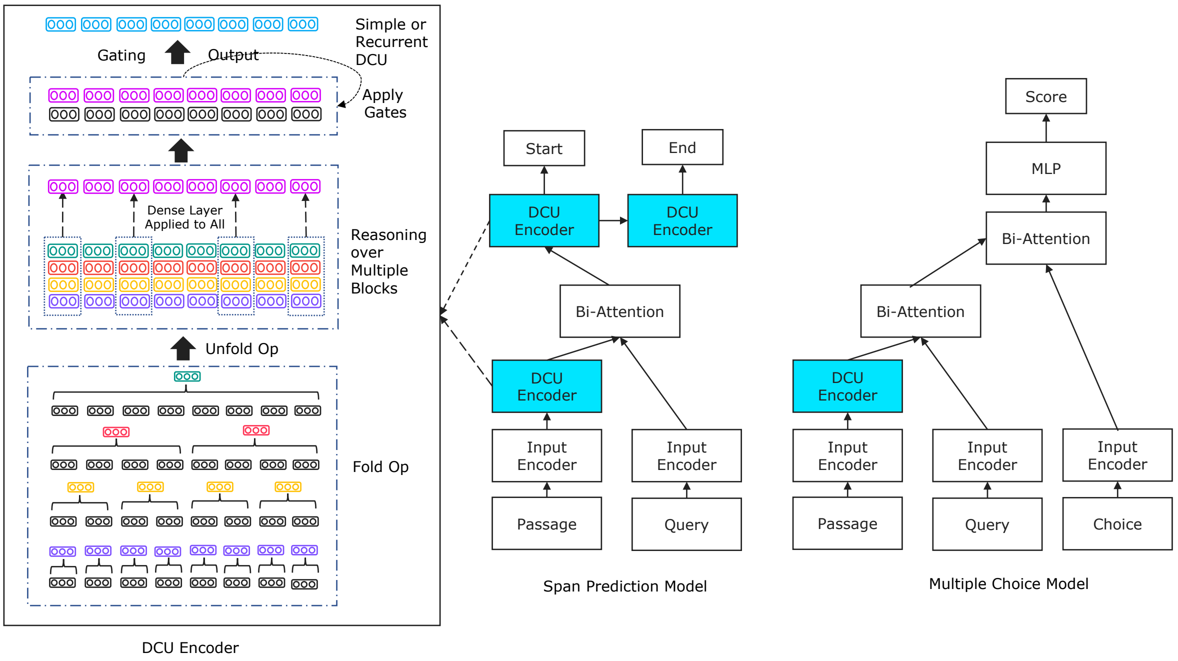

Figure 1: High-level overview of (1) our proposed DCU encoder (left), (2) Span Prediction Architecture (center) and (3) Multiple Choice Architecture (right). In the DCU encoder, blocks are formed at multi-granular levels. A block embedding is learned for each granularity. The composition gates for each word is constructed by modeling the relationships between all NBOW (neural bag-of-words) blocks that it resides in.

where $\mathbf{W}_a \in \mathbb{R}^{d \times d}$ and $\mathbf{b}_a \in \mathbb{R}^d$ are the parameters of the fold layer. σ_r is the ReLU activation function. w_t is the t-th token in the sequence.

2.1.2 Unfold Operation

Given the transformed tokens $\bar{w}_1, \bar{w}_2 \cdots \bar{w}_{\ell/r_j}$, we then expand/unfold them into the original sequence length. Note that for each r_j, the parameters $\mathbf{W}_a, \mathbf{b}_a$ are not shared between blocks. Figure 2 depicts the fold-unfold operation for a single value of r_j.

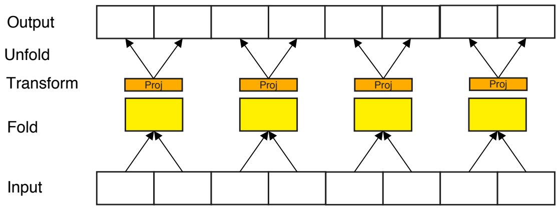

Figure 2: Overview of the Fold-Unfold operation for $r_j = 2$.

Overall, the key intuition of *each* fold-unfold operation is to learn representations of a block of a single granularity (say, blocks of 2). The main rationale for unfolding is to enable reasoning over multiple blocks (or granularities). This is described in the next section.

2.1.3 Multi-Granular Reasoning

From k different calls of the Fold/Unfold operation at different block sizes, we pass the concatenated vector of all transformed tokens into a two layered feed-forward neural network.

$$g_t = \mathbf{F}_2(\mathbf{F}_1([w_t^1; w_t^2; \cdots w_t^k])) \qquad (2)$$

where $\mathbf{F}_1(.), \mathbf{F}_2(.)$ are feed-forward networks with ReLU activations, i.e., $\sigma_r(W_x + b)$. $[;]$ is the concatenation operator. g_t is interpreted as a gating vector learned from multiple granularities and Equation (2) is learning the relationships between a token's representation at multiple hierarchies depending on the values of r_j. Notably, it is easy to see that every n pairs of words will have the same gating vector where n is the lowest value of r_j. As such, the value of the unigram, i.e., $r_j = 1$ (projection of every single token) is critical as it prevents identical gating vectors across the sequence.

2.2 Encoding Operation

To learn the DCU encoded representation of each word, we consider two variations of DCU encoders.

2.2.1 Simple Encoding

In this variation, we use g_t as a gating vector to control the fine-grained balance between the projection of each word w_t in the original input document and the original representation.

$$z_t = \tanh(\mathbf{W}_p\, w_t) + \mathbf{b}_p \quad (3)$$

$$y_t = \sigma(g_t) * w_t + (1 - \sigma(g_t))\, z_t \quad (4)$$

where $\{y_1, y_2, \cdots y_\ell\}$ is the output document representation. σ is the sigmoid function. Note that this formulation is in similar spirit to highway networks (Srivastava et al., 2015). However, since our gating function is learned via reasoning over multi-granular sequence blocks, it captures more compositionality and long range context. Note that an optional and additional projection may be applied to w_t but we found that it did not yield much empirical benefit.

2.2.2 Recurrent Encoding (DCU cell)

In the second variation, we consider a recurrent (sequential) variant. This is in similar spirit to QRNNs (Bradbury et al., 2016) and SRUs (Lei and Zhang, 2017) which reduces computation cost by pre-learning the gating vectors. The following operations describe the operations of the recurrent DCU cell for each time step t.

$$c_t = g_t \odot c_{t-1} + (1 - g_t) \odot z_t \quad (5)$$

$$h_t = o_t \odot c_t \quad (6)$$

where c_t, h_t are the cell and hidden states at time step t. g_t are the gates learned from the output of the multi-range reasoning step. o_t is an additional output gate learned via applying an affine transform on the input vector w_t, i.e., $o_t = W_o(w_t) + b_o$. Similar to RNNs, the Recurrent DCU parses the input sequence word-by-word. However, the cost is significantly reduced because we do not have expensive matrix operations that are executed in an non-parallel fashion. Finally, the outputs of the DCU encoder are a series of hidden vectors $\{h_1, h_2 \cdots h_\ell\}$ for each word in the sequence.

3 Overall Model Architectures

This section describes the overall model architectures that utilize DCU encoders. In our experiments, we focus on both multiple-choice based (RACE) and span prediction RC tasks (SearchQA, NarrativeQA). Since the core focus of this paper is our encoder, we briefly provide the high-level details[4] of our vanilla Bi-Attentive model. The Bi-Attentive models that are used in our experiments act as baselines, often being less complex than current competitive models such as BiDAF (Seo et al., 2016), AMANDA (Kundu and Ng, 2018) or DFN (Xu et al., 2017). Figure 1 (center and right side of the figure) provides a high-level illustration of these architectures.

3.1 Multiple Choice Models

In the Multiple Choice (MCQ) model, there are three types of input sequences, namely Passage (P), Question (Q) and Answers (A_j). The output of the model (for each answer), is a score $s(P, Q, A_j) \in [0, 1]$ denoting the strength of A_j.

Input Encoding Each input sequence is passed into first a projection layer. To enhance the input word representations, we also include the standard EM (exact match) binary feature to each word. In this case, we use a three-way EM adaptation, i.e., $EM(P, Q), EM(Q, A)$ and $EM(P, A)$. The projected embeddings are then passed into a single-layered highway network.

Compositional Encoder In our experiments, we vary the encoder in this layer. Typical choices of encoders in this layer are LSTMs or GRUs. We vary this in our experiments in order to benchmark the effectiveness of our proposed DCU encoder. The output of this layer has the same dimensions as its inputs (typically the hidden states of a RNN model).

Bi-Attention Layer - This layer models the interactions between P, Q and A. Let $B(.)$ be a standard bidirectional attention that utilizes mean-pooling aggregation. The scoring function is the bilinear product of the nonlinearly transformed input, i.e., $F(x)_i^\top \mathbf{M} F(y)_i$. We first apply $B(P, Q)$ to form bi-attentive P^q, Q^p representations. Subsequently, we apply $B(P^q, A_j)$ to learn a vector representation for each answer. A temporal sum pooling is applied on the outputs of P^{qa}, A_j^p and concatenated to form $a_j^f \in \mathbb{R}^{2d}$.

Answer Selection Let $\{a_1, a_2 \cdots a_{N_a}\}$ be the inputs to this layer and N_a is the number of answer candidates. Motivated by the work in retrieval-based QA (Severyn and Moschitti, 2015), we include word overlap features to each answer candidate. This word overlap feature is in similar spirit to the EM feature. Each overlap operation between two sequences returns four features. We convert each answer vector a_j into a scalar via

---

[4] This is primarily due to the lack of space as the main focus of this work is the DCU. Source code will be released at `hhttps://github.com/vanzytay/EMNLP18_DCU`.

$a_j^f = Softmax(\mathbf{W}_2(\sigma_r(\mathbf{W}_1([a_j]) + b_1) + b_2))$ where $\mathbf{W}_*, b_*$ and $* = \{1, 2\}$ are standard dense layer parameters.

Optimization The MCQ-based model minimizes the multi-class cross entropy where the number of classes corresponds to the number of choices.

3.2 Span Prediction Model

In the Span Prediction Model, the goal is to extract (or predict a span s, e) where $P[s : e]$ is the answer to the query. As such, the key interaction in this architecture is between P and Q. For most part, the model architecture remains similar especially for the input encoding layers and compositional encoder layer. The key difference is that we reduce the number of input sequence from three to two.

Input Encoding This follows the same design as the MCQ-based model, albeit for two sequences instead of three. Similarly, the two-way EM feature is added before passing into the highway layer.

Compositional Encoder This layer remains identical to the MCQ-based model.

Bi-Attention Layer We adopt a different bi-attention function for span prediction. More specifically, we use the 'SubMultNN' or the 'Mult' adaptation from (Wang and Jiang, 2016a) (which is tuned) and compare aligned sequences between P and Q to form P^q, the query-dependent passage representation.

Answer Pointer Layer In this layer, we pass P^q through a two layered compositional encoder (which is varied similar to the compositional encoder layer and will be further elaborated in our experiments.). The start pointer and end pointer are determined by $F(H_1), F(H_2)$ where H_1, H_2 are the hidden outputs from the first and second encoders respectively. $F(.)$ is a linear transform, projecting each hidden state to a scalar. We pass both of them into softmax functions to obtain probability distributions.

Optimization Following (Seo et al., 2016; Wang and Jiang, 2016b), we minimize the joint cross entropy loss of the start and end probability distributions. During inference, we follow (Wang and Jiang, 2016b) to find the best answer span.

4 Empirical Evaluation

In this section, we report our experimental results and comparisons against other published works.

4.1 Datasets

For our experiments, we use one challenging multiple choice MC dataset and two span-prediction MC datasets.

RACE (Reading Comprehension from Examinations) (Lai et al., 2017) is a recently proposed dataset that is constructed from real world examinations. Given a passage, there are several questions with four options each. The authors argue that RACE is more challenging compared to popular benchmarks (e.g., SQuAD (Rajpurkar et al., 2016)) as more multi-sentence and compositional reasoning are required. There are two subsets of RACE, namely RACE-M (Middle school) and RACE-H (High school). The latter is considered to be harder than the former.

SearchQA (Dunn et al., 2017) is a recent dataset that emulates a real world QA system. It involves extracting passages from search engine results and requiring models to answer questions by reasoning and reading these search snippets.

NarrativeQA (Kočiskỳ et al., 2017) is a recent benchmark proposed for story-based reading comprehension. Different from many RC datasets, the answers are handwritten by human annotators. We focus on the *summaries* setting instead of reading full stories since our model is targetted at standard RC tasks.

MCQ datasets are evaluated using the standard accuracy metric. For RACE, we train models on the entire dataset, i.e., both RACE-M and RACE-H, and evaluate them separately. For RACE, the model selection is based on each subset's respective development set. For SearchQA, we follow (Kundu and Ng, 2018; Dunn et al., 2017) which evaluates unigram exact match (EM) and n-gram F1 scores. For NarrativeQA, since the answers are human written and not constrained to a span that can be found in the passage, the evaluation metrics are BLEU-1, BLEU-4, Meteor and Rouge-L following (Kočiskỳ et al., 2017).

4.2 Competitor Methods

We describe the key competitors on each dataset.

RACE The key competitors are the Stanford Attention Reader (Stanford AR) (Chen et al., 2016), Gated Attention Reader (GA) (Dhingra et al., 2016), and Dynamic Fusion Networks (DFN) (Xu et al., 2017). GA incorporates a multi-hop attention mechanism that helps to refine the answer representations. DFN is an extremely complex model. It uses (1) BiMPM's matching functions (Wang et al., 2017c) for extensive matching between Q, P and A, (2) multi-hop reasoning powered by ReasoNet (Shen et al., 2017) and (3) employs reinforcement learning techniques for dynamic strategy selection. A leaderboard for this dataset is maintained at `http://www.qizhexie.com/data/RACE_leaderboard`. Note that the current state-of-the-art[5] (Radford et al., 2018), is a generative pre-training model trained on a large external corpus.

SearchQA The main competitor baseline is the AMANDA model proposed by (Kundu and Ng, 2018). AMANDA uses a multi-factor self-attention module, along with a question focused span prediction. AMANDA also uses BiLSTM layers for input encoding and at the span prediction layers. We also compare against the reported ASR (Kadlec et al., 2016) baselines which were reported in (Dunn et al., 2017).

NarrativeQA On this benchmark, we compare with the reported baselines in (Kočiskỳ et al., 2017). We compete on the summaries setting, in which the baselines are a context-less sequence to sequence (seq2seq) model, ASR (Kadlec et al., 2016) and BiDAF (Seo et al., 2016). As per reviewer request, we also benchmark a stronger competitor, namely R-NET (Wang et al., 2017b) on this benchmark. We use the open source implementation[6] at `https://github.com/HKUST-KnowComp/R-Net`.

4.3 Our Methods

Across our experiments, we benchmark several variants of our proposed DCU. The first is denoted as Sim-DCU which corresponds to the Simple DCU model described earlier. The model denoted by DCU (without any prefix) corresponds to the recurrent DCU model. Finally, the final variant is the DCU-LSTM which places a DCU encoder layer on top of a BiLSTM layer. We report the dimensions of the encoder as well as training time (per epoch) for each variant. The encompassing framework for DCU is the Bi-Attentive models described for MCQ-based problems and span prediction problems. Unless stated otherwise, the encoder in the pointer layer for span prediction models also uses DCU. However, for the Hybrid DCU-LSTM models, answer pointer layers use BiLSTMs. For the RACE-dataset, we additionally report scores of an ensemble of nine Sim-DCU models. This is to facilitate comparison against ensemble models of (Xu et al., 2017). We tune the dimensionality of the DCU cell within a range of $100-300$ in denominations of 50. The results reported are the best performing models on the held-out set.

4.4 Implementation Details

We implement all models in TensorFlow (Abadi et al., 2015). Word embeddings are initialized with $300d$ GloVe (Pennington et al., 2014) vectors and are not fine-tuned during training. Dropout rate is tuned amongst $\{0.1, 0.2, 0.3\}$ on all layers including the embedding layer. For our DCU model, we use range values of $\{1, 2, 4, 10, 25\}$. DCU encoders are only applied on the passage and not the query. We adopt the Adam optimizer (Kingma and Ba, 2014) with a learning rate of $0.0003/0.001/0.001$ for RACE/SearchQA/NarrativeQA respectively. The batch size is set to $64/256/32$ accordingly. The maximum sequence lengths are $500/200/1100$ respectively. For NarrativeQA, we use the Rouge-L score to find the best approximate answer relative to the human written answer for training the span model. All models are trained and all runtime benchmarks are based on a TitanXP GPU.

4.5 Experimental Results on RACE

Table 1 reports our results on the RACE benchmark dataset. Our proposed DCU model achieves the best result for both single models and ensemble models. We outperform highly complex models such as DFN. We also pull ahead of other recent baselines such as ElimiNet (Parikh et al., 2018) and GA by at least 5%. The best single model score from RACE-H and RACE-M alternates between Sim-DCU and DCU. Overall, there is a 6% improvement on the RACE-H dataset and

---

[5] This paper was not public at the time of EMNLP 2018 submission.

[6] Note that the authors of this repository state some differences with the original R-NET. However, they get similar scores on the SQuAD benchmark.

Model	RACE-M	RACE-H	RACE	Time
Sliding Window (Lai et al., 2017)	37.3	30.4	32.2	N/A
Stanford AR (Chen et al., 2016)	44.2	43.0	43.3	N/A

Table 2: Experimental Results on SearchQA dataset. (Dunn et al., 2017). Unigram Accuracy and N-gram F1 are reported following (Kundu and Ng, 2018). All models with † use the same encoder in the answer pointer layer. * is an estimate running a replicated model with same batch size ($b = 256$) as our models.

1.8% improvement on the RACE-M dataset. Our Sim-DCU model also runs at 4 minutes per iteration, which is dramatically faster and simpler than DFN or other recurrent models. We believe that this finding highlights the importance of designing strong and fast baselines for the task at hand.

In general, we also found that the usage of a recurrent cell is not really crucial on this dataset since (1) Sim-DCU and DCU can achieve comparable performance to each other, (2) GRU and LSTM models do not have a competitive edge and (3) using no encoder can achieve comparable[7] performance to DFN. Finally, an ensemble of Sim-DCU models achieve state-of-the-art performance on the RACE dataset, achieving an overall score of 53.3%.

4.6 Experimental Results on SearchQA

Table 2 reports our results on the SearchQA dataset. We draw the reader's attention to the performance of the 300d DCU encoder. We achieve the same accuracy as AMANDA without using any LSTM or GRU encoder. This model runs at 2 minutes per epoch, making it 4 times more efficient than AMANDA (estimated, with identical batch size). While AMANDA also uses multi-factor self-attention, along with character enhanced representations, our simple DCU encoder used within a mere baseline bi-attentive framework comes close in performance. Finally, the hybrid combination, DCU-LSTM significantly outperforms AMANDA by 3%.

Contrary to MCQ-based datasets, we found that

---

[7] Nevertheless, this suggests the importance of benchmarking good and strong baselines since a well-tuned baseline model can outperform DFN, a highly complicated model.

Model	BLEU-1	BLEU-4	Meteor	Rouge-L	Time
Seq2Seq†	15.89	1.26	4.08	13.15	N/A
ASR† (Kadlec et al., 2016)	23.20	6.39	7.77	22.26	N/A

Table 3: Experimental Results on the NarrativeQA reading comprehension challenge (Kočiský et al., 2017) using summaries. † are baselines reported by (Kočiský et al., 2017). $^\phi$ was obtained by running an open-source implementation of R-NET on the benchmark.

Sim-DCU model could not achieve comparable results to the recurrent DCU. We hypothesize that this is due to the need to predict spans. Nevertheless, the 300d DCU outperforms an LSTM encoder and remains competitive to a BiLSTM of similar dimensionality[8]. We also observe that LSTM and DCU are complementary. This shows that stacking a DCU encoder over standard LSTMs can give a performance boost relative to using each encoder separately.

4.7 Experimental Results on NarrativeQA

Table 3 reports our results on the NarrativeQA benchmark. First, we observe that 300d DCU can achieve comparable performance with BiDAF (Seo et al., 2016). When compared with a BiLSTM of equal output dimensions (150d), we find that our DCU model performs competitively, with less than 1% deprovement across all metrics. However, the time cost required is significantly reduced. The performance of our model is significantly better than 300d LSTM model while also being significantly faster. Here, we note that Sim-DCU does not produce reasonable results at all, which seems to be in similar vein to results on SearchQA, i.e., a recursive cell that processes word-by-word is mandatory for span prediction. However, our results show that it is not necessary to construct gates in a word-by-word fashion. Finally, DCU-LSTM significantly outperforms all models in terms of ROUGE-L, including BiDAF on this dataset. Performance improvement over the vanilla BiLSTM model ranges from $1\% - 3\%$ across all metrics, suggesting that DCU encoders are also effective as a complementary neural building block.

5 Related Work

A diverse collection of MC datasets such as SQuAD (Rajpurkar et al., 2016) and CNN/DailyMail (Hermann et al., 2015) are readily available for benchmarking new deep learning models. New datasets have been recently released (Kočiský et al., 2017; Joshi et al., 2017; Lai et al., 2017; Welbl et al., 2017; Dhingra et al., 2017; Trischler et al., 2016), claiming to involve a greater need for going beyond simple surface-level matching. As such, these datasets often emphasize the extent of compositional and multi-sentence reasoning required to tackle its questions.

In recent years, a wide range of innovative neural solutions have also been proposed, mainly involving bi-attention (Seo et al., 2016; Xiong et al., 2016; Cui et al., 2016) and answer pointers (Wang and Jiang, 2016b). Recent work also investigates the notion of multi-hop reasoning (Dhingra et al., 2016; Shen et al., 2017; Xu et al., 2017), reinforcement learning (Shen et al., 2017; Wang et al., 2017a; Hu et al., 2017), pretraining on auxilliary tasks (Radford et al., 2018; Peters et al., 2018; McCann et al., 2017, 2018) and self-matching / self-attention (Kundu and Ng, 2018; Wang et al., 2017b; Yu et al., 2018). While many of these works use BiLSTMs as standard building blocks, (Yu et al., 2018) proposed a RNN-less model architecture by utilizing components inspired by the Transformer architecture (Vaswani et al., 2017).

Our work is mainly concerned with designing an efficient encoder that is able to capture not only compositional information but also long-range and

---

[8] In terms of representation and parameter size, we consider a 150d BiLSTM to be equivalent to a 300d LSTM for fair comparison.

short-range information. More specifically, our recurrent DCU encoder takes on a similar architecture to Quasi-Recurrent Neural Networks (Bradbury et al., 2016) and Simple Recurrent Units (Lei and Zhang, 2017). In these models, gates are pre-learned and then applied. However, different from existing models such as QRNNs that use convolution layers as gates, we use block-based fold-unfold layers for learning gates. Our model also draws inspiration from dilation, in particular dilated RNNs (Chang et al., 2017) and dilated convolutions (Kalchbrenner et al., 2016), that intuitively help to model long-range dependencies. Notably, our work is orthogonal to recent advances that are targetted at speeding up the reading process. Such works include residual dilated convolutions (Wu et al., 2017), self-attention (Yu et al., 2018) and coarse-to-fine grained paradigm (Choi et al., 2017). However, while speed is one of the clear benefits of this work, our work is the first to introduce the idea of block-based multi-granular reasoning. We believe that this new building block is complementary/useful to the RC task in general.

6 Conclusion and Future Work

We proposed a novel neural architecture, the DCU encoder and an overall bi-attentive model for both MCQ-based and span prediction MC tasks. We apply it to three MC datasets and achieve competitive performance on all without the use of recurrent and convolution layers. Our proposed method outperforms DFN, an extremely complex model, without using any LSTM/GRU layer. We also remain competitive to AMANDA and BiDAF without any LSTM/GRU. While our proposed encoder demonstrates promise on reasoning and understanding natural language, we believe that our encoder is generalizable to other domains beyond reading comprehension. However, we defer this prospect to future work.

Abstract

Answering compositional questions requiring multi-step reasoning is challenging. We introduce an end-to-end differentiable model for interpreting questions about a knowledge graph (KG), which is inspired by formal approaches to semantics. Each span of text is represented by a denotation in a KG and a vector that captures ungrounded aspects of meaning. Learned composition modules recursively combine constituent spans, culminating in a grounding for the complete sentence which answers the question. For example, to interpret "*not green*", the model represents "*green*" as a set of KG entities and "*not*" as a trainable ungrounded vector—and then uses this vector to parameterize a composition function that performs a complement operation. For each sentence, we build a parse chart subsuming all possible parses, allowing the model to jointly learn both the composition operators and output structure by gradient descent from end-task supervision. The model learns a variety of challenging semantic operators, such as quantifiers, disjunctions and composed relations, and infers latent syntactic structure. It also generalizes well to longer questions than seen in its training data, in contrast to RNN, its tree-based variants, and semantic parsing baselines.

1 Introduction

Compositionality is a mechanism by which the meanings of complex expressions are systematically determined from the meanings of their parts, and has been widely assumed in the study of both artificial and natural languages (Montague, 1973) as a means for allowing speakers to generalize to understanding an infinite number of sentences. Popular neural network approaches to question answering use a restricted form of compositionality, typically encoding a sentence word-by-word, and then executing the complete sentence encoding against a knowledge source (Perez et al., 2017). Such models can fail to generalize from training data in surprising ways. Inspired by linguistic theories of compositional semantics, we instead build a latent tree of interpretable expressions over a sentence, recursively combining constituents using a small set of neural modules. Our model outperforms RNN encoders, particularly when test questions are longer than training questions.

Our approach resembles Montague semantics, in which a tree of interpretable expressions is built over the sentence, with nodes combined by a small set of composition functions. However, both the structure of the sentence and the composition functions are learned by end-to-end gradient descent. To achieve this, we define the parametric form of small set of composition modules, and then build a parse chart over each sentence subsuming all possible trees. Each node in the chart represents a span of text with a distribution over groundings (in terms of booleans and knowledge base nodes and edges), as well as a vector representing aspects of the meaning that have not yet been grounded. The representation for a node is built by taking a weighted sum over different ways of building the node (similar to Maillard et al. (2017)). The trees induced by our model are linguistically plausible, in contrast to prior work on structure learning from semantic objectives (Williams et al., 2018).

Typical neural approaches to grounded question answering first encode a question with a recurrent neural network (RNN), and then evaluate the encoding against an encoding of the knowledge source (for example, a knowledge graph or image) (Santoro et al., 2017). In contrast to classical approaches to compositionality, constituents of complex expressions are not given explicit interpretations in isolation. For example, in *Which cubes are large or green?*, an RNN encoder will not explic-

Brussels, Belgium, October 31 - November 4, 2018.

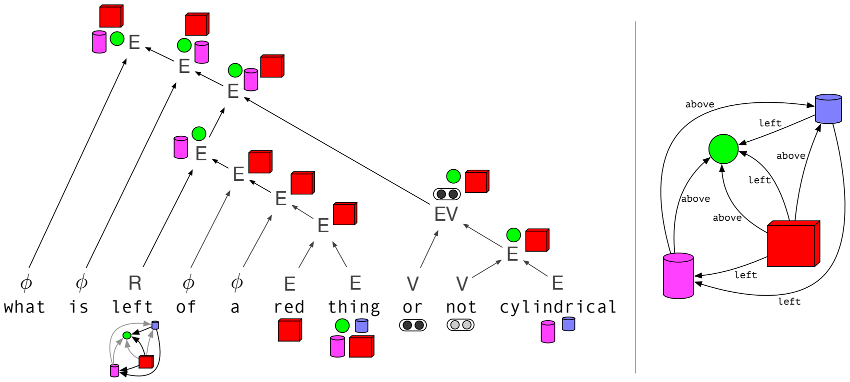

Figure 1: A correct parse for a question given the knowledge graph on the right, using our model. We show the type for each node, and its denotation in terms of the knowledge graph. The words *or* and *not* are represented by vectors, which parameterize composition modules. The denotation for the complete question represents the answer to the question. Nodes here have types E for sets of entities, R for relations, V for ungrounded vectors, EV for a combination of entities and a vector, and ϕ for semantically vacuous nodes. While we show only one parse tree here, our model builds a parse chart subsuming all trees.

itly build an interpretation for the phrase *large or green*. We show that such approaches can generalize poorly when tested on more complex sentences than they were trained on. Our approach instead imposes independence assumptions that give a linguistically motivated inductive bias. In particular, it enforces that phrases are interpreted independently of surrounding words, allowing the model to generalize naturally to interpreting phrases in different contexts. In our model, *large or green* will be represented as a particular set of entities in a knowledge graph, and be intersected with the set of entities represented by the *cubes* node.

Another perspective on our work is as a method for learning layouts of Neural Module Networks (NMNs) (Andreas et al., 2016b). Work on NMNs has focused on construction of the structure of the network, variously using rules, parsers and reinforcement learning (Andreas et al., 2016a; Hu et al., 2017). Our end-to-end differentiable model jointly learns structures and modules by gradient descent.

Our model is a new combination of classical and neural methods, which maintains the interpretability and generalization behaviour of semantic parsing, while being end-to-end differentiable.

2 Model Overview

Our task is to answer a question $q = w_{1..|q|}$, with respect to a Knowledge Graph (KG) consisting of nodes $\mathcal{E}$ (representing entities) and labelled directed edges $\mathcal{R}$ (representing relationship between entities). In our task, answers are either booleans, or specific subsets of nodes from the KG.

Our model builds a parse for the sentence, in which phrases are grounded in the KG, and a small set of composition modules are used to combine phrases, resulting in a grounding for the complete question sentence that answers it. For example, in Figure 1, the phrases *not* and *cylindrical* are interpreted as a function word and an entity set, respectively, and then *not cylindrical* is interpreted by computing the complement of the entity set. The node at the root of the parse tree is the answer to the question. Our model answers questions by:

(a) Grounding individual tokens in a KG, that can either be grounded as particular sets of entities and relations in the KG, as ungrounded vectors, or marked as being semantically vacuous. For each word, we learn parameters that are used to compute a distribution over semantic types and corresponding denotations in a KG (§ 3.1).

(b) Combining representations for adjacent phrases into representations for larger phrases, using trainable neural composition modules (§ 3.2). This produces a denotation for the phrase.

(c) Assigning a binary-tree structure to the question sentence, which determines how words are grounded, and which phrases are combined using which modules. We build a parse chart subsuming all possible structures, and train a parsing model to increase the likelihood of structures leading to the correct answer to questions. Different parses leading to a denotation for a phrase of type t are merged into an expected denotation, allowing dynamic programming (§ 4).

(d) Answering the question, with the most likely grounding of the phrase spanning the sentence.

3 Compositional Semantics

3.1 Semantic Types

Our model classifies spans of text into different semantic types to represent their meaning as explicit denotations, or ungrounded vectors. All phrases are assigned a distribution over semantic types. The semantic type determines how a phrase is grounded, and which composition modules can be used to combine it with other phrases. A phrase spanning $w_{i..j}$ has a denotation $[\![w_{i..j}]\!]^t_{KG}$ for each semantic type t. For example, in Figure 1, *red* corresponds to a set of entities, *left* corresponds to a set of relations, and *not* is treated as an ungrounded vector.

The semantic types we define can be classified into three broad categories.

Grounded Semantic Types: Spans of text that can be fully grounded in the KG.

1. **Entity** (**E**): Spans of text that can be grounded to a set of entities in the KG, for example, *red sphere* or *large cube*. **E**-type span grounding is represented as an attention value for each entity, $[p_{e_1}, \ldots, p_{e_{|\mathcal{E}|}}]$, where $p_{e_i} \in [0, 1]$. This can be viewed as a soft version of a logical set-valued denotation, which we refer to as a soft entity set.
2. **Relation** (**R**): Spans of text that can be grounded to set of relations in the KG, for example, *left of* or *not right of or above*. **R**-type span grounding is represented by a soft adjacency matrix $A \in \mathbb{R}^{|\mathcal{E}| \times |\mathcal{E}|}$ where $A_{ij} = 1$ denotes a directed edge from $e_i \rightarrow e_j$.
3. **Truth** (**T**): Spans of text that can be grounded with a Boolean denotation, for example, *Is anything red?*, *Is one ball green and are no cubes red?*. **T**-type span grounding is represented using a real-value $p_{true} \in [0, 1]$ that denotes the probability of the span being true.

Ungrounded Semantic Types: Spans of text whose meaning cannot be grounded in the KG.

1. **Vector** (**V**): This type is used for spans representing functions that cannot yet be grounded in the KG (e.g. words such as *and* or *every*). These spans are represented using 4 different real-valued vectors v_1-$v_4 \in \mathbb{R}^2$-$\mathbb{R}^5$, that are used to parameterize the composition modules described in §3.2.
2. **Vacuous** (**ϕ**): Spans that are considered semantically vacuous, but are necessary syntactically, e.g. *of* in *left of a cube*. During composition, these nodes act as identity functions.

Partially-Grounded Semantic Types: Spans of text that can only be partially grounded in the knowledge graph, such as *and red* or *are four spheres*. Here, we represent the span by a combination of a grounding and vectors, representing grounded and ungrounded aspects of meaning respectively. The grounded component of the representation will typically combine with another fully grounded representation, and the ungrounded vectors will parameterize the composition module. We define 3 semantic types of this kind: **EV**, **RV** and **TV**, corresponding to the combination of entities, relations and boolean groundings respectively with an ungrounded vector. Here, the word represented by the vectors can be viewed as a binary function, one of whose arguments has been supplied.

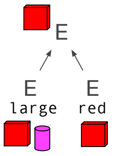
3.2 Composition Modules

Next, we describe how we compose phrase representations (from § 3.1) to represent larger phrases. We define a small set of composition modules, that take as input two constituents of text with their corresponding semantic representations (grounded representations and ungrounded vectors), and outputs the semantic type and corresponding representation of the larger constituent. The composition modules are parameterized by the trainable word vectors. These can be divided into several categories:

Composition modules resulting in fully grounded denotations: Described in Figure 2.

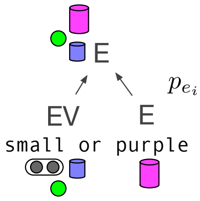
Composition with ϕ-typed nodes: Phrases with type ϕ are treated as being semantically transparent identity functions. Phrases of any other type can combined with these nodes, with no change to their type or representation.

Composition modules resulting in partially grounded denotations: We define several modules that combine fully grounded phrases with ungrounded phrases, by deterministically taking the union of the representations, giving phrases with partially grounded representations (§ 3.1). These modules are useful when words act as binary functions; here they combine with their first argument. For example, in Fig. 1, *or* and *not cylindrical* combine to make a phrase containing both the vectors for *or* and the entity set for *not cylindrical*.



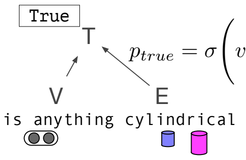
$$p_{e_i} = \sigma\left(\begin{bmatrix} w_1 \\ w_2 \\ b \end{bmatrix} \cdot \begin{bmatrix} p^L_{e_i} \\ p^R_{e_i} \\ 1 \end{bmatrix}\right)$$

E + E → E: This module performs a function on a pair of soft entity sets, parameterized by the model's global parameter vector $[w_1, w_2, b]$ to produce a new soft entity set. The composition function for a single entity's resulting attention value is shown. Such a composition module can be used to interpret compound nouns and entity appositions. For example, the composition module shown above learns to output the intersection of two entity sets.



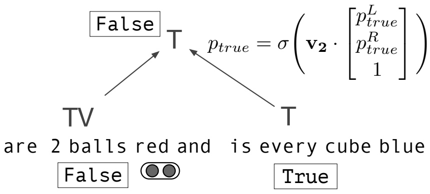
$$p_{e_i} = \sigma\left(\mathbf{v_2} \cdot \begin{bmatrix} p^L_{e_i} \\ p^R_{e_i} \\ 1 \end{bmatrix}\right)$$

EV + E → E: This module combines two soft entity sets into a third set, parameterized by the v_2 word vector. This composition function is similar to a linear threshold unit and is capable of modeling various mathematical operations such as logical conjunctions, disjunctions, differences etc. for different values of v_2. For example, the word *or* learns to model set union.



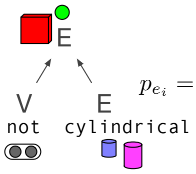
$$p_{true} = \sigma\left(v_3^1\left[\sum_{e_i} \sigma\left(\begin{bmatrix} v_3^3 \\ v_3^4 \end{bmatrix} \cdot \begin{bmatrix} p^R_{e_i} \\ 1 \end{bmatrix}\right)\right] + v_3^2\right)$$

V + E → T: This module maps a soft entity set onto a soft boolean, parameterized by word vector (v_3). The module counts whether a sufficient number of elements are in (or out) of the set. For example, the word *any* should test if a set is non-empty.



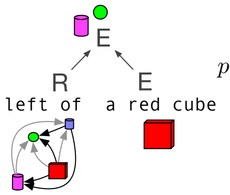
$$p_{true} = \sigma\left(\mathbf{v_2} \cdot \begin{bmatrix} p^L_{true} \\ p^R_{true} \\ 1 \end{bmatrix}\right)$$

TV + T → T: This module maps a pair of soft booleans into a soft boolean using the v_2 word vector to parameterize the composition function. Similar to **EV + E → E**, this module facilitates modeling a range of boolean set operations. Using the same functional form for different composition functions allows our model to use the same ungrounded word vector (v_2) for compositions that are semantically analogous.



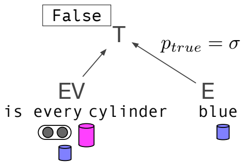
$$p_{e_i} = \sigma\left(\mathbf{v_1} \cdot \begin{bmatrix} p^R_{e_i} \\ 1 \end{bmatrix}\right)$$

V + E → E: This module performs a function on a soft entity set, parameterized by a word vector, to produce a new soft entity set. For example, the word *not* learns to take the complement of a set of entities. The entity attention representation of the resulting span is computed by using the indicated function that takes the $v_1 \in \mathbb{R}^2$ vector of the **V** constituent as a parameter argument and the entity attention vector of the **E** constituent as a function argument.



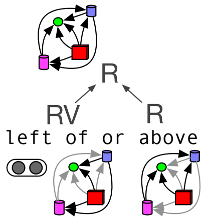
$$p_{e_i} = \max_{e_j} A_{ji} \cdot p^R_{e_j}$$

R + E → E: This module composes a set of relations (represented as a single soft adjacency matrix) and a soft entity set to produce an output soft entity set. The composition function uses the adjacency matrix representation of the **R**-span and the soft entity set representation of the **E**-span.



$$p_{true} = \sigma\left(v_4^1\left[\sum_{e_i} \sigma\left(\begin{bmatrix} v_4^3 \\ v_4^4 \\ v_4^5 \end{bmatrix} \cdot \begin{bmatrix} p^L_{e_i} \\ p^R_{e_i} \\ 1 \end{bmatrix}\right)\right] + v_4^2\right)$$

EV + E → T: This module combines two soft entity sets into a soft boolean, which is useful for modelling generalized quantifiers. For example, in *is every cylinder blue*, the module can use the inner sigmoid to test if an element e_i is in the set of cylinders ($p^L_{e_i} \approx 1$) but not in the set of blue things ($p^R_{e_i} \approx 0$), and then use the outer sigmoid to return a value close to 1 if the sum of elements matching this property is close to 0.



$$A_{ij} = \sigma\left(\mathbf{v_2} \cdot \begin{bmatrix} A^L_{ij} \\ A^R_{ij} \\ 1 \end{bmatrix}\right)$$

RV + R → R: This module composes a pair of soft set of relations to a produce an output soft set of relations. For example, the relations *left* and *above* are composed by the word *or* to produce a set of relations such that entities e_i and e_j are related if either of the two relations exists between them. The functional form for this composition is similar to **EV + E → E** and **TV + T → T** modules.

Figure 2: Composition Modules that compose two constituent span representations into the representation for the combined larger span, using the indicated equations.

4 Parsing Model

Here, we describe how our model classifies question tokens into semantic type spans and computes their representations (§ 4.1), and recursively uses the composition modules defined above to parse the question into a soft latent tree that provides the answer (§ 4.2). The model is trained end-to-end using only question-answer supervision (§ 4.3).

4.1 Lexical Representation Assignment

Each token in the question sentence is assigned a distribution over the semantic types, and a grounded representation for each type. Tokens can only be assigned the **E**, **R**, **V**, and $\boldsymbol{\phi}$ types. For example, the token *cylindrical* in the question in Fig. 1 is assigned a distribution over the 4 semantic types (one shown) and for the **E** type, its representation is the set of *cylindrical* entities.

Semantic Type Distribution for Tokens: To compute the semantic type distribution, our model represents each word w, and each semantic type t using an embedding vector; $v_w, v_t \in \mathbb{R}^d$. The semantic type distribution is assigned with a softmax:

$$p(t|w_i) \propto \exp(v_t \cdot v_{w_i})$$

Grounding for Tokens: For each of the semantic type, we need to compute their representations:

1. **E**-Type Representation: Each entity $e \in \mathcal{E}$, is represented using an embedding vector $v_e \in \mathbb{R}^d$ based on the concatenation of vectors for its properties. For each token w, we use its word vector to find the probability of each entity being part of the **E**-Type grounding:

   $$p^w_{e_i} = \sigma(v_{e_i} \cdot v_w) \;\; \forall\, e_i \in \mathcal{E}$$

   For example, in Fig. 1, the word *red* will be grounded as all the red entities.

2. **R**-Type Representation: Each relation $r \in \mathcal{R}$, is represented using an embedding vector $v_r \in \mathbb{R}^d$. For each token w_i, we compute a distribution over relations, and then use this to compute the *expected* adjacency matrix that forms the **R**-type representation for this token.

   $$p(r|w_i) \propto \exp(v_r \cdot v_{w_i})$$
   $$A^{w_i} = \sum_{r \in \mathcal{R}} p(r|w_i) \cdot A_r$$

   e.g. the word *left* in Fig. 1 is grounded as the subset of edges with label 'left'.

3. **V**-Type Representation: For each word $w \in \mathcal{V}$, we learn four vectors $v_1 \in \mathbb{R}^2, v_2 \in \mathbb{R}^3, v_3 \in \mathbb{R}^4, v_4 \in \mathbb{R}^5$, and use these as the representation for words with the **V**-Type.

4. $\boldsymbol{\phi}$-Type Representation: Semantically vacuous words that do not require a representation.

4.2 Parsing Questions

To learn the correct structure for applying composition modules, we use a simple parsing model. We build a parse-chart over the question encompassing all possible trees by applying all composition modules, similar to a standard CRF-based PCFG parser using the CKY algorithm. Each node in the parse-chart, for each span $w_{i..j}$ of the question, is represented as a distribution over different semantic types with their corresponding representations.

Phrase Semantic Type Potential ($\psi^t_{i,j}$): The model assigns a score, $\psi^t_{i,j}$, to each $w_{i..j}$ span, for each semantic type **t**. This score is computed from all possible ways of forming the span $w_{i..j}$ with type **t**. For a particular composition of span $w_{i..k}$ of type $\mathbf{t_1}$ and $w_{k+1..j}$ of type $\mathbf{t_2}$, using the $\mathbf{t_1} + \mathbf{t_2} \rightarrow \mathbf{t}$ module, the composition score is:

$$\psi^{t_1+t_2\rightarrow t}_{i,k,j} = \psi^{t_1}_{i,k} \cdot \psi^{t_2}_{k+1,j} \cdot e^{\theta \cdot f^{t_1+t_2\rightarrow t}(i,j,k|q)}$$

where θ is a trainable vector and $f^{t_1+t_2\rightarrow t}(i,j,k|q)$ is a simple feature function. Features consist of a conjunction of the composition module type and: the words before (w_{i-1}) and after (w_{j+1}) the span, the first (w_i) and last word (w_k) in the left constituent, and the first (w_{k+1}) and last (w_j) word in the right constituent.
The final **t**-type potential of $w_{i..j}$ is computed by summing scores over all possible compositions:

$$\psi^t_{i,j} = \sum_{k=i}^{j-1} \sum_{\substack{(t_1+t_2\rightarrow t)\\ \in \text{Modules}}} \psi^{t_1+t_2\rightarrow t}_{i,k,j}$$

Combining Phrase Representations ($[\![w_{i..j}]\!]^t_{KG}$): To compute $w_{i..j}$'s **t**-type denotation, $[\![w_{i..j}]\!]^t_{KG}$, we compute an expected output representation from all possible compositions that result in type **t**.

$$[\![w_{i..j}]\!]^t_{KG} = \frac{1}{\psi^t_{i,j}} \sum_{k=i}^{j-1} [\![w_{i..k..j}]\!]^t_{KG}$$

$$[\![w_{i..k..j}]\!]^t_{KG} = \sum_{\substack{(t_1+t_2\rightarrow t)\\ \in \text{Modules}}} \psi^{t_1+t_2\rightarrow t}_{i,k,j} \cdot [\![w_{i..k..j}]\!]^{t_1+t_2\rightarrow t}_{KG}$$

where $[\![w_{i..j}]\!]^t_{KG}$, is the **t**-type representation of the span $w_{i..j}$ and $[\![w_{i..k..j}]\!]^{t_1+t_2\rightarrow t}_{KG}$ is the representation resulting from the composition of $w_{i..k}$ with $w_{k+1..j}$ using the $\mathbf{t_1}+\mathbf{t_2} \rightarrow \mathbf{t}$ composition module.

Answer Grounding: By recursively computing the phrase semantic-type potentials and representations, we can infer the semantic type distribution of the complete question and the resulting grounding for different semantic types t, $[\![w_{1..|q|}]\!]^t_{KG}$.

$$p(t|q) \propto \psi(1, |q|, t) \tag{1}$$

The answer-type (boolean or subset of entities) for the question is computed using:

$$t^* = \underset{t \in \mathbf{T}, \mathbf{E}}{\operatorname{argmax}}\ p(t|q) \tag{2}$$

The corresponding grounding is $[\![w_{1..|q|}]\!]^{t^*}_{KG}$, which answers the question.

4.3 Training Objective

Given a dataset $\mathcal{D}$ of (question, answer, knowledge-graph) tuples, $\{\mathrm{q}^i, \mathrm{a}^i, \mathrm{KG}^i\}_{i=1}^{i=|\mathcal{D}|}$, we train our model to maximize the log-likelihood of the correct answers. We maximize the following objective:

$$\mathcal{L} = \sum_i \log p(\mathrm{a}^i | \mathrm{q}^i, \mathrm{KG}^i) \tag{3}$$

Further details regarding the training objective are given in Appendix A.

5 Dataset

We experiment with two datasets, 1) Questions generated based on the CLEVR (Johnson et al., 2017) dataset, and 2) Referring Expression Generation (GenX) dataset (FitzGerald et al., 2013), both of which feature complex compositional queries.

CLEVRGEN: We generate a dataset of question and answers based on the CLEVR dataset (Johnson et al., 2017), which contains knowledge graphs containing attribute information of objects and relations between them.

We generate a new set of questions as existing questions contain some biases that can be exploited by models.[1] We generate 75K questions for training and 37.5K for validation. Our questions test various challenging semantic operators. These include conjunctions (e.g. *Is anything red and large?*), negations (e.g. *What is not spherical?*), counts (e.g. *Are five spheres green?*), quantifiers (e.g. *Is every red thing cylindrical?*), and relations (e.g. *What is left of and above a cube?*). We create two test sets:

1. **Short Questions:** Drawn from the same distribution as the training data (37.5K).
2. **Complex Questions:** Longer questions than the training data (22.5K). This test set contains the same words and constructions, but chained into longer questions. For example, it contains questions such as *What is a cube that is right of a metallic thing that is beneath a blue sphere?* and *Are two red cylinders that are above a sphere metallic?* Solving these questions require more multi-step reasoning.

REFERRING EXPRESSIONS (GENX) (FitzGerald et al., 2013): This dataset contains human-generated queries, which identify a subset of objects from a larger set (e.g. *all of the red items except for the rectangle*). It tests the ability of models to precisely understand human-generated language, which contains a far greater diversity of syntactic and semantic structures. This dataset does not contain relations between entities, and instead only focuses on entity-set operations. The dataset contains 3920 questions for training, 600 for development and 940 for testing. Our modules and parsing model were designed independently of this dataset, and we re-use hyperparameters from CLEVRGEN.

6 Experiments

Our experiments investigate the ability of our model to understand complex synthetic and natural language queries, learn interpretable structure, and generalize compositionally. We also isolate the effect of learning the syntactic structure and representing sub-phrases using explicit denotations.

6.1 Experimentation Setting

We describe training details, and the baselines.

Training Details: Training the model is challenging since it needs to learn both good syntactic structures and the complex semantics of neural modules—so we use Curriculum Learning (Bengio et al., 2009) to pre-train the model on an easier subset of questions. Appendix B contains the details of curriculum learning and other training details.

---

[1] Johnson et al. (2017) found that many spatial relation questions can be answered only using absolute spatial information, and many long questions can be answered correctly without performing all steps of reasoning. We employ some simple tests to remove trivial biases from our dataset.

Model	Boolean Questions	Entity Set Questions	Relation Questions	Overall
LSTM (No KG)	50.7	14.4	17.5	27.2
LSTM	88.5	99.9	15.7	84.9
Bi-LSTM	85.3	99.6	14.9	83.6
Tree-LSTM	82.2	97.0	15.7	81.2
Tree-LSTM (Unsup.)	85.4	99.4	16.1	83.6
Relation Network	85.6	89.7	97.6	89.4
Our Model (Pre-parsed)	94.8	93.4	70.5	90.8
Our Model	99.9	100	100	99.9

Table 1: **Results for Short Questions** (CLEVRGEN): Performance of our model compared to baseline models on the Short Questions test set. The LSTM (No KG) has accuracy close to chance, showing that the questions lack trivial biases. Our model almost perfectly solves all questions showing its ability to learn challenging semantic operators, and parse questions only using weak end-to-end supervision.

Baseline Models: We compare to the following baselines. **(a)** Models that assume linear structure of language, and encode the question using linear RNNs—LSTM (No KG), LSTM, Bi-LSTM, and a Relation-Network (Santoro et al., 2017) augmented model. [2] **(b)** Models that assume tree-like structure of language. We compare two variants of Tree-structured LSTMs (Zhu et al., 2015; Tai et al., 2015)—Tree-LSTM, that operates on pre-parsed questions, and Tree-LSTM(Unsup.), an unsupervised Tree-LSTM model (Maillard et al., 2017) that learns to jointly parse and represent the sentence. For GenX, we also use an end-to-end semantic parsing model from Pasupat and Liang (2015). Finally, to isolate the contribution of the proposed denotational-semantics model, we train our model on pre-parsed questions. Note that, all LSTM based models only have access to the entities of the KG but not the relationship information between them. See Appendix C for details.

6.2 Experiments

Short Questions Performance: Table 1 shows that our model perfectly answers all test questions, demonstrating that it can learn challenging semantic operators and induce parse trees from end task supervision. Performance drops when using external parser, showing that our model learns an effective syntactic model for this domain. The Relation Network also achieves good performance, particularly on questions involving relations. LSTM baselines work well on questions not involving relations.[3]

Model	Non-relation Questions	Relation Questions	Overall
LSTM (No KG)	46.0	39.6	41.4
LSTM	62.2	49.2	52.2
Bi-LSTM	55.3	47.5	49.2
Tree-LSTM	53.5	46.1	47.8
Tree-LSTM (Unsup.)	64.5	42.6	53.6
Relation Network	51.1	38.9	41.5
Our Model (Pre-parsed)	94.7	74.2	78.8
Our Model	81.8	85.4	84.6

Table 2: **Results for Complex Questions** (CLEVRGEN): All baseline models fail to generalize well to questions requiring longer chains of reasoning than those seen during training. Our model substantially outperforms the baselines, showing its ability to perform complex multi-hop reasoning, and generalize from its training data. Analysis suggests that most errors from our model are due to assigning incorrect structures, rather than mistakes by the composition modules.

Complex Questions Performance: Table 2 shows results on complex questions, which are constructed by combining components of shorter questions. These require complex multi-hop reasoning, and the ability to generalize robustly to new types of questions. We use the same models as in Table 1, which were trained on short questions. All baselines achieve close to random performance, despite high accuracy for shorter questions. This shows the challenges in generalizing RNN encoders beyond their training data. In contrast, the strong inductive bias from our model structure allows it to generalize well to complex questions. Our model outperforms Tree-LSTM (Unsup.) and the version of our model that uses pre-parsed questions, showing the effectiveness of explicit denotations and learning the syntax, respectively.

---

[2] We use this baseline only for CLEVRGEN since GenX does not contain relations.

[3] Relation questions are out of scope for these models.

Model	**Accuracy**
LSTM (NO KG)	0.0
LSTM	64.9
BI-LSTM	64.6
TREE-LSTM	43.5
TREE-LSTM (UNSUP.)	67.7
SEMPRE	48.1
Our Model (Pre-parsed)	67.1
Our Model	73.7

Table 3: **Results for Human Queries** (GENX) Our model outperforms LSTM and semantic parsing models on complex human-generated queries, showing it is robust to work on natural language. Better performance than TREE-LSTM (UNSUP.) shows the efficacy in representing sub-phrases using explicit denotations. Our model also performs better without an external parser, showing the advantages of latent syntax.

Performance on Human-generated Language: Table 3 shows the performance of our model on complex human-generated queries in GENX. Our approach outperforms strong LSTM and semantic parsing baselines, despite the semantic parser's use of hard-coded operators. These results suggest that our method represents an attractive middle ground between minimally structured and highly structured approaches to interpretation. Our model learns to interpret operators such as *except* that were not considered during development. This shows that our model can learn to parse human language, which contains greater lexical and structural diversity than synthetic questions. Trees induced by the model are linguistically plausible (see Appendix D).

Error Analysis: We find that most model errors are due to incorrect assignments of structure, rather than semantic errors from the modules. For example, in the question *Are four red spheres beneath a metallic thing small?*, our model's parse composes *metallic thing small* into a constituent instead of composing *red spheres beneath a metallic thing* into a single node. Future work should explore more sophisticated parsing models.

Discussion: While our model shows promising results, there is significant potential for future work. Performing exact inference over large KGs is likely to be intractable, so approximations such as KNN search, beam search, feature hashing or parallelization may be necessary. To model the large number of entities in KGs such as Freebase, techniques proposed by recent work (Verga et al., 2017; Gupta et al., 2017) that explore representing entities as composition of its properties, such as, types, description etc. could be used. The modules in this work were designed in a way to provide good inductive bias for the kind of composition we expected them to model. For example, **EV** + **E** → **E** is modeled as a linear composition function making it easy to represent words such as *and* and *or*. These modules can be exchanged with any other function with the same 'type signature', with different trade-offs—for example, more general feed-forward networks with greater representation capacity would be needed to represent a linguistic expression equivalent to *xor*. Similarly, more module types would be required to handle certain constructions—for example, a multiword relation such as *much larger than* needs a **V** + **V** → **V** module. This is an exciting direction for future research.

7 Related Work

Many approaches have been proposed to perform question-answering against structured knowledge sources. *Semantic parsing* models have learned structures over pre-defined discrete operators, to produce logical forms that can be executed to answer the question. Early work trained using gold-standard logical forms (Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010), whereas later efforts have only used answers to questions (Clarke et al., 2010; Liang et al., 2011; Krishnamurthy and Kollar, 2013). A key difference is that our model must learn semantic operators from data, which may be necessary to model the fuzzy meanings of function words like *many* or *few*.

Another similar line of work is neural program induction models, such as Neural Programmer (Neelakantan et al., 2017) and Neural Symbolic Machine (Liang et al., 2017). These models learn to produce programs composed of predefined operators using weak supervision to answer questions against semi-structured tables.

Neural module networks have been proposed for learning semantic operators (Andreas et al., 2016b) for question answering. This model assumes that the structure of the semantic parse is given, and must only learn a set of operators. Dynamic Neural Module Networks (D-NMN) extend this approach by selecting from a small set of candidate module structures (Andreas et al., 2016a). We instead learn a model over all possible structures.

Our work is most similar to N2NMN (Hu et al., 2017) model, which learns both semantic operators and the layout in which to compose them. However, optimizing the layouts requires reinforcement learning, which is challenging due to the high variance of policy gradients, whereas our chart-based approach is end-to-end differentiable.

8 Conclusion

We have introduced a model for answering questions requiring compositional reasoning that combines ideas from compositional semantics with end-to-end learning of composition operators and structure. We demonstrated that the model is able to learn a number of complex composition operators from end task supervision, and showed that the linguistically motivated inductive bias imposed by the structure of the model allows it to generalize well beyond its training data. Future work should explore scaling the model to other question answering tasks, using more general composition modules, and introducing additional module types.

Abstract

High-level semantics tasks, e.g., paraphrasing, textual entailment or question answering, involve modeling of text pairs. Before the emergence of neural networks, this has been mostly performed using intra-pair features, which incorporate similarity scores or rewrite rules computed between the members within the same pair. In this paper, we compute scalar products between vectors representing similarity between members of different pairs, in place of simply using a single vector for each pair. This allows us to obtain a representation specific to any pair of pairs, which delivers the state of the art in answer sentence selection. Most importantly, our approach can outperform much more complex algorithms based on neural networks.

1 Introduction

Answer sentence selection (AS) is an important subtask of open-domain Question Answering (QA). Its input are a question Q and a set of candidate answer passages $A = \{A_1, A_2, ..., A_N\}$, which may, for example, be the output of a search engine. The objective consists in selecting A_i, $i \in \{1, ..., N\}$ that contain correct answers.

Pre-deep learning renaissance approaches to AS typically addressed the task by modeling Q-to-A (**intra-pair**) similarities (Yih et al., 2013; Wang et al., 2007; Heilman and Smith, 2010; Wang and Manning, 2010). Q-to-A similarity and alignment are indeed crucial, but, in practice, it is very difficult to automatically extract meaningful relations between Q and A. For example, consider two positive Q/A pairs in Table 1. If we want to learn a model based only on the intra-pair Q-to-A matches, simple lexical matching (marked with italics) will not be enough. One would need to conduct more complex processing and identify that *movie* and *film* are synonyms, and that the n-gram *play in the movie* or *be in the movie* can be paraphrased as *star*. While the former can be easily detected using an external lexical resource, e.g., WordNet (Fellbaum, 1998), the latter would require more complex inference.

On the other hand, Q_1 and Q_2 contain the same pattern **who ... in the movie ...**, and their respective answers contain **film ... starring ...**. If we know that $P_1 = (Q_1, A_1)$ is a positive AS example and want to classify $P_2 = (Q_2, A_2)$, then high Q_2-to-Q_1 and A_2-to-A_1 **cross-pair** similarities can suggest that P_1 and P_2 are likely to have the same label. This idea, for example, was exploited by Severyn and Moschitti (2012), whose system measures syntactic-semantic similarities directly between structural syntactic tree representations of Q_1/Q_2 and A_1/A_2. This model still exhibited state-of-the-art performance in 2016 (Tymoshenko et al., 2016a).

Deep neural networks (DNNs) also naturally use such cross-pair similarity when modeling two input texts, and then further combine it with intra-pair similarity, for example, by means of attention mechanisms (Shen et al., 2017), compare-aggregate architectures (Bian et al., 2017; Wang and Jiang, 2017), or fully-connected layers (Severyn and Moschitti, 2015, 2016; Rao et al., 2016).

In this work, we observe that: (i) the high accuracy of the kernel model by Severyn and Moschitti (2012) was due not only to the use of syntactic structures, but also to the use of cross-pair similarities; and (ii) the success of DNNs for QA can be partially attributed to an implicit combination of cross- and intra-pair similarity.

More specifically, we investigate, whether simple similarity metrics, e.g., cosine similarity between standard vector representations, can perform competitively to the state-of-the-art neural models when employed as cross-pair kernels.

	Question		Answer	Label
Q_1	**who** plays *mary poppins* **in the movie**?	A_1	*Mary Poppins* is a 1964 musical **film** **starring** Julie Andrews, Dick Van Dyke, David Tomlinson, and Glynis Johns, produced by Walt Disney, and based on the *Mary Poppins* books series by P. L. Travers.	TRUE
Q_2	**WHO** WAS **IN THE MOVIE** *I CONFESS* WITH *MONTGOMERY CLIFT*	A_2	*I Confess* is a 1953 drama **film** directed by Alfred Hitchcock, and **starring** *Montgomery Clift* as Fr. Michael William Logan, a Catholic priest, Anne Baxter as Ruth Grandfort, and Karl Malden as Inspector Larrue .	TRUE

Table 1: Question/Answer Sentence pairs from WikiQA corpus. We use italic font to mark intra-pair lexical matches between Q_1 and A_1, Q_2 and A_2, and bold font to mark the cross-pair matches between Q_1 and Q_2, A_1 and A_2.

To this end, we apply linear and cosine kernels to Q_i/Q_j and A_i/A_j pairs ($i, j = 1, ..., N$) represented as a bag-of-words (BoW) or an averaged sum of their pretrained word embeddings. Then, we combine them with the cross-pair Tree Kernels (TKs) and kernels applied to the traditional Q/A intra-pair similarity feature vector representations in a composite kernel and use it in an SVM model.

We experiment with three reference datasets, WikiQA (Yang et al., 2015), TREC13 (Yao et al., 2013; Wang et al., 2007) and SemEval-2016, Task 3.A (Nakov et al., 2016), using a number of lexical-overlap/syntactic kernels. The latter challenge refers to a community question answering (cQA) task. It consists in reranking the responses to user questions from online forums. It is the same setting as AS, but the text of questions and answer sentences can be ungrammatical due to the nature of the online forum language.

We obtain competitive results on WikiQA and SemEval tasks, showing that: (i) simple BoW representations, when used in cross-pair kernels, perform comparably to and even outperform hand-crafted intra-pair features. (ii) In cQA, simple cross-pair embedding- and BoW-based similarity features outperform domain-specific similarity features, which are hand-crafted from intra-pair members. The simple features also perform comparably to syntactic TKs. (iii) We show that a combination of simple cosine- intra- and cross-pair kernels with TKs can outperform the most recent state-of-the-art DNN architectures.

Assuming the conjecture of our paper correct, *cross-pair modeling is the major neural network contribution*, the last point above is not surprising as on relatively small datasets kernels-based models can exploit syntactic information very effectively while neural models cannot.

The paper is structured as follows. We describe the kernels incorporating intra- and cross-pair matches in Sec. 3.2, list the simple cross- and intra-pair features in Sec. 3.3, describe strong hand-crafted baseline features in Sec. 4, and report the experimental results in Sec. 5.

2 Related work

Early approaches to AS typically focused on modeling intra-pair Q-to-A alignment similarities. For example, Yih et al. (2013) proposed a latent alignment model that employed lexical-semantical Q-to-A alignments, Wang et al. (2007) modeled syntactic alignments with probabilistic quasi-synchronous grammar, and Heilman and Smith (2010); Yao et al. (2013); Wang and Manning (2010) employed Tree Edit Distance-based Q-to-A alignments.

Originally, the idea of cross-pair similarity was proposed by Zanzotto and Moschitti (2006) and applied to the recognizing textual entailment task, which consists in detecting whether a text T entails a hypothesis H. They assumed that if two H/T pairs $\langle H_1, T_1\rangle$ and $\langle H_2, T_2\rangle$ share the same T-to-H "rewrite rules", they are likely to share the same label. Based on this idea, they proposed an algorithm applying TKs to (H_1, H_2) and (T_1, T_2) syntactic tree representations, enriched with H-to-T intra-pair rewrite rule information. More concretely, such algorithm aligns the constituents of H with T and then marks them with symbols directly in the trees. This way the alignment information can be matched by tree kernels applied to cross-pair members.

Then, a line of work on AS, started by Severyn and Moschitti (2012, 2013); Severyn et al. (2013), was inspired by a similar idea of incorporating "rewrite rules" directly into the tree representations of Q_1/A_1 and Q_2/A_2. They represent Q and A as syntactic trees enhanced with Q-to-A relational information, and apply TKs (Moschitti, 2006) to (Q_1, Q_2) and (A_1, A_2). Thus they model **cross-pair** similarity, and learn important patterns occurring in Q and A separately. As shown in (Tymoshenko et al., 2016a), this approach is competitive with convolutional neural networks (CNNs).

In our approach, instead of using only one TK, we employ a number of different word-based kernels, most of which can be computed more efficiently than TKs.

Most recent AS models are based on Deep Neural Networks (DNNs), which learn distributed representations of the input data. DNNs are trained to apply series of non-linear transformations to the input Q and A, represented as compositions of word or character embeddings. DNN architectures learn AS-relevant patterns using intra-pair similarities as well as cross-pair, Q-to-Q and A-to-A, similarities, when modeling the input texts. For example, the CNN network by (Severyn and Moschitti, 2015) has two separate embedding layers for Q and A, which are followed by the respective convolution layers, whose output is concatenated and then passed through the final fully-connected joint layer. The weights in the Q and A convolution layers are learned by means of the backpropagation algorithm on the training Q/A pairs. Thus, obviously, classifying a new Q/A pair is partially equivalent to performing the implicit cross-pair Q-to-Q and A-to-A comparison.

Additionally, the DNN approaches model the *Q-to-A relatedness* explicitly in a variety of ways, e.g., by: (i) using a Q-to-A transformation matrix and simple Q-to-A similarity features (Yu et al., 2014; Severyn and Moschitti, 2015), (ii) relying on RNN and LSTM architectures (Wang and Nyberg, 2015; Shen et al., 2017), (iii) employing attention components (Yin et al., 2016; Shen et al., 2017; Wang et al., 2016a), (iv) decomposing input into similarity and dissimilarity matches (Wang et al., 2016b) or (v) using the compare-aggregate method (Wang and Jiang, 2017; Bian et al., 2017).

We believe that the ability of DNNs to implicitly capture cross-pair relational matching, i.e., the capacity of learning from (Q_1, Q_2) and (A_1, A_2), is a very important factor to their high performance. This is of course paired with their ability to learn non-linear patterns and capture Q-to-A relatedness by means of attention mechanisms. It should be noted that the latter are typically hard-coded in kernel models as lexical matching/similarity (Severyn and Moschitti, 2012). This is effective as much as the attention approach, at least with standard-size dataset, also in neural models (Severyn and Moschitti, 2016).

In our work, we model Q-to-A, Q-to-Q and A-to-A similarities with intra- and cross-pair kernels and show that such combination also exhibits state-of-the-art performance on the reference corpora. In addition, our approach can be applied to smaller datasets as it utilizes less parameters, and can provide insights on future DNN design.

3 Cross-pair similarity kernels for text

3.1 Background on Kernel Machines

Kernel Machines (KMs) allow for replacing the dot product with kernel functions directly applied to examples, i.e., they avoid mapping examples into vectors. The main advantage of KMs is a much lower computational complexity than the dot product as the kernel computation does not depend on the size of the feature space.

KMs are linear classifiers: given a labeled training dataset $S = \{(\mathbf{x}_i, y_i) : i = 1, \ldots, n\}$, their classification function can be defined as:

$$f(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x} + b = \sum_{i=1}^{n} \alpha_i y_i \mathbf{x}_i \cdot \mathbf{x} + b.$$

where $\mathbf{x}$ is a classification example, $\mathbf{w}$ is the gradient of the separating hyperplane, and b its bias. The equation shows that the gradient is a linear combination of the training points $\mathbf{x}_i \in \mathbb{R}^n$ multiplied by their labels $y_i \in \{-1, 1\}$ and their weights $\alpha_i \in \mathbb{R}^+$. Note that the latter are different from zero only for the support vectors: this reduces the classification complexity, which will be lower than O(n) for each example.

We can replace the scalar product with a kernel function directly defined over a pair of objects, $K(o_i, o) = \phi(o_i)\phi(o)$, where $\phi : O \to \mathbb{R}^n$ maps from objects to vectors of the final feature space. The new classification function becomes: $f(o) = \sum_{i=1}^{n} \alpha_i y_i K(o_i, o) + b$, which only needs the initial input objects.

3.2 Inter- and intra-pair match kernel

We cast AS as a text pair classification task: given a pair, $P = (Q, A)$, constituted by a question (Q) and a candidate answer sentence (A), we classify it as either correct or incorrect. We used KMs, where $K(\cdot, \cdot)$ operates on two pairs, $P_1 = (Q_1, A_1)$ and $P_2 = (Q_2, A_2)$.

3.2.1 Intra-pair similarity

A traditional baseline approach would (i) represent Q/A pairs as feature vectors, where the components are similarity metrics applied to Q and A, e.g., a world overlap-based similarity; and (ii) train a classification model, e.g., an SVM using the following kernel:

$$K_{IP}(P_1, P_2) = K_v \left(V_{\langle Q_1, A_1 \rangle}, V_{\langle Q_2, A_2 \rangle} \right), \quad (1)$$

where K_v can be any kernel operating on the feature vectors, e.g., the polynomial or linear (as in our work) kernel. $V_{\langle T_1, T_2 \rangle}$ is a vector built on N similarity features, $\langle f_1(\cdot,\cdot), f_2(\cdot,\cdot), ..., f_N(\cdot,\cdot) \rangle$, extracted by applying similarity metrics to two texts, T_1 and T_2 (see Sec. 3.3 for the list of the similarity metrics we used). K_{IP} merely uses intra-pair similarities.

3.2.2 Cross-pair similarity

We incorporate the intuition, *similar questions are likely to demand similar answer patterns*, by means of a cross-pair kernel, which measures similarity between questions and answers from P_1 and P_2 as follows:

$$\begin{aligned} K_{CP}(P_1, P_2) &= V_{\langle Q_1, Q_2 \rangle} \cdot V_{\langle A_1, A_2 \rangle} \\ &= \sum_{i=1}^{N} f_i(Q_1, Q_2) \cdot f_i(A_1, A_2) \end{aligned} \quad (2)$$

K_{CP} measures P_1-to-P_2 similarity in terms of a sum of the products of Q_1-to-Q_2 and A_1-to-A_2 similarities. Note, that within K_{IP}, $f_i(Q_i, A_i)$ is merely an i-th feature in the $V_{\langle Q_i, A_i \rangle}$ feature vector. At the same time, within K_{CP}, $f_i(\cdot,\cdot)$ becomes a kernel, which takes the (Q_1, Q_2) or (A_1, A_2) pairs as input. In other words, $V_{\langle Q_1, Q_2 \rangle} \cdot V_{\langle A_1, A_2 \rangle}$ is a sum of products of $f_i(\cdot,\cdot)$ kernels applied to the (Q_1, Q_2) and (A_1, A_2) pairs. K_{CP} is a valid kernel if the similarity metrics used to compute the $f_i(\cdot,\cdot)$ are valid kernel functions.

Finally, combining K_{IP} and K_{CP} enables learning of two different kinds of valuable cross- and intra-pair AS patterns. We combine various K_{IP} and K_{CP} by summing them or by training a meta-classifier on their outputs. See Section 5.4 for more details. Figure 1 summarizes the differences between the K_{IP} and K_{CP} computation processes described above.

3.3 Similarity features

We employ three similarity feature types as $f_i(\cdot,\cdot)$. Two of them are computed using the cosine similarity metrics and differ only in terms of the input texts, T_1 and T_2, representations. The other type is constituted by TKs applied to the structural representations of T_1 and T_2. Note that, since cosine similarity and TKs are valid kernels, K_{CP} is also guaranteed to be a valid kernel when computed using these similarity features.

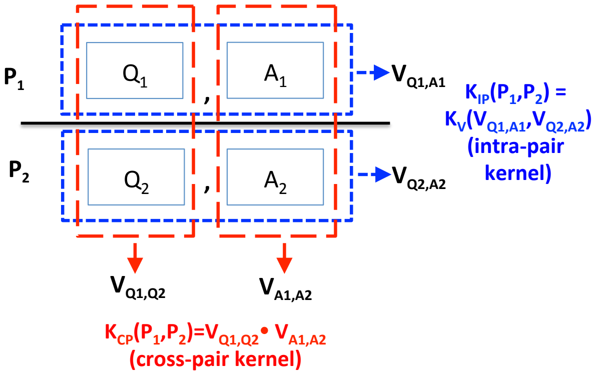

Figure 1: Feature extraction schema for two Q/A pairs, P_1 and P_2. V_{T_1,T_2} is a vector of similarity features extracted for a pair of texts T_1, T_2, the respective dashed boxes show from which pair of input texts they are extracted.

3.3.1 Bag-of-n-grams overlap (B)

$f_B^{t,l,s}(T_1, T_2)$ is a cosine similarity metric applied to the bag-of-n-grams vector representations of T_i, $BOW_{\{t,l,s\}}(T_i)$, $i = 1, 2$. The $\{t, l, s\}$ index describes an n-gram representation configuration: t denotes whether the n-grams are assembled of word lemmas (L), or their part-of-speech tags (POS), or lemmas concatenated with their respective POS-tags (L_{POS}); l is a (n_1, n_2) tuple, with n_1 and n_2 being the minimal and maximal length of n-grams considered, respectively; and s is YES if the representation discards the stopwords and NO, otherwise.

We used $\{t, l, s\}$ configurations from the following set: $C = (\{L, L_{POS}\} \times \{(1,2), (1,3), (1,4), (2,4), (2,3)\} \times \{YES, NO\}) \cup (\{POS\} \times \{(1,4), (2,4)\} \times \{YES\})$. It follows that $|C| = 23$, which means we have 23 similarity features, $f_B^{t,l,s}(T_1, T_2)$, in total, in the intra-pair setting. The respective cross-pair kernels are a composite kernel summing 23 products of cosine kernels applied to 23 different (Q_1, Q_2) and (A_1, A_2) bag-of-ngram representations.

3.3.2 Embedding-based similarities (E).

We represent an input text as an average of embeddings of its lemmas from pre-trained word embedding models. Then, the embedding feature $f_{model}^{E}(T_1, T_2)$ is the cosine kernel applied to the embedding-based representations of T_1 and T_2. We use two pretrained embeddings: Word2Vec (Mikolov et al., 2013) and

GloVe (Pennington et al., 2014), resulting in three[1] embedding-based features (see Sec. 5 for more technical details).

3.3.3 Tree-kernel based similarities

Following the framework defined in (Severyn et al., 2013; Tymoshenko et al., 2016a), we represent T_1 and T_2 as syntactico-semantic structures and use TKs as semantic similarity metrics. When computing K_{CP} with TK as similarities, in Eq.2, we employ summation instead of multiplication[2].

More specifically, we represent T_1 and T_2 as (i) constituency trees and apply subset TK (SST); or (ii) shallow chunk-based trees, similar to the one presented in Figure 2, and apply partial tree (PTK) kernel. In the shallow trees, lemmas are leaves and POS tags are pre-terminals. POS nodes are grouped under chunk nodes, and then under the sentences nodes. These representations encode also some intra-pair similarity information, e.g., prefix `REL` denotes the lexical Q-to-A match. In a structural representation, we prepend it to the parent and grand-parent nodes of lemmas which occur both in Q and A, e.g., "Mary" in the first example of Table 1.

Then, for factoid QA[3], we mark focus words in Q and entities in A, if the answer contains any named entities of types matching the question expected answer type (EAT)[4]. More specifically, we mark the semantic Q-to-A match by prepending the `REL-FOCUS-<EAT>` label to the answer chunk nodes that contain such named entities and also to the question focus word. Here, `<EAT>` stands for the EAT label. For example, in the Q_1/A_1 pair in Table 1, the Q_1 EAT is HUMan, and the matching named entities include "Julie Andrews", "David Tomlinson" and others. Figure 2 depicts Q_1 annotated both with `REL-` and `REL-FOCUS` links. We detect both question focus and EAT automatically. Due to the space limitations, we do not describe the structural representations and matching algorithms in more detail, but refer the reader to the works above.

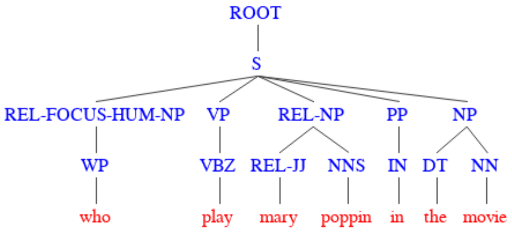

Figure 2: Shallow syntactic representation of A_1 from the running example in Table 1

(i) **cosine similarity** applied to the BoW representations of T_1 and T_2 in terms of word lemmas, bi-, three-, four-grams (computed twice with and without stopwords); POS-tags; dependency triplets;
(ii) **longest common string subsequence** measure w. and w/out stopwords;
(iii) **Jaccard similarity metric** applied to one-, two-, four, three-grams w. and w/out stopwords;
(iv) **word n-gram containment measure** on uni- and bi-grams w. and w/out stopwords (Broder, 1997);
(v) **greedy string tiling** (Wise, 1996) with minimum matching length of 3 ;
(vi) **string kernel similarity** (Lodhi et al., 2002);
(vii) **expected answer type match:** percentage of named entities (NE) in the answer passage compatible with the question class[5];
(viii) **WordNet-based similarity.** WordNet T_1/T_2 common lemma/synonym/hypernym overlap ratio;
(ix) **PTK (Moschitti, 2006) similarity** between constituency or dependency tree representations of input texts;

Table 2: Strong baseline fatures

4 Strong baseline feature vector

As a strong baseline, we use similarity feature vectors and intra-pair K_{IP} kernel.

For the **factoid answer sentence selection** task, we use 47 strong features listed in Table 2. This is a compilation of features used in the top-performing system at SemEval-2012 Semantic Text Similarity workshop (Bär et al., 2012) and earlier factoid QA work (Severyn and Moschitti, 2012), extended with few additional features.

For the **community question answering (cQA)** task, we employ instead a combination of similarity-based and thread-level features shown to be very effective for the cQA task (Nicosia et al., 2015; Barrón-Cedeño et al., 2016). We use the exact feature combination from (Barrón-Cedeño et al., 2016), which includes both lexical and syntactic similarity measures (cosine similarity of bag-of-words, PTK similarity over syntactic tree representations of the input texts) and thread-

---

[1] We use Word2Vec embeddings trained on two different corpora, which result in two features, and GloVe trained on one corpus.

[2] We have opted to use summation in this case to follow the earlier work.

[3] WikiQA and TREC13 are the factoid AS datasets, as their questions ask for a specific fact, e.g. date or a name.

[4] For example, the PERson named entity type matches the HUMan EAT. More specifically, we employ the following NER-to-EAT matching rules: PERson, ORGanization → HUMan; LOCation → LOCation; DATE, TIME, MONEY, PERCENTAGE, DURATION, NUMBER, SET → NUM; ORGanization, PERson, MISCellanious → ENTiTY. We employ the (Li and Roth, 2002) coarse-grained EAT taxonomy and Stanford CoreNLP (Manning et al., 2014) entity types.

Table 3: WikiQA corpus statistics

level domain specific features (*are the question and comment authored by the same person?*, *does the comment contain any questions?*, and so on.).

We cannot directly use these feature vectors in the K_{CP} kernels, as not all functions used to compute features are valid kernels, e.g., the longest common string subsequence is not a kernel function. Moreover, some of them can be computed only on the (Q, A) pairs, e.g., the expected type match feature (vii) in Tab. 2, or many of the cQA domain-specific features.

5 Experiments

We conduct experiments on three corpora, namely TREC13, WikiQA and SemEval, and evaluate the results in terms of Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR). Our code is available at `https://github.com/iKernels/RelTextRank`.

5.1 Datasets

WikiQA dataset. WikiQA (Yang et al., 2015) is a factoid answer sentence selection dataset with Bing query logs as questions. Candidate answer sentences are extracted from Wikipedia and labeled manually. Some of the questions have no correct answer sentence (all$^-$) or have only correct answer sentences (all$^+$). Table 3 reports the statistics of the WikiQA corpus as distributed (raw), without all$^-$ questions, and without both all$^-$ and all$^+$ questions (clean). We train in the "no all$^-$" mode using 10 answer sentences per question[6] and test in the "clean" mode.

TREC13 dataset. A factoid answer sentence selection dataset originally presented in (Wang et al., 2007)[7], also frequently called **QASent** (Yang et al., 2015). We train on 1,229 automatically labeled TREC8-12 questions. We use only 10 candidate answer sentences per question. We test in the "clean" setting defined in (Rao et al., 2016), i.e., we discard the all$^+$ and all$^-$ questions, resulting in 65 DEV and 68 TEST questions, respectively. DEV and TEST contain 1117 and 1442 candidate associated answer sentences, respectively.

SemEval-2016, Task 3.A dataset. SemEval cQA dataset is a benchmark dataset in the SemEval 2016 Task 3. A question-to-comment similarity competition. It is a collection of user questions and the respective answer comment threads from Qatar Living forum, where the user comments to questions were manually labeled as correct or incorrect. Each question has 10 respective candidate answers. The training, dev and test sets have 1790, 244 and 327 questions, respectively. The AS task consists in reranking comments with respect to the question: most questions are non-factoid and the text is often noisy.

5.2 Models

We used the following notation:

B, **E**. Intra-pair K_{IP} kernels (see Sec. 3.2) using the eponymous similarity features from Sec. 3.3.

V. Linear kernel applied to the strong intra-pair feature vector representation defined in Section 4. Note that, as already mentioned in Sec. 4, due to the slightly different nature of the factoid and community question answering tasks, we used different strong feature groups for WikiQA, TREC13 (Table 2) and SemEval-2016.

$\mathbf{B}_{cr}$, $\mathbf{E}_{cr}$. Cross-pair K_{CP} kernel applied to B and E similarity feature vectors respectively. More specifically, B_{cr} and E_{cr} are a sum of 23 and 3 cross-pair kernel products, respectively (see Eq. 2 and Sec. 3.2).

PTK, **SST** are the cross-pair PTK and SST tree kernels applied to the shallow chunk- and constituency-based representations (see Sec. 3.3).

"+" denotes kernel summation. We use this symbol to denote that we sum the gram-matrices for the distinct standalone kernels, and use the resulting kernel matrix as input to SVMs.

$\mathbf{META}_{BASE;PTK}$, $\mathbf{META}_{BASE;SST}$. Logistic regression metaclassifiers trained on the outputs of two standalone systems, namely (i) V+B_{cr}+E_{cr}+E (we denote it as $BASE$ to simplify the notation), and (ii) PTK or SST, respectively. We ran 10-fold cross-validation on the training set and used the resulting predictions as training data for the ensemble classifier. We did not use the development or training sets for any parameter tuning, thus we report the results both on the DEV and TEST sets.

$\mathbf{SUM}_{BASE;PTK}$, $\mathbf{SUM}_{BASE;SST}$. Simple metaclassifiers, summing the output of the BASE and

---

[6] The 10 answer sentences per question limit speeds up training time without loss in performance

[7] We use the version distributed by (Yao et al., 2013) in `https://code.google.com/p/jacana/`

PTK or SST systems, respectively.

5.3 Toolkits

We trained the models using *scikit-learn*[8] by Pedregosa et al. (2012) using the SVC version of SVM with precomputed K_{IP} and K_{CP} kernel matrices and default parameters. We trained the ensemble model using the scikit *LogisticRegression* classifier implementation with the default parameters. We used spaCy library[9] and scikit to obtain bag-of-n-gram representations for the B similarity features, and to compute B- and E- base gram matrices.

We used the RelTextRank framework[10] (Tymoshenko et al., 2017b) to generate the structural representations for the TK similarity features and to extract the strong baseline feature vectors from Sec. 4. We used KeLP (Filice et al.) to compute the TK gram matrices.

Regarding the Embedding-based similarities (E), we obtain three similarity features by using three word embedding models to generate the representations of the input texts, T_1 and T_2, namely GloVe vectors trained on common crawl data[11], Word2Vec vectors pre-trained on Google News[12], and another Word2Vec vectors model[13] pre-trained on Aquaint[14] plus Wikipedia.

5.4 Results and discussion

Table 4 reports the results obtained with the intra- and cross-pair kernels K_{IP}, K_{CP} and their combinations. In the following, we describe the results according to the model categories above.

Intra-pair kernels. Taking into account intra-pair similarity is the standard approach in the majority of the previous non-DNN work. In our experiments, we implement this approach as K_{IP} using B, E, V groups of similarity features. K_{IP} performs worse than the state-of-art (SoA) DNN systems on all the datasets (see tables 5, 6 and 7, for the SoA systems).

The results on WikiQA are particularly low even when the best K_{IP} system, B+V+E, is used, which scores up to 15 points less than the state of the art. This confirms the Yang et al. (2015) observation on WikiQA, according to which, simple word matching methods are likely to underperform on its data, considering how it was built. Nevertheless, despite its simplicity, B+V+E performs comparably to the Yang et al. (2015) reimplementation of LCLR, the complex latent structured approach employing rich lexical and semantic intra-pair similarity features (Yih et al., 2013). Yang et al. (2015) report that on WikiQA LCLR obtains MRR of 60.86 and MAP of 59.93.

Then, on TREC13 and SemEval-2016, the intra-pair *V*, *V+E* and *B+V+E* kernels exhibit rather high performance, however, they are still significantly below the state of the art, thus confirming our hypothesis that intra-pair similarity alone does not guarantee top results.

Cross-pair kernels. B_{cr} and E_{cr} obtain rather high results on WikiQA and SemEval. On WikiQA, both B_{cr} and $B_{cr} + E_{cr}$ outperform all the intra-pair kernels by a large margin, while, on SemEval, they perform comparably to the manually engineered domain-specific V features of Nicosia et al. (2015). On the contrary, on TREC13, V outperforms both B_{cr} and E_{cr}, thus showing that TREC13 is indeed biased towards intra-pair relatedness features by construction.

More complex PTK and SST cross-pair kernels, both alone and combined with B_{cr}, E_{cr}, typically outperform the standalone B_{cr} and E_{cr} on all the corpora (PTK on TREC13 and WikiQA, and SST and B_{cr}+E_{cr}+PTK on SemEval). This can be explained by the fact that PTK and SST are able to learn complex syntactic patterns and also contain some information about intra-pair relations, namely `REL-` labels described in Sec. 3.2. Thus, it is natural that they outperform simpler cross-pair kernels. Nevertheless, on WikiQA-DEV, B_{cr}+E_{cr} performs very close to PTK. Moreover, on SemEval, B_{cr}+E_{cr} outperforms PTK and is behind SST for less than 1 point in terms of MAP. This can be explained by the fact that Q and A, in SemEval, are frequently ungrammatical as the cQA corpus is collected from online forums.

Finally, note that the B_{cr}+E_{cr}+PTK system, which does not use any cQA domain-specific features, is only 0.56 MAP points behind KeLP, the best-performing system in the SemEval competition (see Line 1 of Table 7).

Kernels combining the intra- and cross-pair similarities. The V+B_{cr}+E_{cr}+E combination (we

Table 4: Results on TREC13, WikiQA and SemEval-2016 datasets. Best results in each feature category are highlighted with bold, overall best results are underlined. TK is SST for Semeval and PTK for WikiQA and TREC13. BASE refers to the V+B$_{cr}$+E$_{cr}$+E configuration.

will refer to it as *BASE*), outperforms the standalone domain-specific handcrafted cQA features, V, and both PTK and SST on SemEval 2016 TEST and DEV by at least 2.3 points in all metrics.

Moreover, V+B$_{cr}$+E$_{cr}$+E is only less than 0.5 points behind the #1 system of the SemEval-2016 competition (see Tab. 7). We recall that V+B$_{cr}$+E$_{cr}$+E only uses basic n-gram overlap-based cross- and intra- similarity features and embedding-based cosine similarities.

Finally, when we add tree kernel models to the combination, i.e., V+B$_{cr}$+E$_{cr}$+E+PTK or V+B$_{cr}$+E$_{cr}$+E+SST, we note improvement for SemEval and TREC13 tasks.

Ensemble models. We ensemble cross- and intra-pair kernels-based models by summing the predictions of the standalone SVM classifiers (SUM models) or by training a logistic regression meta-classifier on them (META models). We build the meta-classifiers on the outputs of the standalone system *BASE* and TKs, namely PTK and SST. The "Ensemble" section of Table 4 shows that meta-system combinations mostly outperform the standalone kernels.

In general, combining cross-pair and intra-pair similarities (with kernel sum or meta-classifiers) provides state-of-the-art results without using deep learning. Additionally, the outcome is deterministic, while the DNN accuracy may vary depending on the type of the hardware used or the random initialization parameters (Crane, 2018).

5.5 Comparison with the state of the art

Tables 5, 6 and 7 report the performance of the most recent state-of-the-art systems on WikiQA, TREC13 and SemEval in comparison with our best results. We discuss them with respect to the different datasets.

WikiQA. As already mentioned earlier, WikiQA contains many questions without correct answer (see Tab. 3). When evaluated on the full data, even the oracle system will achieve at most 38.38 points of MAP. Moreover, as originally observed in (Wang et al., 2007), the questions that do not have either correct answers or incorrect answers are not useful for comparing the performance of different answer sentence selection systems. Therefore, they are typically removed from WikiQA and TREC13 before the evaluation.

There has been some discrepancy in the community when evaluating on WikiQA. The original baselines proposed for the corpus in (Yang et al., 2015) were evaluated in the "clean" setting[15]. We

Our model (V+B$_{cr}$+E$_{cr}$+E+SST)	**86.52**	**79.79**

Table 7: Comparison to the SoA on SemEval-2016

also evaluate in the "clean" setting. However, the performance of the most recent state-of-the-art systems listed in the Tab. 5 is reported in the "no all$^-$" setting, in the respective papers, i.e., they keep the all$^+$ questions[16]. Thus, they have 6 extra questions always answered correctly by default. To account for this discrepancy, in Tab. 5, we report the results in both settings. It is trivial to convert the performance figures from one setting to another. In the table, we mark the conversion results with italic.

Our SUM$_{BASE;PTK}$ system (i) outperforms all the state-of-the-art systems, including the sophisticated architectures with attention, such as IWAN-att (Shen et al., 2017), and compare-aggregate (C/A) frameworks (Wang and Jiang, 2017; Bian et al., 2017) in terms of MRR; and (ii) has the same MAP as (Bian et al., 2017). Obviously, this improvement is not statistically significant with respect to C/A systems by Bian et al. (2017). Nevertheless, ours is a very promising result, considering that we only use linear models with simple kernels and do not tune any learning parameter of such models.

TREC13. As shown in Tab. 6, our models do not outperform the state of the art on TREC13, but they still perform comparably to the recent DNN HyperQA model (Tay et al., 2018). In general, our model is behind the state-of-the-art IWAN-att system by 4.55 points in terms of MAP. Note, however, that TREC13 test set contains only 68 questions, therefore this difference in performance is not likely to be statistically significant[17].

Semeval. Table 7 compares performance of B_{cr} + E_{cr} + V + E + SST system on Semeval to that of KeLP and ConvKN, the two top systems in the SemEval 2016 competition, and also to the performance of the recent DNN-based HyperQA and AI-CNN systems. In the Semeval 2016 competition, our model would have been the first[18], with #1 KeLP system being 0.6 MAP points behind. Then, it would have outperformed the state-of-the-art AI-CNN system by 0.35 MAP points.

6 Conclusions

This work proposes a simple, yet effective approach to the task of answer sentence selection based on the intuition that similar patterns in questions are likely to demand similar patterns in answers. We showed that this hypothesis provides an improvement on three benchmark datasets, WikiQA, TREC13, Semeval-2016, and, moreover, it enables simple features to achieve the state of the art on WikiQA and Semeval-2016, outperforming many of state-of-the-art DNN-based systems. There is significant room for further elaboration of this approach, for example, by expanding feature spaces with more syntactic and semantic features, employing new types of kernels for measuring the inter-question/answer pair similarity or trying to implement the same idea in DNN architectures.

Abstract

We present QuAC, a dataset for **Qu**estion **A**nswering in **C**ontext that contains 14K information-seeking QA dialogs (100K questions in total). The dialogs involve two crowd workers: (1) a student who poses a sequence of freeform questions to learn as much as possible about a hidden Wikipedia text, and (2) a teacher who answers the questions by providing short excerpts from the text. QuAC introduces challenges not found in existing machine comprehension datasets: its questions are often more open-ended, unanswerable, or only meaningful within the dialog context, as we show in a detailed qualitative evaluation. We also report results for a number of reference models, including a recently state-of-the-art reading comprehension architecture extended to model dialog context. Our best model underperforms humans by 20 F1, suggesting that there is significant room for future work on this data. Dataset, baseline, and leaderboard available at `http://quac.ai`.

1 Introduction

In information-seeking dialog, students repeatedly ask teachers questions to learn about a topic of interest (Stede and Schlangen, 2004). Modeling such conversations is challenging, as the questions can be highly context-dependent, elliptical, and even unanswerable. To enable learning from rich information-seeking dialog, we present QuAC (henceforth 🦆), a large-scale dataset for **Qu**estion **A**nswering in **C**ontext that contains 14K crowdsourced QA dialogs (100K total QA pairs).[1]

Figure 1 shows an example 🦆 dialog. The interaction is student driven and centered around a short evidence text (a section from Daffy Duck's Wikipedia page), which only the teacher can access. Given just the section's heading, "Origin & History", the student aims to learn as much as possible about its contents by asking questions. The teacher answers these questions with spans from the evidence text, as in existing reading comprehension tasks (Rajpurkar et al., 2016). Additionally, the teacher uses dialog acts to provide the student with feedback (e.g., "ask a follow up ques-

Section: 🦆Daffy Duck, Origin & History

STUDENT: **What is the origin of Daffy Duck?**

TEACHER: ↪ first appeared in Porky's Duck Hunt

STUDENT: **What was he like in that episode?**

TEACHER: ↪ assertive, unrestrained, combative

STUDENT: **Was he the star?**

TEACHER: ⇢ No, barely more than an unnamed bit player in this short

STUDENT: **Who was the star?**

TEACHER: ↛ No answer

STUDENT: **Did he change a lot from that first episode in future episodes?**

TEACHER: ↪ Yes, the only aspects of the character that have remained consistent (...) are his voice characterization by Mel Blanc

STUDENT: **How has he changed?**

TEACHER: ↪ Daffy was less anthropomorphic

STUDENT: **In what other ways did he change?**

TEACHER: ↪ Daffy's slobbery, exaggerated lisp (...) is barely noticeable in the early cartoons.

STUDENT: **Why did they add the lisp?**

TEACHER: ↪ One often-repeated "official" story is that it was modeled after producer Leon Schlesinger's tendency to lisp.

STUDENT: **Is there an "unofficial" story?**

TEACHER: ↪ Yes, Mel Blanc (...) contradicts that conventional belief

...

Figure 1: An example dialog about a Wikipedia section. The student, who does not see the section text, asks questions. The teacher provides a response in the form of a text span (or No answer), optionally yes or no (Yes / No), and encouragement about continuing a line of questioning (should, ↪, could ⇢, or should not ↛ ask a follow-up question).

---

[1] We use "dialog" to refer to a sequence of QA pairs.

Table 1: Comparison of the QUAC dataset to other question answering datasets.

tion"), which makes the dialogs more productive.

We collect the dataset in an interactive setting where two crowd workers play the roles of teacher and student. To encourage natural and diverse questions, we do not follow previous dialog-style QA datasets that semi-automatically generate questions (Talmor and Berant, 2018; Saha et al., 2018). Furthermore, unlike QA datasets such as SQuAD and CoQA (Reddy et al., 2018), students in do not know the answers to their questions prior to asking them, which lessens the role of string matching and simple paraphrasing in answering their questions. This property makes similar to datasets that contain real user queries on search engines (Nguyen et al., 2016).

contains many challenging phenomena unique to dialog, such as coreference to previous questions and answers and open-ended questions that must be answered without repeating previous information (Section 3). Additionally, despite lacking access to the section text, we find that students start dialogs by asking questions about the beginning of the section before progressing to asking questions about the end. These observations imply that models built for must incorporate the dialog context to achieve good performance.

We present a strong neural baseline (Clark and Gardner, 2018) that considers both dialog context and section text. While this model achieves within 6 F1 of human performance on SQuAD, it performs 20 F1 points below the human upper bound on , indicating room for future improvement.

2 Dataset collection

This section describes our data collection process, which involves facilitating QA dialogs between crowd workers. Table 1 shows shares many of the same positive characteristics of existing QA datasets while expanding upon the dialog aspect.

	Train	Dev.	Test	Overall
questions	83,568	7,354	7,353	98,407
dialogs	11,567	1,000	1,002	13,594
unique sections	6,843	1,000	1,002	8,854
tokens / section	396.8	440.0	445.8	401.0
tokens / question	6.5	6.5	6.5	6.5
tokens / answer	15.1	12.3	12.3	14.6
questions / dialog	7.2	7.4	7.3	7.2
% yes/no	26.4	22.1	23.4	25.8
% unanswerable	20.2	20.2	20.1	20.2

Table 2: Statistics summarizing the dataset.

2.1 Interactive Task

Our task pairs up two workers, a *teacher* and a *student*, who discuss a section s (e.g., "Origin & History" in the example from Figure 1) from a Wikipedia article about an entity e (Daffy Duck). The student is permitted to see only the section's title t and the first paragraph of the main article b, while the teacher is additionally provided with full access to the section text.

The task begins with the student formulating a free-text question q from the limited information they have been given. The teacher is not allowed to answer with free text; instead, they must select a contiguous span of text defined by indices (i, j) into the section text s.[2] While this decision limits the expressivity of answers, it makes evaluation simpler and more reliable; as such, it has been adopted in other reading comprehension datasets such as SQuAD, TriviaQA (Joshi et al., 2017), and NewsQA (Trischler et al., 2016).

To facilitate more natural interactions, teachers must also provide the student with a list of dialog acts v that indicates the presence of any of n discrete statements. We include three types of di-

---

[2] We set the maximum answer length to 30 tokens to prevent teachers from revealing the full article all at once.

Figure 2: A treemap visualization of the eight most frequent "Wh" words in , where box area is proportional to number of occurrences. Compared to other machine comprehension datasets, we observe increased contextuality and open-endedness, as well as a variety of both general and specific questions.

alog acts: (1) continuation (`follow up`, `maybe follow up`, or `don't follow up`), (2) affirmation (`yes`, `no`, or `neither`) and (3) answerability (`answerable` or `no answer`). The continuation act is crucial for workers to have productive dialogs, as it allows teachers to guide the student's questioning towards aspects of the article that are especially important or interesting. Altogether, a teacher's complete answer to a question q includes a pair of indices and dialog indicators, $a = (i, j, v)$. If a question is marked `no answer`, the indices are ignored.

After receiving an answer from the teacher, the student asks another question. At every turn, the student has more information about the topic than they did previously, which encourages them to ask follow-up questions about what they have just learned. The dialog continues until (1) twelve questions are answered, (2) one of the partners decides to end the interaction, or (3) more than two unanswerable questions were asked.

2.2 Collection Details

We used Amazon Mechanical Turk for collection, restricting the task to workers in English-speaking countries and with more than 1000 HITs with at least a 95% acceptance rate. We paid workers per the number of completed turns in the dialog, which encourages workers to have long dialogs with their partners, and discarded dialogs with less than three QA pairs.[3] To ensure quality, we created a qualification task and allowed workers to report their partner for various problems. More details on data collection can be found in our datasheet.[4]

Article selection Our early pilot studies showed that articles about people generally require less background knowledge to write good questions than other categories. To find articles about people with varied backgrounds, we retrieved articles from a list of category keywords (culture, animal, people associated with event, geography, health, celebrity) using a web interface provided by the Wikimedia foundation.[5] We pruned by popularity by selecting articles with at least 100 incoming links, and we additionally removed non-person entities using YAGO (Suchanek et al., 2007). After article selection, we filtered sections from these articles based on the number of paragraphs, number of tokens, and average words per sentence. [6]

Dataset validation To create our evaluation sets, we collected four additional annotations per question. Workers were presented with questions from a previously collected dialog and asked to

---

[3] On average, we paid $0.33 per question, increasing pay per question as dialogs got longer to encourage completion.

[4] `http://quac.ai/datasheet.pdf`

[5] https://petscan.wmflabs.org/

[6] These filtering steps bias our data towards entertainers; see datasheet for details.

provide answer spans.[7] Acquiring many annotations is important since many questions in 🦆 have multiple valid answers.

Train / Dev / Test Differences Table 2 shows small differences between training, development and testing splits. Sections in the training set are shorter than those in the evaluation folds because we permit multiple dialogs about the same section only in training; since workers preferred reading shorter sections, these were more likely to result in multiple dialogs. Variations in answer span length arise from two sources: (1) having multiple annotations in the validation task and (2) differing incentives between the data collection and validation procedures.[8] An analysis measuring the effect of these variations shows that they result in little difference in evaluation.[9]

3 Dataset Analysis

🦆 differs from other reading comprehension datasets due to our dialog-style collection process and the information asymmetry between teacher and student. In the following sections, we provide a qualitative analysis of the dataset in 🦆 that highlights challenging question types as well as the impact of the dialog context.

Question and answer types Table 2 shows dataset summary statistics. 🦆 has long answers of 15 tokens on average compared to 3 for SQuAD, which is unsurprising as most SQuAD answers are either entities or numerics (Jurczyk et al., 2018) while 🦆 questions can be more open-ended. While the average question length (6.5 tokens) is shorter than that of SQuAD (11 tokens), this does not indicate reduced question complexity, as the student (1) cannot access the section to paraphrase it and (2) can be more concise by coreferencing previous interactions.

Section: Augusto Pinochet : Intellectual life...

STUDENT: **Was he known for being intelligent?**
TEACHER: $\hookrightarrow$ No, Pinochet was publicly known as a man with a lack of culture.
STUDENT: **why did people feel that way?**
TEACHER: $\hookrightarrow$ reinforced by the fact that he also portrayed himself as a common man
STUDENT: **did he have any hobbies?**
TEACHER: $\hookrightarrow$ Yes, Before wresting power from Allende, Pinochet had written two books.
STUDENT: **what is the name of a book written by him?**
TEACHER: $\hookrightarrow$ Geopolitica (1968) and Campana de Tarapaca (1972).
STUDENT: **what were the books about?**
TEACHER: $\hookrightarrow$ Chile's military literature.
STUDENT: **was there anything noteworthy regarding his books?**
TEACHER: $\hookrightarrow$ Yes, In Geopolitica Pinochet plagiarized (...) Gregorio Rodriguez Tascon
STUDENT: **did he deny those allegations?**
TEACHER: $\not\hookrightarrow$ No answer
STUDENT: **what did he plagiarize in Geopolitica?**
TEACHER: $\bar{\hookrightarrow}$ In Geopolitica Pinochet plagiarized (...) paragraphs from a 1949 presentation
. . .

Figure 3: An example successful dialog from 🦆. Questions build on each other and interesting aspects (e.g., plagiarism) are explored as they are discovered.

Figure 2 visualizes the most frequent question types in 🦆 based on "Wh" words.[10] For a more fine-grained analysis, we randomly sampled 100 questions (each from a different dialog) and manually labeled different phenomena in Table 3. Unlike most current QA datasets that focus on factoid questions, our task setup encourages more open-ended questions: about half of 🦆 questions are non-factoid. Furthermore, 86% of questions are contextual, requiring reading the context to resolve coreference; of these, 44% refer to entities or events in the dialog history, while 61% refer to the subject of the article.

The role of context Dialog context is crucial to understanding and answering 🦆 questions. Figure 5a shows that the location of the answer within the text is influenced by the number of questions asked previously. Early questions are mostly answered in the beginning of the section, while later questions tend to focus on the end of the section. Interestingly, text in the middle of the section is not asked about as frequently (Figure 5c). As more questions get asked, the more likely a question is to be unanswerable.

Figure 5b shows how the answers progress through different chunks of the evidence text (where each section is divided into 12 chunks of

---

[7] After submitting an answer, they were shown the original teacher's answer so that they could understand the context of the subsequent questions.

[8] Validation workers did not have to maintain the dialog and so did not include as much information in the response.

[9] More specifically, we analyze whether references from the initial data collection significantly differ from references collected during validation. We observe a difference of less than 1 F1 when using the original answer as system output versus using validation answers.

[10] To more effectively visualize sub-boxes like "what did", we exclude questions from the tail of the distribution.

Section: Gaelic Ireland : Invasion

STUDENT: **What year did the invasion happen?**
TEACHER: ↪ in 1169 the main body of Norman, Welsh and Flemish forces landed in Ireland and quickly retook Leinster and the cities of Waterford and Dublin on behalf of Diarmait.
STUDENT: **Who was Diarmait?**
TEACHER: ⇢ King Diarmait Mac Murchada of Leinster.
STUDENT: **Where is Leinster located?**
TEACHER: ↛ landed in Ireland and quickly retook Leinster.
STUDENT: **Were invasions common?**
TEACHER: ↛ No answer
STUDENT: **Are there any other interesting aspects about this article?**
TEACHER: ⇢ Yes, IPope Adrian IV, the only English pope, had already issued a Papal Bull in 1155 giving Henry II of England authority to invade Ireland.
STUDENT: **Who lead the invasion?**
TEACHER: ↛ No answer
STUDENT: **Did England defeat the Irish armies?**
TEACHER: ↛ No answer

Figure 4: A less successful dialog from . The student struggles to get information despite asking good questions. The teacher attempts to provide extra context to guide the student, but the dialog ultimately ends because of too many unanswerable questions.

Question type	%	Example
Non-factoid	54	Q: **Were** the peace talks **a success?** Q: **What was** her childhood **like?**
Contextual	86	
Coref (article)	61	Title: Paul Cézanne: Early years Q: When did **he** start painting?
Coref (history)	44	Q: What was special about the Harrah's? A: project was built by Trump with financing from the Holiday Corporation. Q: **Which led to what?**
Anything else?	11	Q: What **other acting** did he do? Q: **What else** did he research?

Table 3: An analysis of questions. **Non-factoid** questions do not ask about specific facts, while **contextual** questions require reading the history to resolve coreferences to the dialog history and/or article.

equal size). The answer to the next question is most frequently either in the same chunk as the previous question or an adjacent chunk, and most dialogs in the dataset cover three to six of the chunks (Figure 5d). These observations suggest that models for must take into account the dialog context. However, results in Section 5 show that solely relying on the location of previous answers is not sufficient.

Finally, we examine properties of the questions as a function of the turn position in the dialog (Figure 6). The frequency of yes/no questions increases significantly as the dialogs progress; again, at the beginning of the dialog, students have very little information, so it is harder to formulate a yes/no question. The percentage of questions that have multiple answers declines as the dialog progresses, implying students ask general questions first and specific ones later.

Qualitative examples Figures 3 and 4 contain two representative dialogs from . Longer dialogs sometimes switch topics (such as in Figure 3 about "academic work") and often go from general to specific questions. Students whose questions go unanswered commonly resort to asking their teacher for any interesting content; even if this strategy fails to prolong the dialog as in Figure 4, models can still use the dialog to learn when to give no answer.

4 Experimental Setup

We consider the following QA task: given the first k questions and k ground-truth answers in the dialog, all supporting material (entity e, topic t, background b, and section text s), and question q_{k+1}, we predict the answer span indices i, j in the section text s. Since affirmation questions are incomplete without a yes/no answer and the continuation feedback is important for information-seeking dialog, we predict the dialog acts v, which with the span form the final answer prediction a_{k+1}.

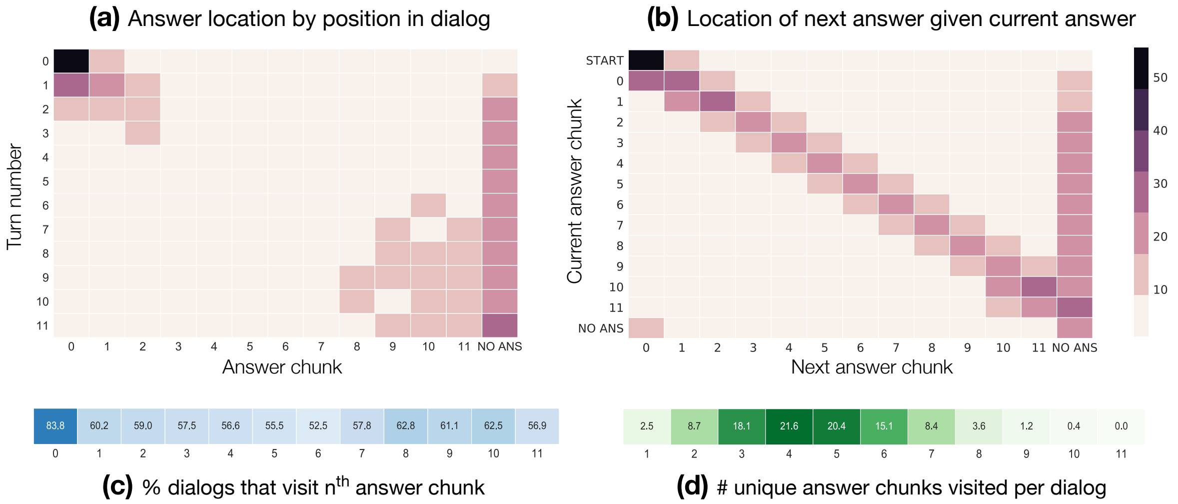
All of our experiments are carried out on a train/dev/test split of 83.5k/7.3k/7.3k questions/answer pairs, where no sections are shared between the different folds. Questions in the training set have one reference answer, while dev and test questions have five references each. For all experiments, we do not evaluate on questions with a human F1 lower than 40, which eliminates roughly 10% of our noisiest annotations.[11]

4.1 Evaluation Metrics

Our core evaluation metric, word-level F1, is implemented similarly to SQuAD (Rajpurkar et al.,

---

[11] A manual inspection of annotations below this threshold revealed many lower quality questions; however, we also report unthresholded F1 in the final column of Table 4.



(a) Answer location by position in dialog

(b) Location of next answer given current answer

(c) % dialogs that visit nth answer chunk

(d) # unique answer chunks visited per dialog

Figure 5: Heatmaps depicting the importance of context in 🦆 dialogs, where (a) and (b) share the same color scale. The student's earlier questions are answered mostly by the first few chunks, while the end of the section is covered in later turns (a). The middle is the least covered portion (c), and dialogs cover around five unique chunks of the section on average (d). The transition matrix (b) shows that the answer to the next question is more likely to be located within a chunk adjacent to the current answer than in one farther away.

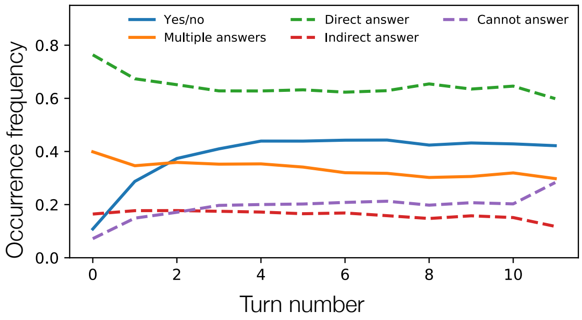


Figure 6: The number of turns in the dialog influences the student's behavior: they start by asking general questions (i.e., easier to answer, with multiple possible answers) and progress to more specific ones.

2016): precision and recall are computed by considering the portion of words in the prediction and references that overlap after removing stopwords.[12] For `no answer` questions, we give the system an F1 of one if it correctly predicts `no answer` and zero otherwise.[13] Like SQuAD, we compute the maximum F1 among all references; however, since many 🦆 questions have multiple valid answers, this metric varies significantly with the number of reference annotations. To make oracle human and system performance comparable, given n references, we report the average of the maximum F1 computed from each $n-1$ subset with respect to the heldout reference.

Additionally, since averaged F1 can be misleading for questions with multiple valid answers, we introduce the human equivalence score (HEQ), a performance measure for judging whether a system's output is as good as that of an average human.[14] HEQ measures the percentage of examples for which system F1 exceeds or matches human F1. We compute two variants: (1) the percentage of questions for which this is true (HEQ-Q), and (2) the percentage of dialogs for which this is true for every question in the dialog (HEQ-D). A system that achieves a value of 100 on HEQ-D can by definition maintain average human quality output over full dialogs.

For dialog acts, we report accuracy with respect to the majority annotation, breaking ties randomly.

5 Experiments

5.1 Sanity checks

Random sentence This baseline selects a random sentence in the section text s as the answer (including `no answer`).

---

[12] Since our answer spans have vaguer boundaries than the shorter ones in SQuAD, exact match is not a useful metric.

[13] Because the validation task was more susceptible to spam by constant annotation of "no-answer," we only allow "no-answer" if the majority of references marked "no-answer", removing other answers. If "no-answer" is not the majority answer, we remove all instances of "no-answer".

[14] In cases with lower human agreement on F1, if a system produces one reference exactly (F1 = 100), it will get points that it can use to offset poor performance on other examples.

Majority The majority answer outputs `no answer` and the majority class for all other dialog acts (`neither` for affirmation and `don't follow up` for continuation).

Transition matrix We divide the supporting text into 12 chunks (with a special chunk for `no answer`) and use the transition matrix (computed from the training set) in Figure 5b to select an answer given the position of the previous answer. This baseline does not output other dialog acts.

5.2 Upper bounds

Gold NA + TM This is the same transition matrix (TM) baseline as before, except that for questions whose gold annotations are `no answer`, we always output `no answer`.

Gold sentence + NA To see if 🦆 can be treated as an answer sentence selection problem, we output the sentence from s with the maximal F1 with respect to references, or `no answer` for unanswerable questions.

Human performance We pick one reference as a system output and compute the F1 with respect to the remaining references using the method described in Section 4.1. By definition, all HEQ measures are 100, and we report agreement for the affirmation dialog act.[15]

5.3 Baselines

Pretrained InferSent To test the importance of lexical matching in our dataset, we output the sentence in s whose pretrained InferSent representation (Conneau et al., 2017) has the highest cosine similarity to that of the question.

Feature-rich logistic regression We train a logistic regression using Vowpal Wabbit (Langford et al., 2007) to select answer sentences. We use simple matching features (e.g., n-gram overlap between questions and candidate answers), bias features (position and length of a candidate), and contextual features (e.g., matching features computed with previous questions / answers, turn number).

BiDAF++ We use a re-implementation of a top-performing SQuAD model (Peters et al., 2018) that augments bidirectional attention flow (Seo et al., 2016, BiDAF) with self-attention (Clark and Gardner, 2018) and contextualized embeddings.[16]

A token for `no answer` is appended to s to enable its prediction following Levy et al. (2017). Additionally, we modify the model for our task to also predict dialog acts, placing a classifier over the same representation used to predict the end position of the predicted span.

BiDAF++ w/ k-ctx As BiDAF++ does not model any dialog context, we modify the passage and question embedding processes to consider the dialog history. We consider context from the previous k QA pairs.[17]

- **Passage embedding** We explicitly identify the previous k answers within the section text by concatenating marker embeddings to the existing word embeddings.

- **Question embedding** Naively prepending the previous k questions to the current question did not show gains in initial experiments. We opt instead to simply encode the dialog turn number within the question embedding.

5.4 Results

Table 4 summarizes our results (each cell displays dev/test scores), where dialog acts are Yes/No (affirmation) and Follow up (continuation). For comparison to other datasets, we report F1 without filtering low-agreement QA pairs (F1').

Sanity check Overall, the poor sanity check results imply that 🦆 is very challenging. Of these, following the transition matrix (TM) gives the best performance, reinforcing the observation that the dialog context plays a significant role in the task.

Upper bounds The human upper bound (80.8 F1) demonstrates high agreement. While Gold sentence + NA does perform well, indicating that significant progress can be made by treating the problem as answer sentence selection, HEQ measures show that span-based approaches will be needed achieve average human equivalence. Finally, the Gold NA + TM shows that 🦆 cannot be solved by ignoring question and answer text.

---

[15] We did not collect multiple annotations for the continuation dialog act and so omit it.

[16] The AllenNLP (Gardner et al., 2017) implementation we use reaches 82.7 on the SQuAD development set, compared to the paper's reported 85.8 on SQuAD; regardless, this implementation would have been state-of-the-art less than a year ago, making it an extremely strong baseline.

[17] Our implementation is available in AllenNLP.

	F1	HEQ-Q	HEQ-D	Yes / No	Follow up	F1 (All)
Random sentence	15.7 / 15.6	6.9 / 6.9	0.0 / 0.1	—	—	16.4 / 16.3
Majority answer	22.7 / 22.5	22.7 / 22.5	0.5 / 0.4	78.8 / 77.6	57.9 / 56.7	20.2 / 20.0

Pretrained InferSent	21.4 / 20.8	10.2 / 10.0	0.0 / 0.0	—	—	22.0 / 21.4
Logistic regression	34.3 / 33.9	22.4 / 22.2	0.6 / 0.2	—	—	34.3 / 33.8
BiDAF++ (no ctx)	51.8 / 50.2	45.3 / 43.3	2.0 / 2.2	86.4 / 85.4	59.7 / 59.0	50.1 / 48.2
BiDAF++ (w/ 1-ctx)	59.9 / 59.0	54.9 / 53.6	4.7 / 3.4	86.5 / **86.1**	61.3 / 60.3	57.5 / 56.5
BiDAF++ (w/ 2-ctx)	**60.6 / 60.1**	**55.7 / 54.8**	**5.3** / 4.0	**86.6** / 85.7	**61.6 / 61.3**	**58.3 / 57.8**
BiDAF++ (w/ 3-ctx)	**60.6** / 59.5	55.6 / 54.5	5.0 / **4.1**	86.1 / 85.7	**61.6** / 61.2	58.1 / 57.0
Gold NA + TM	43.0 / 42.6	27.4 / 27.4	1.0 / 0.8	—	—	41.0 / 40.6
Gold sentence + NA	72.4 / 72.7	61.8 / 62.7	9.8 / 9.7	—	—	70.8 / 71.2
Human performance	80.8 / 81.1	100 / 100	100 / 100	89.4 / 89.0	—	74.6 / 74.7

Table 4: Experimental results of sanity checks (top), baselines (middle) and upper bounds (bottom) on . Simple text matching baselines perform poorly, while models that incorporate the dialog context significantly outperform those that do not. Humans outperform our best model by a large margin, indicating room for future improvement.

Baselines Text similarity methods such as bag-of-ngrams overlap and InferSent are largely ineffective on , which shows that questions have little direct overlap with their answers. On the other hand, BiDAF++ models make significant progress, demonstrating that existing models can already capture a significant portion of phenomena in . The addition of information from previous turns (w/ 1-ctx) helps significantly, indicating that integration of context is essential to solving the task. While increasing the context size in BiDAF++ continues to help, we observe saturation using contexts of length 3, suggesting that more sophisticated models are necessary to take full advantage of the context. Finally, even our best model underperforms humans: the system achieves human equivalence on only 60% of questions and 5% of full dialogs.

5.5 Error Analysis

In this section, we analyze the development set performance of our best context-aware model (BiDAF++ w/ 2-ctx), our best context-agnostic model (BiDAF++), and humans. Figure 7 contains three plots showing how F1 scores of baseline models and human agreement vary with (1) turn number, (2) distance from previous answer,[18] and (3) answer length in tokens. Taken as a whole, our analysis reveals significant qualitative differences between our context-aware and context-agnostic models beyond simply F1; additionally, human behavior differs from that of both models.

In the first plot, human agreement is unchanged throughout the dialog while the performance of both models decreases as the number of turns increases, although the context-aware model degrades less. While continuing a dialog for more turns does not affect human agreement, the second plot shows that human disagreement increases as the distance between the current answer's location within the section text and that of the previous answer increases. Larger distances indicate shifts in the student's line of questioning (e.g., if the teacher told the student not to follow up on the previous question). The plot also shows that model performance suffers (significantly more than humans) as distance increases, although the context-aware model can tolerate smaller shifts better than the context-agnostic model. In the last plot, human agreement is higher when the answer span is short; in contrast, our model struggles to pin down short answers compared to longer ones.

The plots demonstrate the increased robustness of the context-aware model compared to BiDAF++. This finding is reinforced by examining the difference in model performance on questions where previously the teacher recommended the student to "follow up" vs. not to follow up. The context-aware baseline performs 6 HEQ-Q higher on the "follow up" questions; in contrast, the context-agnostic baseline shows no HEQ-Q difference between the two types of questions. This discrepancy stems from the context-agnostic

---

[18] We divide the text into 12 equally-sized chunks and compute the difference of the current and previous chunk indices.

model's inability to take advantage of the location of the previous answer.

6 Related Work

Reading Comprehension Our work builds on span based reading comprehension (Rajpurkar et al., 2016; Joshi et al., 2017; Trischler et al., 2016), while also incorporating innovations such as curating questions independently of supporting text to reduce trivial lexical overlap (Joshi et al., 2017; Kociský et al., 2017) and allowing for unanswerable questions (Trischler et al., 2016; Rajpurkar et al., 2018). We handle open-ended questions like in MSMARCO (Nguyen et al., 2016), with multiple references, but we are the first to incorporate these into information-seeking dialog.

Sequential QA Our work is similar to sequential question answering against knowledge bases (Iyyer et al., 2017) and the web (Talmor and Berant, 2018), but instead of decomposing a single question into smaller questions, we rely on the curiosity of the student to generate a sequence of questions. Such open information seeking was studied in semantic parsing on knowledge bases (Dahl et al., 1994) and more recently with modern approaches (Saha et al., 2018), but with questions paraphrased from templates. Concurrent to our work, Saeidi et al. (2018) proposed a task of generating and answering yes/no questions for rule focused text (such as traffic laws) by interacting with a user through dialog. Also concurrently, Reddy et al. (2018) propose conversational question answering (CoQA) from text but allow both students and questioners to see the evidence. As a result, a large percentage of CoQA answers are named entities or short noun phrases, much like those in SQuAD. In contrast, the asymmetric nature of 🦆 forces students to ask more exploratory questions whose answers can be potentially be followed up on.[19]

Dialog 🦆 fits into an increasing interest in open domain dialog, mostly studied in the context of social chit-chat (Li et al., 2016; Ritter et al., 2011; Fang et al., 2017; Ghazvininejad et al., 2018). Most related to our effort is visual dialog (Das et al., 2017), which relies on images as evidence instead of text. More explicit goal driven scenarios, such as bargaining (Lewis et al., 2017) and item guessing (He et al., 2017) have also been explored, but the language is more constrained than in 🦆. Information-seeking dialog specifically was studied in Stede and Schlangen (2004).

7 Conclusion

In this paper, we introduce 🦆, a large scale dataset of information-seeking dialogs over sections from Wikipedia articles. Our data collection process, which takes the form of a teacher-student interaction between two crowd workers, encourages questions that are highly contextual, open-ended, and even unanswerable from the text. Our baselines, which include top performers on existing machine comprehension datasets, significantly underperform humans on 🦆. We hope this discrepancy will spur the development of machines that can more effectively participate in information seeking dialog.

Acknowledgments

🦆 was jointly funded by the Allen Institute for Artificial Intelligence and the DARPA CwC program through ARO (W911NF-15-1-0543). We would like to thank anonymous reviewers and Hsin-Yuan Huang who helped improve the draft.

---

[19] On average, CoQA answers are 2.7 tokens long, while SQuAD's are 3.2 tokens and 🦆 's are over 14 tokens.

Knowledge Base Question Answering via Encoding of Complex Query Graphs

Abstract

Answering complex questions that involve multiple entities and multiple relations using a standard knowledge base is an open and challenging task. Most existing KBQA approaches focus on simpler questions and do not work very well on complex questions because they were not able to simultaneously represent the question and the corresponding complex query structure. In this work, we encode such complex query structure into a uniform vector representation, and thus successfully capture the interactions between individual semantic components within a complex question. This approach consistently outperforms existing methods on complex questions while staying competitive on simple questions.

1 Introduction

The knowledge-based question answering (KBQA) is a task which takes a natural language question as input and returns a factual answer using structured knowledge bases such as Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and DBpedia (Auer et al., 2007). One simple example is a question like this: "What's the capital of the United States?" A common answer to such question is to identify the focus entity and the main relation predicate (or a sequence) in the question, and map the question to a triple fact query (US, $capital$, ?) over KB. The object answers are returned by executing the query. The mapping above is typically learned from question-answer pairs through distant supervision.

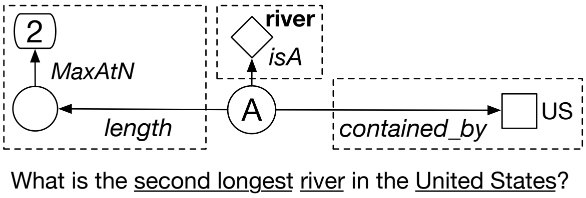

Figure 1: Running example of complex question.

While the above question can be answered by querying a single predicate or predicate sequence in the KB, many other more complex questions cannot, e.g. the question in Figure 1. To answer the question "What is the second longest river in United States", we need to infer several semantic clues: 1) the answer is contained by United States; 2) the answer is a river; 3) the answer ranks second by its length in descending order. Thus, multiple predicates are required to constrain the answer set, and we call such questions "complex questions" throughout this paper.

For answering complex questions, it's more important to understand the compositional semantic meanings of the question. As a classic branch of KBQA solutions, semantic parsing (SP) technique (Berant et al., 2013; Yih et al., 2015; Reddy et al., 2016; Hu et al., 2018) aims at learning semantic parse trees or equivalent query graphs [1] for representing semantic structures of the questions. For example in Figure 1, the query graph forms a tree shape. The answer node A, serving as the root of the tree, is the variable vertex that represents the real answer entities. The focus nodes (*US*, *river*, *2nd*) are extracted from the mentions of the question, and they constrain the answer node via predicate sequences in the knowledge base. Recently, neural network (NN) models have shown great promise in improving the performance of KBQA systems, and SP+NN techniques become the state-of-the-art on several KBQA datasets (Qu et al., 2018; Bao et al., 2016). According to the discussion above, our work extends the current research in the SP+NN direction.

The common step of SP-based approaches

---

[1] The term "query graph" is interchangeable with "query structure" and "semantic parsing tree" throughout this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2185–2194
Brussels, Belgium, October 31 - November 4, 2018.

is to first collect candidate query graphs using bottom up parsing (Berant et al., 2013; Cai and Yates, 2013) or staged query generation methods (Yih et al., 2015; Bao et al., 2016), then predict the best graph mainly based on the semantic similarity with the given question. Existing NN-based methods follow an encode-and-compare framework for answering simple questions, where both the question and the predicate sequence are encoded as semantic vectors in a common embedding space, and the semantic similarity is calculated by the cosine score between vectors. In order to define the similarity function between one question and a complex query graph, an intuitive solution is to split the query graph into multiple semantic components, as the predicate sequences separated by dashed boxes in Figure 1. Then previous methods can be applied for modeling the similarity between the question and each part of the graph. However, such approach faces two limitations. First, each semantic component is not directly comparable with the whole question, since it conveys only partial information of the question. Second, and more importantly, the model encodes different components separately, without learning the representation of the whole graph, hence it's not able to capture the compositional semantics in a global perspective.

In order to attack the above limitations, we propose a neural network based approach to improve the performance of semantic similarity measurement in complex question answering. Given candidate query graphs generated from one question, our model embeds the question surface and predicate sequences into a uniform vector space. The main difference between our approach and previous methods is that we integrate hidden vectors of various semantic components and encode their interaction as the hidden semantics of the entire query graph. In addition, to cope with different semantic components of a query graph, we leverage dependency parsing information as a complementary of sentential information for question encoding, which makes the model better align each component to the question. The contribution of this paper is summarized below.

- We propose a light-weighted and effective neural network model to solve complex KBQA task. To the best of our knowledge, this is the first attempt to explicitly encode the complete semantics of a complex query graph (Section 2.2);
- We leverage dependency parsing to enrich question representation in the NN model, and conduct thorough investigations to verify its effectiveness (Section 2.2.2);
- We propose an ensemble method to enrich entity linking from a state-of-the-art linking tool, which further improves the performance of the overall task (Section 2.3);
- We perform comprehensive experiments on multiple QA datasets, and our proposed method consistently outperforms previous approaches on complex questions, and produces competitive results on datasets made up of simple questions (Section 3).

2 Approach

In this section, we present our approach for solving complex KBQA. First, we generate candidate query graphs by staged generation method (Section 2.1). Second, we measure the semantic similarities between the question and each query graph using deep neural networks (Section 2.2). Then we introduce an ensemble approach for entity linking enrichment (Section 2.3), Finally, we discuss the prediction and parameter learning step of this task (Section 2.4).

2.1 Query Graph Generation

We illustrate our staged candidate generation method in this section. Compared to previous methods, such as Bao et al. (2016), we employ a more effective candidate generation strategy, which takes advantage of implicit type information in query graphs and time interval information in the KB. In our work, we take 4 kinds of semantic constraints into account: **entity**, **type**, **time** and **ordinal** constraints. Figure 2 shows a concrete example of our candidate generation. For simplicity of discussion, we assume Freebase as the KB in this section.

Step 1: Focus linking. We extract possible (mention, focus node) pairs from the question. Focus nodes are the starting points of various semantic constraints, refer to Figure 2(a). For entity linking, we generate (mention, entity) pairs using the state-of-the-art entity linking tool S-MART (Yang and Chang, 2015). For type linking, we brutally combine each type with all uni-, bi-

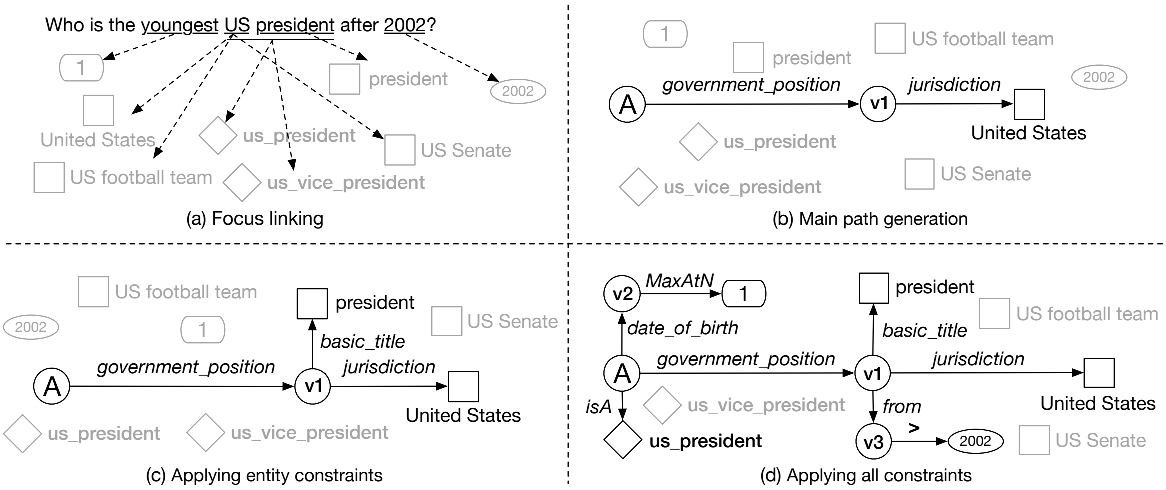

Figure 2: Running example of candidate generation.

and tri-gram mentions in the question, and pick top-10 (mention, type) pairs with the highest word embedding similarities of each pair. For time linking, we extract time mentions by simply matching year regex. For ordinal linking, we leverage a predefined superlative word list[2] and recognize mentions by matching superlative words, or the "ordinal number + superlative" pattern. The ordinal node is an integer representing the ordinal number in the mention.

Step 2: Main path generation. We build different main paths by connecting the answer node to different focus entities using 1-hop or 2-hop-with-mediator[3] predicate sequence. Figure 2(b) shows one of the main paths. Further constraints are attached by connecting an anchor node x to an unused focus node through predicate sequences, where the anchor node x is a non-focus node in the main path (A or v_1 in the example).

Step 3: Attaching entity constraints. We apply a depth-first search to search for combinations of multiple entity constraints to the main path through 1-hop predicate. Figure 2(c) shows a valid entity constraint, $(v_1, basic\_title, president)$. The advantage of depth-first search is that we can involve unlimited number of entities in a query graph, which has a better coverage than template-based methods.

Step 4: Type constraint generation. Type constraints can only be applied at the answer node using *IsA* predicate. Our improvement in this step is to filter type constraints using **implicit types** of the answer, derived from the outgoing predicates of the answer node. For example in Figure 2(c), the domain type of the predicate *government_position* is *politician*, which becomes the implicit type of the answer. Thus we can filter type constraints which are irrelevant to the implicit types, preventing semantic drift and speeding up the generation process. To judge whether two types in Freebase are relevant or not, we adopt the method in Luo et al. (2015) to build a rich type hierarchy of Freebase. Focus types are discarded, if they are not the super- or sub- types of any implicit types of the answer.

Step 5: Time and ordinal constraint generation. As shown in Figure 2(d), the time constraint is represented as a 2-hop predicate sequence, where the second is a virtual predicate determined by the preposition before the focus time, indicating the time comparing operation, like "before", "after" and "in". Similarly, the ordinal constraint also forms a 2-hop predicate sequence, where the second predicate represents descending (*MaxAtN*) or ascending order (*MinAtN*).

For the detail of time constraint, while existing approaches (Yih et al., 2015; Bao et al., 2016) link the focus time with only single time predicate, our improvement is to leverage **paired time predicates** for representing a more accurate time constraint. In Freebase, paired time predicates are used to represent facts within certain time intervals, like $from$ and to[4] in Figure 2(d). For time comparing operation "in", we link the time focus to the starting time predicate, but use both predi-

---

[2] ~20 superlative words, such as largest, highest, latest.

[3] Mediator is a kind of auxiliary nodes in Freebase maintaining N-ary facts.

[4] Short for $governmental\_position\_held.from$ and $governmental\_position\_held.to$ respectively.

cates in SPARQL query, restricting that the focus time lies in the time interval of the paired predicates.

After finishing all these querying stages, we translate candidate graphs into SPARQL query, and produce their final output answers. Finally, we discard query graphs with zero outputs, or using overlapped mentions.

2.2 NN-based Semantic Matching Model

The architecture of the proposed model is shown in Figure 3. We first replace all entity (or time) mentions used in the query graph by dummy tokens $\langle E \rangle$ (or $\langle Tm \rangle$). To encode the complex query structure, we split it into predicate sequences starting from answer to focus nodes, which we call *semantic components*. The predicate sequence doesn't include the information of focus nodes, except for type constraints, where we append the focus type to the *IsA* predicate, resulting in the predicate sequence like $\{$*IsA*, *river*$\}$. We introduce in detail the encoding methods for questions and predicate sequences, and how to calculate the semantic similarity score.

2.2.1 Semantic Component Representation

To encode a semantic component p, we take the sequence of both predicate ids and predicate names into consideration. As the example shown in Figure 3, the id sequence of the first semantic component is $\{$*contained_by*$\}$, and the predicate word sequence is the concatenation of canonical names for each predicate, that is $\{$"contained", "by"$\}$.

Given the word sequence $\{p_1^{(w)}, \dots, p_n^{(w)}\}$, we first use a word embedding matrix $E_w \in \mathbb{R}^{|V_w| \times d}$ to convert the original sequence into word embeddings $\{\boldsymbol{p}_1^{(w)}, \dots, \boldsymbol{p}_n^{(w)}\}$, where $|V_w|$ denotes the vocabulary size of natural language words, and d denotes the embedding dimension. Then we represent the word sequence using word averaging: $\boldsymbol{p}^{(w)} = \frac{1}{n} \sum_i \boldsymbol{p}_i^{(w)}$.

For the id sequence $\{p_1^{(id)}, \dots, p_m^{(id)}\}$, we simply take it as a whole unit, and directly translate it into vector representation using the embedding matrix $E_p \in \mathbb{R}^{|V_p \times d|}$ at path level, where $|V_p|$ is the vocabulary size of predicate sequences. There are two reasons for using such path embedding: 1) the length of id sequence is not larger than two, based on our generation method; 2) the number of distinct predicate sequences is roughly the same as the number of distinct predicates. We get the final vector of the semantic component by element-wise addition: $\boldsymbol{p} = \boldsymbol{p}^{(w)} + \boldsymbol{p}^{(id)}$.

2.2.2 Question Representation

We encode the question in both global and local level, which captures the semantic information with respect to each component p.

The global information takes the token sequence as the input. We use the same word embedding matrix E_w to convert the token sequence into vectors $\{\boldsymbol{q}_1^{(w)}, \dots, \boldsymbol{q}_n^{(w)}\}$. Then we encode the token sequence by applying bidirectional GRU network (Cho et al., 2014). The representation of the token sequence is the concatenation of the last forward and backward hidden states through the Bi-GRU layer, $\boldsymbol{q}^{(tok)} = [\overleftarrow{\boldsymbol{h}}_1^{(w)}; \overrightarrow{\boldsymbol{h}}_n^{(w)}]$.

To encode the question at local level, we leverage dependency parsing to represent long-range dependencies between the answer and the focus node in p. Since the answer is denoted by the wh-word in the question, we extract the dependency path from the answer node to the focus mention in the question. Similar with Xu et al. (2016), we treat the path as the concatenation of words and dependency labels with directions. For example, the dependency path between "what" and "United States" is $\{$what, $\overrightarrow{nsubj}$, is, $\overrightarrow{prep}$, in, $\overrightarrow{pobj}$, $\langle E \rangle\}$. We apply another bidirectional GRU layer to produce the vector representation at dependency level $\boldsymbol{q}_p^{(dep)}$, capturing both syntactic features and local semantic features. Finally we combine global and local representation by element-wise addition, returning the representation of the question with respect to the semantic component, $\boldsymbol{q}_p = \boldsymbol{q}^{(tok)} + \boldsymbol{q}_p^{(dep)}$.

2.2.3 Semantic Similarity Calculation

Given the query graph with multiple semantic components, $G = \{p^{(1)}, \dots, p^{(N)}\}$, now all its semantic components have been projected into a common vector space, representing hidden features in different aspects. We apply max pooling over the hidden vectors of semantic components, and get the compositional semantic representation of the entire query graph. Similarly, we perform max pooling for the question vectors with respect to each semantic component. Finally, we compute the semantic similarity score between the graph and question:

$$S_{sem}(q, G) = cos(\max_i \boldsymbol{p}^{(i)}, \max_i \boldsymbol{q}_p^{(i)}). \qquad (1)$$

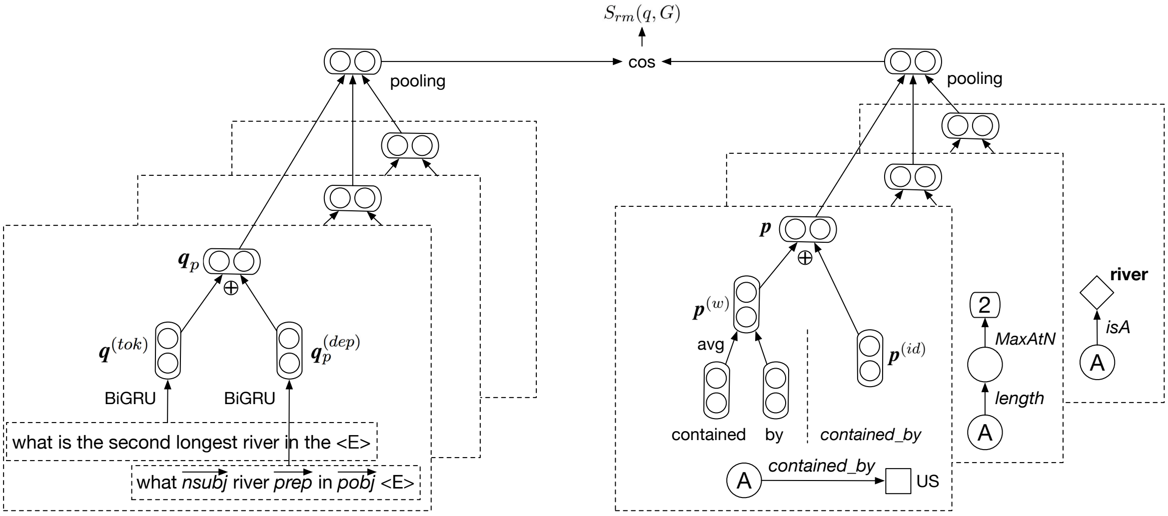

Figure 3: Overview of proposed semantic matching model.

Based on this framework, our proposed method ensures the vector spaces of the question and the entire query graph are comparable, and captures complementary semantic features from different parts of the query graph. It's worth mentioning that the semantic matching model is agnostic to the candidate generation method of the query graphs, hence it can be applied to the other existing semantic parsing frameworks.

2.3 Entity Linking Enrichment

The S-MART linker is a black box for our system, which is not extendable and tend to produce high precision but low recall linking results. To seek a better balance at entity linking, we propose an ensemble approach to enrich linking results. We first build a large lexicon by collecting all (mention, entity) pairs from article titles, anchor texts, redirects and disambiguation pages of Wikipedia. Each pair is associated with statistical features, such as linking probability, letter-tri-gram jaccard similarity and popularity of the entity in Wikipedia. For the pairs found in S-MART results, we take the above features as the input to a 2-layer linear regression model fitting their linking scores. Thus we learn a pseudo linking score for every pair in the lexicon, and for each question, we pick top-K highest pairs to enrich S-MART linking results, where K is a hyperparameter.

2.4 Training and Prediction

To predict the best query graph from candidates, we calculate the overall association score $S(q, G)$ between the question q and each candidate G, which is the weighted sum of features over entity linking, semantic matching and structural level. Table 1 lists the detail features.

During training step, we adopt hinge loss to maximize the margin between positive graphs G^+ and negative graphs G^-:

$$loss = max\{0, \lambda - S(q, G^+) + S(q, G^-)\}. \quad (2)$$

For each question, we pick a candidate graph as positive data, if the F_1 score of its answer is larger than a threshold (set to 0.1 in our work). We randomly sample 20 negative graphs G^- from the candidate set whose F_1 is lower than the corresponding G^+.

Category	Description
Entity	Sum of S-MART scores of all entities; Number of entities from S-MART; Number of entities from enriched lexicon;
Semantics	Semantic similarity score $S_{sem}(q, G)$;
Structural	Number of each kind of constraints in G; Whether a kind of constraints is used in G; Whether the main path is one-hop; Number of output answers.

Table 1: Full set of features.

3 Experiments

In this section, we introduce the QA datasets and state-of-the-art systems that we compare. We show the end-to-end results of the KBQA task, and perform detail analysis to investigate the importance of different modules used in our approach.

3.1 Experimental Setup

QA datasets: We conduct our experiments on ComplexQuestions (Bao et al., 2016), WebQuestions (Berant et al., 2013) and SimpleQuestions (Bordes et al., 2015). We use CompQ, WebQ and SimpQ as abbreviations of the above datasets, respectively. CompQ contains 2,100 complex questions collected from Bing search query log, and the dataset is split into 1,300 training and 800 testing questions. WebQ contains 5,810 questions collected from Google Suggest API, and is split into 3,778 training and 2,032 testing QA pairs. Each question is manually labeled with at least one answer entity in both datasets. SimpQ consists of more than 100K questions, and the gold answer of each question is a gold focus entity paired with a single predicate. This dataset is designed mainly for answering simple questions, and we use it for complementary evaluation.

Knowledge bases: For experiments on both CompQ and WebQ, we follow the settings of Berant et al. (2013) and Xu et al. (2016) to use the full Freebase dump [5] as the knowledge base, which contains 46M entities and 5,323 predicates. We host the knowledge base with Virtuoso engine [6]. For the experiments on SimpQ, the knowledge base we use is FB2M, which is a subset of Freebase provided with the dataset, consisting 2M entities and 10M triple facts.

Implementation detail: For all experiments in this section, we initialize word embeddings using GloVe (Pennington et al., 2014) word vectors with dimensions set to 300, and the size of Bi-GRU hidden layer is also set to 300. We tune the margin λ in $\{0.1, 0.2, 0.5\}$, the ensemble threshold K in $\{1, 2, 3, 5, 10, +\text{INF}\}$, and the batch size B in $\{16, 32, 64\}$. All the source codes, QA datasets, and detail results can be downloaded from `http://202.120.38.146/CompQA/`.

3.2 End-to-End Results

Now we perform KBQA experiments on WebQ and CompQ. We use the average F_1 score over all questions as our evaluation metric. The official evaluation script [7] measures the correctness of output entities at string level. While in CompQ, the annotated names of gold answer entities don't match the case of their names in Freebase, thus we follow Bao et al. (2016) to lowercase both annotated names and the output answer names before calculating the F_1 score. We set $\lambda = 0.5$, $B = 32$, $K = 3$ for WebQ and $K = 5$ for CompQ, as reaching the highest average F_1 on the validation set of each dataset.

We report the experimental results in Table 2. The result of Yih et al. (2015) on CompQ is reported by Bao et al. (2016) as their implemented result. Our approach outperforms existing approaches on CompQ dataset, and ranks 2nd on WebQ among a long list of state-of-the-art works. Jain (2016) achieves highest F_1 score on WebQ using memory networks, which is not semantic parsing based, and thus less interpretable. We point out that Xu et al. (2016) uses Wikipedia texts as the external community knowledge for verifying candidate answers, and achieves a slightly higher F_1 score (53.3) than our model, but the performance decreases to 47.0 if this step is removed. Besides, Yih et al. (2015) and Bao et al. (2016) used ClueWeb dataset for learning more accurate semantics, while based on the ablation test of Yih, the F_1 score of WebQ drops by 0.9 if ClueWeb information is removed.

Method	CompQ	WebQ
Dong et al. (2015)	-	40.8
Yao (2015)	-	44.3
Bast and Haussmann (2015)	-	49.4
Berant and Liang (2015)	-	49.7
Yih et al. (2015)	36.9	52.5
Reddy et al. (2016)	-	50.3
Xu et al. (2016) (w/o text)	-	47.0
Bao et al. (2016)	40.9	52.4
Jain (2016)	-	**55.6**
Abujabal et al. (2017)	-	51.0
Cui et al. (2017)	-	34.0
Hu et al. (2018)	-	49.6
Talmor and Berant (2018)	39.7	-
Ours (w/o linking enrich)	42.0	52.0
Ours (w/ linking enrich)	**42.8**	52.7

Table 2: Average F_1 scores on CompQ and WebQ datasets.

Our results show that entity enrichment method improves the results on both datasets by a large margin (0.8), which is a good help to our approach. We argue that the enriched results are directly comparable with other approaches, as S-MART itself is learned from semi-structured information in Wikipedia, such as anchor texts, redirect links and disambiguation pages, the enrichment step does not bring extra knowledge into our system. In addition, the improvements of the candidate generation step also show a positive effect. If we remove our implicit type filtering in Step 4 and time interval constraints in Step 5, the F_1 of CompQ slightly drops from 42.84 to 42.37. Al-

[7] The evaluation script is available at http://www-nlp.stanford.edu/software/sempre/.

though these improvements mainly concern time-related questions (around 25% in CompQ), we believe these strategies can be useful tricks in the further researches.

As a complementary evaluation, we perform semantic matching experiments on SimpQ. Given the gold entity of each question, we recognize the entity mention in the question, replace it with $\langle E \rangle$, then predict the correct predicate. Table 3 shows the experimental results. The best result is from Qu et al. (2018), which learns the semantic similarity through both attentive RNN and similarity matrix based CNN. Yu et al. (2017) proposed another approach using multi-layer BiLSTM with residual connections. Our semantic matching model performs slightly below these two systems, since answering simple questions is not the main goal of this paper. Comparing with these approaches, our semantic matching model is lightweighted, with a simpler structure and fewer parameters, thus is easier to tune and remains effective.

Method	Relation Inputs	Accuracy
BiLSTM w/ words	words	91.2
BiLSTM w/ rel_name	rel_name	88.9
Yih et al. (2015)	char-3-gram	90.0
Yin et al. (2016)	words	91.3
Yu et al. (2017)	words+rel_name	93.3
Qu et al. (2018)	words+rel_separated	**93.7**
Ours	words+path	93.1

Table 3: Accuracy on the SimpleQuestions dataset.

3.3 Ablation Study

In this section, we explore the contributions of various components in our system.

Semantic component representation: We first evaluate the results on CompQ and WebQ under different path encoding methods. Recap that the encoding result of a semantic component is the summation of its word and id path representations (Section 2.2.1), thus we compare encoding methods by multiple combinations. For encoding predicate word sequence, we use BiGRU (the same setting as encoding question word sequence) as the alternative of average word embedding. For encoding predicate id sequence, we use average predicate embedding as the alternative of the current path-level embedding ($PathEmb$).

The experimental results are shown in Table 4. The encoding method $None$ means that we don't encode the id or word sequence, and simply take the result of the other sequence as the representation of the whole component. we observe that the top three combination settings, ignoring either word or id sequence, perform worse than the bottom three settings. The comparison demonstrates that predicate word and id representation can be complementary to each other. The performance gain is not that large, mainly because predicate id features are largely covered by their word name features.

For the encoding of id sequences, $PathEmb$ works better than average embedding, consistently boosting F_1 by 0.65 on both datasets. The former method treats the whole sequence as a single unit, which is more flexible and can potentially learn diverse representations of id sequences that share the same predicates. For the encoding of word sequences, the average word embedding method outperforms BiGRU on CompQ, and the gap becomes smaller when running on WebQ. This is mainly because the training set of WebQ is about 3 times larger than that of CompQ, making it easier for training a more complex model.

Word repr.	Id repr.	CompQ F_1	WebQ F_1
None	PathEmb	41.11	51.86
Average	None	42.18	51.74
BiGRU	None	41.80	51.87
Average	Average	42.16	52.00
BiGRU	PathEmb	41.52	52.33
Average	PathEmb	**42.84**	**52.66**

Table 4: Ablation results on path representation.

Semantic composition and question representation: To demonstrate the effectiveness of semantic composition, we construct a straightforward baseline, where we remove the max pooling operation in Eq. (2), and instead calculate the semantic similarity score as the summation of individual cosine similarities: $S_{sem}(q, G) = \sum_i cos(\boldsymbol{p}^{(i)}, \boldsymbol{q}_p^{(i)})$. For methods of question encoding, we setup ablations by turning off either sentential encoding or dependency encoding.

Table 5 shows the ablation results on CompQ and WebQ. When dependency path information is augmented with sentential information, the performance boosts by 0.42 on average. Dependency paths focus on hidden features at syntactic and functional perspective, which is a good complementary to sentential encoding results. However, performances drop by 2.17 if only dependency information is used, we find that under certain dependency structures, crucial words (bolded) are not in the path between the answer and the focus mention (underlined), for example, "who did draco malloy end up **marrying**" and "who did the philippines gain **independence** from". While we observe about 5% of such questions in WebQ, it's hard to predict the correct query graph without crucial words.

In terms of semantic composition, Our max pooling based method consistently outperforms the baseline method. The improvement on WebQ is smaller than on CompQ, largely due to the fact that 85% questions in WebQ are simple questions (Bao et al., 2016). As a result of combination, our approach significantly outperforms the vanilla SP+NN approach on CompQ by 1.28, demonstrating the effectiveness of our approach. Theoretically, the pooling outcome may lead to worse end-to-end result when there are too many semantic components in one graph, because the pooling layer takes too many vectors as input, different semantic features between similar query graphs become indistinguishable. In our task, only 0.5% of candidate graphs have more than 3 semantic components, so pooling is a reasonable way to aggregate semantic components in this scenario.

Composition	Q_repr	CompQ F_1	WebQ F_1
Baseline	sentential	41.56	52.14
Baseline	both	42.35	52.39
Ours	dependency	41.48	49.69
Ours	sentential	42.59	52.28
Ours	both	**42.84**	**52.66**

Table 5: Ablation results on question representation and compositional strategy.

To further explain the advantage of semantic composition, we take the following question as an example: "who is gimli's father in the hobbit". Two query graphs are likely to be the final answer: 1) ($?$, $children$, $gimli\_person$); 2) ($?$, $fictional\_children$, $gimli\_character$) $\wedge$ ($?$, $appear\_in$, $hobbit$). If observing semantic components individually, the predicate $children$ is most likely to be the correct one since "'s father" is highly related and with plenty of positive training data. Both $fictional\_children$ and $appear\_in$ get a much lower similarity compared with $children$, hence the baseline method prefer the first query graph. In the meantime, our proposed method learns the hidden semantics of the second candidate by absorbing salient features from both predicates, and such compositional representation is closer to the semantics of the entire question than a simple "children" predicate. That's why our method manages to answer it correctly.

3.4 Error Analysis

We randomly analyzed 100 questions from CompQ where no correct answers are returned. We list the major causes of errors as follows:

Main path error (10%): This type of error occurred when the model failed to understand the main semantics when facing some difficult questions (e.g. "What native american sports heroes earning two gold medals in the 1912 Olympics");

Constraint missing (42%): These types of questions involve implicit constraints, for example, the question "Who was US president when Traicho Kostov was teenager" is difficult to answer because it implies an implicit time constraint "when Traicho Kostov was teenager";

Entity linking error (16%): This error occurs due to the highly ambiguity of mentions. For example, the question "What character did Robert Pattinson play in Harry Potter" expects the film "Harry Potter and the Goblet of Fire" as the focus, while there are 7 movies in Harry Potter series;

Miscellaneous (32%): This error class contains questions with semantic ambiguity or not reasonable. For example, the question "Where is Byron Nelson 2012" is hard to understand, because "Byron Nelson" died in 2006 and maybe this question wants to ask where did he die.

4 Related Work

Knowledge Base Question Answering(KBQA) has been a hot research top in recent years. Generally speaking, the most popular methods for KBQA can be mainly divided into two classes: information retrieval and semantic parsing.

Information retrieval based system tries to obtain target answer directly from question information and KB knowledge without explicit considering interior query structure. There are various methods (Yao and Van Durme, 2014; Bordes et al., 2015; Dong et al., 2015; Xu et al., 2016) to select candidate answers and to rank results.

Semantic parsing based approach focuses on constructing a semantic parsing tree or equivalent query structure that represents the semantic meaning of the question. In terms of logical representation of natural language questions, many methods have been tried, such as query graph (Yih et al., 2014, 2015) or RDF query language (Unger et al., 2012; Cui et al., 2017; Hu et al., 2018).

Recently, as the development of deep learning, NN-based approaches have been combined into the KBQA task (Bordes et al., 2014), showing promising result. These approaches tries to use neural network models to encode both questions and answers (or query structures) into the vector space. Subsequently, similarity functions are used to select the most appropriate query structure to generate the final answer. For example, Bordes et al. (2014) focuses on embedding the subgraph of the candidate answer; Yin et al. (2016) uses character-level CNN and word-level CNN to match different information; Yu et al. (2017) introduces the method of hierarchical residual RNN to compare questions and relation names; Qu et al. (2018) proposes the AR-SMCNN model, which uses RNN to capture semantic-level correlation and employs CNN to extract literal-level words interaction.

Belonging to NN-based semantic parsing category, our approach employs a novel encoding structure method to solve complex questions. Previous works such as Yih et al. (2015) and Bao et al. (2016) require a recognition of a main relation and regard other constraints as variables added to this main relation. Unlike their approaches, our method encodes multiple relations (paths) into a uniform query structure representation (semantic composition), which allows more flexible query structures.

There are also some works can't be simply classified in to IR based methods or SP based methods. Jain (2016) introduces Factual Memory Network, which tries to encode KB and questions in same word vector space, extract a subset of initial candidate facts, then try to employ multi-hop reasoning and refinement to find a path to answer entity. Reddy et al. (2016), Abujabal et al. (2017), and Cui et al. (2017) try to interpret question intention by templates, which learned from KB or QA corpora. Talmor and Berant (2018) attempts to answering complex questions by decomposing them into a sequence of simple questions.

5 Conclusion

To the best of our knowledge, this is the first work to handle complex KBQA task by explicitly encoding the complete semantics of a complex query graph using neural networks. We studied different methods to further improve the performance, mainly leveraging dependency parse and the ensemble method for linking enrichment. Our model becomes the state-of-the-art on ComplexQuestions dataset, and produces competitive results on other simple question based datasets. Possible future work includes supporting more complex semantics like implicit time constraints.

Abstract

Extracting relations is critical for knowledge base completion and construction in which distant supervised methods are widely used to extract relational facts automatically with the existing knowledge bases. However, the automatically constructed datasets comprise amounts of low-quality sentences containing noisy words, which is neglected by current distant supervised methods resulting in unacceptable precisions. To mitigate this problem, we propose a novel word-level distant supervised approach for relation extraction. We first build Sub-Tree Parse (STP) to remove noisy words that are irrelevant to relations. Then we construct a neural network inputting the subtree while applying the entity-wise attention to identify the important semantic features of relational words in each instance. To make our model more robust against noisy words, we initialize our network with a priori knowledge learned from the relevant task of entity classification by transfer learning. We conduct extensive experiments using the corpora of New York Times (NYT) and Freebase. Experiments show that our approach is effective and improves the area of Precision/Recall (PR) from 0.35 to 0.39 over the state-of-the-art work.

1 Introduction

Relation extraction aims to extract relations between pairs of marked entities in raw texts. Traditional supervised methods are time-consuming for the requirement of large-scale manually labeled data. Thus, Mintz et al. (2009) propose the distant supervised relation extraction, in which amounts of sentences are crawled from web pages of New York Times (NYT) and labeled with a known knowledge base automatically. The method assumes that if two entities have a relation in a known knowledge base, all instances that mention these two entities will express the same relation. Obviously, this assumption is too strong, since a sentence that mentions the two entities does not necessarily express the relation contained in a known knowledge base. As described in Riedel et al. (2010), the assumption leads to the wrong labeling problem. In order to tackle the wrong labeling problem, various multi-instance learning methods are adopted by mitigating noise between sentences (Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016). Despite the wrong labeling problem, distant supervised methods may suffer from the low quality of sentences which derive from the large-scale automatically constructed dataset by crawling web pages (Yang et al., 2017). To handle the problem of low-quality sentences, we have to face two major challenges: (1) Reduce word-level noise within sentences; (2) Improve the robustness of relation extraction against noise.

To explain the influence of word-level noise within sentences, we consider the following sentence as an example: *[It is no accident that the main event will feature the junior welterweight champion miguel cotto, a puerto rican, against Paul Malignaggi, an Italian American from Brooklyn.]*, where *Paul Malignaggi* and *Brooklyn* are two corresponding entities. The subsentence *[Paul Malignaggi, an Italian American from Brooklyn.]* keeps enough words to express the relation */people/person/place_of_birth*, and the other words could be regarded as noise that may hamper the extractor's performance. Meanwhile, as shown in Figure 1, half of the original sentences are longer than 40 words, which means that there are many irrelevant words inside sentences. To be more detail, there are about 12 noisy words in each sentence on average, and 99.4% of sentences in the NYT-10 dataset have noise. Although the Shortest Dependency Path (SDP) proposed by Xu et al. (2015) tries to get rid of irrelevant words for relation extraction, it is not suitable to handle such informal sentences. Moreover, word-level attention has been leveraged to alleviate the impact of noisy

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2195–2204
Brussels, Belgium, October 31 - November 4, 2018.

words (Zhou et al., 2016), but it weakens the importance of entity features for relation extraction.

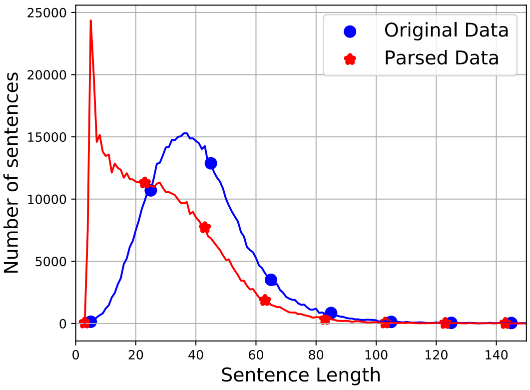

Figure 1: Comparison of sentence length distribution between original data and parsed data.

As for the second challenge, a robust model could extract precise relation features even from low-quality sentences containing noisy words. However, previous neural methods are always lacking in robustness because parameters are initialized randomly and hard to tune with noisy training data, resulting in the poor performance of extractors. Inspired by Kumagai (2016), initializing neural networks with a priori knowledge learned from relevant tasks by transfer learning could improve the robustness of the target task. For the relation extraction, entity type classification can be used as the relevant task since entity types provide abundant background knowledge. For instance, the sentence *[Alfead Kahn, the Cornell-University economist who led the fight to deregulate airplanes.]* has a relation *business/person/company*, which is hard to decide without the information that *Alfead Kahn* is a person and *Cornell-University* is a company. Therefore, type features learned from entity type classification are proper a priori knowledge to initialize the relation extractor.

In this paper, we propose a novel word-level approach for distant supervised relation extraction by reducing inner-sentence noise and improving robustness against noisy words. To reduce inner-sentence noise, we utilize a novel Sub-Tree Parse (STP) method to remove irrelevant words by intercepting a subtree under the parent of entities' lowest common ancestor. As shown in Figure 1, the average length of the parsed sentences is much shorter. Furthermore, the entity-wise attention is adopted to alleviate the influence of noisy words in the subtree and emphasize the task-relevant features. To tackle the second challenge, we initialize our model parameters with a priori knowledge learned from the entity type classification task by transfer learning. The experimental results show that our model can achieve satisfactory performance among the state-of-the-art works. Our contributions are summarized as follows:

- To handle the problem of low-quality sentences, we propose the STP to remove noisy words of sentences and the entity-wise attention mechanism to enhance semantic features of relational words.
- We first propose to initialize the neural relation extractor with a priori knowledge learned from entity type classification, which strengthens its robustness against low-quality corpus.
- Our model achieves significant results for distant supervised relation extraction, which improves the Precision/Recall (PR) curve area from 0.35 to 0.39 and increases top 100 predictions by 6.3% over the state-of-the-art work.

2 Related Work

The distant supervised method plays an increasingly essential role in relation extraction due to its less requirement of human labor (Mintz et al., 2009). However, an evident drawback of the method is the wrong labeling problem. Thus, multi-instance and multi-label learning methods are proposed to address this issue (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). Meanwhile, other researches (Angeli et al., 2014; Han and Sun, 2016) incorporate human-designed features and leverage Natural Language Processing (NLP) tools.

As neural networks have been widely used, an increasing number of researches have been proposed. Zeng et al. (2015) use a piecewise convolutional neural network with multi-instance learning. Furthermore, selective attention over instances with the neural network is proposed (Lin et al., 2016). Making use of entity description, Ji et al. (2017) assign more precise attention weights. Focused on the imbalance of datasets, a soft label method has been proposed by Liu et al. (2017).

Recently, reinforcement learning and adversarial learning are widely used to select the valid instances for relation extraction (Feng et al., 2018; Qin et al., 2018b,a).

However, above methods ignore inner-sentence noise. To better remove irrelevant words, the SDP between entities is proved to be effective (De Marneffe and Manning, 2008; Chen and Manning, 2014; Xu et al., 2015; Miwa and Bansal, 2016). Nevertheless, in our observation, the SDP deals with informal texts difficultly (See Section 3.1 for details). Furthermore, word-level attention is adopted to focus on relational words for relation extraction (Zhou et al., 2016), but it hinders the effect of entity words.

Transfer learning proposed by Pratt (1993) provides a new approach to leverage knowledge extracted by related tasks to enhance the performance of the target task. Furthermore, parameter transfer learning is proved to be effective to improve the stability of models by initializing model parameters reasonably (Pan and Yang, 2010; Kumagai, 2016).

3 Methodology

In this section, we present our methodology for distant supervised relation extraction. Figure 2 shows the overall architecture of our model. Our model is divided into three parts:

Sub-Tree Parser. Input instances are parsed to dependency parse trees by the Stanford parser[1] (Chen and Manning, 2014) at first. Then words in the STP and relative positions are transformed to distributed representations.

Entity-Wise Neural Extractor. Given the representation of each subtree, Bidirectional Gated Recurrent Unit (BGRU) extracts specific features. Then, entity-wise attention combined with word-level attention is applied to reducing irrelevant features for relation extraction. Finally, the sentence-level attention is used to alleviate the influence of wrong labeling sentences.

Parameter-Transfer Initializer. The transfer learning method pre-trains our model parameters from the task of entity type classification aiming at boosting the performance of relation extraction.

3.1 Sub-Tree Parser

Each instance is put into the dependency parse module to build the dependency parse tree in the first place. Then we can tailor the sentences based on the STP method. Finally, we transform word tokens and position tokens of each instance to distributed representations by embedding matrixes.

Sub-Tree Parse

In order to reduce inner-sentence noise and extract relational words, we propose the STP method which intercepts the subtree of each instance under the parent of entities' lowest common ancestor. For instance, in Figure 2(b), *China* and *Shanghai* are entities connected directly with the appositive relation. The instance *[In 1990, he lives in Shanghai, China.]* will be transformed to *[in Shanghai, China.]* on the basis of the STP, where *in* is the parent of *Shanghai* and *China* lowest common ancestor and kept as important information for expressing the relation *location/location/contain*. Words connected by the imaginary line indicating the extracted subtree are reorganized into their original sequence order to form network inputs.

Among the parse tree, the SDP has been widely used by Chen and Manning (2014) and Xu et al. (2015) to help models focus on relational words. However, in our observation, the SDP is not appropriate in the condition that key relation words are not in the SDP. Although additional information (dependency relations between words) is adopted to enhance the performance of SDP, we found they have the minor effect through our experiment. Thus, we do not make use of other types of linguistic information. As Figure 2(b) shows, in the SDP method, the original sentence will be transformed to *[Shanghai China]* because *Shanghai* and *China* are connected with each other directly in the dependency parse tree, which results in deleting the keyword *in* and may confuse the model when extracting relations. Compared with SDP, the STP method is more appropriate to extract useful information in informal sentences where relational words are always not in the SDP.

Word and Position Embeddings

The inputs of the network are word and position tokens, which are transformed to the distributed representations before they are fed into the neural model. We map j^{th} word in the i^{th} instance to a vector of k dimensions denoted as $x_{ij}^{w} \in R^{k}$ through the Skip-Gram model (Mikolov et al., 2013). Like Zeng et al. (2014), we leverage Pos1 and Pos2 to specify entity pairs, which are defined as the relative distances of current word from head

---

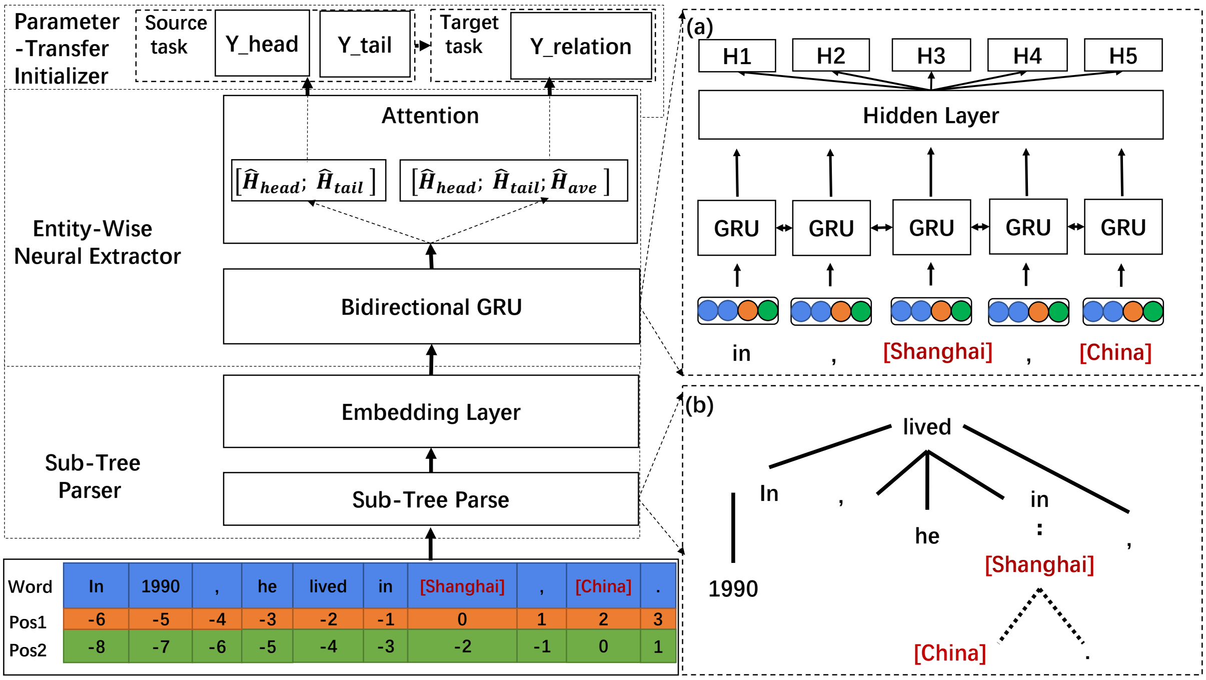

Figure 2: Overall architecture of our model is used for distant supervised relation extraction, expressing the process of handling instances. There are two modules described in detail: (a) One is the BGRU; (b) Another is the STP, where words in the red brackets represent entities (better viewed in color).

entity and tail entity. For instance, in Figure 2 relative distances of *lived* from *Shanghai* and *China* are -2 and -4 respectively. Then, the position token of each word is transformed to a vector in l dimensions. Position embeddings are denoted as $x_{ij}^{p1} \in R^l$ and $x_{ij}^{p2} \in R^l$ respectively. Finally, the input representation for x_{ij} is concatenated by word embedding x_{ij}^{w}, position embeddings x_{ij}^{p1} and x_{ij}^{p2} , which is denoted as $x_{ij} = [x_{ij}^{w}; x_{ij}^{p1}; x_{ij}^{p2}]$ where $x_{ij} \in R^{k+2l}$.

3.2 Entity-Wise Neural Extractor

As shown in Figure 2, we transform the STP into feature vectors by BGRU at first. Next, entity-wise attention combined with the hierarchical-level attention mechanism is applied to enhancing semantic features of each instance.

BGRU over STP

Since the transfer learning and entity-wise attention require the specific features of entities in tree parsed instances as their input, we adopt Gated Recurrent Unit (GRU) (Cho et al., 2014) to be our based relation extractor, which can extract global information of each word by pointing out its corresponding position in the sequence. It can be briefly described as below:

$$h_{it} = GRU(x_{it}) \tag{1}$$

where x_{it} is the t^{th} word representation in the i^{th} parsed instance as described in the input layer, and $h_{it} \in R^m$ is the hidden state of GRU in m dimensions.

Furthermore, BGRU implementing GRU in a different direction can access future as well as past context. Under our circumstance, BGRU combined with the STP can extract semantic and syntactic features adequately. Figure 2(a) shows the processing of BGRU over STP. The following equation defines the operation mathematically.

$$h_{it} = [\overrightarrow{h_{it}} \oplus \overleftarrow{h_{it}}] \tag{2}$$

In above equation, the t^{th} word output $h_{it} \in R^m$ of BGRU is the element-wise addition of the t^{th} hidden states of forward GRU and backward one.

Entity-wise Attention

To reduce noise within sentences, we propose the entity-wise attention mechanism to help our model focus on relational words, especially entity words for relation extraction. Assume that H_i is the i^{th} instance matrix consisting of T word vectors $[h_{i1}, h_{i2}, \cdots, h_{iT}]$ produced by BGRU.

Not all words contribute equally to the representation of the sentence. Entity words are of great importance because they are significantly beneficial to relation extraction. In our model, entity-wise attention assigns the weight α^e_{it} to focus on the target entity and removes noise further. It is defined as follows:

$$\alpha^e_{it} = \begin{cases} 1 & t = head, tail \\ 0 & others \end{cases} \tag{3}$$

In the above equation, $\alpha^e_{it} = 1$ if t^{th} word belongs to the head or tail entity.

Hierarchical-level Attention

To reduce inner-sentence noise further and de-emphasize noisy sentences, we incorporate word-level attention and sentence-level attention as hierarchical-level attention which is introduced in Yang et al. (2016).

Word-level Attention. It assigns an additional weight α^w_{it} to relational word h_{it} due to its relevance to the relation as described by Zhou et al. (2016). It can be described as follows:

$$\alpha^w_{it} = \frac{exp(h_{it}A^w r^w)}{\sum_{t=1}^{T} exp(h_{it}A^w r^w)} \tag{4}$$

where A^w is a weighted matrix, and vector r^w can be seen as a high level representation in a fixed query what is the informative word over the other words.

The i^{th} sentence representation $S_i \in R^m$ is computed as a weighted sum of h_{it}:

$$S_i = \sum_{t=1}^{T} (\alpha^w_{it} + \alpha^e_{it}) h_{it} \tag{5}$$

Sentence-level Attention. After we get the instance representation S_i, we adopt the selective attention mechanism over instances to de-emphasize the noisy sentence (Lin et al., 2016), which is described as follows:

$$S = \sum_i \alpha^s_i S_i \tag{6}$$

$$\alpha^s_i = \frac{exp(S_i A^s r^s)}{\sum_i exp(S_i A^s r^s)} \tag{7}$$

where A^s is a weighted matrix, r^s is the query vector associated with the relation, and $S \in R^m$ is the output of the sentence-level attention layer.

3.3 Parameter-Transfer Initializer

The transfer learning method pre-trains our model parameters in the entity type classification task, which in turn contributes to the relation extraction.

Pre-learn the Entity Type

As entity type information plays a significant role in detecting relation types, the entity type classification task is considered to be the source task, which is learned before the relation extraction task. According to Eq. 6, outputs of the sentence-level attention layer for the head entity and tail entity task are S_{head} and S_{tail} respectively. They are ultimately fed into the softmax layer:

$$\hat{p}^i = softmax(W_i S_i + b_i); \ i \in \{head, tail\} \tag{8}$$

where W_i and b_i are the weight and bias for the entity type classification task respectively, $\hat{p}^i \in R^{z_t}$ is the predicted probability of each class and z_t is the number of entity classes. The loss function of the source task is the negative log-likelihood of the true labels:

$$\begin{aligned} & J_e(\theta_0, \theta_{head}, \theta_{tail}) = \beta \|\theta_0\|^2 \\ & + \sum_t (-\frac{1}{z_t} \lambda_t \sum_{i=1}^{z_t} y^t_i log(\hat{p}^t_i) + \beta \|\theta_t\|^2) \\ & t \in \{head, tail\} \end{aligned} \tag{9}$$

where λ_t is the weight of each task, θ_0 is the shared model parameters, θ_{head} and θ_{tail} are individual parameters for the head and tail entity classification tasks respectively, $y^t \in R^{z_t}$ is the one-hot vector representing ground truth, and β is the hyper-parameter for $L2$ regularization.

Train the Relation Extractor

Based on the pre-trained model in the entity type classification task, the relation extractor initializes shared parameters θ_0 within the best state of the pre-trained model and independent parameters θ_r randomly. Same as the entity type classification task, the output S_r of the attention layer for the relation extraction task is finally fed into the softmax layer and the loss is calculated by cross entropy, which is defined as follows:

$$\hat{p} = softmax(W_r S_r + b_r) \tag{10}$$

$$\begin{aligned} J_r(\theta_0, \theta_r) = & -\frac{1}{z_r} \sum_{i=1}^{z_r} y_i log(\hat{p}_i) \\ & + \beta(\|\theta_0\|^2 + \|\theta_r\|^2) \end{aligned} \tag{11}$$

where W_r, b_r, $y \in R^{z_r}$, $\hat{p} \in R^{z_r}$, θ_r and β are defined similarly in the entity type classification task.

As shown in Figure 2, two tasks share all layers except attention and output layers. Assume that the set of total model parameters is θ. Thus, θ, θ_0, θ_r, θ_{head} and θ_{tail} have a relationship described in the following equations:

$$\theta = \theta_0 \cup \theta_{head} \cup \theta_{tail} \cup \theta_r \tag{12}$$

$$\begin{aligned} \theta_i = \{A_i^w, r_i^w, A_i^s, r_i^s, W_i, b_i\} \\ i \in \{head, tail, r\} \end{aligned} \tag{13}$$

where A_i^w, r_i^w, A_i^s, r_i^s, W_i and b_i are parameters in attention and output layers.

Optimize the Objective Function

At first, we minimize J to obtain θ_0 at the best model state $\hat{\theta}_0$ for entity type classification. Then we minimize J_r for the best performance of relation extraction under the initialization of θ_0 to be $\hat{\theta}_0$. Above process can be summarized as the following equation:

$$\begin{aligned} min \quad J(\theta) = &\lambda J_e(\theta_0, \theta_{head}, \theta_{tail}) + \\ &(1-\lambda) J_r(\theta_0, \theta_r) \end{aligned} \tag{14}$$

where $\lambda \in (0,1)$ is the hyperparameter to determine the importance of each task at different training steps. We use Adam (Kingma and Ba, 2014) optimizer to minimize the objective $J(\theta)$.

4 Experiments

Our experiments are designed to demonstrate that our model alleviates the influence of word-level noise arising from low-quality sentences. In this section, we first introduce the dataset and evaluation metrics. Next, we describe parameter settings. Then we evaluate effects of the STP, entity-wise attention and the parameter-transfer initializer. Finally, we compare our model with the state-of-the-art works by several evaluation metrics.

4.1 Dataset and Evaluation Metrics

To evaluate the performance of our model, we adopt a widely used dataset NYT-10 developed by Riedel et al. (2010). NYT-10 dataset is constructed by aligning relational facts in Freebase (Bollacker et al., 2008) with the NYT corpus, where sentences from 2005-2006 are used as training set, and sentences from 2007 are used for testing. For training data, there are 522,611 sentences, 281,270 entity pairs, and 18,252 relational facts; for testing data, there are 172,448 sentences, 96,678 entity pairs and 1,950 relational facts. There are 53 relations including a special relation NA, which means that there is no relation between the entity pair in the instance. Meanwhile, all relations in Freebase are defined on head types and tail types. Therefore, we can construct datasets for type prediction tasks with the same dataset. The dataset has 29 head types and 26 tail types.

Like previous works, we evaluate our model with the held-out metrics, which compare relations found by models with those in Freebase. The held-out evaluation provides a convenient way to assess models. We report both the PR curve and Precision at top N predictions (P@N) at various numbers of instances under each entity pair:

One: For each entity pair, we randomly select one instance to represent the relation.

Two: For each entity pair, we randomly select two instances to represent the relation.

All: For each entity pair, we select all instances to represent the relation.

4.2 Experimental Settings

In the experiment, we utilize word2vec[2] to train word embeddings on NYT corpus. We use the cross-validation to tune our model and grid search to determine model parameters. The grid search approach is used to select optimal learning rate lr for Adam optimizer among $\{0.1, 0.001, 0.0005, 0.0001\}$, GRU size $m \in \{100, 160, 230, 400\}$, position embedding size $l \in \{5, 10, 15, 20\}$. Table 1 shows all parameters for our task. We follow experienced settings for other parameters because they make little influence to our model performance.

GRU size m	230
Word embedding dimension k	50
POS embedding dimension l	5
Batch size n	50
Entity-Task weights($\lambda_{head}, \lambda_{tail}$)	0.5,0.5
Entity-Relation Task weight λ	0.3
Learning rate lr	0.001
Dropout probability p	0.5
l_2 penalty β	0.0001

Table 1: Parameter Settings

---

4.3 Effect of Various Model Parts

In this section, we utilize the PR curve to evaluate the effects of three main parts in our model: the STP, entity-wise attention and the parameter-transfer initializer.

Effect of the STP

To demonstrate the effect of the STP, we adopt BGRU with Word-Level Attention (WLA) proposed by Zhou et al. (2016) as our base model. We compare the performance of BGRU, BGRU+STP, and BGRU+SDP.

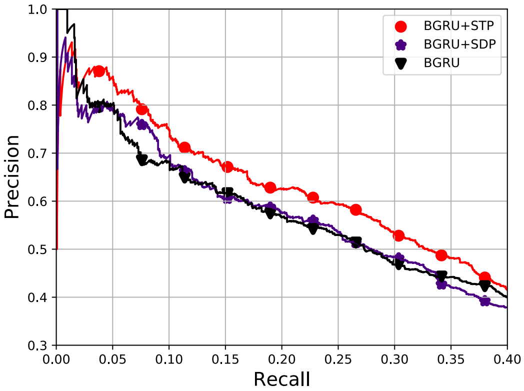

Figure 3: PR curves for BGRU, BGRU+SDP and BGRU+STP.

From Figure 3, we can observe that the model with the STP performs best, and the SDP model obtains an even worse result than the pure one. The PR curve areas of BGRU+SDP and BGRU are about 0.332 and 0.337 respectively, while BGRU+STP increases it to 0.366. The result indicates: (1) Our STP can get rid of irrelevant words in each instance and obtain more precise sentence representation for relation extraction. It proves that our STP module is effective. (2) The SDP method is not appropriate to handle low-quality sentences where key relation words are not in the SDP.

Effect of Entity-wise Attention

Test Settings	PR Curve Area	
Dataset	Original Data	STP Data
BGRU	0.337	0.366
-WLA+EWA	0.365	0.375
+EWA	**0.372**	**0.383**

Table 2: PR curve areas for BGRU, BGRU-WLA+EWA and BGRU+EWA on various datasets.

To evaluate the effect of entity-wise attention combined with word-level attention, we utilize BGRU in three settings on our tree parsed data and original data. One setting is to use WLA mechanism only (BGRU). The second one is to replace WLA with the Entity-Wise Attention (EWA) mechanism (BGRU-WLA+EWA). The third one is to incorporate two mechanisms (BGRU+EWA).

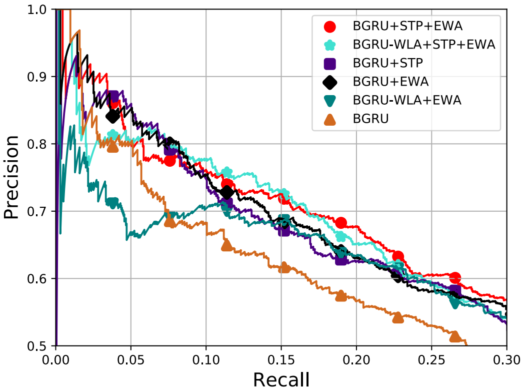

Figure 4: PR curves for BGRU, BGRU-WLA+EWA and BGRU+EWA on various datasets.

From Table 2 and Figure 4, we can obtain: (1) Regardless of the dataset that we employ, BGRU-WLA(+STP)+EWA outperforms BGRU(+STP). To be more specific, the PR curve area has a relative improvement of over 2.3%, which demonstrates that entity-wise hidden states in the BGRU present more precise relational features than other word states. (2) BGRU(+STP)+EWA achieves further improvements and outperforms the baseline by over 4.6%, because it considers more information than entity or relational words alone. Thus, it indicates that entity words are essential for relation extraction, but they can not represent features of the whole sentence without other words.

Effect of Parameter-Transfer Initializer

To evaluate the effect of the parameter-transfer initializer in our model, we leverage BGRU under four circumstances. The first one is to directly apply it on the original dataset. The second one tests BGRU combined with Transfer Learning (TL) on the original dataset. The third one uses BGRU on our STP dataset. The fourth one examines BGRU+TL on our STP dataset.

From Figure 5, we can conclude: (1) Regardless of the dataset that we use, models with TL achieve better performance, which improve the PR curve area by over 4.7%. It demonstrates that

Test Settings	One				Two				All			
P@N	100	200	300	Mean	100	200	300	Mean	100	200	300	Mean

Table 3: P@N for relation extraction in the entity pairs with different number of sentences

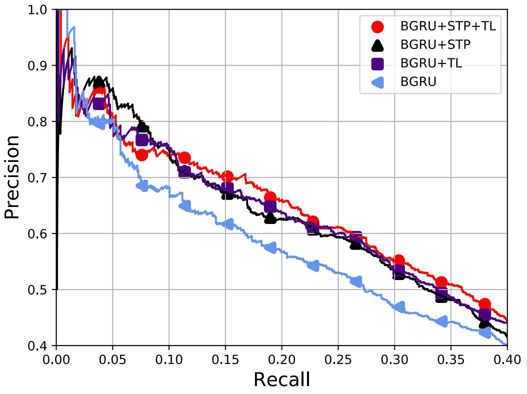

Figure 5: PR curves for BGRU, BGRU+TL, BGRU+STP and BGRU+STP+TL

transfer learning helps our model become more robust against noise. (2) BGRU+STP+TL achieves the best performance and increases the area to 0.383, while areas of BGRU, BGRU+STP and BGRU+TL are 0.337, 0.366 and 0.372 respectively. It means that the TL method works well with the STP and can resist noisy words further.

4.4 Comparison with Baselines

To evaluate our approach, we select the following six methods as our baseline:

Mintz (Mintz et al., 2009) proposes the human-designed feature model.

MultiR (Hoffmann et al., 2011) puts forward a graphical model.

MIML (Surdeanu et al., 2012) proposes a multi-instance multi-label model.

PCNN (Zeng et al., 2015) puts forward a piecewise CNN for relation extraction.

PCNN+ATT (Lin et al., 2016) proposes the selective attention mechanism with PCNN.

BGRU (Zhou et al., 2016) proposes a BGRU with the word-level attention mechanism.

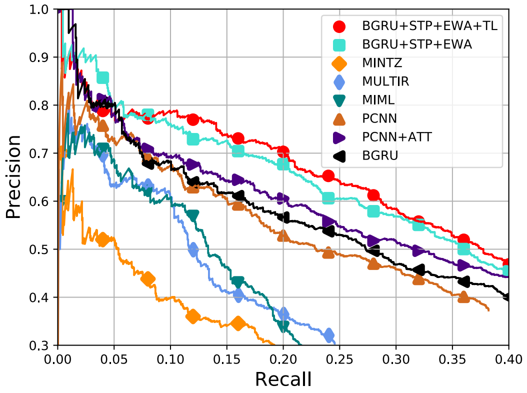

Figure 6: Performance comparison of the proposed method with baselines.

As Figure 6 shows, we can observe: (1) BGRU+STP+EWA achieves the best PR curve over baselines, which improves the area to 0.38 over 0.33 of PCNN, 0.34 of BGRU and 0.35 of PCNN+ATT. At the recall rate of 0.25, our model can still achieve a precision rate above 0.6. It demonstrates that BGRU+STP+EWA is effective because the STP and entity-wise attention combined with word-level attention can reduce inner-sentence noise at a fine-grained level. (2) Integrated with transfer learning, BGRU+STP+EWA+TL performs much better and increases the PR curve area to 0.392. It means that the model is pre-trained for better parameter initialization so the TL model becomes more robust against noisy words. Parameter transfer learning can be applied in better feature extractors for further improvement.

Following previous works, we adopt P@N as a quantitative indicator to compare our model with baselines based on various instances under each relational tuple. In Table 3, we report P@100, P@200, P@300 and the mean of them for each model in the held-out evaluation. We can find: (1) Compared with baselines, BGRU+STP+EWA+TL achieves the best performance in all test settings, which increases the performance of PCNN+ATT in three settings by 6.3%, 7.6%, and 7.7% respectively. It demonstrates that the integrated model is the most effective; (2) Our STP and entity-wise attention combined with word-level attention reduce inner-sentence noise effectively, and outperform baselines by over 5%; (3) Our neural extractor initialized with a priori knowledge learned from entity type classification is more robust against word-level noise where BGRU+STP+EWA+TL has an improvement of 2% over BGRU+STP+EWA.

5 Conclusion

In this paper, we propose a novel word-level approach for distant supervised relation extraction. It aims at tackling the low-quality corpus by reducing inner-sentence noise and improving the robustness against noisy words. To alleviate the influence of word-level noise, we propose the STP. Meanwhile, entity-wise attention combined with word-level attention helps the model focus more on relational words. Furthermore, parameter transfer learning makes our model more robust against noise by reasonable initialization of parameters. The experimental results show that our model significantly and consistently outperforms the state-of-the-art method.

In the future, we will incorporate the SDP and STP to obtain more precise shortened sentences. Furthermore, we will conduct research in how to utilize entity information to assign more appropriate initial parameters of the relation extractor.

Graph Convolution over Pruned Dependency Trees Improves Relation Extraction

Yuhao Zhang,* Peng Qi,* Christopher D. Manning

Abstract

Dependency trees help relation extraction models capture long-range relations between words. However, existing dependency-based models either neglect crucial information (e.g., negation) by pruning the dependency trees too aggressively, or are computationally inefficient because it is difficult to parallelize over different tree structures. We propose an extension of graph convolutional networks that is tailored for relation extraction, which pools information over arbitrary dependency structures efficiently in parallel. To incorporate relevant information while maximally removing irrelevant content, we further apply a novel pruning strategy to the input trees by keeping words immediately around the shortest path between the two entities among which a relation might hold. The resulting model achieves state-of-the-art performance on the large-scale TACRED dataset, outperforming existing sequence and dependency-based neural models. We also show through detailed analysis that this model has complementary strengths to sequence models, and combining them further improves the state of the art.

1 Introduction

Relation extraction involves discerning whether a relation exists between two entities in a sentence (often termed *subject* and *object*, respectively). Successful relation extraction is the cornerstone of applications requiring relational understanding of unstructured text on a large scale, such as question answering (Yu et al., 2017), knowledge base population (Zhang et al., 2017), and biomedical knowledge discovery (Quirk and Poon, 2017).

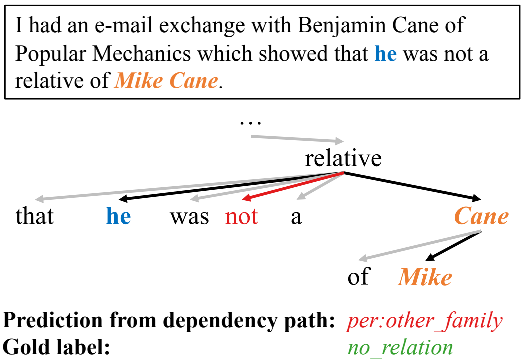

Figure 1: An example modified from the TAC KBP challenge corpus. A subtree of the original UD dependency tree between the subject ("he") and object ("Mike Cane") is also shown, where the shortest dependency path between the entities is highlighted in bold. Note that negation ("not") is off the dependency path.

Models making use of dependency parses of the input sentences, or *dependency-based models*, have proven to be very effective in relation extraction, because they capture long-range syntactic relations that are obscure from the surface form alone (e.g., when long clauses or complex scoping are present). Traditional feature-based models are able to represent dependency information by featurizing dependency trees as overlapping paths along the trees (Kambhatla, 2004). However, these models face the challenge of sparse feature spaces and are brittle to lexical variations. More recent neural models address this problem with distributed representations built from their computation graphs formed along parse trees. One common approach to leverage dependency information is to perform bottom-up or top-down computation along the parse tree or the subtree below the lowest common ancestor (LCA) of the entities (Miwa and Bansal, 2016). Another popular approach, inspired by Bunescu and Mooney (2005), is to reduce the parse tree to the *shortest dependency path* between the entities (Xu et al., 2015a,b).

However, these models suffer from several

[*] Equal contribution. The order of authorship was decided by a tossed coin.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2205–2215
Brussels, Belgium, October 31 - November 4, 2018.

drawbacks. Neural models operating directly on parse trees are usually difficult to parallelize and thus computationally inefficient, because aligning trees for efficient batch training is usually nontrivial. Models based on the shortest dependency path between the subject and object are computationally more efficient, but this simplifying assumption has major limitations as well. Figure 1 shows a real-world example where crucial information (i.e., negation) would be excluded when the model is restricted to only considering the dependency path.

In this work, we propose a novel extension of the graph convolutional network (Kipf and Welling, 2017; Marcheggiani and Titov, 2017) that is tailored for relation extraction. Our model encodes the dependency structure over the input sentence with efficient graph convolution operations, then extracts entity-centric representations to make robust relation predictions. We also apply a novel *path-centric pruning* technique to remove irrelevant information from the tree while maximally keeping relevant content, which further improves the performance of several dependency-based models including ours.

We test our model on the popular SemEval 2010 Task 8 dataset and the more recent, larger TACRED dataset. On both datasets, our model not only outperforms existing dependency-based neural models by a significant margin when combined with the new pruning technique, but also achieves a 10–100x speedup over existing tree-based models. On TACRED, our model further achieves the state-of-the-art performance, surpassing a competitive neural sequence model baseline. This model also exhibits complementary strengths to sequence models on TACRED, and combining these two model types through simple prediction interpolation further improves the state of the art.

To recap, our main contributions are: (i) we propose a neural model for relation extraction based on graph convolutional networks, which allows it to efficiently pool information over arbitrary dependency structures; (ii) we present a new path-centric pruning technique to help dependency-based models maximally remove irrelevant information without damaging crucial content to improve their robustness; (iii) we present detailed analysis on the model and the pruning technique, and show that dependency-based models have complementary strengths with sequence models.

2 Models

In this section, we first describe graph convolutional networks (GCNs) over dependency tree structures, and then we introduce an architecture that uses GCNs at its core for relation extraction.

2.1 Graph Convolutional Networks over Dependency Trees

The graph convolutional network (Kipf and Welling, 2017) is an adaptation of the convolutional neural network (LeCun et al., 1998) for encoding graphs. Given a graph with n nodes, we can represent the graph structure with an $n \times n$ adjacency matrix $\mathbf{A}$ where $A_{ij} = 1$ if there is an edge going from node i to node j. In an L-layer GCN, if we denote by $h_i^{(l-1)}$ the input vector and $h_i^{(l)}$ the output vector of node i at the l-th layer, a graph convolution operation can be written as

$$h_i^{(l)} = \sigma\big(\sum_{j=1}^{n} A_{ij} W^{(l)} h_j^{(l-1)} + b^{(l)}\big), \qquad (1)$$

where $W^{(l)}$ is a linear transformation, $b^{(l)}$ a bias term, and σ a nonlinear function (e.g., ReLU). Intuitively, during each graph convolution, each node gathers and summarizes information from its neighboring nodes in the graph.

We adapt the graph convolution operation to model dependency trees by converting each tree into its corresponding adjacency matrix $\mathbf{A}$, where $A_{ij} = 1$ if there is a dependency edge between tokens i and j. However, naively applying the graph convolution operation in Equation (1) could lead to node representations with drastically different magnitudes, since the degree of a token varies a lot. This could bias our sentence representation towards favoring high-degree nodes regardless of the information carried in the node (see details in Section 2.2). Furthermore, the information in $h_i^{(l-1)}$ is never carried over to $h_i^{(l)}$, since nodes never connect to themselves in a dependency tree.

We resolve these issues by normalizing the activations in the graph convolution before feeding it through the nonlinearity, and adding self-loops to each node in the graph:

$$h_i^{(l)} = \sigma\big(\sum_{j=1}^{n} \tilde{A}_{ij} W^{(l)} h_j^{(l-1)} / d_i + b^{(l)}\big), \qquad (2)$$

where $\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{I}$ with $\mathbf{I}$ being the $n \times n$ identity matrix, and $d_i = \sum_{j=1}^{n} \tilde{A}_{ij}$ is the degree of token i in the resulting graph.

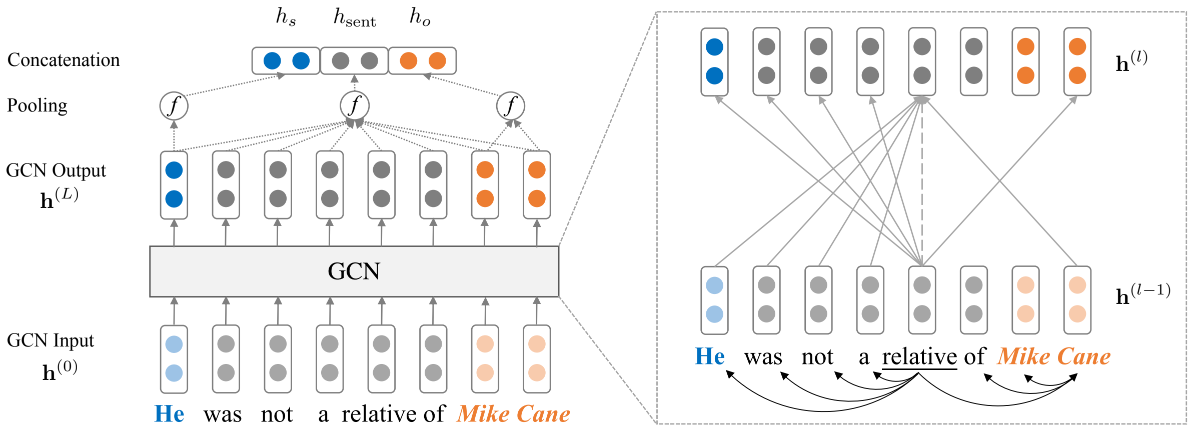

Figure 2: Relation extraction with a graph convolutional network. The left side shows the overall architecture, while on the right side, we only show the detailed graph convolution computation for the word "relative" for clarity. A full unlabeled dependency parse of the sentence is also provided for reference.

Stacking this operation over L layers gives us a deep GCN network, where we set $h_1^{(0)}, \ldots, h_n^{(0)}$ to be input word vectors, and use $h_1^{(L)}, \ldots, h_n^{(L)}$ as output word representations. All operations in this network can be efficiently implemented with matrix multiplications, making it ideal for batching computation over examples and running on GPUs. Moreover, the propagation of information between tokens occurs in parallel, and the runtime does not depend on the depth of the dependency tree.

Note that the GCN model presented above uses the same parameters for all edges in the dependency graph. We also experimented with: (1) using different transformation matrices W for top-down, bottom-up, and self-loop edges; and (2) adding dependency relation-specific parameters for edge-wise gating, similar to (Marcheggiani and Titov, 2017). We found that modeling directions does not lead to improvement,[1] and adding edge-wise gating further hurts performance. We hypothesize that this is because the presented GCN model is usually already able to capture dependency edge patterns that are informative for classifying relations, and modeling edge directions and types does not offer additional discriminative power to the network before it leads to overfitting. For example, the relations entailed by "*A*'s son, *B*" and "*B*'s son, *A*" can be readily distinguished with "'s" attached to different entities, even when edge directionality is not considered.

2.2 Encoding Relations with GCN

We now formally define the task of relation extraction. Let $\mathcal{X} = [x_1, ..., x_n]$ denote a sentence, where x_i is the i^{th} token. A subject entity and an object entity are identified and correspond to two spans in the sentence: $\mathcal{X}_s = [x_{s_1}, \ldots, x_{s_2}]$ and $\mathcal{X}_o = [x_{o_1}, \ldots, x_{o_2}]$. Given $\mathcal{X}$, $\mathcal{X}_s$, and $\mathcal{X}_o$, the goal of relation extraction is to predict a relation $r \in \mathcal{R}$ (a predefined relation set) that holds between the entities or "no relation" otherwise.

After applying an L-layer GCN over word vectors, we obtain hidden representations of each token that are directly influenced by its neighbors no more than L edges apart in the dependency tree. To make use of these word representations for relation extraction, we first obtain a sentence representation as follows (see also Figure 2 left):

$$h_{\text{sent}} = f\big(\mathbf{h}^{(L)}\big) = f\big(\text{GCN}(\mathbf{h}^{(0)})\big), \quad (3)$$

where $\mathbf{h}^{(l)}$ denotes the collective hidden representations at layer l of the GCN, and $f : \mathbb{R}^{d \times n} \to \mathbb{R}^d$ is a max pooling function that maps from n output vectors to the sentence vector.

We also observe that information close to entity tokens in the dependency tree is often central to relation classification. Therefore, we also obtain a subject representation h_s from $\mathbf{h}^{(L)}$ as follows

$$h_s = f\big(\mathbf{h}^{(L)}_{s_1:s_2}\big), \quad (4)$$

as well as an object representation h_o similarly.

Inspired by recent work on relational learning between entities (Santoro et al., 2017; Lee et al., 2017), we obtain the final representation used for classification by concatenating the sentence and the entity representations, and feeding them

---

[1] We therefore treat the dependency graph as undirected, i.e. $\forall i, j, A_{ij} = A_{ji}$.

through a feed-forward neural network (FFNN):

$$h_{\text{final}} = \text{FFNN}\big([h_{\text{sent}}; h_s; h_o]\big). \quad (5)$$

This h_{final} representation is then fed into a linear layer followed by a softmax operation to obtain a probability distribution over relations.

2.3 Contextualized GCN

The network architecture introduced so far learns effective representations for relation extraction, but it also leaves a few issues inadequately addressed. First, the input word vectors do not contain contextual information about word order or disambiguation. Second, the GCN highly depends on a correct parse tree to extract crucial information from the sentence (especially when pruning is performed), while existing parsing algorithms produce imperfect trees in many cases.

To resolve these issues, we further apply a Contextualized GCN (C-GCN) model, where the input word vectors are first fed into a bi-directional long short-term memory (LSTM) network to generate contextualized representations, which are then used as $\mathbf{h}^{(0)}$ in the original model. This BiLSTM contextualization layer is trained jointly with the rest of the network. We show empirically in Section 5 that this augmentation substantially improves the performance over the original model.

We note that this relation extraction model is conceptually similar to graph kernel-based models (Zelenko et al., 2003), in that it aims to utilize local dependency tree patterns to inform relation classification. Our model also incorporates crucial off-path information, which greatly improves its robustness compared to shortest dependency path-based approaches. Compared to tree-structured models (e.g., Tree-LSTM (Tai et al., 2015)), it not only is able to capture more global information through the use of pooling functions, but also achieves substantial speedup by not requiring recursive operations that are difficult to parallelize. For example, we observe that on a Titan Xp GPU, training a Tree-LSTM model over a minibatch of 50 examples takes 6.54 seconds on average, while training the original GCN model takes only 0.07 seconds, and the C-GCN model 0.08 seconds.

3 Incorporating Off-path Information with Path-centric Pruning

Dependency trees provide rich structures that one can exploit in relation extraction, but most of the information pertinent to relations is usually contained within the subtree rooted at the lowest common ancestor (LCA) of the two entities. Previous studies (Xu et al., 2015b; Miwa and Bansal, 2016) have shown that removing tokens outside this scope helps relation extraction by eliminating irrelevant information from the sentence. It is therefore desirable to combine our GCN models with tree pruning strategies to further improve performance. However, pruning too aggressively (e.g., keeping only the dependency path) could lead to loss of crucial information and conversely hurt robustness. For instance, the negation in Figure 1 is neglected when a model is restricted to only looking at the dependency path between the entities. Similarly, in the sentence "*She was diagnosed with cancer last year, and succumbed this June*", the dependency path *She←diagnosed→cancer* is not sufficient to establish that *cancer* is the cause of death for the subject unless the conjunction dependency to *succumbed* is also present.

Motivated by these observations, we propose *path-centric pruning*, a novel technique to incorporate information off the dependency path. This is achieved by including tokens that are up to distance K away from the dependency path in the LCA subtree. $K = 0$, corresponds to pruning the tree down to the path, $K = 1$ keeps all nodes that are directly attached to the path, and $K = \infty$ retains the entire LCA subtree. We combine this pruning strategy with our GCN model, by directly feeding the pruned trees into the graph convolutional layers.[2] We show that pruning with $K = 1$ achieves the best balance between including relevant information (e.g., negation and conjunction) and keeping irrelevant content out of the resulting pruned tree as much as possible.

4 Related Work

At the core of fully-supervised and distantly-supervised relation extraction approaches are statistical classifiers, many of which find syntactic information beneficial. For example, Mintz et al. (2009) explored adding syntactic features to a statistical classifier and found them to be useful when sentences are long. Various kernel-based approaches also leverage syntactic information to measure similarity between training and test examples to predict the relation, finding that tree-

---

[2] For our C-GCN model, the LSTM layer still operates on the full sentence regardless of the pruning.

based kernels (Zelenko et al., 2003) and dependency path-based kernels (Bunescu and Mooney, 2005) are effective for this task.

Recent studies have found neural models effective in relation extraction. Zeng et al. (2014) first applied a one-dimensional convolutional neural network (CNN) with manual features to encode relations. Vu et al. (2016) showed that combining a CNN with a recurrent neural network (RNN) through a voting scheme can further improve performance. Zhou et al. (2016) and Wang et al. (2016) proposed to use attention mechanisms over RNN and CNN architectures for this task.

Apart from neural models over word sequences, incorporating dependency trees into neural models has also been shown to improve relation extraction performance by capturing long-distance relations. Xu et al. (2015b) generalized the idea of dependency path kernels by applying a LSTM network over the shortest dependency path between entities. Liu et al. (2015) first applied a recursive network over the subtrees rooted at the words on the dependency path and then applied a CNN over the path. Miwa and Bansal (2016) applied a Tree-LSTM (Tai et al., 2015), a generalized form of LSTM over dependency trees, in a joint entity and relation extraction setting. They found it to be most effective when applied to the subtree rooted at the LCA of the two entities.

More recently, Adel et al. (2016) and Zhang et al. (2017) have shown that relatively simple neural models (CNN and augmented LSTM, respectively) can achieve comparable or superior performance to dependency-based models when trained on larger datasets. In this paper, we study dependency-based models in depth and show that with a properly designed architecture, they can outperform and have complementary advantages to sequence models, even in a large-scale setting.

Finally, we note that a technique similar to path-centric pruning has been applied to reduce the space of possible arguments in semantic role labeling (He et al., 2018). The authors showed pruning words too far away from the path between the predicate and the root to be beneficial, but reported the best pruning distance to be 10, which almost always retains the entire tree. Our method differs in that it is applied to the shortest dependency path between entities, and we show that in our technique the best pruning distance is 1 for several dependency-based relation extraction models.

5 Experiments

5.1 Baseline Models

We compare our models with several competitive dependency-based and neural sequence models.

Dependency-based models. In our main experiments we compare with three types of dependency-based models. (1) A logistic regression (LR) classifier which combines dependency-based features with other lexical features. (2) Shortest Dependency Path LSTM (SDP-LSTM) (Xu et al., 2015b), which applies a neural sequence model on the shortest path between the subject and object entities in the dependency tree. (3) Tree-LSTM (Tai et al., 2015), which is a recursive model that generalizes the LSTM to arbitrary tree structures. We investigate the child-sum variant of Tree-LSTM, and apply it to the dependency tree (or part of it). In practice, we find that modifying this model by concatenating dependency label embeddings to the input of forget gates improves its performance on relation extraction, and therefore use this variant in our experiments. Earlier, our group compared (1) and (2) with sequence models (Zhang et al., 2017), and we report these results; for (3) we report results with our own implementation.

Neural sequence model. Our group presented a competitive sequence model that employs a position-aware attention mechanism over LSTM outputs (PA-LSTM), and showed that it outperforms several CNN and dependency-based models by a substantial margin (Zhang et al., 2017). We compare with this strong baseline, and use its open implementation in further analysis.[3]

5.2 Experimental Setup

We conduct experiments on two relation extraction datasets: (1) **TACRED**: Introduced in (Zhang et al., 2017), TACRED contains over 106k mention pairs drawn from the yearly TAC KBP[4] challenge. It represents 41 relation types and a special *no_relation* class when the mention pair does not have a relation between them within these categories. Mentions in TACRED are typed, with subjects categorized into person and organization, and objects into 16 fine-grained types (e.g., date and location). We report micro-averaged F_1 scores on this dataset as is conventional. (2) **SemEval**

Table 2: F_1 scores on SemEval. † marks results reported in the original papers; ‡ marks results produced by using the open implementation. The last two columns show results from *with-mention* evaluation and *mask-mention* evaluation, respectively. $*$ marks statistically significant improvements over PA-LSTM with $p < .05$ under a bootstrap test.

2010 Task 8: The SemEval dataset is widely used in recent work, but is significantly smaller with 8,000 examples for training and 2,717 for testing. It contains 19 relation classes over untyped mention pairs: 9 directed relations and a special *Other* class. On SemEval, we follow the convention and report the official macro-averaged F_1 scores.

For fair comparisons on the TACRED dataset, we follow the evaluation protocol used in (Zhang et al., 2017) by selecting the model with the median dev F_1 from 5 independent runs and reporting its test F_1. We also use the same "entity mask" strategy where we replace each subject (and object similarly) entity with a special *SUBJ-<NER>* token. For all models, we also adopt the "multi-channel" strategy by concatenating the input word embeddings with POS and NER embeddings.

Traditionally, evaluation on SemEval is conducted without entity mentions masked. However, as we will discuss in Section 6.4, this method encourages models to overfit to these mentions and fails to test their actual ability to generalize. We therefore report results with two evaluation protocols: (1) *with-mention*, where mentions are kept for comparison with previous work; and (2) *mask-mention*, where they are masked to test the generalization of our model in a more realistic setting.

Due to space limitations, we report model training details in the supplementary material.

5.3 Results on the TACRED Dataset

We present our main results on the TACRED test set in Table 1. We observe that our GCN model outperforms all dependency-based models by at least 1.6 F_1. By using contextualized word representations, the C-GCN model further outperforms the strong PA-LSTM model by 1.3 F_1, and achieves a new state of the art. In addition, we find our model improves upon other dependency-based models in both precision and recall. Comparing the C-GCN model with the GCN model, we find that the gain mainly comes from improved recall. We hypothesize that this is because the C-GCN is more robust to parse errors by capturing local word patterns (see also Section 6.2).

As we will show in Section 6.2, we find that our GCN models have complementary strengths when compared to the PA-LSTM. To leverage this result, we experiment with a simple interpolation strategy to combine these models. Given the output probabilities $P_G(r|x)$ from a GCN model and $P_S(r|x)$ from the sequence model for any relation r, we calculate the interpolated probability as

$$P(r|x) = \alpha \cdot P_G(r|x) + (1 - \alpha) \cdot P_S(r|x)$$

where $\alpha \in [0, 1]$ is chosen on the dev set and set to 0.6. This simple interpolation between a GCN and a PA-LSTM achieves an F_1 score of 67.1, outperforming each model alone by at least 2.0 F_1. An interpolation between a C-GCN and a PA-LSTM further improves the result to 68.2.

5.4 Results on the SemEval Dataset

To study the generalizability of our proposed model, we also trained and evaluated our best C-GCN model on the SemEval test set (Table 2). We find that under the conventional *with-entity* evaluation, our C-GCN model outperforms all existing dependency-based neural models on this sep-

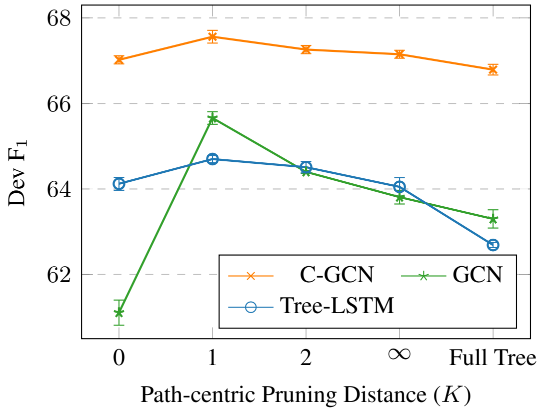

Figure 3: Performance of dependency-based models under different pruning strategies. For each model we show the F_1 score on the TACRED dev set averaged over 5 runs, and error bars indicate standard deviation of the mean estimate. $K = \infty$ is equivalent to using the subtree rooted at the LCA.

arate dataset. Notably, by properly incorporating off-path information, our model outperforms the previous shortest dependency path-based model (SDP-LSTM). Under the *mask-entity* evaluation, our C-GCN model also outperforms PA-LSTM by a substantial margin, suggesting its generalizability even when entities are not seen.

5.5 Effect of Path-centric Pruning

To show the effectiveness of path-centric pruning, we compare the two GCN models and the Tree-LSTM when the pruning distance K is varied. We experimented with $K \in \{0, 1, 2, \infty\}$ on the TACRED dev set, and also include results when the full tree is used. As shown in Figure 3, the performance of all three models peaks when $K = 1$, outperforming their respective dependency path-based counterpart ($K = 0$). This confirms our hypothesis in Section 3 that incorporating off-path information is crucial to relation extraction. Miwa and Bansal (2016) reported that a Tree-LSTM achieves similar performance when the dependency path and the LCA subtree are used respectively. Our experiments confirm this, and further show that the result can be improved by path-centric pruning with $K = 1$.

We find that all three models are less effective when the entire dependency tree is present, indicating that including extra information hurts performance. Finally, we note that contextualizing the GCN makes it less sensitive to changes in the tree structures provided, presumably because the model can use word sequence information in the LSTM layer to recover any off-path information that it needs for correct relation extraction.

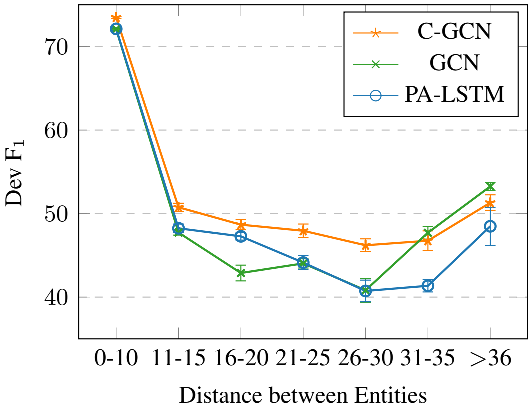

Figure 4: Dev set performance with regard to distance between the entities in the sentence for C-GCN, GCN and PA-LSTM. Error bars indicate standard deviation of the mean estimate over 5 runs.

Model	Dev F_1
Best C-GCN	67.4
– h_s, h_o, and Feedforward (FF)	66.4
– LSTM Layer	65.5
– Dependency tree structure	64.2
– FF, LSTM, and Tree	57.1
– FF, LSTM, Tree, and Pruning	47.4

Table 3: An ablation study of the best C-GCN model. Scores are median of 5 models.

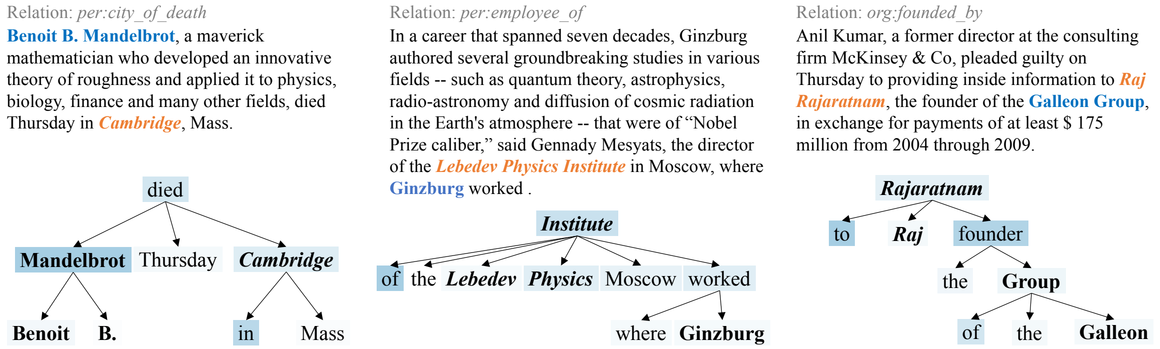
6 Analysis & Discussion

6.1 Ablation Study

To study the contribution of each component in the C-GCN model, we ran an ablation study on the TACRED dev set (Table 3). We find that: (1) The entity representations and feedforward layers contribute 1.0 F_1. (2) When we remove the dependency structure (i.e., setting $\tilde{\mathbf{A}}$ to $\mathbf{I}$), the score drops by 3.2 F_1. (3) F_1 drops by 10.3 when we remove the feedforward layers, the LSTM component and the dependency structure altogether. (4) Removing the pruning (i.e., using full trees as input) further hurts the result by another 9.7 F_1.

6.2 Complementary Strengths of GCNs and PA-LSTMs

To understand what the GCN models are capturing and how they differ from a sequence model such as the PA-LSTM, we compared their performance



Relation: *per:city_of_death*

Benoit B. Mandelbrot, a maverick mathematician who developed an innovative theory of roughness and applied it to physics, biology, finance and many other fields, died Thursday in ***Cambridge***, Mass.

Relation: *per:employee_of*

In a career that spanned seven decades, Ginzburg authored several groundbreaking studies in various fields -- such as quantum theory, astrophysics, radio-astronomy and diffusion of cosmic radiation in the Earth's atmosphere -- that were of "Nobel Prize caliber," said Gennady Mesyats, the director of the ***Lebedev Physics Institute*** in Moscow, where **Ginzburg** worked .

Relation: *org:founded_by*

Anil Kumar, a former director at the consulting firm McKinsey & Co, pleaded guilty on Thursday to providing inside information to ***Raj Rajaratnam***, the founder of the **Galleon Group**, in exchange for payments of at least $ 175 million from 2004 through 2009.

Figure 5: Examples and the pruned dependency trees where the C-GCN predicted correctly. Words are shaded by the number of dimensions they contributed to h_{sent} in the pooling operation, with punctuation omitted.

Relation	Dependency Tree Edges		
per:children	`S-PER` ← son	son → `O-PER`	`S-PER` ← survived
per:other_family	`S-PER` ← stepson	niece → `O-PER`	`O-PER` ← stepdaughter
per:employee_of	a ← member	`S-PER` ← worked	`S-PER` ← played
per:schools_attended	`S-PER` ← graduated	`S-PER` ← earned	`S-PER` ← attended
org:founded	founded → `O-DATE`	established → `O-DATE`	was ← founded
org:number_of_employees	`S-ORG` ← has	`S-ORG` → employs	`O-NUMBER` ← employees
org:subsidiaries	`S-ORG` ← `O-ORG`	`S-ORG` → 's	`O-ORG` → division
org:shareholders	buffett ← `O-PER`	shareholder → `S-ORG`	largest ← shareholder

Table 4: The three dependency edges that contribute the most to the classification of different relations in the TACRED dev set. For clarity, we removed edges which 1) connect to common punctuation (i.e., commas, periods, and quotation marks), 2) connect to common prepositions (i.e., of, to, by), and 3) connect between tokens within the same entity. We use `PER`, `ORG` for entity types of `PERSON`, `ORGANIZATION`. We use `S-` and `O-` to denote subject and object entities, respectively. We also include edges for more relations in the supplementary material.

over examples in the TACRED dev set. Specifically, for each model, we trained it for 5 independent runs with different seeds, and for each example we evaluated the model's accuracy over these 5 runs. For instance, if a model correctly classifies an example for 3 out of 5 times, it achieves an accuracy of 60% on this example. We observe that on 847 (3.7%) dev examples, our C-GCN model achieves an accuracy at least 60% higher than that of the PA-LSTM, while on 629 (2.8%) examples the PA-LSTM achieves 60% higher. This complementary performance explains the gain we see in Table 1 when the two models are combined.

We further show that this difference is due to each model's competitive advantage (Figure 4): dependency-based models are better at handling sentences with entities farther apart, while sequence models can better leverage local word patterns regardless of parsing quality (see also Figure 6). We include further analysis in the supplementary material.

6.3 Understanding Model Behavior

To gain more insights into the C-GCN model's behavior, we visualized the partial dependency tree it is processing and how much each token's final representation contributed to h_{sent} (Figure 5). We find that the model often focuses on the dependency path, but sometimes also incorporates off-path information to help reinforce its prediction. The model also learns to ignore determiners (e.g., "the") as they rarely affect relation prediction.

To further understand what dependency edges contribute most to the classification of different relations, we scored each dependency edge by summing up the number of dimensions each of its connected nodes contributed to h_{sent}. We present the top scoring edges in Table 4. As can be seen in the table, most of these edges are associated with indicative nouns or verbs of each relation.[5]

6.4 Entity Bias in the SemEval Dataset

In our study, we observed a high correlation between the entity mentions in a sentence and its relation label in the SemEval dataset. We experimented with PA-LSTM models to analyze this

---

[5] We do notice the effect of dataset bias as well: the name "Buffett" is too often associated with contexts where shareholder relations hold, and therefore ranks top in that relation.

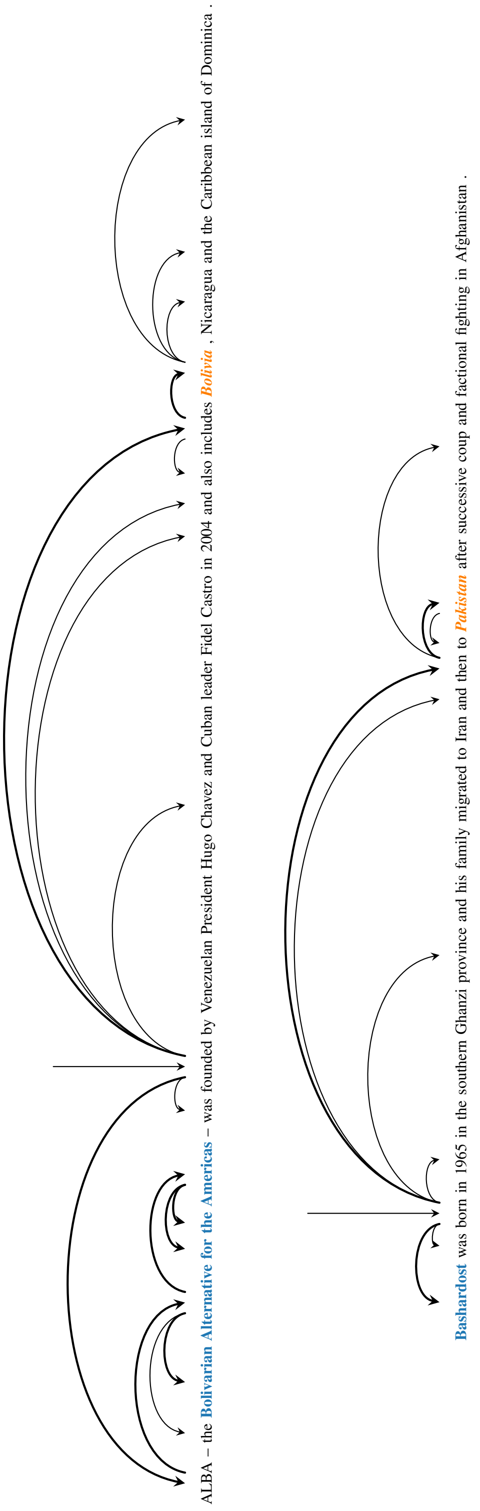


Figure 6: Dev set examples where either the C-GCN (upper) or the PA-LSTM (lower) predicted correctly in five independent runs. For each example, the predicted and pruned dependency tree corresponding to $K = 1$ in path-centric pruning is shown, and the shortest dependency path is thickened. We omit edges to punctuation for clarity. The first example shows that the C-GCN is effective at leveraging long-range dependencies while reducing noise with the help of pruning (while the PA-LSTM predicts *no_relation* twice, *org:alternate_names* twice, and *org:parents* once in this case). The second example shows that the PA-LSTM is better at leveraging the proximity of the word "migrated" regardless of attachment errors in the parse (while the C-GCN is misled to predict *per:country_of_birth* three times, and *no_relation* twice).

phenomenon.[6] We started by simplifying every sentence in the SemEval training and dev sets to "*subject* and *object*", where *subject* and *object* are the actual entities in the sentence. Surprisingly, a trained PA-LSTM model on this data is able to achieve 65.1 F_1 on the dev set if GloVe is used to initialize word vectors, and 47.9 dev F_1 even without GloVe initialization. To further evaluate the model in a more realistic setting, we trained one model with the original SemEval training set (unmasked) and one with mentions masked in the training set, following what we have done for TACRED (masked). While the unmasked model achieves a 83.6 F_1 on the original SemEval dev set, F_1 drops drastically to 62.4 if we replace dev set entity mentions with a special <*UNK*> token to simulate the presence of unseen entities. In contrast, the masked model is unaffected by unseen entity mentions and achieves a stable dev F_1 of 74.7. This suggests that models trained without entities masked generalize poorly to new examples with unseen entities. Our findings call for more careful evaluation that takes dataset biases into account in future relation extraction studies.

7 Conclusion

We showed the success of a neural architecture based on a graph convolutional network for relation extraction. We also proposed path-centric pruning to improve the robustness of dependency-based models by removing irrelevant content without ignoring crucial information. We showed through detailed analysis that our model has complementary strengths to sequence models, and that the proposed pruning technique can be effectively applied to other dependency-based models.

Abstract

Attention mechanisms are often used in deep neural networks for distantly supervised relation extraction (DS-RE) to distinguish valid from noisy instances. However, traditional 1-D vector attention models are insufficient for the learning of different contexts in the selection of valid instances to predict the relationship for an entity pair. To alleviate this issue, we propose a novel multi-level structured (2-D matrix) self-attention mechanism for DS-RE in a multi-instance learning (MIL) framework using bidirectional recurrent neural networks. In the proposed method, a structured word-level self-attention mechanism learns a 2-D matrix where each row vector represents a weight distribution for different aspects of an instance regarding two entities. Targeting the MIL issue, the structured sentence-level attention learns a 2-D matrix where each row vector represents a weight distribution on selection of different valid instances. Experiments conducted on two publicly available DS-RE datasets show that the proposed framework with a multi-level structured self-attention mechanism significantly outperform state-of-the-art baselines in terms of PR curves, P@N and F1 measures.

1 Introduction

Relation extraction is a fundamental task in information extraction (IE), which studies the issue of predicting semantic relations between pairs of entities in a sentence (Zelenko et al., 2003; Bunescu and Mooney, 2005; Zhou et al., 2005). One crucial problem in RE is the relative lack of large-scale, high-quality labeled data. In recent years, one commonly used and effective technique for dealing with this challenge is the distant supervision method via knowledge bases (KBs) (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011), which assumes that if one entity pair appearing in some sentences can be observed in a KB with a certain relationship, then these sentences will be labeled as the context of this entity pair and this relationship. The distant supervision strategy is an effective and efficient method for automatically labeling large-scale training data. However, it also introduces a severe mislabelling problem due to the fact that a sentence that mentions two entities does not necessarily express their relation in a KB (Surdeanu et al., 2012; Zeng et al., 2015).

Plenty of research work has been proposed to deal with distantly supervised data and has achieved significant progress, especially with the rapid development of deep neural networks (DNN) for relation extraction in recent years (Zeng et al., 2014, 2015; Lin et al., 2016, 2017a; Wang et al., 2016; Zhou et al., 2016; Ji et al., 2017; Yang et al., 2017; Zeng et al., 2017). DNN models under an MIL framework for DS-RE have become state-of-the-art, replacing statistical methods, such as feature-based and graphical models (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). In the MIL framework for distantly supervised RE, each entity pair often has multiple instances where some are noisy and some are valid. The attention mechanism in DNNs, such as convolutional (CNN) and recurrent neural networks (RNN), is an effective way to select valid instances by learning a weight distribution over multiple instances. However, there are two important representation learning problems in DNN-based distantly supervised RE: (1) **Problem I**: entity pair-targeted context representation learning from an instance; and (2) **Problem II**: valid instance selection representation learning over multiple instances. The former can use a word-level attention mechanism to learn a weight distribution on words and then a weighted sentence representation regarding two entities; the latter can employ a sentence-level attention mechanism to

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2216–2225
Brussels, Belgium, October 31 - November 4, 2018.

learn a weight distribution on multiple instances so that valid sentences with higher weights can be focused and selected, and noisy instances with lower weights are suppressed.

Both the word-level and sentence-level attention mechanisms in previous work on the RE task are simple 1-D vectors which are learned using the hidden states of the RNN, or via pooling from either the RNNs' hidden states or convolved n-grams (Zeng et al., 2014, 2015; Zhou et al., 2016; Wang et al., 2016; Ji et al., 2017; Yang et al., 2017). The deficiency of the 1-D attention vector is that it only focuses on one or a small number of aspects of the sentence, or one or a small number of instances (Lin et al., 2017b), with the result that different semantic aspects of the sentence, or different multiple valid sentences are ignored, and cannot be utilised.

Inspired by the structured self-attentive sentence embedding in Lin et al. (2017b), we propose a novel multi-level structured (2-D) self-attention mechanism (MLSSA) in a bidirectional LSTM-based (BiLSTM) (Hochreiter and Schmidhuber, 1997) MIL framework to alleviate two **problems** in the distantly supervised RE. Regarding **Problem I**, we propose a 2-D matrix-based word-level attention mechanism, which contains multiple vectors, each focusing on different aspects of the sentence for better context representation learning. In terms of **Problem II**, we propose a 2-D sentence-level attention mechanism for multiple instance learning, where it contains multiple vectors, each focusing on different valid instances for a better sentence selection. "**structured**" indicates that the weight vectors in the learned 2-D matrix try to construct a structural dependency relationship by learning different weight distributions for different contexts or instances given the entity pair. We can see that our structured attention mechanism is different from that in Kim et al. (2017) which incorporates richer structural distributions and are simple extensions of the basic attention procedure. We verify the proposed framework on two distantly supervised RE datasets, namely the New York Times (NYT) dataset (Riedel et al., 2010) and the DBpedia Portuguese dataset (Batista et al., 2013). Experimental results show that our MLSSA framework significantly outperforms state-of-the-art baseline systems in terms of different evaluation metrics.

The main contributions of this paper include: (1) we propose a novel multi-level structured (2-D) self-attention mechanism for DS-RE which can make full use of input sequences to learn different contexts, without integrating extra resources; (2) we propose a 2-D matrix-based word-level attention for better context representation learning targeting two entities; (3) we propose a 2-D sentence-level attention mechanism over multiple instances to select different valid instances; and (4) we verify the proposed framework on two publicly available distantly supervised datasets.

2 Related Work

Most existing work on distant supervision data mainly focuses on denoising the data under the MIL strategy by learning a valid sentence representation or features, and then selecting one or more valid instances for relation classification (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015; Lin et al., 2016, 2017a; Zhou et al., 2016; Ji et al., 2017; Zeng et al., 2017; Yang et al., 2017).

Riedel et al. (2010) and Surdeanu et al. (2012) use a graphical model and MIL to select the valid sentences and classify the relations. However, these models are based on statistical methods and feature engineering, i.e. extracting sentence features using other NLP tools. Zeng et al. (2015) proposed a piece-wise CNN (PCNN) method to automatically learn sentence-level features and select one valid instance for the relation classification. The one-sentence-selection strategy does not make full use of the supervision information among multiple instances.

Lin et al. (2016) and Ji et al. (2017) introduce an attention mechanism to the PCNN-based MIL framework to select informative sentences, which outperforms all baseline systems on the NYT data set. However, their attention mechanism is only a sentence-level model without incorporating word-level attention. Zhou et al. (2016) introduce a word-level attention model to the BiLSTM-based MIL framework and obtain significant improvements on the SemEval2010 (Hendrickx et al., 2010) data set. Wang et al. (2016) extend the single word-level attention model to multiple word levels in CNNs to discern patterns in heterogeneous contexts of the input sentence, and achieve best performance on the SemEval2010 data set. However, these two works were not targeting the distantly supervised RE problem.

Yang et al. (2017) experiment with word-level and sentence-level attention models in the bidirectional RNN on the NYT dataset on the basis of the open source DS-RE system,[1] and verify that a two-level attention mechanism achieves best performance compared to PCNN/CNN models. Both the word-level and sentence-level attention models are 1-D vectors.

From previous work, we can see that the attention mechanism in DNNs has made significant progress on the RE task. However, both word-level and sentence-level attention models are still based on 1-D vectors which have the following insufficiencies: (1) although the 1-D attention model can learn weights for different contexts, it only focuses on one or very few aspects of a single sentence (Lin et al., 2017b), or one or very few instances; (2) in order to allow the attention mechanism to learn more aspects of the sentence, or different instances, extra knowledge needs to be integrated, such as the work in Ji et al. (2017) and Lin et al. (2017a). The former integrates entity descriptions generated from Freebase and Wikipedia as supplementary background knowledge to disambiguate the entity. The latter introduces a multilingual framework which employs a monolingual attention mechanism to utilize the information within monolingual texts, and further uses a cross-lingual attention mechanism to consider the information consistency and complementarity among cross-lingual texts. However, extra resources are difficult to obtain in many practical scenarios.

In order to alleviate the burden of integrating extra knowledge, and make full use of the input sentence (i.e. learning different aspects of context and focusing on different valid instances), we propose a multi-level structured self-attention mechanism in a BiLSTM-based MIL framework without integrating extra resources.

3 Approach

The distantly supervised RE can be formalised as follows: given an entity pair (e_1, e_2), a bag $\mathcal{G}$ containing $\mathcal{J}$ instances, and the relation label r for $\mathcal{G}$, the goal of the training process is to denoise these instances by selecting valid candidates based on r, and the goal of the testing process is to denoise multiple instances by selecting valid candidates to predict the relation r for $\mathcal{G}$.

To alleviate the aforementioned two problems, improving the following two representation learning issues is clearly important for a DNN-based RE classifier:

- *Entity pair-targeted context representation*: The model should have the capability to learn a better context representation from the input sentence targeting the entity pair;
- *Instance selection representation*: The model should have the capability to learn a better weight distribution over multiple instances to select valid instances regarding an entity pair.

Motivated by these two issues, we propose a multi-level structured self-attention framework.

3.1 Architecture

The proposed framework consists of three parts as shown in Figure 1. The first part includes the input layer, embedding layer and BiLSTM layer which transform the input sequence at different time steps to LSTM hidden states.

The second part implements the entity pair-targeted context representation learning, including:

- *a structured word-level self-attention layer*: this generates a set of summation weight vectors (or a 2-D matrix) taking the LSTM hidden states as input. Each vector in the 2-D matrix represents the weights for different aspects of the input sentence.
- *a structured context representation layer*: the weight vectors learned by the 2-D word-level self-attention are dotted with the BiLSTM hidden states. Accordingly, a 2-D matrix or a set of weighted LSTM hidden state vectors, denoted as "M_{L1}" in Figure 1, is obtained. Each weighted vector represents a sentence embedding reflecting a different aspect of the sentence targeting the entity pair. By this means, a dependency parsing-like structure of the input sentence can be constructed, obtaining different semantic representations of the sentence for the two entities in question.
- *a flattened representation layer*: this concatenates each vector in the 2-D matrix of the sentence embedding to one vector. Then, the

---

[1] `https://github.com/frankxu2004/TensorFlow-NRE`

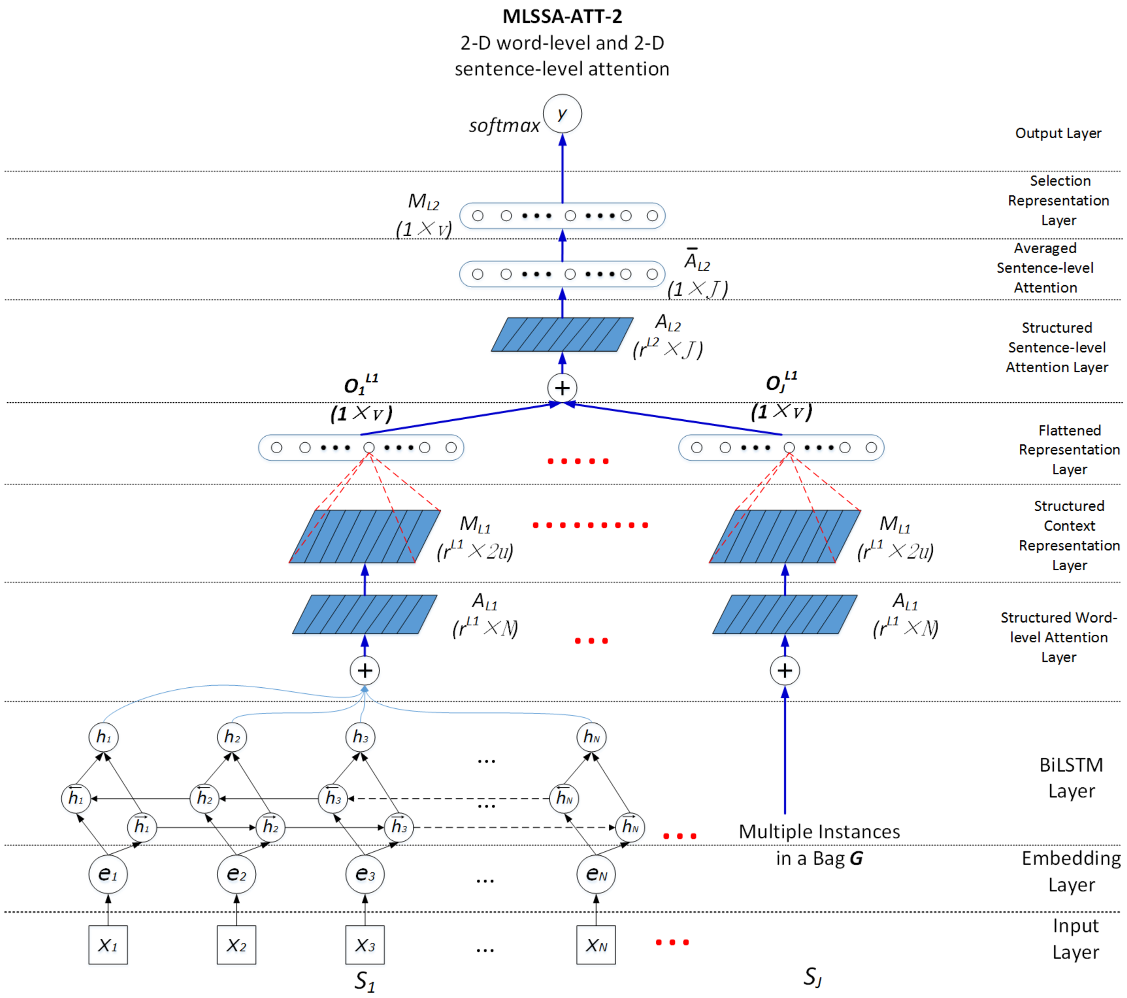

Figure 1: Multi-level structured self-attention framework for distantly supervised RE

flattened vector connects to a 1-layer multi-layer perceptron (MLP) with ReLU activation function, generating an aggregated sentence representation.

The first and second parts operate on the single instance level, i.e. given a bag $\mathcal{G}$ and feeding each instance into the framework, the structured word-level self-attention mechanism will construct J individual structured sentence representations corresponding to J input instances.

The third part targets the instance selection representation learning issue, and operates on the bag level, i.e. considering weighted context representations of all instances in the bag $\mathcal{G}$ and learning probability distributions to distinguish informative from noisy sentences. This part includes:

- *a structured sentence-level attention model*: this has a similar structure to the structured word-level attention mechanism, except that it generates a set of summation weight vectors for all input instances in the same bag $\mathcal{G}$. Each vector is a weight distribution over all instances. Accordingly, the 2-D sentence-level matrix is expected to learn a set of different weight distributions focusing on different informative instances. As a result, informative sentences are expected to contribute more with higher weights, and noisy sentences are expected to contribute less with smaller weights, to the relation classification.

- *an averaged sentence-level attention layer*: the 2-D sentence-level attention matrix is averaged and converted to a 1-D vector.

- *a selection representation layer*: the 1-D averaged attention vector is dotted with the output of the flattened representation layer. Accordingly, a 1-D vector, denoted as “M_{L2}” in Figure 1, is obtained which represents an averaged weighted selection representation of multiple sentences.

- *an output layer*: this connects to a *softmax* layer and produces a probability distribution corresponding to relation classes.

3.2 Structured Word-Level Self-Attention and its Penalisation Function

Given a bag $\mathcal{G} = (S_1, S_2, \ldots, S_J)$ containing J instances, and a sentence S_j in $\mathcal{G}$ consisting of N tokens, S_j can be represented using a sequence of word embeddings, as in (1):

$$S_j = (e_1, e_2, \ldots, e_N) \tag{1}$$

where e_i is a d-dimension vector for the i-th word, and S_j is the j-th instance in $\mathcal{G}$.

We denote the hidden state of the BiLSTM as in (2):

$$H = (\mathbf{h_1}, \mathbf{h_2}, \ldots, \mathbf{h_N})^T \tag{2}$$

where $\mathbf{h_t}$ is a concatenation of the forward hidden state $\overrightarrow{h}_t$ and the backward hidden state $\overleftarrow{h}_t$ at time step t. T is the transpose operation. If the size of each unidirectional LSTM is u, then H has the size $2u$-by-N.

Then, the structured word-level self-attention mechanism is defined as in (3):

$$A_{L1} = softmax(W_{s2}^{L1} tanh(W_{s1}^{L1} H)) \tag{3}$$

where $L1$ stands for the first-level attention mechanism, i.e. the word-level; W_{s1}^{L1} is a weight matrix of size $d_a^{L1} \times 2u$, where d_a^{L1} is a hyper-parameter for the number of neurons in the attention network; W_{s2}^{L1} is a weight matrix with the shape $r^{L1} \times d_a^{L1}$, where r^{L1} ($r^{L1} > 1$) is the hyper-parameter representing the size of multiple vectors in the 2-D attention matrix. The size of r^{L1} is defined based on how many different aspects of the sentence need to be focused on; A_{L1} is the annotation matrix of size $r^{L1} \times N$. We can see that in A_{L1}, there are r^{L1} attention vectors for the N-token input sentence.

Finally, we compute the r^{L1} weighted sums by multiplying the annotation matrix A_{L1} and BiLSTM hidden states H. The resulting structured sentence representation M_{L1} is (4):

$$M_{L1} = A_{L1} H^T \tag{4}$$

where M_{L1} has the shape $r^{L1} \times 2u$. It can be seen that the traditional 1-D sentence representation is extended to a 2-D representation ($r^{L1} > 1$).

Subsequently, the output of the flattened representation layer for the instance S_j in $\mathcal{G}$ is (5):

$$O_j^{L1} = ReLU(W_o^{L1} M_{L1}^{FT} + b_o^{L1}) \tag{5}$$

where W_o^{L1} is the weight matrix that has the shape v-by-$r^{L1} * 2u$, where v is the amount of neurons in the $ReLU$-based MLP layer; M_{L1}^{FT} is the flattened structured sentence representation which is a concatenated vector of each row in M_{L1} and has the dimension $r^{L1} * 2u$; b_o^{L1} is the bias vector of size v; O_j^{L1} is the aggregated sentence representation of the j-th instance in the bag $\mathcal{G}$ with size v.

Then, the output of all instances in $\mathcal{G}$ from the flattened representation layer is denoted as in (6):

$$O^{L1} = (O_1^{L1}, O_2^{L1}, \ldots, O_J^{L1})^T \tag{6}$$

where O^{L1} has the shape of $v \times J$.

As in Lin et al. (2017b), the penalisation term for the structured word-level attention is as in (7):

$$P_{L1} = ||(A_{L1} A_{L1}^T - I)||_F^2 \tag{7}$$

where $|| \cdot ||_F$ is the Frobenius norm of a matrix. I is an identity matrix. Minimising this penalisation term means that we learn an orthogonal matrix for A_{L1} so that each row in A_{L1} only focuses on a single aspect of semantics.

3.3 Structured Sentence-Level Self-Attention and Averaged Selection Representation

Taking O^{L1} as the input to the structured 2-D sentence-level attention model, the annotation matrix A_{L2} is calculated as in (8):

$$A_{L2} = softmax(W_{s2}^{L2} tanh(W_{s1}^{L2} O^{L1})) \tag{8}$$

where W_{s1}^{L2} is the weight matrix of size $d_a^{L2} \times v$, and d_a^{L2} is the number of neurons in the attention network; W_{s2}^{L2} is the weight matrix of shape $r^{L2} \times d_a^{L2}$, where r^{L2} ($r^{L2} > 1$) is the hyper-parameter representing the size of multiple vectors in the 2-D sentence-level attention matrix. The r^{L2} multiple vectors are expected to focus on different informative instances for the relation classification; A_{L2} is the sentence-level annotation matrix of size $r^{L2} \times J$. We can see that the traditional 1-D sentence-level attention model is expanded to a multi-vector attention ($r^{L2} > 1$).

Then, we average the 2-D A_{L2} to a 1-D vector $\bar{A}_{L2}$ which has the dimension of J.

Accordingly, we calculate the averaged weighted sum by multiplying $\bar{A}_{L2}$ and the aggregated sentence representation O^{L1}, with the resulting instance selection representation M_{L2} being (9):

$$M_{L2} = \bar{A}_{L2} \cdot (O^{L1})^T \tag{9}$$

where M_{L2} has the size of v.

The probability distribution of the predicted relation type, i.e. the final output for relation prediction, can be calculated as in (10):

$$p(\hat{y}|G) = softmax(W_o^{L2} tanh(M_{L2}) + b_o^{L2}) \tag{10}$$

3.4 Loss Function and Optimisation

The total loss of the network is the summation of the penalisation term P_{L1}, *softmax* loss in Eq. (10) and the $L2$ regularisation loss.

We use the ADAM optimiser (Kingma and Ba, 2014) to minimize the loss function on the mini-batch basis which is randomly selected from the training set.

4 Experiments

4.1 Datasets

We use two distantly supervised datasets, namely the NYT corpus (NYT) and the DBpedia Portuguese dataset (PT),[2] to verify our method.

In the NYT dataset, there are 53 relationships including a special relation *NA* which indicates a *None Relation* between two entities. The training set contains 580,888 sentences, 292,484 entity pairs and 19,429 relational facts (Non-NA). The test set contains 172,448 sentences, 96,678 entity pairs and 1,950 relational facts (Non-NA). There are 19.24% and 22.57% entity pairs corresponding to multiple instances in the training set and test set, respectively.

The DBpedia Portuguese dataset is smaller, containing just 10 relationships including a special relation *Other*. After preprocessing the original dataset, we obtain 96,847 sentences, 85,528 entity pairs and 77,321 relational facts (Non-Other). There are 8.61% entity pairs corresponding to multiple instances in the whole dataset. As in Batista et al. (2013), we use two different settings for the training and test sets: (1) a manually reviewed subset that contains 602 sentences (PT-MANUAL) as the test set; and (2) 70%–30% out of the whole data as the training set and test set, respectively (PT-SPLIT).

4.2 Word Embeddings and Relative Position Features

For the NYT dataset, we use the 200-dimensional word vectors pre-trained using the NYT corpus;[3] for the PT dataset, we use a pre-trained 300-dimensional word vector model.[4] For the two-word entities in the data set, we use *underscore* to connect them as one word. The word embeddings of unknown words are intialised using the normal distribution with the standard deviation 0.05. Similar to previous work, we also use position embeddings specified by entity pairs. It is defined as the combination of the relative distances from the current word to head or tail entities (Zeng et al., 2014, 2015; Lin et al., 2016).

4.3 Baselines and Our MLSSA Systems

Neural RE systems have become the state-of-the-art, such as CNN-based (Zeng et al., 2014; Lin et al., 2017a), Piecewise CNN-based (Zeng et al., 2015; Lin et al., 2016; Ji et al., 2017), and BiLSTM-based (Zhou et al., 2016) models with or without an attention mechanism. In order to carry out a fair comparison, we select CNN+ATT, PCNN+ATT, BiGRU+ATT (bidirectional gated recurrent unit) and BiGRU+2ATT models as baselines on the NYT data, PCNN+ATT and BiGRU+2ATT as baselines on the PT data, where ATT indicates that the model has a sentence-level attention mechanism, and 2ATT indicates that the model has a 1-D word-level and a 1-D sentence-level attention.[5]

To show the incremental effectiveness of structured 2-D word-level and 2-D sentence-level self-attention mechanisms, we use two different settings for our MLSSA system: (1) **MLSSA-1**: this has a 2-D word-level self-attention and a 1-D sentence-level attention, i.e. A_{L2} in Figure 1 is a 1-D vector. This system is used to verify the context representation learning targeting **Problem I**;

---

[2] There are several reasons to use the Portuguese dataset: (i) the data sets reported in previous work, such as the KBP data, are not publicly available, or (ii) SemEval data sets which are not distantly supervised data. Google has also released a dataset (https://github.com/google-research-datasets/relation-extraction-corpus), but it is smaller and only has 4 relation types. For all these reasons, the Portuguese data is a better option to verify our method.

[3] `https://catalog.ldc.upenn.edu/ldc2008t19`

[4] `https://s3-us-west-1.amazonaws.com/fasttext-vectors/wiki.pt.vec`

[5] All the baseline systems are obtained from `https://github.com/thunlp/NRE` and `https://github.com/thunlp/TensorFlow-NRE`.

(2) **MLSSA-2**: both the word-level and sentence-level attentions are structured 2-D matrices. This system verifies the instance selection representation learning targeting **Problem II**.

4.4 Experiment Setup and Evaluation Metrics

Following previous work, we use different evaluation metrics on these two datasets. For the NYT dataset:

- Overall evaluation: all training data is used for the model training, and all test data is used for the evaluation in terms of Precision-Recall (PR) curves;
- P@N evaluation: we select those entity pairs that have more than one instance to carry out the comparison in terms of the *precision* at n (P@N) measure.[6] As in Lin et al. (2016), there are three settings: (1) One: for each testing entity pair corresponding to multiple instances, we randomly select one sentence to predict the relation; (2) Two: for each testing entity pair with multiple instances, we randomly select two sentences for the relation extraction; and (3) All: for each entity pair having multiple instances, we use all of them to predict the relation. Note that these three selections are only applied to the test set, and we keep all sentences in the training data for model building.

For the PT dataset, we use Macro F1 to evaluate system performance.[7]

4.5 Hyper-parameter Settings

We use cross-validation to determine the hyper-parameters of our system regarding two different settings and datasets. The in-common and different parameters for our two systems and two datasets are shown in Table 1.

Parameters for MLSSA-1/2	**NYT**	**PT**
Word embedding dimension d	200	300
Position embedding dimension	50	50
Batch size B	64	50
Time steps T	70	70
Learning rate λ	0.001	0.001
Hidden size in BiLSTM u	300	300
d_a^{L1} at word-level attention	300	300
r^{L1} at word-level attention	9	5
MLP size v	1000	1000
Coefficient of the penalisation term	1.0	1.0
Parameters for MLSSA-2 only	**NYT**	**PT**
d_a^{L2} at sentence-level attention	300	300
r^{L2} at sentence-level attention	9	3

Table 1: Hyper-parameter settings

4.6 PR Curves on NYT Dataset

The comparison results for the NYT test set are shown in Figure 2. We have the following observations: (1) BiGRU+ATT outperforms CNN+ATT and PCNN+ATT in terms of the PR curve, showing that it can learn a better semantic representation from the sequential input; (2) BiGRU+2ATT has better overall performance compared to BiGRU+ATT, showing that word-level attention is beneficial to sentence-level attention compared to single-attention models, i.e. the sentence-level attention model can select more informative sentences based on a more reasonable sentence embedding learned by the word-level attention model; (3) MLSSA-1 outperforms all baseline systems in terms of the PR curve, which demonstrates that the structured 2-D word-level attention model can learn a better sentence representation by focusing on different aspects of the sentence, so that the sentence-level attention has a better chance of selecting the most informative sentences; and (4) the PR curve of MLSSA-2 is higher than that of MLSSA-1, demonstrating that the 2-D sentence-level attention model can better select the most informative sentences compared to the 1-D sentence-level attention model targeting those entity pairs with multiple instances.

4.7 P@N Evaluation on NYT Dataset

The results on the NYT dataset regarding P@100, P@200, P@300 and the mean of three settings for each model are shown in Table 2. From the table, we have similar observations to the PR Curves: (1) BiGRU+2ATT outperforms CNN+ATT, PCNN+ATT and BiGRU+ATT in most cases in terms of all P@N scores; and (2) MLSSA-1 and MLSSA-2 significantly outperform all baselines for all measures. We observe that MLSSA-1 performs better than MLSSA-2 on tasks **One** and **Two**, but worse on **All**. We infer that in our 2-D sentence-level attention model, we

---

[6] P@N considers only the topmost results returned by the model.

[7] Regarding the metric, we keep the evaluation consistent with the work in Batista et al. (2013) where they used F1 to measure their RE systems on the Portuguese dataset, in order to maintain a fair comparison with their work using the same metric.

Test Settings	One				Two				All			
P@N(%)	100	200	300	Mean	100	200	300	Mean	100	200	300	Mean
CNN+ATT	72.0	67.0	59.5	66.2	75.5	69.0	63.3	69.3	74.3	71.5	64.5	70.1
PCNN+ATT	73.3	69.2	60.8	67.8	77.2	71.6	66.1	71.6	76.2	73.1	67.4	72.2
BiGRU+ATT	75.0	69.5	64.7	69.7	80.0	72.5	69.3	73.9	82.0	76.5	71.3	76.6
BiGRU+2ATT	81.0	74.0	67.3	74.1	81.0	75.5	70.7	75.7	81.0	76.0	72.7	76.6
MLSSA-1	**88.0**	**77.0**	**70.0**	**78.3**	88.0	**79.0**	**73.3**	**80.1**	87.0	**81.5**	76.0	81.5
MLSSA-2	87.0	76.0	**70.0**	77.7	**89.0**	78.5	72.3	79.9	**90.0**	**81.5**	**77.0**	**82.8**

Table 2: Precision values for the top-100, top-200, and top-300 relation instances that are randomly selected in terms of one, two and all sentences.

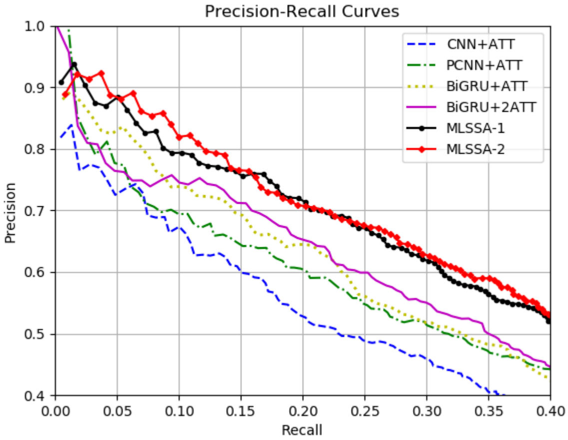

Figure 2: Comparison results of a variety of methods in terms of precision/recall curves.

set r^{L2} to 9, but there are only *one* and *two* instances for selection in tasks **One** and **Two**, so the 2-D matrix cannot demonstrate its full potential. However, in **All**, many entity pairs contain multiple or more than 9 instances, so it can learn a better 2-D matrix to focus on different instances.

4.8 Results on PT Dataset

Based on results from the NYT dataset, we choose PCNN+ATT and BiGRU+2ATT as representative baselines to compare against our MLSSA-1/2 systems on the PT test sets. The results in terms of Macro F1 are shown in Table 3.

It can be seen that on both test sets, our MLSSA-2 model achieved the best performance which shows that the structured 2-D word-level and sentence-level self-attention models can be well applied to datasets of a smaller scale and with a smaller ratio of multiple instances.

4.9 Examples and Analysis

In order to show the effectiveness of structured self-attention mechanisms, we show some examples by visualising the attentions on different aspects of a sentence, and on different sentences comparing with BiLSTM+2ATT model.

SYS	PT-MANUAL (%)	PT-SPLIT (%)
PCNN+ATT	62.3	74.1
BiGRU+2ATT	63.5	75.3
MLSSA-1	66.0	77.2
MLSSA-2	**69.6**	**78.1**

Table 3: Results on the PT test sets

Figure 3 shows the comparison of word-level attention mechanism between BiGRU+2ATT and MLSSA-1 reflecting their capability of context representation learning (*Problem I*). MLSSA-2 has a similar probability distribution to MLSSA-1 in terms of this example.

The *pink* fonts indicate lower probability and *red* indicates higher probability. We observe that: (1) BiGRU+2ATT mainly focuses on one word *baltimore*. We can see that it has little attention on the entity word *maryland*. In this example, the comma implies a semantic relationship *location/location/contains* for the entity pair (*Maryland, Baltimore*). However, BiGRU+2ATT allocates quite a small probability to it; and (2) we can see that our model focuses on different words via different attention vectors (9 in total). Words with a *red* background have a high probability of 0.98 or so. For rows 5, 6, 8 and 9, the focus is on the *BLANK* tokens. In both systems, the maximum time step is set to 70, which indicates that shorter sentences are padded with *BLANK* tokens and longer sentences are cut off. The last row shows the summation of **9** annotation vectors, and it constructs a dependency-like context of the relation for the entity pair. Attentions on different words are attributed to the penalisation P_{L1} which is optimised to learn orthogonal eigenvectors.

Figure 4 shows the comparison of sentence-level attentions between BiGRU+2ATT, MLSSA-1 and MLSSA-2. The first, second and third columns are probability distributions over multi-

Figure 4: Comparison of sentence-level attentions.

ple instances. The entity pair is (*vinod khosla, sun microsystems*), and their relation is *Business/Person/Company*. From this figure, we observe that: (1) BiGRU+2ATT allocates high probabilities to **Sentences 1** and **2** by learning the context of "*a founder of*", but does not recognise that "*co-founder*" is semantically the same as "*founder*"; and (2) our two models almost evenly focus on all sentences because they express the same semantic concept of "*a person is a founder of a company*" in terms of the given entity pair. Therefore, the structured self-attention mechanism is helpful to learn a better representation and select informative sentences.

5 Conclusion and Future Work

This paper has proposed a multi-level structured self-attention mechanism for distantly supervised RE. In this framework, the traditional 1-D word-level and sentence-level attentions are extended to 2-D structured matrices which can learn different aspects of a sentence, and different informative instances. Experimental results on two distant supervision data sets show that (1) the structured 2-D word-level attention can learn a better sentence representation; (2) the structured 2-D sentence-level attention and averaged selection can perform better selection from multiple instances for relation classification; (3) the proposed framework significantly outperforms state-of-the-art baseline systems for a range of different measures, which verifies its effectiveness on two representation learning issues. A subsequent manual investigation via examples also show its effectiveness on two representation learning issues.

In future work, we will build a domain-specific distant supervision dataset with a higher ratio of multiple instances and compare our system with others. Furthermore, we will consider not using RNNs or CNNs, but a deeper neural networks with only attentions for distantly supervised RE, similar to the work in Vaswani et al. (2017).

Abstract

Cross-sentence n-ary relation extraction detects relations among n entities across multiple sentences. Typical methods formulate an input as a *document graph*, integrating various intra-sentential and inter-sentential dependencies. The current state-of-the-art method splits the input graph into two DAGs, adopting a DAG-structured LSTM for each. Though being able to model rich linguistic knowledge by leveraging graph edges, important information can be lost in the splitting procedure. We propose a graph-state LSTM model, which uses a parallel state to model each word, recurrently enriching state values via message passing. Compared with DAG LSTMs, our graph LSTM keeps the original graph structure, and speeds up computation by allowing more parallelization. On a standard benchmark, our model shows the best result in the literature.

1 Introduction

As a central task in natural language processing, relation extraction has been investigated on news, web text and biomedical domains. It has been shown to be useful for detecting explicit facts, such as cause-effect (Hendrickx et al., 2009), and predicting the effectiveness of a medicine on a cancer caused by mutation of a certain gene in the biomedical domain (Quirk and Poon, 2017; Peng et al., 2017). While most existing work extracts relations within a sentence (Zelenko et al., 2003; Palmer et al., 2005; Zhao and Grishman, 2005; Jiang and Zhai, 2007; Plank and Moschitti, 2013; Li and Ji, 2014; Gormley et al., 2015; Miwa and Bansal, 2016; Zhang et al., 2017), the task of cross-sentence relation extraction has received increasing attention (Gerber and Chai, 2010; Yoshikawa et al., 2011). Recently, Peng et al. (2017) extend cross-sentence relation extraction by further detecting relations among several entity mentions (n-ary relation). Table 1 shows an example, which conveys the fact that cancers caused by the *858E* mutation on *EGFR* gene can respond to the *gefitinib* medicine. The three entity mentions form a ternary relation yet appear in distinct sentences.

The deletion mutation on exon-19 of **EGFR** gene was present in 16 patients, while the **858E** point mutation on exon-21 was noted in 10. All patients were treated with **gefitinib** and showed a partial response.

Table 1: An example showing that tumors with *L858E* mutation in *EGFR* gene respond to *gefitinib* treatment.

Peng et al. (2017) proposed a graph-structured LSTM for n-ary relation extraction. As shown in Figure 1 (a), graphs are constructed from input sentences with dependency edges, links between adjacent words, and inter-sentence relations, so that syntactic and discourse information can be used for relation extraction. To calculate a hidden state encoding for each word, Peng et al. (2017) first split the input graph into two directed acyclic graphs (DAGs) by separating left-to-right edges from right-to-left edges (Figure 1 (b)). Then, two separate gated recurrent neural networks, which extend tree LSTM (Tai et al., 2015), were adopted for each single-directional DAG, respectively. Finally, for each word, the hidden states of both directions are concatenated as the final state. The bi-directional DAG LSTM model showed superior performance over several strong baselines, such as tree-structured LSTM (Miwa and Bansal, 2016), on a biomedical-domain benchmark.

However, the bidirectional DAG LSTM model suffers from several limitations. First, important information can be lost when converting a graph

Brussels, Belgium, October 31 - November 4, 2018.

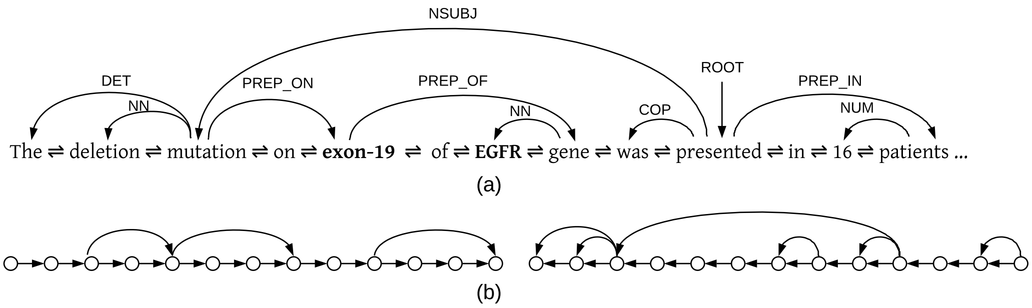

Figure 1: (a) A fraction of the dependency graph of the example in Table 1. For simplicity, we omit edges of discourse relations. (b) Results after splitting the graph into two DAGs.

into two separate DAGs. For the example in Figure 1, the conversion breaks the inner structure of "exon-19 of EGFR gene", where the relation between "exon-19" and "EGFR" via the dependency path "exon-19 $\xrightarrow{\text{PREP\_OF}}$ gene $\xrightarrow{\text{NN}}$ EGFR" is lost from the original subgraph. Second, using LSTMs on both DAGs, information of only ancestors and descendants can be incorporated for each word. Sibling information, which may also be important, is not included.

A potential solution to the problems above is to model a graph as a whole, learning its representation without breaking it into two DAGs. Due to the existence of cycles, naive extension of tree LSTMs cannot serve this goal. Recently, graph convolutional networks (GCN) (Kipf and Welling, 2017; Marcheggiani and Titov, 2017; Bastings et al., 2017) and graph recurrent networks (GRN) (Song et al., 2018; Zhang et al., 2018) have been proposed for representing graph structures for NLP tasks. Such methods encode a given graph by hierarchically learning representations of neighboring nodes in the graphs via their connecting edges. While GCNs use CNN for information exchange, GRNs take gated recurrent steps to this end. For fair comparison with DAG LSTMs, we build a graph LSTM by extending Song et al. (2018), which strictly follow the configurations of Peng et al. (2017) such as the source of features and hyper parameter settings. In particular, the full input graph is modeled as a single state, with words in the graph being its sub states. State transitions are performed on the graph recurrently, allowing word-level states to exchange information through dependency and discourse edges. At each recurrent step, each word advances its current state by receiving information from the current states of its adjacent words. Thus with increasing numbers of recurrent steps each word receives information from a larger context. Figure 2 shows the recurrent transition steps where each node works simultaneously within each transition step.

Compared with bidirectional DAG LSTM, our method has several advantages. First, it keeps the original graph structure, and therefore no information is lost. Second, sibling information can be easily incorporated by passing information up and then down from a parent. Third, information exchange allows more parallelization, and thus can be very efficient in computation.

Results show that our model outperforms a bidirectional DAG LSTM baseline by 5.9% in accuracy, overtaking the state-of-the-art system of Peng et al. (2017) by 1.2%. Our code is available at `https://github.com/freesunshine0316/nary-grn`.

Our contributions are summarized as follows.

- We empirically compared graph LSTM with DAG LSTM for n-ary relation extraction tasks, showing that the former is better by more effective use of structural information;
- To our knowledge, we are the first to investigate a graph recurrent network for modeling dependency and discourse relations.

2 Task Definition

Formally, the input for cross-sentence n-ary relation extraction can be represented as a pair $(\mathcal{E}, \mathcal{T})$, where $\mathcal{E} = (\epsilon_1, \ldots, \epsilon_N)$ is the set of entity mentions, and $\mathcal{T} = [S_1; \ldots; S_M]$ is a text consisting of multiple sentences. Each entity mention ϵ_i belongs to one sentence in $\mathcal{T}$. There is a predefined relation set $\mathcal{R} = (r_1, \ldots, r_L, None)$, where *None* represents that no relation holds for the entities.

This task can be formulated as a binary classification problem of determining whether $\epsilon_1, \ldots, \epsilon_N$ together form a relation (Peng et al., 2017), or a multi-class classification problem of detecting which relation holds for the entity mentions. Take Table 1 as an example. The binary classification task is to determine whether *gefitinib* would have an effect on this type of cancer, given a cancer patient with *858E* mutation on gene *EGFR*. The multi-class classification task is to detect the exact drug effect: response, resistance, sensitivity, etc.

3 Baseline: Bi-directional DAG LSTM

Peng et al. (2017) formulate the task as a graph-structured problem in order to adopt rich dependency and discourse features. In particular, Stanford parser (Manning et al., 2014) is used to assign syntactic structure to input sentences, and heads of two consecutive sentences are connected to represent discourse information, resulting in a graph structure. For each input graph $G = (V, E)$, the nodes V are words within input sentences, and each edge $e \in E$ connects two words that either have a relation or are adjacent to each other. Each edge is denoted as a triple (i, j, l), where i and j are the indices of the source and target words, respectively, and the edge label l indicates either a dependency or discourse relation (such as "nsubj") or a relative position (such as "next_tok" or "prev_tok"). Throughout this paper, we use $E_{in}(j)$ and $E_{out}(j)$ to denote the sets of incoming and outgoing edges for word j.

For a bi-directional DAG LSTM baseline, we follow Peng et al. (2017), splitting each input graph into two separate DAGs by separating left-to-right edges from right-to-left edges (Figure 1). Each DAG is encoded by using a DAG LSTM (Section 3.2), which takes both source words and edge labels as inputs (Section 3.1). Finally, the hidden states of entity mentions from both LSTMs are taken as inputs to a logistic regression classifier to make a prediction:

$$\hat{y} = \text{softmax}(W_0[h_{\epsilon_1}; \ldots; h_{\epsilon_N}] + b_0), \quad (1)$$

where h_{ϵ_j} is the hidden state of entity ϵ_j. W_0 and b_0 are parameters.

3.1 Input Representation

Both nodes and edge labels are useful for modeling a syntactic graph. As the input to our DAG LSTM, we first calculate the representation for each edge (i, j, l) by:

$$x_{i,j}^{l} = W_1\Big([e_l; e_i]\Big) + b_1, \quad (2)$$

where W_1 and b_1 are model parameters, e_i is the embedding of the source word indexed by i, and e_l is the embedding of the edge label l.

3.2 State transition

The baseline LSTM model learns DAG representations sequentially, following word orders. Taking the edge representations (such as $x_{i,j}^{l}$) as input, gated state transition operations are executed on both the forward and backward DAGs. For each word j, the representations of its incoming edges $E_{in}(j)$ are summed up as one vector:

$$x_j^{in} = \sum_{(i,j,l) \in E_{in}(j)} x_{i,j}^{l} \quad (3)$$

Similarly, for each word j, the states of all incoming nodes are summed to a single vector before being passed to the gated operations:

$$h_j^{in} = \sum_{(i,j,l) \in E_{in}(j)} h_i \quad (4)$$

Finally, the gated state transition operation for the hidden state h_j of the j-th word can be defined as:

$$\begin{aligned}
i_j &= \sigma(W_i x_j^{in} + U_i h_j^{in} + b_i) \\
o_j &= \sigma(W_o x_j^{in} + U_o h_j^{in} + b_o) \\
f_{i,j} &= \sigma(W_f x_{i,j}^{l} + U_f h_i + b_f) \\
u_j &= \sigma(W_u x_j^{in} + U_u h_j^{in} + b_u) \\
c_j &= i_j \odot u_j + \sum_{(i,j,l) \in E_{in}(j)} f_{i,j} \odot c_i \\
h_j &= o_j \odot \tanh(c_j),
\end{aligned} \quad (5)$$

where i_j, o_j and $f_{i,j}$ are a set of input, output and forget gates, respectively, and W_x, U_x and b_x ($x \in \{i, o, f, u\}$) are model parameters.

3.3 Comparison with Peng et al. (2017)

Our baseline is computationally similar to Peng et al. (2017), but different on how to utilize edge labels in the gated network. In particular, Peng et al. (2017) make model parameters specific to edge labels. They consider two model variations, namely *Full Parametrization (FULL)* and *Edge-Type Embedding (EMBED)*. *FULL* assigns distinct

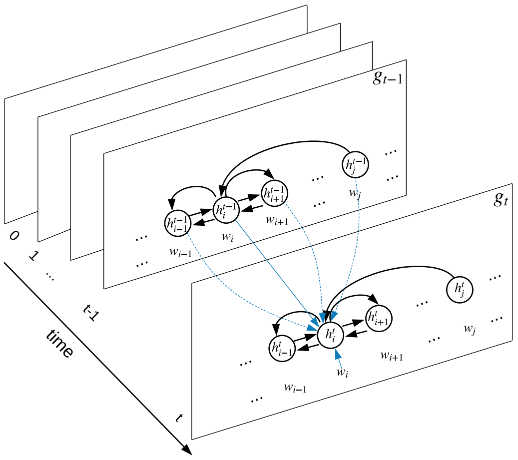

Figure 2: Graph state transitions via message passing, where each w_i is a word.

Us (in Equation 5) to different edge types, so that each edge label is associated with a 2D weight matrix to be tuned in training. On the other hand, *EMBED* assigns each edge label to an embedding vector, but complicates the gated operations by changing the Us to be 3D tensors.[1]

In contrast, we take edge labels as part of the input to the gated network. In general, the edge labels are first represented as embeddings, before being concatenated with the node representation vectors (Equation 2). We choose this setting for both the baseline and our graph state LSTM model in Section 4, since it requires fewer parameters compared with *FULL* and *EMBED*, thus being less exposed to overfitting on small-scaled data.

4 Graph State LSTM

Our input graph formulation strictly follows Section 3. In particular, our model adopts the same methods for calculating input representation (as in Section 3.1) and performing classification as the baseline model. However, different from the baseline bidirectional DAG LSTM model, we leverage a graph-structured LSTM to directly model the input graph, without splitting it into two DAGs.

Figure 2 shows an overview of our model. Formally, given an input graph $G = (V, E)$, we define a state vector h^j for each word $v_j \in V$. The state of the graph consists of all word states, and thus can be represented as:

$$g = \{h^j\}|_{v_j \in V} \tag{6}$$

In order to capture non-local information, our model performs information exchange between words through a recurrent state transition process, resulting in a sequence of graph states $g_0, g_1, \ldots, g_t$, where $g_t = \{h_t^j\}|_{v_j \in V}$. The initial graph state g_0 consists of a set of initial word states $h_0^j = h_0$, where h_0 is a zero vector.

4.1 State transition

Following the approches of Song et al. (2018) and Zhang et al. (2018), a recurrent neural network is utilized to model the state transition process. In particular, the transition from g_{t-1} to g_t consists of hidden state transition for each word, as shown in Figure 2. At each step t, we allow information exchange between a word and all words that are directly connected to the word. To avoid gradient diminishing or bursting, gated LSTM cells are adopted, where a cell c_t^j is taken to record memory for h_t^j. We use an input gate i_t^j, an output gate o_t^j and a forget gate f_t^j to control information flow from the inputs and to h_t^j.

The inputs to a word v_j, include representations of edges that are connected to v_j, where v_j can be either the source or the target of the edge. Similar to Section 3.1, we define each edge as a triple (i, j, l), where i and j are indices of the source and target words, respectively, and l is the edge label. $x_{i,j}^l$ is the representation of edge (i, j, l). The inputs for v_j are distinguished by incoming and outgoing directions, where:

$$\begin{aligned} x_j^i &= \sum_{(i,j,l) \in E_{in}(j)} x_{i,j}^l \\ x_j^o &= \sum_{(j,k,l) \in E_{out}(j)} x_{j,k}^l \end{aligned} \tag{7}$$

Here $E_{in}(j)$ and $E_{out}(j)$ denote the sets of incoming and outgoing edges of v_j, respectively.

In addition to edge inputs, a cell also takes the hidden states of its incoming and outgoing words during a state transition. In particular, the states of all incoming words and outgoing words are summed up, respectively:

$$\begin{aligned} h_j^i &= \sum_{(i,j,l) \in E_{in}(j)} h_{t-1}^i \\ h_j^o &= \sum_{(j,k,l) \in E_{out}(j)} h_{t-1}^k, \end{aligned} \tag{8}$$

Based on the above definitions of x_j^i, x_j^o, h_j^i and h_j^o, the recurrent state transition from g_{t-1} to g_t,

---

[1] For more information please refer Section 3.3 of Peng et al. (2017).

as represented by h_t^j, is defined as:

$$\begin{aligned}
i_t^j &= \sigma(W_i x_j^i + \hat{W}_i x_j^o + U_i h_j^i + \hat{U}_i h_j^o + b_i)\\
o_t^j &= \sigma(W_o x_j^i + \hat{W}_o x_j^o + U_o h_j^i + \hat{U}_o h_j^o + b_o)\\
f_t^j &= \sigma(W_f x_j^i + \hat{W}_f x_j^o + U_f h_j^i + \hat{U}_f h_j^o + b_f)\\
u_t^j &= \sigma(W_u x_j^i + \hat{W}_u x_j^o + U_u h_j^i + \hat{U}_u h_j^o + b_u)\\
c_t^j &= f_t^j \odot c_{t-1}^j + i_t^j \odot u_t^j\\
h_t^j &= o_t^j \odot \tanh(c_t^j),
\end{aligned}$$

where i_t^j, o_t^j and f_t^j are the input, output and forget gates, respectively. W_x, $\hat{W}_x$, U_x, $\hat{U}_x$, b_x ($x \in \{i, o, f, u\}$) are model parameters.

Graph State LSTM vs bidirectional DAG LSTM A contrast between the baseline DAG LSTM and our graph LSTM can be made from the perspective of information flow. For the baseline, information flow follows the natural word order in the input sentence, with the two DAG components propagating information from left to right and from right to left, respectively. In contrast, information flow in our graph state LSTM is relatively more concentrated at individual words, with each word exchanging information with all its graph neighbors simultaneously at each sate transition. As a result, wholistic contextual information can be leveraged for extracting features for each word, as compared to separated handling of bi-directional information flow in DAG LSTM. In addition, arbitrary structures, including arbitrary cyclic graphs, can be handled.

From an initial state with isolated words, information of each word propagates to its graph neighbors after each step. Information exchange between non-neighboring words can be achieved through multiple transition steps. We experiment with different transition step numbers to study the effectiveness of global encoding. Unlike the baseline DAG LSTM encoder, our model allows parallelization in node-state updates, and thus can be highly efficient using a GPU.

5 Training

We train our models with a cross-entropy loss over a set of gold standard data:

$$l = -\log p(y_i | X_i; \theta), \tag{9}$$

where X_i is an input graph, y_i is the gold class label of X_i, and θ is the model parameters. Adam (Kingma and Ba, 2014) with a learning rate of 0.001 is used as the optimizer, and the model that yields the best devset performance is selected to evaluate on the test set. Dropout with rate 0.3 is used during training. Both training and evaluation are conducted using a Tesla K20X GPU.

Data	Avg. Tok.	Avg. Sent.	Cross
TERNARY	73.9	2.0	70.1%
BINARY	61.0	1.8	55.2%

Table 2: Dataset statistics. *Avg. Tok.* and *Avg. Sent.* are the average number of tokens and sentences, respectively. *Cross* is the percentage of instances that contain multiple sentences.

6 Experiments

We conduct experiments for the binary relation detection task and the multi-class relation extraction task discussed in Section 2.

6.1 Data

We use the dataset of Peng et al. (2017), which is a biomedical-domain dataset focusing on drug-gene-mutation ternary relations,[2] extracted from PubMed. It contains 6987 ternary instances about drug-gene-mutation relations, and 6087 binary instances about drug-mutation sub-relations. Table 2 shows statistics of the dataset. Most instances of ternary data contain multiple sentences, and the average number of sentences is around 2. There are five classification labels: “resistance or non-response”, “sensitivity”, “response”, “resistance” and “None”. We follow Peng et al. (2017) and binarize multi-class labels by grouping all relation classes as “Yes” and treat “None” as “No”.

6.2 Settings

Following Peng et al. (2017), five-fold cross-validation is used for evaluating the models,[3] and the final test accuracy is calculated by averaging the test accuracies over all five folds. For each fold, we randomly separate 200 instances from the training set for development. The batch size is set as 8 for all experiments. Word embeddings are initialized with the 100-dimensional GloVe (Pennington et al., 2014) vectors, pretrained on 6 billion words from Wikipedia and web text. The edge label embeddings are 3-dimensional and randomly

---

[2] The dataset is available at `http://hanover.azurewebsites.net`.

[3] The released data has been separated into 5 portions, and we follow the exact split.

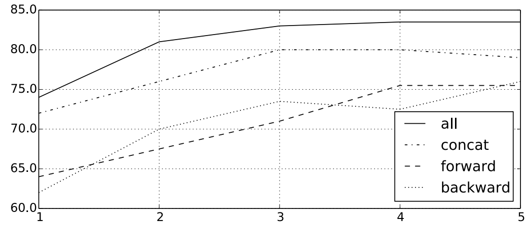

Figure 3: Dev accuracies against transition steps for the graph state LSTM model.

initialized. Pretrained word embeddings are not updated during training. The dimension of hidden vectors in LSTM units is set to 150.

6.3 Development Experiments

We first analyze our model on the drug-gene-mutation ternary relation dataset, taking the first among 5-fold cross validation settings for our data setting. Figure 3 shows the devset accuracies of different state transition numbers, where *forward* and *backward* execute our graph state model only on the forward or backward DAG, respectively. *Concat* concatenates the hidden states of *forward* and *backward*. *All* executes our graph state model on original graphs.

The performance of *forward* and *backward* lag behind *concat*, which is consistent with the intuition that both forward and backward relations are useful (Peng et al., 2017). In addition, *all* gives better accuracies compared with *concat*, demonstrating the advantage of simultaneously considering forward and backward relations during representation learning. For all the models, more state transition steps result in better accuracies, where larger contexts can be integrated in the representations of graphs. The performance of *all* starts to converge after 4 and 5 state transitions, so we set the number of state transitions to 5 in the remaining experiments.

6.4 Final results

Table 3 compares our model with the bidirectional DAG baseline and the state-of-the-art results on this dataset, where *EMBED* and *FULL* have been briefly introduced in Section 3.3. *+multi-task* applies joint training of both ternary (drug-gene-mutation) relations and their binary (drug-mutation) sub-relations. Quirk and Poon (2017) use a statistical method with a logistic regression classifier and features derived from shortest paths between all entity pairs. *Bidir DAG LSTM* is our bidirectional DAG LSTM baseline, and *GS GLSTM* is our graph state LSTM model.

Model	Single	Cross
Quirk and Poon (2017)	74.7	77.7
Peng et al. (2017) - EMBED	76.5	80.6
Peng et al. (2017) - FULL	77.9	80.7
+ multi-task	–	82.0
Bidir DAG LSTM	75.6	77.3
GS GLSTM	**80.3***	**83.2***

Table 3: Average test accuracies for TERNARY drug-gene-mutation interactions. *Single* represents experiments only on instances within single sentences, while *Cross* represents experiments on all instances. *: significant at $p < 0.01$

Using all instances (the *Cross* column in Table 3), our graph state LSTM model shows the highest test accuracy among all methods, which is 5.9% higher than our baseline.[4] The accuracy of our baseline is lower than *EMBED* and *FULL* of Peng et al. (2017), which is likely due to the differences mentioned in Section 3.3. Our final results are better than Peng et al. (2017), despite the fact that we do not use multi-task learning.

We also report accuracies only on instances within single sentences (column *Single* in Table 3), which exhibit similar contrasts. Note that all systems show performance drops when evaluated only on single-sentence relations, which are actually more challenging. One reason may be that some single sentences cannot provide sufficient context for disambiguation, making it necessary to study cross-sentence context. Another reason may be overfitting caused by relatively fewer training instances in this setting, as only 30% instances are within a single sentence. One interesting observation is that our baseline shows the least performance drop of 1.7 points, in contrast to up to 4.1 for other neural systems. This can be a supporting evidence for overfitting, as our baseline has fewer parameters at least than *FULL* and *EMBED*.

6.5 Analysis

Efficiency. Table 4 shows the training and decoding time of both the baseline and our model. Our model is 8 to 10 times faster than the baseline in training and decoding speeds, respectively. By revisiting Table 2, we can see that the average number of tokens for the ternary-relation data is

---

[4] $p < 0.01$ using t-test. For the remaining of this paper, we use the same measure for statistical significance.

Model	Train	Decode
Bidir DAG LSTM	281s	27.3s
GS GLSTM	36.7s	2.7s

Table 4: The average times for training one epoch and decoding (seconds) over five folds on drug-gene-mutation TERNARY cross sentence setting.

74, which means that the baseline model has to execute 74 recurrent transition steps for calculating a hidden state for each input word. On the other hand, our model only performs 5 state transitions, and calculations between each pair of nodes for one transition are parallelizable. This accounts for the better efficiency of our model.

Accuracy against sentence length Figure 5 (a) shows the test accuracies on different sentence lengths. We can see that *GS GLSTM* and *Bidir DAG LSTM* show performance increase along increasing input sentence lengths. This is likely because longer contexts provide richer information for relation disambiguation. *GS GLSTM* is consistently better than *Bidir DAG LSTM*, and the gap is larger on shorter instances. This demonstrates that *GS GLSTM* is more effective in utilizing a smaller context for disambiguation.

Accuracy against the maximal number of neighbors Figure 5 (b) shows the test accuracies against the maximum number of neighbors. Intuitively, it is easier to model graphs containing nodes with more neighbors, because these nodes can serve as a "supernode" that allow more efficient information exchange. The performances of both *GS GLSTM* and *Bidir DAG LSTM* increase with increasing maximal number of neighbors, which coincide with this intuition. In addition, *GS GLSTM* shows more advantage than *Bidir DAG LSTM* under the inputs having lower maximal number of neighbors, which further demonstrates the superiority of *GS GLSTM* over *Bidir DAG LSTM* in utilizing context information.

Case study Figure 4 visualizes the merits of *GS GLSTM* over *Bidir DAG LSTM* using two examples. *GS GLSTM* makes the correct predictions for both cases, while *Bidir DAG LSTM* fails to.

The first case generally mentions that *Gefitinib* does not have an effect on *T790M* mutation on *EGFR* gene. Note that both "However" and "was not" serve as indicators; thus incorporating them into the contextual vectors of these entity mentions is important for making a correct prediction. However, both indicators are leaves of the dependency tree, making it impossible for *Bidir DAG LSTM* to incorporate them into the contextual vectors of entity mentions up the tree through dependency edges.[5] On the other hand, it is easier for *GS GLSTM*. For instance, "was not" can be incorporated into "Gefitinib" through "suppressed $\xrightarrow{\text{agent}}$ treatment $\xrightarrow{\text{nn}}$ Gefitinib".

Model	Single	Cross
Quirk and Poon (2017)	73.9	75.2
Miwa and Bansal (2016)	75.9	75.9
Peng et al. (2017) - EMBED	74.3	76.5
Peng et al. (2017) - FULL	75.6	76.7
+ multi-task	–	78.5
Bidir DAG LSTM	76.9	76.4
GS GLSTM	**83.5***	**83.6***

Table 5: Average test accuracies in five-fold cross-validation for BINARY drug-mutation interactions.

The second case is to detect the relation among "cetuximab" (drug), "EGFR" (gene) and "S492R" (mutation), which does not exist. However, the context introduces further ambiguity by mentioning another drug "Panitumumab", which does have a relation with "EGFR" and "S492R". Being sibling nodes in the dependency tree, "can not" is an indicator for the relation of "cetuximab". *GS GLSTM* is correct, because "can not" can be easily included into the contextual vector of "cetuximab" in two steps via "bind $\xrightarrow{\text{nsubj}}$cetuximab".

6.6 Results on Binary Sub-relations

Following previous work, we also evaluate our model on drug-mutation binary relations. Table 5 shows the results, where Miwa and Bansal (2016) is a state-of-the-art model using sequential and tree-structured LSTMs to jointly capture linear and dependency contexts for relation extraction. Other models have been introduced in Section 6.4.

Similar to the ternary relation extraction experiments, *GS GLSTM* outperforms all the other systems with a large margin, which shows that the message passing graph LSTM is better at encoding rich linguistic knowledge within the input graphs. Binary relations being easier, both *GS GLSTM* and *Bidir DAG LSTM* show increased or similar performances compared with the ternary relation ex-

---

[5] As shown in Figure 1, a directional DAG LSTM propagates information according to the edge directions.

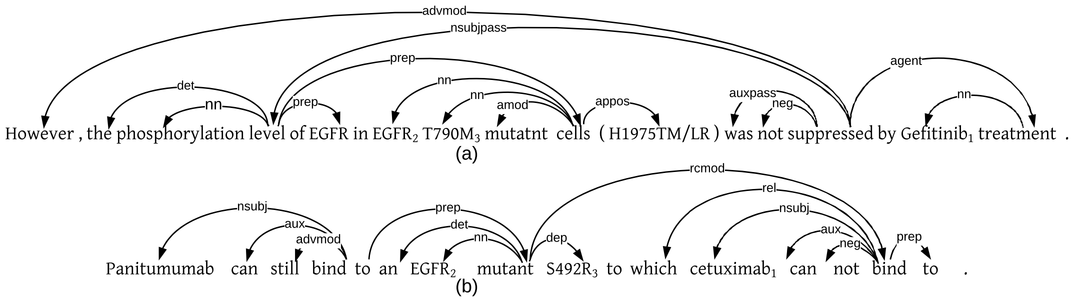

Figure 4: Example cases. Words with subindices 1, 2 and 3 represent drugs, genes and mutations, respectively. References for both cases are “No”. For both cases, *GS GLSTM* makes the correct predictions, while *Bidir DAG LSTM* does incorrectly.

periments. On this set, our bidirectional DAG LSTM model is comparable to *FULL* using all instances (“Cross”) and slightly better than *FULL* using only single-sentence instances (“Single”).

6.7 Fine-grained Classification

Our dataset contains five classes as mentioned in Section 6.1. However, previous work only investigates binary relation detection. Here we also study the multi-class classification task, which can be more informative for applications.

Table 6 shows accuracies on multi-class relation extraction, which makes the task more ambiguous compared with binary relation extraction. The results show similar comparisons with the binary relation extraction results. However, the performance gaps between *GS GLSTM* and *Bidir DAG LSTM* dramatically increase, showing the superiority of *GS GLSTM* over *Bidir DAG LSTM* in utilizing context information.

7 Related Work

N-ary relation extraction N-ary relation extractions can be traced back to MUC-7 (Chinchor, 1998), which focuses on entity-attribution relations. It has also been studied in biomedical domain (McDonald et al., 2005), but only the instances within a single sentence are considered. Previous work on cross-sentence relation extraction relies on either explicit co-reference annotation (Gerber and Chai, 2010; Yoshikawa et al., 2011), or the assumption that the whole document refers to a single coherent event (Wick et al., 2006; Swampillai and Stevenson, 2011). Both simplify the problem and reduce the need for learning better contextual representation of entity mentions. A notable exception is Quirk and Poon (2017), who adopt distant supervision and integrated contextual evidence of diverse types without relying on these assumptions. However, they only study binary relations. We follow Peng et al. (2017) by studying ternary cross-sentence relations.

Graph encoder Liang et al. (2016) build a graph LSTM model for semantic object parsing, which aims to segment objects within an image into more fine-grained, semantically meaningful parts. The nodes of an input graph come from image superpixels, and the edges are created by connecting spatially neighboring nodes. Their model is similar as Peng et al. (2017) by calculating node states sequentially: for each input graph, a start node and a node sequence are chosen, which determines the order of recurrent state updates. In contrast, our graph LSTM do not need ordering of graph nodes, and is highly parallelizable.

Graph convolutional networks (GCNs) and very recently graph recurrent networks (GRNs) have been used to model graph structures in NLP tasks, such as semantic role labeling (Marcheggiani and Titov, 2017), machine translation (Bastings et al., 2017), text generation (Song et al., 2018), text representation (Zhang et al., 2018) and semantic parsing (Xu et al., 2018b,a). In particular, Zhang et al. (2018) use GRN to represent raw sentences by building a graph structure of neighboring words and a sentence-level node, showing that the encoder outperforms BiLSTMs and Transformer (Vaswani et al., 2017) on classification and sequence labeling tasks; Song et al. (2018) build a GRN for encoding AMR graphs, showing that the representation is superior compared to BiLSTM on serialized AMR. Our work is in line with their work in the investigation of GRN on NLP. To our knowledge, we are the first to use GRN for representing dependency and discourse structures. Under the same recurrent framework, we show that modeling the original graphs with one GRN model is more useful than two DAG LSTMs for our relation extraction task. We choose GRN as our main method because it gives a more fair comparison with DAG LSTM. We leave it to future work to compare GCN and GRN for our task.

8 Conclusion

We explored a graph-state LSTM model for cross-sentence n-ary relation extraction, which uses a recurrent state transition process to incrementally refine a neural graph state representation capturing graph structure contexts. Compared with a bidirectional DAG LSTM baseline, our model has several advantages. First, it does not change the input graph structure, so that no information can be lost. For example, it can easily incorporate sibling information when calculating the contextual vector of a node. Second, it is better parallelizable. Experiments show significant improvements over the previously reported numbers, including that of the bidirectional graph LSTM model.

For future work, we consider adding coreference information as an entity mention can have coreferences, which help on information collection. Another possible direction is including word sense information. Confusing caused by word senses can be a severe problem. Not only content words, but also propositions can introduce word sense problem (Gong et al., 2018).

Abstract

Distantly supervised relation extraction employs existing knowledge graphs to automatically collect training data. While distant supervision is effective to scale relation extraction up to large-scale corpora, it inevitably suffers from the wrong labeling problem. Many efforts have been devoted to identifying valid instances from noisy data. However, most existing methods handle each relation in isolation, regardless of rich semantic correlations located in relation hierarchies. In this paper, we aim to incorporate the hierarchical information of relations for distantly supervised relation extraction and propose a novel hierarchical attention scheme. The multiple layers of our hierarchical attention scheme provide coarse-to-fine granularity to better identify valid instances, which is especially effective for extracting those long-tail relations. The experimental results on a large-scale benchmark dataset demonstrate that our models are capable of modeling the hierarchical information of relations and significantly outperform other baselines. The source code of this paper can be obtained from `https://github.com/thunlp/HNRE`.

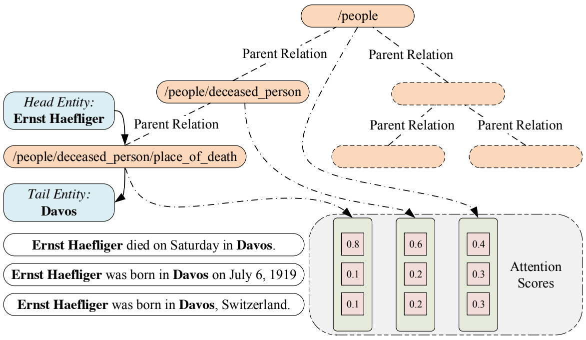

Figure 1: An example of hierarchical relation extraction.

1 Introduction

Relation extraction (RE) aims to predict relational facts from plain text. Conventional supervised RE models (Zelenko et al., 2003; Mooney and Bunescu, 2006) usually suffer from the lack of high-quality training data, because manual labeling of training data is time-consuming and human-intensive. Mintz et al. (2009) propose distant supervision to automatically label training instances by aligning existing knowledge graphs (KGs) and text: For an entity pair in KGs, those sentences containing both the entities will be labeled with the corresponding relation of the entity pair in KGs. RE relies on distant supervision to scale up to large-scale training corpora. However, this automatic mechanism is inevitably accompanied by the wrong labeling problem, because not all sentences containing two entities can exactly express their relations in KGs, e.g., we may mistakenly label "*Bill Gates* retired from *Microsoft*" with the relation `business/company/founders`.

To alleviate the wrong labeling problem, many efforts (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Zeng et al., 2015) have been devoted to identifying valid instances from noisy data, especially the recent state-of-the-art attention-based methods (Lin et al., 2016; Ji et al., 2017; Liu et al., 2017; Wu et al., 2017). Nevertheless, each relation is handled in isolation in most existing methods. For each relation, there is often a separate model (e.g. neural attention scheme) to select relation-related informative instances from noisy data, regardless of rich semantic correlations among relations, typically located in the form of relation hierarchies.

We take the KG Freebase (Bollacker et al., 2008) as an example, in which relations are labeled as hierarchical structures. For example, the

Brussels, Belgium, October 31 - November 4, 2018.

relation `/location/province/capital` in Freebase indicates the relation between a province and its capital. It is labeled under the `location` branch. Under this branch, there are some other relations `/location/location/contains` and `/location/country/capital`, which are closely correlated to each other. The rich correlations among relations are well revealed by these relation hierarchies. In fact, McCallum et al. (1998) take advantage of hierarchies of classes to improve classification models and inspire many later models (Rousu et al., 2005; Weinberger and Chapelle, 2009). Furthermore, the hierarchical information of entities in KGs has also been utilized and demonstrated to be effective for model enhancement (Hu et al., 2015; Xie et al., 2016).

To take advantage of the rich correlated information among relations, we propose a novel hierarchical attention scheme via utilizing the relation hierarchies, rather than directly utilizing hierarchical information as features for models. Similar to the conventional attention-based method, our method also computes an attention score for each instance according to its significance of expressing the corresponding relation. The key difference is that, as illustrated in Figure 1, our hierarchical attention scheme follows the relation hierarchies to compute scores for those instances containing the same entity pair on the each layer of the hierarchies.

The hierarchical attention scheme provides coarse-to-fine granularity for identifying valid instances. The attention on the bottom layer can capture more specific features of the relation, which has a comparable ability of fine-grained instance selection like conventional attention-based methods. The attention on the top-layer can capture the common features shared by several related subrelations, which provides coarse-grained instance selection. Since there are more sufficient data for training the top-layer attention, the whole hierarchical attention scheme can enhance RE models for solving those long-tail relations.

We conduct experiments on a large-scale benchmark dataset for RE in this paper. The experimental results show that the proposed coarse-to-fine grained attention scheme based on relation hierarchies significantly outperforms other baseline methods, even as compared to the recent state-of-the-art attention-based models, especially for those long-tail relations.

2 Related Works

Supervised models (Zelenko et al., 2003; Zhou et al., 2005; Mooney and Bunescu, 2006) for RE require adequate amounts of annotated data for their training. It is time-consuming to manually label large-scale training data. Hence, Mintz et al. (2009) propose distant supervision to automatically label data. Distant supervision inevitably accompanies with the wrong labeling problem. To alleviate the noise issue caused by distant supervision, Riedel et al. (2010) and Hoffmann et al. (2011) propose multi-instance learning (MIL) mechanisms. Riedel et al. (2013) propose universal schema to transmit information between relations of KGs and textual patterns to enhance extraction performance.

These early RE methods mainly extract semantic features using NLP tools to build relation classifiers. Recently, neural models have been widely used for RE. These neural models can accurately capture textual relations without explicit linguistic analysis (Zeng et al., 2014; Xu et al., 2015; Santos et al., 2015; Zhang and Wang, 2015; Verga et al., 2016; Verga and McCallum, 2016). Zeng et al. (2015) employ the MIL scheme by selecting one most valid instance for distantly supervised neural relation extraction (NRE), whose denoising capability is far from satisfactory because most informative instances are neglected. Lin et al. (2016) and Zhang et al. (2017) propose neural attention schemes to select those informative instances. To further improve the attention performance, some works incorporate knowledge information (Zeng et al., 2017; Ji et al., 2017; Han et al., 2018) and advanced training strategies (Liu et al., 2017; Huang and Wang, 2017). More sophisticated mechanisms, such as reinforcement learning (Feng et al., 2018; Zeng et al., 2018) and adversarial training (Wu et al., 2017), have also been adapted for RE recently.

However, most existing works model each relation in isolation to identify informative instances, neglecting rich correlations among relations, especially the hierarchical information of those relations. Hierarchical information is widely applied for model enhancement, especially for classification models (McCallum et al., 1998; Rousu et al., 2005; Weinberger and Chapelle, 2009; Zhao et al., 2011; Bi and Kwok, 2011; Zhou et al., 2011; Verma et al., 2012). Many efforts are also devoted to utilizing hierarchical information in KGs.

Leacock and Chodorow (1998) and Ponzetto and Strube (2007) adopt hierarchical information derived from KGs to construct concept relatedness. Morin and Bengio (2005) propose a neural language model by utilizing hierarchical information in WordNet. Further, Hu et al. (2015) learn entity representations by considering the whole entity hierarchies of Wikipedia and inspire many works (Krompaß et al., 2015; Xie et al., 2016) to utilize hierarchical type structures to help the representation learning of KGs.

Different from the recent hierarchical models that mainly focus on entity hierarchies and directly utilize hierarchical information as simple features, we incorporate relation hierarchies to build a hierarchical attention scheme with coarse-to-fine granularity to enhance RE performance. As compared with the existing models for RE, our models could take advantage of relation correlations to better identify informative instances, especially for those long-tail relations, by transferring the knowledge from their related relations of high-frequency.

3 Methodology

In this section, we introduce the overall framework of our hierarchical attention for RE, starting with notations and definitions.

3.1 Notations

We denote a KG as $\mathcal{G} = \{\mathcal{E}, \mathcal{R}, \mathcal{F}\}$, where $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{F}$ indicate the sets of entities, relations and facts respectively. $(h, r, t) \in \mathcal{F}$ indicates that there is a relation $r \in \mathcal{R}$ between $h \in \mathcal{E}$ and $t \in \mathcal{E}$. We follow the MIL setting and split the entire instances into multiple entity-pair bags $\{\mathcal{S}_{h_1,t_1}, \mathcal{S}_{h_2,t_2}, \ldots\}$. Each bag $\mathcal{S}_{h_i,t_i}$ contains multiple instances $\{s_1, s_2, \ldots\}$ mentioning both the entities h_i and t_i. The distant supervision mechanism will label the bag with the corresponding relation of the mentioned entity pair. Each instance s in these bags is denoted as a word sequence $s = \{w_1, w_2, \ldots\}$.

3.2 Framework

Given an entity pair (h, t) and its entity-pair bag $\mathcal{S}_{h,t}$, we adopt our models to measure the probability of each relation $r \in \mathcal{R}$ holding between the pair. As shown in Figure 2, the overall framework of our models includes a sentence encoder and a coarse-to-fine grained hierarchical attention. The sentence encoder adopts several convolutional neural networks to represent sentence semantics with embeddings, and the hierarchical attention is used to select the most informative instances to exactly express their relations.

For each instance $s_i \in \mathcal{S}_{h,t}$, we use the sentence encoder to represent its semantic information as an embedding $\mathbf{s}_i$. The details of the sentence encoder will be introduced in Section 3.3. Since not all instances in the bag $\mathcal{S}_{h,t}$ are positive to express the relation between h and t, we apply the hierarchical attention to compute an instance weight α_i for each instance s_i. The details of the hierarchical attention will be introduced in Section 3.4. We build the global textual relation representation $\mathbf{r}_{h,t}$ with the weighted sum of instance output embeddings,

$$\mathbf{r}_{h,t} = \sum_{i=1}^{m} \alpha_i \mathbf{s}_i, \quad s_1, \ldots, s_m \in \mathcal{S}_{h,t}. \tag{1}$$

Here α_i is the instance weight for the ith instance output embedding $\mathbf{s}_i$. By taking $\mathbf{r}_{h,t}$ as the textual relation representation of the entity pair (h, t), we estimate its probability over each relation $r \in \mathcal{R}$, i.e., whether there is a specific relation r between h and t. We define the conditional probability $P(r|h, t, \mathcal{S}_{h,t})$,

$$P(r|h, t, \mathcal{S}_{h,t}) = \frac{\exp(\mathbf{o}_r)}{\sum_{\tilde{r}\in\mathcal{R}} \exp(\mathbf{o}_{\tilde{r}})}, \tag{2}$$

where $\mathbf{o}$ is the scores of all relations, which is defined as follows,

$$\mathbf{o} = \mathbf{M}\mathbf{r}_{h,t}, \tag{3}$$

where $\mathbf{M}$ is the representation matrix to calculate the relation scores.

3.3 Sentence Encoder

Given an instance s containing two entities, we apply several neural architectures to encode the instance into its corresponding embeddings $\mathbf{s}$.

Input Layer

The input layer of the sentence encoder aims to embed both semantic information and positional information of words into their input embeddings.

Word Embedding is proposed by Hinton (1986), which aims to transform words into distributed representations to capture syntactic and semantic meanings of words. Given a sentence s consisting of multiple words $s = \{w_1, \ldots, w_n\}$, we adopt Skip-Gram (Mikolov et al., 2013) to

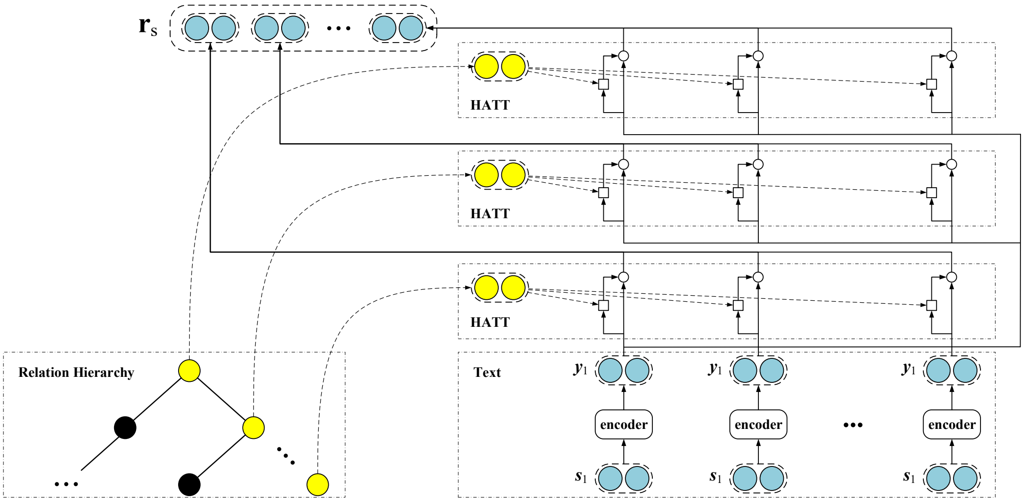

Figure 2: The architecture of hierarchical attention model.

compute all k_w-dimensional word embeddings $\{\mathbf{w}_1, \dots, \mathbf{w}_n\}$.

Position Embedding is proposed by Zeng et al. (2014). Position embedding is used to embed the relative distances of each word to the two entities into two k_p-dimensional vectors. By concatenating the distance embeddings for the current word w_i to the both head and tail entities, we get a unified position embedding $\mathbf{p}_i \in \mathbb{R}^{k_p \times 2}$.

For each word w_i, we concatenate its word embedding $\mathbf{w}_i$ and position embedding $\mathbf{p}_i$ to build its input embedding $\mathbf{x}_i \in \mathbb{R}^{k_i} (k_i = k_w + k_p \times 2)$.

Encoding Layer

The encoding layer aims to compose the input embeddings of the given instance into its corresponding instance embedding. In this paper, we choose two convolutional neural architectures, CNN (Zeng et al., 2014) and PCNN (Zeng et al., 2015), to encode input embeddings into instance embeddings.

Other neural architectures such as recurrent neural architectures (Zhang and Wang, 2015) can also be used as sentence encoders. Since previous works show that both convolutional and recurrent architectures can achieve comparable state-of-the-art performance, we simply select convolutional architectures in this paper. Note that, our hierarchical attention scheme is designed independently to the encoder choices, hence it can be easily adapted to fit other encoder architectures.

CNN slides a convolution kernel with the window size m over the input sequence $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ to get the k_h-dimensional hidden embeddings.

$$\mathbf{h}_i = \text{CNN}\big(\mathbf{x}_{i-\frac{m-1}{2}}, \dots, \mathbf{x}_{i+\frac{m-1}{2}}\big). \tag{4}$$

A max-pooling is then applied over these hidden embeddings to output the final instance embedding $\mathbf{s}$ as follows,

$$[\mathbf{s}]_j = \max_{1 \le i \le n} \{[\mathbf{h}_i]_j\}, \tag{5}$$

where $[\cdot]_j$ is the j-th value of a vector.

PCNN is an extension to CNN, which also adopts a convolution kernel to obtain hidden embeddings. Then, a piecewise max-pooling is applied over the hidden embeddings,

$$\begin{aligned} [\mathbf{s}^{(1)}]_j &= \max_{1 \le i \le i_1} \{[\mathbf{h}_i]_j\}, \\ [\mathbf{s}^{(2)}]_j &= \max_{i_1+1 \le i \le i_2} \{[\mathbf{h}_i]_j\}, \\ [\mathbf{s}^{(3)}]_j &= \max_{i_2+1 \le i \le n} \{[\mathbf{h}_i]_j\}, \end{aligned} \tag{6}$$

where $[\cdot]_j$ is the j-th value of a vector, i_1 and i_2 are entity positions. The final instance embedding $\mathbf{s}$ is achieved by concatenating these three pooling results as follows,

$$\mathbf{s} = [\mathbf{s}^{(1)}; \mathbf{s}^{(2)}; \mathbf{s}^{(3)}]. \tag{7}$$

3.4 Hierarchical Selective Attention

Given the entity pair (h, t) and its bag of instances $S_{h,t} = \{s_1, s_2, \dots, s_m\}$, we achieve the instance embeddings $\{\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_m\}$ using the sentence encoder. Afterwards, we apply a hierarchical selective attention over them to get the textual relation representation $\mathbf{r}_{h,t}$ for extracting relations. In this part, we will first introduce a plain selective attention, and then introduce our hierarchical attention.

Plain Selective Attention

The plain selective attention scheme computes the attention score α_i for each instance s_i to indicate how well the instance can express the relation between the two entities. We assign a query vector $\mathbf{q}_r$ to each relation $r \in \mathcal{R}$ and the attention for each sentence in $\mathcal{S}_{h,t} = \{s_1, s_2, \ldots, s_m\}$ is defined as follows,

$$\begin{aligned} e_i &= \mathbf{q}_r^\top \mathbf{W}_s \mathbf{s}_i, \\ \alpha_i &= \frac{\exp(e_i)}{\sum_{j=1}^{m} \exp(e_j)}, \end{aligned} \tag{8}$$

where $\mathbf{W}_s$ is the weight matrix. The attention scores can be used in Eq. 1 to compute textual relation representations. For simplicity, we denote such a plain selective attention operation as the following equation,

$$\mathbf{r}_{h,t} = \mathrm{ATT}(\mathbf{q}_r, \{\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_m\}). \tag{9}$$

Hierarchical Selective Attention

The inherent hierarchical structure of relations lead us to modeling hierarchical attention. Generally, given a relation set $\mathcal{R}$ of a KG $\mathcal{G}$ (e.g. Freebase), which consists of base-level relations (e.g. `/location/province/capital`), we can generate the corresponding higher-level relation set $\mathcal{R}^H$. The relations in the high-level set (e.g. `location`) are more general and common, which usually contain several sub-relations in the base-level set. We assume that the sub-relations of different relations are disjoint, in other words, the relation hierarchies are tree-structured. The generation process can be done recursively. In practice, we start from $\mathcal{R}^0 = \mathcal{R}$ which is the set of all relations we focus for RE, and generate $k-1$ times to get a total of k-level hierarchical relation sets $\{\mathcal{R}^0, \mathcal{R}^1, \ldots, \mathcal{R}^{k-1}\}$.

As shown in Figure 2, for a relation $r = r^0 \in \mathcal{R} = \mathcal{R}^0$, which is the focus for RE, we construct its hierarchical chain of parent relations by backtracking the relation hierarchy as follows,

$$(r^0, \ldots, r^{k-1}) \in \mathcal{R}^0 \times \ldots \times \mathcal{R}^{k-1}, \tag{10}$$

where r^{i-1} is the sub-relation of r^i.

As with the plain attention, we assign a query vector $\mathbf{q}_r$ to each relation $r \in \bigcup_{i=0}^{k-1} \mathcal{R}^i$. With the hierarchical chain, we compute attention operations on the each layer of the relation hierarchies to obtain corresponding textual relation representations,

$$\mathbf{r}_{h,t}^i = \mathrm{ATT}(\mathbf{q}_{r^i}, \{\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_m\}). \tag{11}$$

During the training process, those relation query vectors of high-level relations (i.e., $\mathbf{q}_{r^i}$ with larger i) have more instances for training than those query vectors of base-level relations. Hence, the high-level query vectors are more robust for instance selection but with coarse-grained capability. In contrast, the base-level query vectors (i.e., $\mathbf{q}_{r^i}$ with smaller i) always suffer from data sparsity, especially for those long-tail base relations. Hence, the base-level query vectors can perform fine-grained instance selection but the performance is not stable.

Based on the hierarchical selective attention, we can simply concatenate the textual relation representations on different layers as the final representation,

$$\mathbf{r}_{h,t} = [\mathbf{r}_{h,t}^0; \ldots; \mathbf{r}_{h,t}^{k-1}]. \tag{12}$$

The representation $\mathbf{r}_{h,t}$ will be finally fed to compute the conditional probability $P(r|h, t, \mathcal{S}_{h,t})$ in Eq. 2. Note that, those high-level representations (i.e., $\mathbf{r}_{h,t}^i$ with larger i) are coarse-grained, and those base-level representations (i.e., $\mathbf{r}_{h,t}^i$ with smaller i) are fine-grained. These hierarchical representations can provide more informative information than single-layered attention for relation prediction, especially for those long-tail relations.

3.5 Initialization and Implementation Details

Here we introduce the learning and optimization details for our hierarchical attention model. During the training process, we minimize the cross entropy loss function. Given the collection of entity-pair bags $\pi = \{\mathcal{S}_{h_1,t_1}, \mathcal{S}_{h_2,t_2}, \ldots\}$ and corresponding labeled relations $\{r_1, r_2, \ldots\}$, we define the loss function as follows,

$$J(\theta) = -\frac{1}{|\pi|} \sum_{i=1}^{|\pi|} \log P(r_i | h_i, t_i, \mathcal{S}_{h_i,t_i}) + \lambda \|\theta\|_2^2, \tag{13}$$

where λ is a harmonic factor, and $\|\theta\|_2^2$ is the regularizer defined as L_2 normalization. All models are optimized using stochastic gradient descent (SGD).

4 Experiments

4.1 Datasets and Evaluation

We evaluate our models on the New York Times (NYT) dataset developed by Riedel et al. (2010), which is widely used in recent works (Lin et al., 2016; Zeng et al., 2017; Ji et al., 2017; Han et al., 2018; Liu et al., 2017; Wu et al., 2017; Huang and Wang, 2017; Feng et al., 2018; Zeng et al., 2018). The dataset has 53 relations including the `NA` relation which indicates relations of instances are not available. The training set has $522,611$ sentences, $281,270$ entity pairs and $18,252$ relational facts. In the test set, there are $172,448$ sentences, $96,678$ entity pairs and $1,950$ relational facts. In both the training and test set, we truncate the sentences which have more than 120 words into 120 words.

We evaluate all models in the held-out evaluation. It evaluates models by comparing the relational facts discovered from the test articles with those in Freebase and provides an approximate measure of precision without human evaluation. For evaluation, we draw precision-recall curves for all models. Besides precision-recall curves, we also show the precision values at the specific recall rate to conduct a more direct comparison, and calculate the micro and macro average precision scores to show the overall effect of different models. To further verify the effect of our hierarchical attention for few-shot entity pairs, we follow the previous works to report the Precision@N results. The dataset and baseline code can be found from Github [1] (Lin et al., 2016; Wu et al., 2017; Liu et al., 2017).

4.2 Parameter Settings

To fairly compare the results of our hierarchical attention models with those baselines, we also set most of the experimental parameters following Lin et al. (2016). Table 1 shows all experimental parameters used in the experiments. We apply dropout on the output layers of our models to prevent overfitting. For CNN, we set the dropout rate to 0.5. For PCNN, we observe that this model tends to overfit on the training set very quickly, and hence we set the dropout rate to 0.9 to alleviate the overfitting problem. We also pre-train the sentence encoder of PCNN before training our hierarchical attention.

Batch Size B	160
Learning Rate α	0.2
Hidden Layer Dimension k_c for CNNs	230
Word Dimension k_w	50
Position Dimension k_p	5
Convolution Kernel Size m	3

Table 1: Parameter settings.

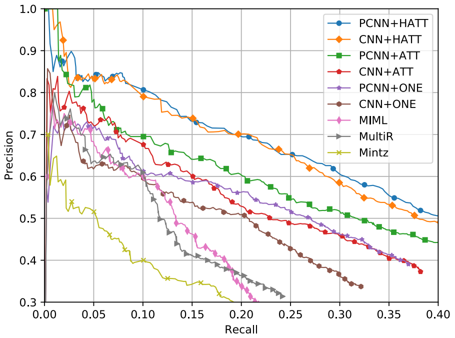

Figure 3: Precision-recall curves for the proposed model and various baseline models.

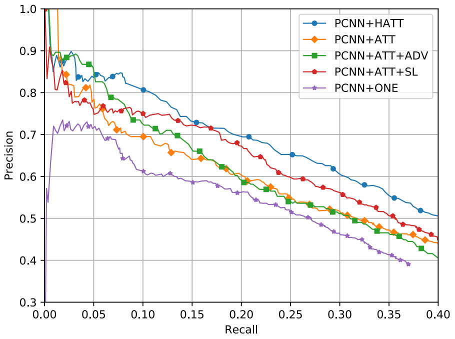

Figure 4: Precision-recall curves for the proposed model and various attention-based neural models.

4.3 Overall Evaluation Results

To evaluate the performance of our proposed hierarchical models, we compare the precision-recall curves of our models with various previous relation extraction models. The evaluation results are shown in Figure 3 and Figure 4. We report the results of the neural architectures including CNN and PCNN with various attention-based methods: **+HATT** is our hierarchical attention method; **+ATT** is the plain selective attention method over instances (Lin et al., 2016); **+ATT+ADV** is the denoising attention method by adding a small adversarial perturbation to instance embeddings (Wu et al., 2017); **+ATT+SL** is the attention-based model using soft-labeling method to mitigate the side effect of the wrong label-

---

[1] NRE, AtNRE and soft-label-RE

ing problem at entity-pair level (Liu et al., 2017); **+ONE** is a vanilla MIL neural model without attention schemes (Zeng et al., 2015). We also compare our method with feature-based models, including **Mintz** (Mintz et al., 2009), **MultiR** (Hoffmann et al., 2011) and **MIML** (Surdeanu et al., 2012).

From the results, we observe that:

(1) All methods have reasonable precision when recall is smaller than 0.05. When the recall gradually grows, the performance of the feature-based methods drops much more faster than those neural models. It shows that human-designed features are very limited as compared to neural models, especially in a noisy data environment. Hence, for simplicity, we mainly show the results of our models and other attention-based neural models in the following experiments.

(2) Both for CNNs and PCNNs, the models with attention schemes outperform the vanilla models without attention schemes. Though vanilla neural models are powerful for relation classification, it is still difficult to address data noise. The attention-based methods apply attentions over multiple instances and dynamically reduce the influence of noisy instances, which can effectively improve the performance of RE and achieve the state-of-the-art results.

(3) As shown in both of the figures, the models using hierarchical attention (HATT) achieve the best results among all the attention-based models. Even when compared with PCNN+ATT+ADV and PCNN+ATT+SL which adopt sophisticated denoising schemes and extra information, our models still keep significant advantages. This indicates that, as compared to the conventional plain attention schemes which handle each relation in isolation, our method can better take advantage of the rich correlations among relations. We believe the performance of our hierarchical attention scheme can be further improved by adopting extra mechanisms like adversarial training, reinforcement learning and soft-labeling at entity-pair level, which will be left as our future work.

Method		0.1	0.2	0.3

4.4 Effect of Hierarchical Attention for Different Relations

To further verify the effectiveness of our hierarchical attention method for different relations, we evaluate the RE performance of our method and conventional attention methods. Since we focus more on the performance of those top-ranked results, we report the precision scores when the recall is 0.1, 0.2, 0.3 and their mean. We also report micro average scores and macro average scores in this experiment. As an approximation of the area under the precision-recall curve, the micro average score gives a more complete view of the model performance. Since the micro average score generally overlooks the influences of those long-tail relations, we use the macro average score to give more emphasis on long-tail relations in test sets, which is often neglected by the previous works.

The evaluation results are shown in Table 2, and from the results we observe that: Our HATT method achieves consistent and significant improvements as compared to the plain ATT method. From the micro and macro average precision scores, we find that our HATT method effectively improves RE performance especially for those long-tail relations. As compared to the plain ATT method, our method can take advantage of correlations among relations to achieve the improvement, especially on the long-tail relations.

To further demonstrate the improvements in performance on long-tail relations after introduc-

Test Mode	ONE				TWO				ALL

Table 5: Example sentences for case study.

ing relation hierarchies, we extract a subset of the test dataset in which all the relations has fewer than $100/200$ training instances. We employ the Hits@K metric for evaluation. For each entity pair, the evaluation requires its corresponding golden relation in the first K candidate relations recommanded by the models. Because it is difficult for the existing models to extract long-tail relations, we select K from $\{10, 15, 20\}$. We report the both micro and macro average Hits@K accuracies for these subsets. From the evaluation results in Table 3, we observe that:

(1) For both CNN and PCNN models, our hierarchical attention outperforms the plain attention model. By taking advantage of the relation hierarchy, our models can learn better about long-tail relations via correlation information among relations. We also observe that even our hierarchical CNN model presents a better performance than the plain PCNN model. This shows the power of relation hierarchies, which makes our simpler CNN model outperforms the PCNN model on those long-tail relations.

(2) Although our HATT method has achieved obvious progress on the long-tail relations as compared with the plain ATT method, the results of all these methods are still far from satisfactory. This indicates that distantly supervised RE models suffer from not only the wrong labeling problem, but also the long-tail relation problem. We will incorporate more schemes and extra information to solve this problem in the future.

4.5 Effect of Hierarchical Attention with Different Instances

Since our method mainly focuses on modifications over selective attention, we also conduct Precision@N tests on those entity pairs with few instances following (Lin et al., 2016). We use the three test settings for this experiment: the ONE test set where we randomly select one instance for each entity pair for evaluation; the TWO test set where we randomly select two instances for each entity pair; the ALL test set where we use all instances for each remaining entity pair for evaluation. For the ONE and TWO test set, we intend to show that taking correlation information among relations into consideration can lead to a better relation classifier. The ALL test set is designed to show the effect of our attention over multiple instances. We report the precision values of top N triples extracted, where $N \in \{100, 200, 300\}$.

The evaluation results are shown in Table 4, and from the results we observe that:

(1) The performance of all methods is generally improved as the instance number increases. This shows that the selective attention model can effectively take advantage of information from multiple noisy instances by combining useful instances while discarding useless ones.

(2) Our HATT method has higher precision values in the ONE test set. This indicates that even in an insufficient information scenario, correlations among relations can be caught by our hierarchical attention.

4.6 Case Study

We give some examples of how our hierarchical selective attention takes effect in selecting the sentences. In Table 5, we display the sentences that are scored highest ("Good") or lowest ("Bad") by the attention of different hierarchical levels ("High" and "Base").

The relation `/people/person/children`

has fewer than 1000 training instances and it is a long-tail relation. For this relation, the instance recommended by the higher-level attention straightforwardly expresses the relational fact that *Nathan* is the child of *David* by telling that *Nathan* is *David*'s son, while the sentence with the low attention score actually gives the relationship of being at the same generation. On the contrary, the lower-level attention mistakenly assigns high attention to the incorrect sentence. This example shows that our hierarchical attention is beneficial for these long-tail relations.

5 Conclusion and Future Work

In this paper, we take advantage of relation hierarchies and propose a novel hierarchical instance-level attention for relation extraction. As compared with previous attention-based methods, our hierarchical attention provides coarse-to-fine granularity in instance selection and performs better extraction for long-tail relations. We conduct various experiments and the evaluation results show that incorporating the inherent hierarchical structure of relations into attention schemes can take advantage of correlations among relations and improve the performance significantly.

In the future, we plan to explore the following directions: (1) It will be promising to adopt extra information to help train more efficient models for solving the long-tail relation problem. (2) We may also combine our attention method with recent denoising methods to further improve model performance.

Abstract

Distant supervision is an effective method to generate large scale labeled data for relation extraction, which assumes that if a pair of entities appears in some relation of a Knowledge Graph (KG), all sentences containing those entities in a large unlabeled corpus are then labeled with that relation to train a relation classifier. However, when the pair of entities has multiple relationships in the KG, this assumption may produce noisy relation labels. This paper proposes a label-free distant supervision method, which makes no use of the relation labels under this inadequate assumption, but only uses the prior knowledge derived from the KG to supervise the learning of the classifier directly and softly. Specifically, we make use of the type information and the translation law derived from typical KG embedding model to learn embeddings for certain sentence patterns. As the supervision signal is only determined by the two aligned entities, neither hard relation labels nor extra noise-reduction model for the bag of sentences is needed in this way. The experiments show that the approach performs well in current distant supervision dataset.

1 Introduction

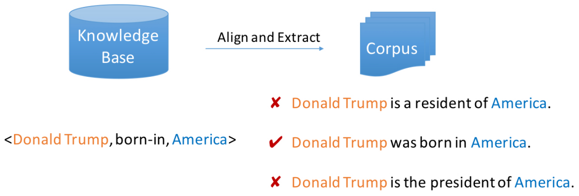

Figure 1: The mislabeled sentences produced by Distant Supervision.

Distant Supervision was first proposed by Mintz (2009), which used seed triples in Freebase instead of manual annotation to supervise text. It marked text as relation r if (h, r, t) can be found in a known KG, where (h, t) is the pair of entities contained in the text. This method can generate large amounts of training data, therefore widely used in recent research. But it can also produce much noise when there are multiple relations between the entities. For instance in Figure 1, we may wrongly mark the sentence "*Donald Trump is the president of America*" as relation *born-in*, with the seed triple (*Donald Trump, born-in, America*).

Previous works have tried different ways to address this issue. One way named Multi-Instance Learning(MIL) divided the sentences into different bags by (h, t), and tried to select well-labeled sentences from each bag (Zeng et al., 2015) or reduced the weight of mislabeled data (Lin et al., 2016). Another way tended to capture the regular pattern of the translation from true label to noise label, and learned the true distribution by modeling the noisy data (Riedel et al., 2010; Luo et al., 2017). Some novel methods like (Feng et al., 2017) used reinforcement learning to train an instance-selector, which will choose true labeled sentences from the whole sentence set. These methods focus on adding an extra model to reduce the noisy label. However, stacking extra model does not fundamentally solve the problem of inadequate supervision signals of distant supervision, and will introduce expensive training costs.

Another solution is to exploit extra supervision signal contained in a KG. Weston (2013) added the confidence of (h, r, t) in the KG as extra supervision signal. Han (2018) used mutual attention of KG and text to calculate a weight distribution of train data. Both of them got a better performance by introducing more information from KG. However, they still used the hard relation label derived from distant supervision, which also brought

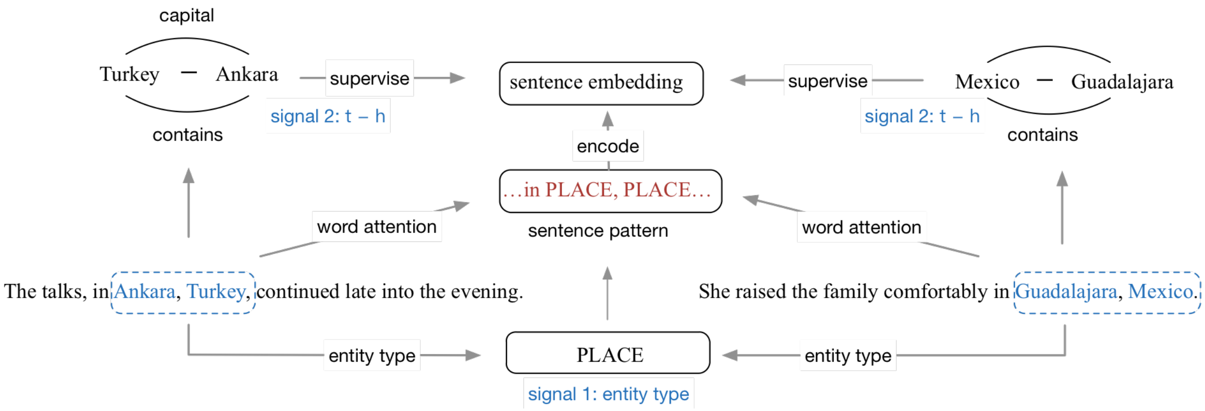

Figure 2: An instance of our label-free distant supervision method.

in much noise.

In this paper, we tend to avoid supervision by hard relation labels, and make full use of prior knowledge from a KG as soft supervision signal. We consider the TransE model proposed by Bordes (2013), which encodes entities and relations of a KG into a continuous low-dimensional space with the translation law $h + r \approx t$, where h, r, t describe the head entity, the relation and the tail entity respectively. Inspired by TransE model, we use $t - h$, instead of a concrete relation label r, as the supervision signal and make the sentence embedding close to $t - h$. Concrete relation labels may introduce mislabeled sentences, while $t - h$ is label-free, which is only determined by the two aligned entities and the the translation law.

Our assumption is that *each relation r in a KG has one or more sentence patterns that can describe the meaning of r*. For the example in Figure 2, we first replace the entity mentions in a sentence with the types of the aligned entities in the KG to form a sentence pattern. For example, "in Guadalajara, Mexico" will be replaced by "in PLACE, PLACE" to form a sentence pattern "in A, B" which conveys the meaning of "B contains A" and indicates the relation $contains$. For this sentence pattern, there may be a group of sentences sharing the same pattern but with different aligned entity pairs. In the first sentence "*The talks, in Ankara, Turkey, continued late into the evening*", $(Turkey - Ankara)$ implies both "*/location/country/capital*" and "*/location/location/contains*" as there are multiple relations between Ankara and Turkey in the KG. But in the similar sentence "*She raised the family comfortably in Guadalajara, Mexico.*", $(Mexico - Guadalajara)$ only implies "*/location/location/contains*" as there is no relation of "*/location/country/capital*" between Mexico and Guadalajara in the KG. As both $(Turkey - Ankara)$ and $(Mexico - Guadalajara)$ will be used to supervise the learning of the encoder for the pattern "in A, B", it makes the embedding of the sentence pattern closer to the correct relation "*/location/location/contains*" instead of the wrong relation "*/location/country/capital*". In this way, we do not need to label the sentences with the hard relation labels anymore.

The main contributions of this paper can be summarized as follows:

- As compared to existing distant supervision for relation extraction, our method makes better use of the prior knowledge derived from KG to address the wrong labeling problem.

- The proposed approach tends to supervise the learning process directly and softly by the type information and translation law, both derived from KG. Neither hard labels nor extra noise-reduction model for the bag of sentences is needed in this way.

- In the experiments, we show that the label-free approach performs well in current distant supervision dataset.

2 Related works

Relation extraction is intended to find the relationship between two entities given an unstructured text. Traditional methods use artificial characteristics or tree kernels to train a classification model (Culotta and Sorensen, 2004; Guodong et al., 2002). Recent works concentrate on deep neural networks to avoid error propagation during generating features (Ebrahimi and Dou, 2010; Zeng et al., 2014; Zhou et al., 2016; Zheng et al., 2017). More complicated models were proposed to learn deeper semantic features, like PCNN (Zeng et al., 2015) and attention pooling CNN (Wang et al., 2016), graph LSTMs (Peng et al., 2017).

Most of the early works were trained on the standard dataset by manual annotation, such as SemEval-2010 Task 8. In actual scenarios, it will cost a lot of manual resources to generate labeled data. Distant supervision (Mintz et al., 2009) aimed to obtain large-scale training data automatically, which becomes the most versatile supervision method. However, it suffers from the noisy label problem. Many works concentrate on dealing with the noise of distant supervision. Multi-instance learning (Riedel et al., 2010; Surdeanu et al., 2012) addresses the problem in bag-level, which divides sentences into different bags by (h, t). Zeng (2015) selects the most correct sentence from each bag. Lin (2016) introduces attention mechanism by distributing different weight to each sentence in the same bag, which reduces the effect of noisy labels and increases utilization of train data. Luo (2017) uses a transition matrix to characterize the inherent noise, convert true distribution to noise distribution. The model is enhanced by curriculum learning. Feng (2017) trains an instance selector to select correct labeled sentences by reinforcement learning.

Most of the above methods introduce a complicated extra model to deal with the noisy label problem. Our work tends to avoid the noisy label from distant supervision, by using entity information and translation law in KG to introduce more supervision signal.

KG is composed of many triples like (*head, relation, tail*), which describe relationships between head entities and tail entities. TransE is first proposed by (Bordes et al., 2013) to encode triples into a continuous low-dimensional space, which based on the translation $h+r \approx t$. Many follow-up works like TransH (Wang et al., 2014), DistMult (Yang et al., 2014), and TransR (Lin et al., 2015), proposed advanced method of translation by introducing different embedding spaces. Some recent works attempt to jointly learn text and KG triples, including (Xie et al., 2016) and (Xiao et al., 2016). These models tend to strengthen the representation of entities and relationships for KG tasks, but not for text representation.

3 Methodology

Here we present LFDS (Label-Free Distant Supervision) that essentially avoids noisy labels introduced by traditional distant supervision. Figure 2 shows an instance of our method. First, we pre-train representations for entities and relations based on the translation law $h + r \approx t$ defined by typical KG embedding models such as TransE. Second, for each sentence in the train sets, we replace the entity mentions with the types of the entities in the KG. An attention mechanism is then applied to calculate the importance of words with regard to the sentence pattern. Third, we train the sentence encoder by the margin loss between $t-h$ and sentence embedding. Note we do not use the noisy relation labels to train the model. Finally, for prediction, we calculate the embedding of test sentences, then compare the sentence embedding with all relation embeddings learned by TransE, and choose the closest relation as our predicted result. We describe these four parts in details as below.

3.1 KG Embedding

We use typical KG embedding models such as TransE to pre-train the embedding of entities and relations. We intend to supervise the learning by $t - h$ instead of hard relation label r. Concretely speaking, given two entities, h and t, we regard the translation based upon TransE between h and t as the target relation representation. TransE interprets relationships as translations operating on low-dimensional embeddings of entities, with the formula $h+r \approx t$, where h, r, t represent head entity, relation, and tail entity separately. The model is proved to perform well in predicting the tail entity when given head entity and relation.

The problem is that there may be multiple relations between t and h. As the example in Figure 2, the vector calculated by $Turkey - Ankara$ contains information for both relations: "*/location/country/capital*" and "*/location/location/contains*". While supervising the learning of the sentence pattern "in PLACE, PLACE", it is difficult to distinguish the two relations by supervision signal from only one sentence. However, other sentences with the similar pattern but different aligned entity pairs can push the embedding of the pattern close to another vector, such as $Mexico - Guadalajara$, which only represents "*/location/location/contains*" relation. As a result, the pattern will be closer to its correct relation "*/location/location/contains*".

Our work chooses TransE instead of other KG embedding models such as TransH or TransR, because TransE builds representations for h and t independent from fixed relation type r as the model assumes we do not know the specific relation r when training the encoder with supervision from $t - h$.

3.2 Sentence Embedding

In order to get a better representation of sentences, we had tried a variety of NRE models, such as Bi-LSTM(Zhou et al., 2016), SDP-LSTM (Yan et al., 2015), and typical CNN models. We chose PCNN (Zeng et al., 2015) to encode the sentence finally, which performs the best in our experiments. The encoder contains three parts as below.

Word Embeddings and Attentions. Instead of encoding sentences directly, we first replace the entity mentions e in the sentences with corresponding entity types $type_e$ in the KG, such as PERSON, PLACE, ORGANIZATION, etc. We then pre-train the word embedding by word2vec.

Attention mechanism is further applied to capture the importance of words with regards to the types information of entities as we assume the words close to the types information are more important.

First, we calculate the similarity between each word w^j and two entity types respectively:

$$A_1^j = f(type_{e_1}, w^j) \tag{1}$$

$$A_2^j = f(type_{e_2}, w^j) \tag{2}$$

$f(type_e, w^j)$ is the similarity function, which is defined as cosine similarity in this paper. $type_{e_1}$ and $type_{e_2}$ are the embeddings of the two entity types. Then the weight distribution for each word can be derived by exponential function:

$$\alpha_1^j = \frac{exp(A_1^j)}{\sum_{i=1}^n exp(A_1^i)} \tag{3}$$

$$\alpha_2^j = \frac{exp(A_2^j)}{\sum_{i=1}^n exp(A_2^i)} \tag{4}$$

We use the average weights of two entities as the attention of word w^j. Finally, the word embedding WF^j is derived as follows:

$$WF^j = \frac{\alpha_1^j + \alpha_2^j}{2} * w^j \tag{5}$$

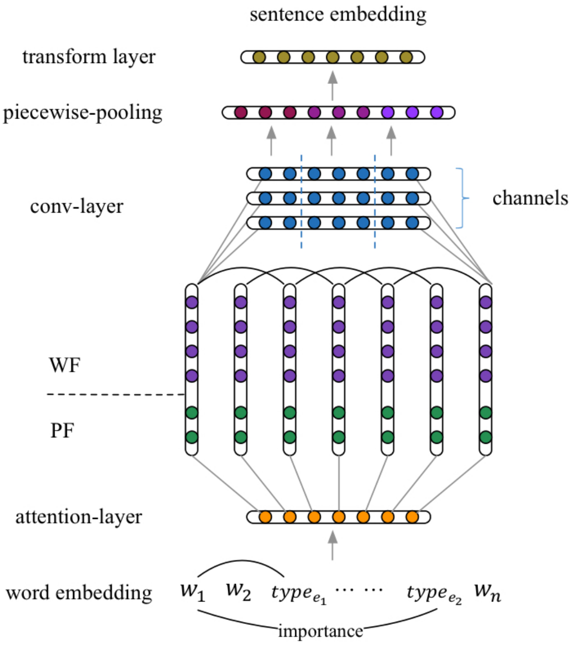

Figure 3: The sentence encoder with word attention and PCNN.

Position embedding. Zeng (2014) first proposed PFs to specify entity pairs. PF is a series of relative distances from current word to the two entities. For instance, for the sentence "*Damascus, the capital of Syria*", the distances from "capital" to the two entities are 3 and -2 respectively. The initial embedding matrix is randomly generated. Then we look up vector in the matrix by the two relative distances. The final position embedding will be the concatenation of $[PF_1, PF_2]$. As a result, we get a representation for each word:

$$w^j = [WF^j, PF_1^j, PF_2^j]$$

Then the input sentence representation will be:

$$x = w^1, w^2, ..., w^n$$

Piecewise-CNN. It was proved by (Zeng et al., 2015) that piecewise max pooling layer performs well in relation extraction, which tends to capture structural information between two entities. For each sentence, we use CNN to obtain a representation, then divide it into three parts by the two entities index. For each part, we perform a max pooling layer, thus we get 3-dimensional vector:

$$p_i = [p_{i_1}, p_{i_2}, p_{i_3}]$$

The shape of final vector will be $(bz, dc * 3)$, where bz represents batch size and dc is the number of channels.

The structure of whole model is shown in Figure 3.

3.3 Margin loss

In order to make the sentence embedding encoded by the PCNN model and relation embedding specified by $t - h$ based on the translation law as close as possible, we use margin loss with linear layer instead of cross-entropy loss with softmax layer. For the sentence embedding via PCNN layer, we perform a linear transformation to make its dimension equal to the relation representation.

$$s_e = \mathbf{W} * PCNN(x) + \mathbf{b} \tag{6}$$

Where **W** is the transformation matrix with shape $(dc*3, embedding\_dim)$. Then we define margin loss between $t - h$ and s_e as follows:

$$L = \sum_{s_e \in S} [(t - h - s_e + \gamma - (rand(t' - h, t - h') - s_e))]_+ \tag{7}$$

Where $rand(a, b)$ means choosing a or b. $t' - h$ is a negative instance of $t - h$, which is generated by randomly replacing t with other entities in KG, so does $t - h'$. For each sentence, we decrease the distance between $t - h$ and s_e, while increase the distance between the negative instance and s_e. γ is the reasonable margin between positive triple and negative triple. If the margin is already larger than γ, the loss of the sentence will be zero.

Another point to note is the special label NA in the dataset, which means there is no relationship between the two entities in the KG. In this case, $t - h$ is pointless and will confuse our encoder. To deal with this issue, we generate a fixed relation for NA, used as the negative relation for those sentences having some relationships. The minimum distance from NA to other relations is forced to be greater than $2 * \gamma$, where γ is the margin in loss function. When the model is used for prediction, the NA is also included.

The training target of our model is shown as Figure 4, including the sentence encoder we introduced above.

3.4 Prediction

We build a sentence encoder which can output a sentence embedding with the same dimension as relation embedding from the KG. For a new test sentence, we first encode it with the model, then calculate the similarity between the sentence embedding and the embeddings of all candidate relations. The most similar relation to the sentence embedding is the predicted category.

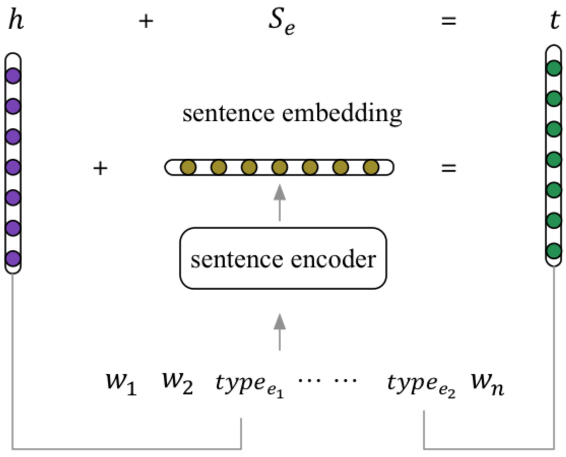

Figure 4: The training target.

$$r = arg\max_i(f(S_e, r_i)) \tag{8}$$

4 Experiments

Our experiments aim to provide positive evidence for the two main questions: (1) Whether or not the sentence pattern can express the essential part of the sentence? (2) Whether the abundant supervision signal in a KG is helpful to predict the true label for those mislabeled sentences?

To this end, we first introduce the widely used dataset for distant supervision, and evaluate our performance on the dataset. To further investigate the effectiveness of our model with noisy data, We divide the sentences in dataset into different categories, and show the study about some specific cases.

4.1 Datasets

The most widely used dataset was generated by Riedel (2010). It aligns the entities in Freebase with the New York Times (NYT) corpus, which contains all the news during 2005-2007. The sentences derived from news in 2005-2006 were used as the training data, while those from year 2007 were used as test data. After the alignment, there are 522,611 training sentences and 172,448 test sentences, labeled by 53 candidate relations in Freebase, and an extra label NA, which means there is no relation between the two entities in Freebase.

According to previous work (Mintz et al., 2009), we evaluate our model in the held-out evaluation and manual evaluation. The held-out evalu-

Parameter	**Settings**

Dropout	0.5
Batch size	128

Table 1: Parameter settings.

ation calculates the precision-recall curves on the whole test set. For the false positives produced by the noisy labels in the test data, the precision will drop rapidly as the recall increases. In order to measure the precision, we need manual evaluation to check misclassified samples.

4.2 Experimental settings

4.2.1 Word Embeddings

In this paper, we use word2vec to train word embeddings on the NYT corpus. The window size of word2vec model is set as 5, and the embedding size is 50. We preserve those words appearing more than 10 times as vocabulary.

4.2.2 KG embeddings

We train the entities and relationships on FB40k[1] (Lin et al., 2015), which is generated for knowledge graph completion, with about 40,000 entities and 1318 relations. We set the embedding size as 100 instead of 50, which performs better in our experiment. Besides, we set the margin as 1 and train with learning rate 0.01. In order to test the performance of the vectors, we evaluate our model in KG completion tasks. The hit@10 of our final TransE model is 0.67, which is evaluated by predicting the closest 10 tail entities with specified head entities and relationships.

4.2.3 Parameter Settings

We use three-fold validation to determine the hyper-parameters. In the network layer, we try {3, 4, 5} for the kernel size, {100, 150, 200, 250, 300} for the number of channels, {5, 10, 15} for the position embedding size. In the update procedure, we use adaptive gradient descent with trying {0.1, 0.05, 0.01, 0.001} for the initial learning rate, and {64, 128, 256} for the mini-batch size. In the dropout operation, we set the probability as 0.5 referring to most of the classical experiments. Table 1 shows our final setting for all hyper-parameters.

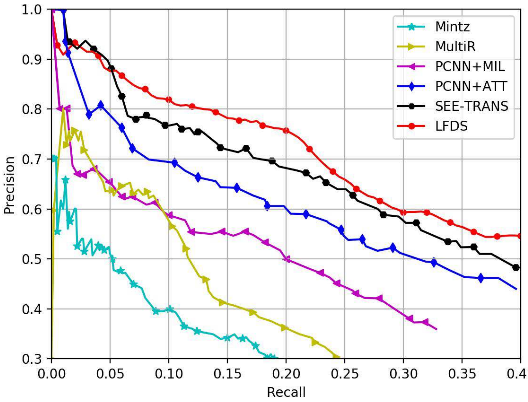

Figure 5: Performance comparison with Traditional methods.

4.3 Comparison with Traditional Methods

4.3.1 Held-out Evaluation

The held-out evaluation is performed directly on the test data. For the labels produced by distant supervision may not be precise, held-out evaluation is an approximate measure of our model, which is usually depicted by the precision-recall curve.

We select six representative models for comparison. *Mintz* (Mintz et al., 2009) proposed a feature-based model that first used distant supervision. *MultiR* (Hoffmann et al., 2011) is a multi-instance learning model under the at-least-one assumption. *PCNN+MIL* (Zeng et al., 2015) proposed the piece-wise pooling method, which is used as the encoder of our works. *PCNN+ATT* (Lin et al., 2016) performed selective attention over instances and got better results in the datasets. *SEE* (He et al., 2018) is a novel work that learned syntax-aware entity embedding for relation extraction and achieved state-of-the-art. The precision-recall curves are shown in Figure 5, where *LFDS* denotes our label-free distant supervision method.

We can observe from the figure that our LFDS method has an overall good performance compared to current works, especially with the growth of recall. It demonstrates that our model has a good classification ability in general, because the sentence pattern can capture the meaning of relations better than a sentence. The result can answer the first question we proposed at section 4.

LFDS	0.90	**0.88**	**0.83**	**0.869**

Table 2: Precision values for the top 100, 200 and 500 sentences.

4.3.2 Manual Evaluation

For the wrong labels produced by distant supervision, there will be many false positives in our evaluation inevitably, thus causing a sharp decline in the held-out precision-recall curves. Manual evaluation is necessary to evaluate the model more precisely. Following the previous works, we selected the top 100, top 200, and top 500 sentences, which is ranked by the predicted confidence, then evaluated the precision artificially. The result is shown in table 2.

We can see that the precision is higher than held-out evaluation, because manual evaluation avoid the effect of wrong labels. Our LFDS method achieved a consistently higher precision compared with current works, especially when recall increases. Compared to held-out evaluation, manual evaluation can show our model's ability in differentiating noisy sentence. Detail analysis will be shown in Section 4.4.

In the manual procedure, we found some wrong cases caused by entity types. The entity types in Freebase can be ambiguous, where "ORGANIZATION" may be confused with "PLACE". It causes error propagation in our experiments.

4.4 Case Study

To further prove the effectiveness of our model, especially in distinguishing noisy labels, we select some specific relationships for detail analysis. The noisy labels are produced by the entity pairs which have multiple relationships between them. In this case, different relationships will share the same entity pairs in knowledge graph. We defined this kind of relationships as "overlapping" relationships. The more entity pairs it shares with other relation, the overlapping degree of the relation is higher, which means the relation is harder to distinguish.

Case 1: Non-overlapping Relations. The first case is the non-overlapping relation. For triples of the non-overlapping relation r_1 as (h, r_1, t), there are few triples like (h, r_2, t) in KG, where r_2 is another relation in our candidate relations set. That means for this kind of relation, almost no noisy label will be produced. One of these relation is */business/person/company*. There are near 200 sentences in the test set, with our evaluation of precision achieving 0.98. It proves that our encoder with sentence pattern and label-free supervision is effective in basic classification, which is a convincing answer of the first question we proposed at section 4.

Case 2: Partly-overlapping Relations. The second case is the partly-overlapping relation, in which two relations may share a certain number of entity pairs in Freebase. For instance, the relation */location/country/capital* shares many entity pairs with */location/location/contains* but not all entity pairs in Freebase have both $capital$ and $contain$ relations.

For those entity pairs having both relations, traditional distant supervision would produce two labels for sentences such as:

> "The talks, in Ankara, Turkey, continued late into the evening."

The noisy labels in the train set are hard to differentiate. Recent noise reduction methods commit to improving the distinguishing ability of the model by adding extra models. Our experiment proves that our label-free supervision method not only achieves better differentiation performance but also does not need to train extra noise reduction models. Cases are shown in Table 3.

The prediction results indicate that the model is capable of learning the embedding of the sentence pattern we want. For instance, the model captures the pattern like "in PLACE, PLACE", and tends to predict the sentence with this pattern for */location/location/contains*, while the pattern "PLACE, the capital of PLACE" for */location/country/capital* respectively. When both two relations are labeled for the same sentence in the test set, our model can predict the correct label with the corresponding patterns.

Another similar but more interesting example is */people/person/nationality* and */people/person/place_lived*. In this case, the two relations share a certain number of entity pairs in Freebase like the previous example. But because of the incompleteness of Freebase, many sentences with only one label are actually wrongly labeled.

Sentence	**Label with normal distant supervision**	**Prediction with LFDS**	**Pattern**
The talks, in *Ankara*, *Turkey*, continued late into the evening.	/location/location/contains /location/country/capital	/location/location/contains	in PLACE, PLACE
..., said Mr.Cho, 25, who was born in *Seoul*, *South Korea*, and educated at a boarding school in Scotland.	/location/location/contains /location/country/capital	/location/location/contains	in PLACE, PLACE
On Wednesday, suicide bombings killed 33 people in *Algiers*, the capital of *Algeria*.	/location/location/contains /location/country/capital	/location/country/capital	PLACE, the capital of PLACE
Farah has lived in *India*, Europe and South Africa, and only started revisiting Mogadishu in 1996, after two decades away.	/people/person/nationality	/people/person/place_lived	PERSON lived in PLACE
He was George Mcgovern of South Dakota – not *Frank church* of *Idaho*, who was involved in other antiwar legislation.	/people/person/place_lived	/people/person/nationality	PERSON of PLACE

Table 3: The comparison between labels from normal distant supervision and our label-free relation prediction

For example,the sentence "Farah has lived in India, ..." is labeled with only one relation */people/person/nationality* because there is only one $nationality$ relation in Freebase. But the actual meaning of the sentence is to say $Farah$'s $place\_lived$ is $India$. This type of wrongly labeling problem is caused by incompleteness of Freebase which is very common for many other knowledge graphs.

However, our label-free method can correct this problem because it essentially learns the sentence patterns that are determined only by the sentence itself and the aligned entity pairs. As shown by the last two examples in Table 3, our model successfully learned the patterns "PERSON lived in PLACE" for */people/person/place_lived* and "PERSON of PLACE" for */people/person/nationality* respectively.

These instances show that our model is capable of learning some sentence patterns and mapping them to the corresponding relations in Freebase, which can distinguish noise sentences effectively. It indicates that our label-free supervision with prior knowledge introduced by the translation laws and entity types in KG is effective in avoiding noise, which can answer the second question we proposed at section 4 credibly.

Case 3: Mostly-overlapping Relations. The final case is mostly-overlapping relations, in which the two relations share most entity pairs in Freebase. One example is */people/person/place_of_birth*, which shares most of its entity pairs with */people/person/place_lived* in FB40k, because a person‘s birthplace and residence are likely to be the same. That means in the process of training with TransE, the two relations are updated by similar gradients, which will produce similar representations for $t - h$. In this case, the relations are really hard to differentiate, because there are not enough distinct supervision signals in the KG. We tend to resolve this situation in future work by utilizing prior knowledge derived from relation paths.

5 Conclusion

In this paper, we argue that the noise label problem in distant supervision is mainly caused by the incomplete use of KG information. Thus we propose a label-free distant supervision method, which supervises the learning of the embedding of sentence patterns by $t - h$ and entity types, instead of hard relation labels. We conducted experiments on the widely used relation extraction dataset and showed that with the recall increasing, our model performs better than state-of-the-art results. This demonstrates that our approach can effectively deal with the noise problem and encoding sentence pattern for relation extraction.

In the future, we plan to utilize more information in knowledge graphs to improve the distant supervision signal. For instance, the reasoning path can introduce new prior knowledge, which is a key direction in current works of KG. The path may produce new supervision signals for two entities even there is no direct connection between them. We also plan to apply this method to other datasets.

Abstract

We investigate the task of joint entity relation extraction. Unlike prior efforts, we propose a new lightweight joint learning paradigm based on minimum risk training (MRT). Specifically, our algorithm optimizes a global loss function which is flexible and effective to explore interactions between the entity model and the relation model. We implement a strong and simple neural network where the MRT is executed. Experiment results on the benchmark ACE05 and NYT datasets show that our model is able to achieve state-of-the-art joint extraction performances.

1 Introduction

Detecting entities and relations is usually the first step towards extracting structured knowledge from plain texts. Its goal is to identify text spans representing typed objects (*entities*) and semantic relations among those text spans (*relations*). For example, in the following sentence,

> [Associated Press]$_{\text{ORG}}$ [writer]$_{\text{PER}}$ [Patrick McDowell]$_{\text{PER}}$ in [Kuwait City]$_{\text{GPE}}$.

"Associate Press" is an organization entity (`ORG`), "writer" is a person entity (`PER`), and the two entities have an affiliation relation (`ORG-AFF`).

Two types of models have been applied to the extraction task, the pipeline model and the joint model. In the pipeline setting, the task is broken down into independently learned components (an entity model and a relation model). Despite its flexibility, the pipeline ignores interactions between the two models. For example, the entity model doesn't look at relation annotations which are useful for identifying entities (e.g., if an `ORG-AFF` relation exists, the entity model can only assign `ORG` and `AFF` to its entities). The joint setting, on the other hand, extracts entities and relations in a unified model, which can explore shared information and alleviate error propagations between models. Here we will focus on joint models.

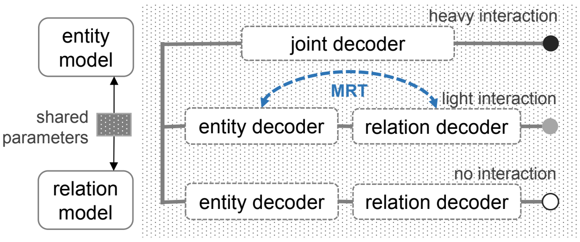

Figure 1: Paradigms of joint entity relation extraction.

One simple joint learning paradigm is through sharing parameters (Miwa and Bansal, 2016; Katiyar and Cardie, 2017). Typically, instead of training two independent models, the entity and relation model can share some input features or internal hidden states. It has an advantage that no additional constraint is required on the two sub-models. But the connections among sub-models are still not fully explored due to independent sub-model decoders. For example, to get signals from relation annotations, the entity model needs to wait for the relation model to update the shared parameters. To further utilize the interaction between decoders, some complex joint decoding algorithms (e.g., simultaneously decoding entities and relations in beam search) have been carefully studied (Li and Ji, 2014; Katiyar and Cardie, 2016; Zhang et al., 2017; Zheng et al., 2017). In this paradigm, it is important (and hard) to make a good balance between the exactness of the joint decoding algorithm and capacities of individual sub-models.

In this work, we propose a joint minimum risk training (MRT) (Och, 2003; Smith and Eisner, 2006) method for the entity and relation extraction

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2256–2265
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

task. It provides a lightweight way to strengthen connections between the entity model and the relation model, and keeps their capacities unaffected. Given an input $\mathbf{x}$ and a loss function $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ (measuring the difference between model output $\hat{\mathbf{y}}$ and the true $\mathbf{y}$), MRT seeks a posterior $P(\hat{\mathbf{y}}|\mathbf{x})$ to minimize the expected loss $\mathbf{E}_{\hat{\mathbf{y}} \sim P(\hat{\mathbf{y}}|\mathbf{x})} \Delta(\hat{\mathbf{y}}, \mathbf{y})$. Comparing with prior joint decoding algorithms, the MRT-based algorithm is simple and can be applied to a broad range of entity relation extraction models without changing the original sub-models and decoders (Figure 1).

One advantage of the MRT-based method is that it can explicitly optimize a global sentence-level loss (e.g., F1 score) rather than local token-level losses. Therefore, it may catch more sentence-level information in the training time and match evaluation metrics better in the testing time. Furthermore, besides the handcrafted losses, we also try to directly learn a loss function from data during the joint MRT process. The automatically obtained loss would help MRT to calibrate its risk estimation with knowledge from the data distribution. On the other hand, comparing with preivous single task MRT, the joint MRT algorithm here will integrate messages from different sub-models, which is the key step for enhancing decoder interactions in the joint learning. As a result, the training of the entity model now can directly acknowledge the loss of the relation model (without waiting for shared parameters) and vice versa.

We compile the proposed joint MRT with a strong neural network-based model which uses recurrent neural networks (RNN) in the entity model and convolutional neural networks (CNN) in the relation model. On benchmark ACE05 and NYT datasets, we show that the new RNN+CNN structure outperforms previous neural network-based models. After adding the joint MRT, our model is able to achieve state-of-the-art performances.

To summarize, our main contributions include

1. proposing a new joint learning paradigm based on minimum risk training for the joint entity relation extraction task.

2. implementing a strong and simple neural-network-based entity relation extraction model which carries the proposed MRT algorithm. [1]

3. achieving state-of-the-art results on two benchmark datasets (ACE05 and NYT).

2 Related Work

In many pipelined entity relation extraction systems, one first learns an entity model, then learns a relation model based on entities generated by the entity model (Miwa et al., 2009; Chan and Roth, 2011; Lin et al., 2016). Such systems are often flexible to incorporate different data sources and different learning algorithms. However, they may also suffer from error propagation and data inefficiency. To tackle the problem, many recent studies try to develop joint extraction algorithms.

Parameter sharing is a basic strategy in joint learning paradigms. For example, in (Miwa and Bansal, 2016), the entity model is a sentence-level RNN, and the relation model is a dependency tree path RNN which takes hidden states of the entity model as features (i.e., the shared parameters). Our basic extraction model is similar to theirs but with a CNN-based relation model. Similarly, Katiyar and Cardie (2017) build a simplified relation model on the entity RNN using the attention mechanism.

To further explore interactions between the entity decoder and the relation decoder, some joint decoding algorithms were studied. For example, Katiyar and Cardie (2016) propose a CRF-based model which conducts joint decoding with augmented transition matrices. Zheng et al. (2017) propose to directly encode relations in the sequential labelling tag set. Both of them are exact decoding algorithms, but they need adding constraints on the relation model (e.g., Zheng et al. (2017) cannot handle entities which appear in multiple relations). On the other side, Li and Ji (2014) develop a joint decoding algorithm based on beam search. Zhang et al. (2017) study a globally normalized joint model. They retain capacities of sub-models, while their decoding algorithms are inexact. Here, we introduce MRT to the task, which is a more lightweight setting of joint learning.

Minimum risk training is a learning framework which tries to handle models with arbitrary discrepancy metrics (i.e., losses of a model output w.r.t. the true answer) (Och, 2003; Smith and Eisner, 2006; Gimpel and Smith, 2010). It has been successfully applied to many NLP tasks. Some recent work include (He and Deng, 2012; Shen et al., 2016) which apply MRT to (neural) ma-

---

[1] Our implementation is available at `https://github.com/changzhisun/entrel-joint-mrt`.

chine translation, (Xu et al., 2016) which develops a shift-reduce CCG parser to directly optimize F1, and (Ayana et al., 2016) which uses a MRT-based model for summarization. We note that most previous applications of MRT focus on a single job, while the joint entity relation extraction consists of two sub-tasks. Investigating MRT in joint learning scenarios is the main topic of this work.

Finally, the sampling algorithm of solving MRT is similar to the policy gradient algorithm in reinforcement learning (RL) (Sutton and Barto, 1998). Some recent NLP applications which share the key idea of MRT but are described with RL language also show promising results (e.g., dialog systems (Li et al., 2016), machine translation (Nguyen et al., 2017)). The idea of learning loss functions from data is similar to inverse reinforcement learning (Abbeel and Ng, 2004; Ratliff et al., 2006).

3 The Approach

We define the joint entity and relation extraction task following the setting of (Miwa and Bansal, 2016). Given an input sentence $s = w_1, \ldots, w_{|s|}$ (w_i is a word), the task is to extract a set of entities $\mathcal{E}$ and a set of relations $\mathcal{R}$. An entity $e \in \mathcal{E}$ is a sequence of words labelling with an entity type (e.g., person (`PER`), organization (`ORG`)). Let $\mathcal{T}_e$ be the set of possible entity types. A relation r is a triple (e_1, e_2, l), where e_1 and e_2 are two entities, l is a relation type describing the semantic relation between e_1 and e_2 (e.g., organization affiliation relation (`ORG-AFF`)). Let $\mathcal{T}_r$ be the set of possible relation types.

In our joint extraction method (Figure 2), we treat entity detection as a sequence labelling task (Section 3.1) and relation detection as a classification task (Section 3.2). Models of the two tasks share parameters and are trained jointly. Departing from previous joint learning algorithms (Miwa and Bansal, 2016; Katiyar and Cardie, 2017; Zhang et al., 2017), we introduce minimum risk training to the joint extraction model. It optimizes a global loss function and bridges the discrepancy between training and testing (Section 3.3).

3.1 Entity Detection

To represent entities in s, we assign a tag t_i to each word w_i following the BILOU tagging scheme: t_i takes a value in $\{\texttt{B-}*, \texttt{I-}*, \texttt{L-}*, \texttt{O}, \texttt{U-}*\}$, where `B`, `I`, `L` and `O` denote the begin, inside, end and outside of an entity, `U` denotes a single word entity and $* \in \mathcal{T}_e$ represents different entity types. For example, for a person (`PER`) entity "Patrick McDowell", we assign `B-PER` to "Patrick" and `L-PER` to "McDowell". Given an input sentence s, the entity model predicts the tags of words $\hat{\mathbf{t}} = \hat{t}_1, \hat{t}_2, \ldots, \hat{t}_{|s|}$ by learning from the true tags $\mathbf{t} = t_1, t_2, \ldots, t_{|s|}$.

We use a bidirectional long short term memory (bi-LSTM) network (Hochreiter and Schmidhuber, 1997) to solve the sequence labelling task. At each sentence position i, a forward LSTM chain computes a hidden state vector $\vec{\mathbf{h}}_i$ by recursively collecting information from the beginning of s to the current position i. Similarly, a backward LSTM chain collects information $\overleftarrow{\mathbf{h}}_i$ from the end of s to the position i.

$$\vec{\mathbf{h}}_i = \mathrm{LSTM}(\mathbf{x}_i, \vec{\mathbf{h}}_{i-1}; \vec{\boldsymbol{\theta}}),$$
$$\overleftarrow{\mathbf{h}}_i = \mathrm{LSTM}(\mathbf{x}_i, \overleftarrow{\mathbf{h}}_{i+1}; \overleftarrow{\boldsymbol{\theta}}).$$

The word representation $\mathbf{x}_i$ of w_i has two parts $\mathbf{x}_i = \mathbf{w}_i \oplus \mathbf{c}_i$ ($\oplus$ is the vector concatenation). $\mathbf{w}_i$ is a word embedding of word w_i (from an embedding look-up table $\mathbf{W}_e$). $\mathbf{c}_i$ is a character-based representation of w_i which is obtained by running a convolution neural network on the character sequence of w_i: $\mathbf{c}_i = \mathrm{CNN}(\mathrm{char}(w_i); \boldsymbol{\theta}_c)$.

To predict the tag $\hat{t}_i$, we combine the forward and the backward hidden vector to $\mathbf{h}_i = \vec{\mathbf{h}}_i \oplus \overleftarrow{\mathbf{h}}_i$, and apply a softmax function on $\mathbf{h}_i$ to get the posterior of $\hat{t}_i$,

$$P_{\text{ent}}(\hat{t}_i | s; \boldsymbol{\theta}_E) = \mathrm{Softmax}(\mathbf{W}_E \cdot \mathbf{h}_i), \quad (1)$$

where $\boldsymbol{\theta}_E = \{\mathbf{W}_e, \boldsymbol{\theta}_c, \vec{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}, \mathbf{W}_E\}$ are parameters of the entity model. Given an input sentence s and its ground truth tag sequence $\mathbf{t}$, the training objective is to minimize $\mathcal{L}_{\text{ent}}$,[2]

$$\mathcal{L}_{\text{ent}}(\boldsymbol{\theta}_E) = -\frac{1}{|s|} \sum_{i=1}^{|s|} \log P_{\text{ent}}(\hat{t}_i = t_i | s; \boldsymbol{\theta}_E).$$

3.2 Relation Detection

Given a set of detected entities $\hat{\mathcal{E}}$ (obtaining from the entity tag sequence $\hat{\mathbf{t}}$), we consider all entity pairs in $\hat{\mathcal{E}}$ as candidate relations. The task of relation detection is to predict a relation type $l \in \mathcal{T}_r$ for each pair,[3] and output a relation set

---

[2] We have also tried biLSTM-CRF (Huang et al., 2015) as an advanced entity model, but performances are nearly the same in our experiments.

[3] We include a `NONE` relation type in $\mathcal{T}_r$ which means that there exists no relation between e_1 and e_2.

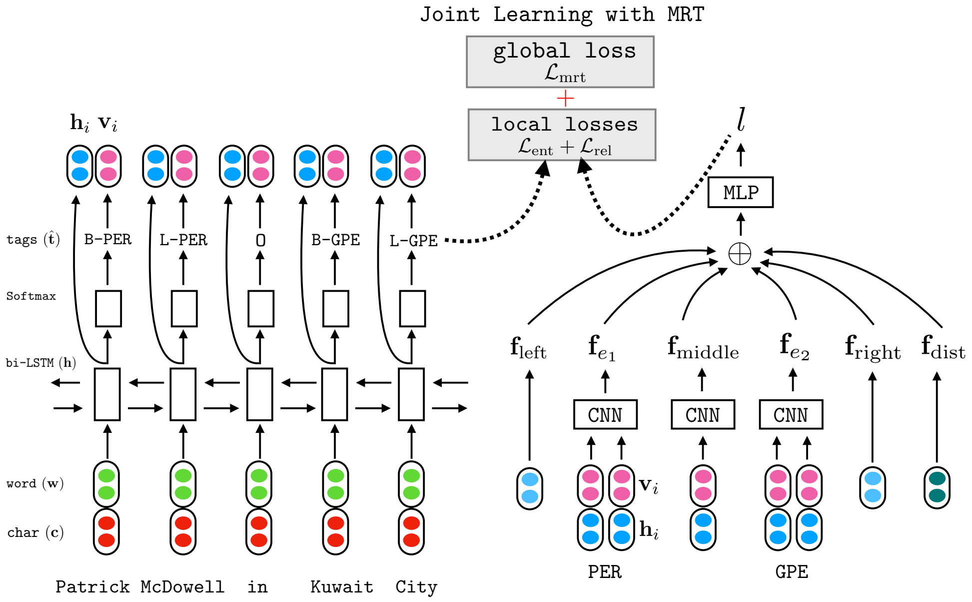

Figure 2: Our network structure for the joint entity and relation extraction.

$\hat{\mathcal{R}} = \{(e_1, e_2, l) | e_1, e_2 \in \hat{\mathcal{E}}, e_1 \neq e_2, l \in \mathcal{T}_r\}$. To build the relation model, we extract two types of features, namely, features regarding words in e_1, e_2 and features regarding contexts of the entity pair (e_1, e_2).

To extract features on words in e_1, e_2, we use two convolutional neural networks. Taking e_1 as an example, for each word w_i in e_1, we first collect w_i's bi-LSTM hidden vector $\mathbf{h}_i$ from the entity model. Then, we concatenate $\mathbf{h}_i$ with a one-hot entity tag representation $\mathbf{v}_i$ of $\hat{t}_i$. We build a feature vector $\mathbf{f}_{e_1}$ for e_1 by running a CNN (a single convolution layer with a max-pooling layer) on vectors $\{\mathbf{h}_i \oplus \mathbf{v}_i | w_i \in e_1\}$. Similarly, we build $\mathbf{f}_{e_2}$ for e_2 with another CNN.

For context features of the entity pair (e_1, e_2), we build three feature vectors by looking at words between e_1 and e_2 ($\mathbf{f}_{\text{middle}}$), words on the left of the pair ($\mathbf{f}_{\text{left}}$) and words on the right of the pair ($\mathbf{f}_{\text{right}}$). For $\mathbf{f}_{\text{middle}}$, we run a CNN on words between e_1 and e_2 like the case of $\mathbf{f}_{e_1}, \mathbf{f}_{e_2}$. For $\mathbf{f}_{\text{left}}$ and $\mathbf{f}_{\text{right}}$, we use the "LSTM-Minus" method as (Wang and Chang, 2016; Zhang et al., 2017). Assume that the left context of (e_1, e_2) is from sentence position 0 to i, then $\mathbf{f}_{\text{left}} = \overrightarrow{\mathbf{h}}_i \oplus (\overleftarrow{\mathbf{h}}_0 - \overleftarrow{\mathbf{h}}_{i+1})$. Similarly, if the right context of (e_1, e_2) is from j to $|s| - 1$, then $\mathbf{f}_{\text{right}} = (\overrightarrow{\mathbf{h}}_{|s|-1} - \overrightarrow{\mathbf{h}}_{j-1}) \oplus \overleftarrow{\mathbf{h}}_j$. We also use a one-hot feature $\mathbf{f}_{\text{dist}}$ to describe the distance between e_1 and e_2 in the sentence.

Finally, $\mathbf{f}_{e_1}$, $\mathbf{f}_{e_2}$, $\mathbf{f}_{\text{middle}}$, $\mathbf{f}_{\text{left}}$, $\mathbf{f}_{\text{right}}$ and $\mathbf{f}_{\text{dist}}$ are concatenated to a single vector $\mathbf{f}_{e_1,e_2}$. To get the posterior of the relation type $\hat{l}$, we apply a multi-layer perceptron with one hidden layer on $\mathbf{f}_{e_1,e_2}$,

$$\begin{aligned} &\mathrm{P}_{\text{rel}}(\hat{l} | s, e_1, e_2; \boldsymbol{\theta}_R) \\ &= \mathrm{Softmax}(\mathbf{W}_2 \cdot \mathrm{ReLU}(\mathbf{W}_1 \cdot \mathbf{f}_{e_1,e_2})), \quad (2) \end{aligned}$$

where $\boldsymbol{\theta}_R = \{\boldsymbol{\theta}_{e_1}, \boldsymbol{\theta}_{e_2}, \boldsymbol{\theta}_{\text{middle}}, \mathbf{W}_1, \mathbf{W}_2\}$ contains parameters of the relation model (shared parameters with the entity model are omitted).

Given an input sentence s, the training objective is to minimize

$$\mathcal{L}_{\text{rel}}(\boldsymbol{\theta}_R) = - \sum_{\substack{e_1, e_2 \in \hat{\mathcal{E}} \\ e_1 \neq e_2}} \frac{\log P_{\text{rel}}(\hat{l} = l | s, e_1, e_2; \boldsymbol{\theta}_R)}{|\hat{\mathcal{E}}|(|\hat{\mathcal{E}}| - 1)},$$

where the true label l of a candidate entity pair (e_1, e_2) can be read from true annotations.

3.3 Joint Minimum Risk Training

To jointly learn the entity model and the relation model, one common strategy is to optimize the combined objective function $\widetilde{\mathcal{L}} = \mathcal{L}_{\text{ent}} + \mathcal{L}_{\text{rel}}$, where the joint learning is accomplished by the shared parameters. However, we would think that $\widetilde{L}$ optimizes a "local" loss by observing that a) in both $\mathcal{L}_{\text{ent}}$ and $\mathcal{L}_{\text{rel}}$, the loss functions are calculated by only looking at local parts. For example, the loss in $\mathcal{L}_{\text{ent}}$ is based on the correctness of local entity tags t_i rather than a global measurement (e.g., F1 score of extracted entities), b) both the entity model and the relation model are unaware of the loss from the other side. For example, the entity model needs to wait for the relation model to update the shared parameters rather than get direct supervision from the loss of the relation model.

Here we introduce the minimum risk training framework to the joint model. Comparing with optimizing the local loss in $\widetilde{\mathcal{L}}$, the joint MRT will optimize a global loss and provide a tighter connection between the entity decoder and the relation decoder. To illustrate the algorithm, we first aggregate some notations.

Let $\mathbf{y} \triangleq (\mathcal{E}, \mathcal{R})$ contain the ground truth entity tag sequence and relations, $\hat{\mathbf{y}} \triangleq (\hat{\mathcal{E}}, \hat{\mathcal{R}})$ contain outputs of the joint extraction model and $\mathcal{Y}(s)$ be the set of all possible outputs of the input sentence s ($\mathbf{y}, \hat{\mathbf{y}} \in \mathcal{Y}(s)$). We define the joint probability,

$$
\begin{aligned}
&P(\hat{\mathbf{y}}|s;\boldsymbol{\theta}) = P(\hat{\mathcal{E}}|s;\boldsymbol{\theta}_E)P(\hat{\mathcal{R}}|s,\hat{\mathcal{E}};\boldsymbol{\theta}_R)\\
&= \prod_i P_{\text{ent}}(\hat{t}_i|s;\boldsymbol{\theta}_E) \prod_{\substack{e_1,e_2\in\hat{\mathcal{E}}\\ e_1\neq e_2}} P_{\text{rel}}(\hat{l}|s,e_1,e_2;\boldsymbol{\theta}_R),
\end{aligned}
$$

where $\boldsymbol{\theta} = \boldsymbol{\theta}_E \bigcup \boldsymbol{\theta}_R$ is the joint model parameter, and $P_{\text{ent}}, P_{\text{rel}}$ are in Equation 1 and 2.

The objective of MRT is to minimize the following expected loss (i.e., *risk*),

$$
\mathbf{E}_{\hat{\mathbf{y}}\sim P(\hat{\mathbf{y}}|s;\boldsymbol{\theta})}\Delta(\hat{\mathbf{y}},\mathbf{y}) = \sum_{\hat{\mathbf{y}}\in\mathcal{Y}(s)} P(\hat{\mathbf{y}}|s;\boldsymbol{\theta})\Delta(\hat{\mathbf{y}},\mathbf{y}), \tag{3}
$$

where $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ is a (arbitrary) loss function describing the difference between $\hat{\mathbf{y}}$ and $\mathbf{y}$.

In our model, the loss function $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ is the key factor to enhance the joint extraction performances. First, in $\Delta(\hat{\mathbf{y}}, \mathbf{y})$, we consider sentence-level F1 scores of entity and relation extraction results (denoted by $\mathrm{F}_{\text{ent}}(\hat{\mathcal{E}}, \mathcal{E})$, $\mathrm{F}_{\text{rel}}(\hat{\mathcal{R}}, \mathcal{R})$). Specifically, we use $1 - \mathrm{F}_{\text{ent}}(\hat{\mathcal{E}}, \mathcal{E})$ and $1 - \mathrm{F}_{\text{rel}}(\hat{\mathcal{R}}, \mathcal{R})$ as the metric of the entity loss and the relation loss respectively. On the one hand, F1 scores characterize the overall performance of the outputs and make the training objective be consistent with the testing time evaluation metric. On the other hand, F1 scores cannot be decomposed onto local predictions of $\hat{\mathcal{E}}$ and $\hat{\mathcal{R}}$ like the log losses in $\mathcal{L}_{\text{ent}}$ and $\mathcal{L}_{\text{rel}}$, thus we need a different training algorithm.

Second, different from previous applications of MRT on single tasks (Xu et al., 2016; Shen et al., 2016), we have two sources of losses in the joint extraction. By integrating losses of individual tasks in the learning algorithm, the entity model could forecast how plausible a candidate entity is according to the relation model, and the relation model could also know the confidence of the entity extraction results. Here, we define a global loss by adding losses of the two models,

$$
\Delta_{E+R}(\hat{\mathbf{y}}, \mathbf{y}) = 1 - \frac{1}{2}[\mathrm{F}_{\text{ent}}(\hat{\mathcal{E}}, \mathcal{E}) + \mathrm{F}_{\text{rel}}(\hat{\mathcal{R}}, \mathcal{R})].
$$

Algorithm 1 The Sampling Algorithm

```
Input: Entity model $\boldsymbol{\theta}_E$, relation model $\boldsymbol{\theta}_R$, sentence $s$, the
    sample size $K$
Output: A subset $\mathcal{Y}'(s)$ of $\mathcal{Y}(s)$
$\mathcal{Y}'(s) \leftarrow \{(\mathcal{E},\mathcal{R})\}$ // add the ground truth
while $|\mathcal{Y}'(s)| \leq K$ do
    $i \leftarrow 1$
    while $i \leq |s|$ do
        with prob. $0.9$, sample $t'_i \sim P_{\text{ent}}(\cdot|s;\boldsymbol{\theta}_E)$
        with prob. $0.1$, sample $t'_i$ uniformly
        $i \leftarrow i + 1$
    end while
    $\mathcal{E}' \leftarrow \mathbf{t}' = t'_1, t'_2, \cdots, t'_{|s|}$
    $\mathcal{R}' \leftarrow \emptyset$
    for $e_1, e_2 \in \hat{\mathcal{E}}, e_1 \neq e_2$ do
        sample $l' \sim P_{\text{rel}}(\cdot|s, e_1, e_2; \boldsymbol{\theta}_R)$
        $\mathcal{R}' \leftarrow \mathcal{R}' \cup \{(e_1, e_2, l')\}$
    end for
    $\mathcal{Y}'(s) \leftarrow \mathcal{Y}'(s) \cup \{(\mathcal{E}', \mathcal{R}')\}$
end while
```

To compare with Δ_{E+R}, we also try two alternatives of $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ in experiments, namely, $\Delta_E(\hat{\mathbf{y}}, \mathbf{y}) = 1 - \mathrm{F}_{\text{ent}}(\hat{\mathcal{E}}, \mathcal{E})$ and $\Delta_R(\hat{\mathbf{y}}, \mathbf{y}) = 1 - \mathrm{F}_{\text{rel}}(\hat{\mathcal{R}}, \mathcal{R})$. They only look one model's loss.

Third, in addition to handcrafted loss functions, we further ask whether the joint MRT model could benefit from automatic "loss engineering". Specifically, let $\Gamma(\hat{\mathbf{y}})$ be the loss learned from the training set, we augment $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ of the MRT objective with $\Gamma(\hat{\mathbf{y}})$, and require the learning process to assign a smaller Γ value (with a margin) to the ground truth output $\mathbf{y}$ than other $\hat{\mathbf{y}} \in Y\backslash\{\mathbf{y}\}$,

$$
\begin{aligned}
&\min. \sum_{\hat{\mathbf{y}}\in\mathcal{Y}(s)} P(\hat{\mathbf{y}}|s;\boldsymbol{\theta}) \left(\Delta(\hat{\mathbf{y}},\mathbf{y}) + \Gamma(\hat{\mathbf{y}})\right) + \xi\\
&\text{s.t.} \quad \Gamma(\mathbf{y}^*) - \Gamma(\mathbf{y}) \geq 1 - \xi,\ \xi \geq 0,
\end{aligned} \tag{4}
$$

where $\mathbf{y}^* = \arg\min_{\hat{y}\in Y(s)} \Gamma(\hat{\mathbf{y}})$. Here, we simply set $\Gamma(\hat{\mathbf{y}}) = 1 - P(\hat{\mathbf{y}}|s;\boldsymbol{\theta})$ [4] and reformulate above objective as

$$
\begin{aligned}
&\sum_{\hat{\mathbf{y}}\in\mathcal{Y}(s)} P(\hat{\mathbf{y}}|s;\boldsymbol{\theta}) \left(\Delta(\hat{\mathbf{y}},\mathbf{y}) - P(\hat{\mathbf{y}}|s;\boldsymbol{\theta})\right)\\
&\qquad + [1 - P(\mathbf{y}|s;\boldsymbol{\theta}) + P(\mathbf{y}^*|s;\boldsymbol{\theta})]_+ .
\end{aligned} \tag{5}
$$

where $[u]_+ = \max(u, 0)$ is the hinge loss.

Optimizing the expected loss is hard since the size of $\mathcal{Y}(s)$ is exponential. In practice, we could

---

[4] Further study on different $\Gamma(\hat{\mathbf{y}})$ is left for future work.

approximate the expectation in Equation 3 by sampling a tractable subset $\mathcal{Y}'(s)$ of $\mathcal{Y}(s)$. Specifically, we first obtain an entity set $\mathcal{E}'$ by sampling (without replacement) an entity tag sequence $\mathbf{t}'$ from P_{ent}. [5] Then based on the sampled entities, we get a relation set $\mathcal{R}'$ by sampling l' from P_{rel} for each entity pairs. Algorithm 1 lists the pseudo code. [6] In experiments, we also try a variant of Algorithm 1 which only samples from the entity model, and selects relation labels with the maximum posterior (i.e., doesn't sample relations).

With the sampled subset $\mathcal{Y}'(s)$, we consider a revised version of the original MRT objective,

$$\mathcal{L}_{\text{mrt}}(\boldsymbol{\theta}) = \sum_{\hat{\mathbf{y}}\in\mathcal{Y}'(s)} Q(\hat{\mathbf{y}}|s;\boldsymbol{\theta},\mu,\alpha)\Delta(\hat{\mathbf{y}},\mathbf{y}), \quad (6)$$

where $Q(\hat{\mathbf{y}}|s;\boldsymbol{\theta},\mu,\alpha)$ is a re-normalization of $P(\hat{\mathbf{y}}|s;\boldsymbol{\theta})$ on the subset $\mathcal{Y}'(s)$, [7]

$$Q(\hat{\mathbf{y}}|s;\boldsymbol{\theta},\mu,\alpha) = \frac{1}{Z}[P(\hat{\mathcal{E}}|s,\boldsymbol{\theta}_E)^{\mu}P(\hat{\mathcal{R}}|s,\hat{\mathcal{E}},\boldsymbol{\theta}_R)^{1-\mu}]^{\alpha}$$

$$Z = \sum_{(\mathcal{E}',\mathcal{R}')\in\mathcal{Y}'(s)} [P(\mathcal{E}'|s,\boldsymbol{\theta}_E)^{\mu}P(\mathcal{R}'|s,\mathcal{E}',\boldsymbol{\theta}_R)^{1-\mu}]^{\alpha}$$

The hyper-parameter α controls the sharpness of the Q distribution (Och, 2003), and μ weights the importance of the entity model and the relation model in Q. Similary, we can rewrite the objective in Equation 5 with $\mathcal{Y}'(s)$ and Q.

Finally, we remark that if we view MRT as a fine tuning step, it can be applied in any joint learning model based on building the joint distribution $P(\hat{\mathbf{y}}|s,\boldsymbol{\theta})$ (e.g., the globally normalized P in (Zhang et al., 2017)). Thus, we would think that MRT is a flexible and lightweight framework for the joint learning.

3.4 Training

To train the joint extraction model, we first pretrain the model with objective $\widetilde{\mathcal{L}}$ (i.e., minimize the local loss), then optimize the local loss and the global loss simultaneously with objective $\widetilde{\mathcal{L}} + \mathcal{L}_{mrt}$. The setting is slightly different from previous work which only optimize $\mathcal{L}_{\text{mrt}}$ in the second step. We find that adding $\widetilde{\mathcal{L}}$ in the experiments could make the training more stable.

When training with $\widetilde{\mathcal{L}}$ in the pre-training step, we apply the scheduled sampling strategy (Bengio et al., 2015) in the entity model as (Miwa and Bansal, 2016). Models are regularized with dropout and trained using Adadelta (Zeiler, 2012). We give the full derivation of Equation 6's gradient in the supplementary. [8]

We select models using development sets: within a fix number of epochs, the model with the best relation extraction performance on the development set is picked out for testing. [9]

4 Experiments

We evaluate the proposed model on two datasets. **ACE05** is a standard corpus for the entity relation extraction task. It is labelled with 7 entity types and 6 relation types. We use the same split of ACE05 documents as previous work (351 training, 80 development, and 80 testing). [10] **NYT** (Riedel et al., 2010) is a larger corpus which is labelled with 3 entity types and 24 relation types. [11] The training set has 353k relation triples which are generated by distant supervision. It also provides another 3880 manually labelled relation triples. Following (Ren et al., 2017; Zheng et al., 2017), we exclude the `None` relation label and randomly select 10% of the labelled data as the development set. We will mainly discuss the results on ACE05 where many previous joint learning models are available for comparison.

We list detailed hyper-parameter settings in the supplementary. Note that, except μ, α, K which are introduced in the joint MRT and selected on the development set, [12] we don't tune hyper-parameters extensively. For example, we use the same setting in both ACE 05 and NYT rather than tune parameters on each of them.

As previous work, we evaluate performances

---

[5] To accelerate sampling, we borrow the idea of ε-greedy in reinforcement learning: with probability 0.9, we sample t_i' from P_{ent}, and with probability 0.1, we sample it uniformly.

[6] The time complexity is $O(K|s|)$ which is the same to the beam search algorithm with beam size K (Zhang et al., 2017).

[7] Here we follow the literature of MRT to apply the renormalization on $\mathcal{Y}'(s)$. Another formulation is the policy gradient framework which sticks to the original probability.

[8] We remark that the MRT objective (Equation 6) is differentiable with respect to model parameters (Shen et al., 2016). The non-decomposability of the F1 score does not make the model non-differentiable. In our implementation, the gradient is automatically calculated using autograd tools. Please see the supplementary for more details.

[9] We focus on the performance of the ent-to-end relation extraction, so we select models by the relation extraction results. It is also possible to consider both the performances of the entity model and the relation model. We leave the study of advanced model selection algorithms for future work.

[10] We use the dataset in https://github.com/tticoin/LSTM-ER, which is from (Miwa and Bansal, 2016).

[11] https://github.com/shanzhenren/CoType.

[12] The default setting is $\alpha = 10^{-4}, \mu = 1.0, K = 3$ in systems without self-learned Γ loss and $\alpha = 1, \mu = 1.0, K = 2$ in systems with Γ loss.

Model	Entity			Relation		
	P	R	F	P	R	F
L&J (2014)	**85.2**	76.9	80.8	**65.4**	39.8	49.5
M&B (2016)	82.9	**83.9**	83.4	57.2	54.0	55.6
Zhang (2017)	-	-	83.5	-	-	57.5
K&C (2017)	84.0	81.3	82.6	55.5	51.8	53.6
NN	84.0	82.9	83.4	59.5	**56.3**	57.8
MRT	83.9	83.2	**83.6**	64.9	55.1	**59.6**

Table 1: Results on the ACE05 test data. (Miwa and Bansal, 2016) and (Katiyar and Cardie, 2017) are joint training systems without joint decoding. (Li and Ji, 2014) and (Zhang et al., 2017) are joint decoding algorithms. NN is our neural network model without minimum risk training. MRT is minimum risk training with loss Γ (Equation 5). We omit pipeline methods which underperform joint models (see (Li and Ji, 2014) for details).

Settings		F1 of Entity	F1 of Relation
Default sampling	Δ_E	**83.8** $_{+0.4}$	57.9 $_{+0.1}$
	Δ_R	83.5 $_{+0.1}$	58.9 $_{+1.1}$
	Δ_{E+R}	83.6 $_{+0.2}$	59.0 $_{+1.2}$
	Γ	83.6 $_{+0.2}$	58.3 $_{+0.5}$
	$\Gamma + \Delta_{E+R}$	83.6 $_{+0.2}$	**59.6** $_{+1.8}$
Only sampling entity	Δ_E	**83.7** $_{+0.3}$	57.4 $_{-0.4}$
	Δ_R	83.5 $_{+0.1}$	59.1 $_{+1.3}$
	Δ_{E+R}	83.6 $_{+0.2}$	57.9 $_{+0.1}$
	Γ	83.6 $_{+0.2}$	58.7 $_{+0.9}$
	$\Gamma + \Delta_{E+R}$	83.3 $_{-0.1}$	**59.2** $_{+1.4}$

Table 2: MRT with different loss functions and sampling methods. The numbers in subscripts indicate improvements over the NN setting in Table 1.

using precision (P), recall (R) and F1 scores. Specifically, an output entity e is correct if its type and the region of its head are correct, and an output relation r is correct if its e_1, e_2, l are correct (i.e., "exact match").

4.1 Results on ACE05

We first compare proposed models with previous work (Table 1). In general, our plain neural network model (NN) is competitive, and after compiling with MRT, it achieves non-negligible improvement over existing state-of-the-art systems. (both on the entity and the relation extraction). [13] We have following two detailed comparisons.

Among systems which only rely on shared parameters ((Miwa and Bansal, 2016; Katiyar and Cardie, 2017) and NN), NN gives the best result (we give detailed results on different relation types in the supplement). One possible reason is that the "RNN+CNN" network structure is not fully explored in previous joint learning models. More importantly, it suggests that how to build powerful sub-models and utilize shared parameters are still among the key problems of the task.

Comparing with the best joint decoding system which adopts global normalization in training (Zhang et al., 2017), MRT mainly improves the relation extraction results. We think that the improvement may come from the sentence-level loss applied in MRT: both systems consider interactions between decoders, and both objectives are approximated by sampling, but MRT optimizes F1 score while Zhang et al. (2017) optimize label accuracy. For the joint decoding system in (Li and Ji, 2014), although it cannot beat recent neural network-based models, it is interesting to compare MRT with a feature-enriched version of (Li and Ji, 2014)'s model in the future work.

Next, we evaluate the joint MRT with different loss functions and sampling methods.

As mentioned in Section 3.3, we have three options (Δ_{E+R}, Δ_E, Δ_R) for $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ and a self-learned loss function Γ. The first five rows of Table 2 show their performances on the test data. We have three observations regarding the results.

1. Δ_R, Δ_{E+R} have higher relation F1 scores than Δ_E and NN. Thus, adding relation loss in $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ is helpful for relation extraction. We think that knowing the relation loss could bias the entity model to highlight the entities appearing in relations, which provides a better candidate relation set for the relation extraction model.

2. Δ_E has the best entity extraction results, which implies that the sentence-level entity loss alone could benefit entity extraction. While after adding relation loss (Δ_{E+R}), the entity performance slightly decreases. One reason might be that our model selection strategy only focuses on the relation part (footnote 9), thus the model with improved entity performances may not be selected.

3. The learned loss Γ can help to improve performances, but only using Γ is not as effective as the handcrafted Δ functions (which are tailored to the evaluation metrics). By combining both the prior knowledge and information from the dataset, $\Gamma + \Delta_{E+R}$ achieves the best results.

Regarding the sampling method, we test a variant of Algorithm 1 which samples entities but not

---

[13] It is worth noting that our models don't access additional linguistic resources such as POS tags and dependency trees. We have tried to add syntactic features in (Zhang et al., 2017), but didn't observe improvements.

relations (the last five rows of Table 2). Comparing with the default sampling algorithm, it has similar entity extraction performances, but its behaviour on the relation extraction is different. Specifically, adding entity loss in $\Delta(\hat{\mathbf{y}}, \mathbf{y})$ (i.e., Δ_E, Δ_{E+R}) now affects relation results negatively. It may suggest that when only exploring the output of entity extraction, the entity loss may dominate the relation loss, and trap the joint model to exploit the entity model only. On the other hand, the performances of self-learned loss Γ are less sensitive to the sampling method. We haven't had a clear understanding of the relationship between sampling algorithms and loss functions, but the above results show that adding data-related loss function could improve the robustness of MRT in practice.

Thirdly, we present influences of hyper-parameters for MRT with Δ_{E+R} on the development set in Figure 3 and 4 (other settings have similar results). We find that, for the parameters examined here, it is hard for the entity model and the relation model to agree with each other: parameters achieving high relation performances usually get low entity performances, and vise versa. Thus, if we perform the model selection by only looking at relation extraction results, the joint model may sacrifice entity extraction performances. For α and μ (Figure 3), we observe that on the ACE05 dataset, the model prefers a small α (which means a sharper Q) and μ at boundary (i.e., Q is either close to the entity model or the relation model). Regarding the sample size K (Figure 4), we don't observe a convergence of performances in a small range of K. Since the computation cost increases rapidly as we increase the sample size ($K = 5$ is about 2x slower than $K = 3$ in our implementation), we stick to a small K.

Finally, due to lack of space, we provide more discussions on model configurations (including results regarding different entity pair distances, additional experiments on tuning hyper parameters etc.), and detailed error analyses on concrete samples in the supplementary.

4.2 Results on NYT

We briefly list results on the NYT dataset in Table 3. The baseline methods are (Ren et al., 2017) which is based on a joint embedding of entities and relations, and (Zheng et al., 2017) which conducts joint decoding with an augmented sequence labelling tag set. Both NN and MRT outperform baseline results. In particular, comparing with the joint tagging scheme in (Zheng et al., 2017), MRT adds no constraint on the relation extraction model and can explore the large NYT training set more effectively. At the same time, since the training set is automatically generated, the global losses observed in MRT are also noisy. Like recent work on bandit structured prediction (Kreutzer et al., 2017; Nguyen et al., 2017), the results here suggest that MRT could be a reasonable choice when the supervision of the joint learning is partial and noisy.

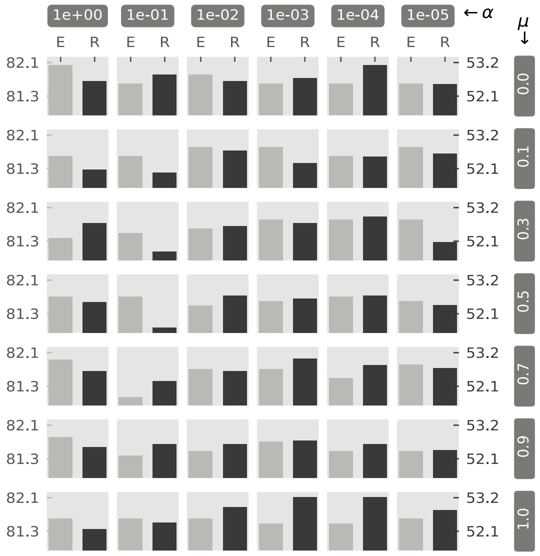

Figure 3: MRT with different Q distributions on the development set. Rows are settings of μ, and columns are settings of α. In each cell, we draw F1 scores of the entity extraction (the left gray bar) and the relation extraction (the right dark bar) under the combination of corresponding α and μ.

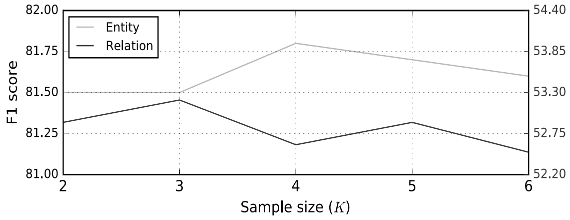

Figure 4: MRT with different sample size K on the development set.

5 Conclusion

We introduced minimum risk training to the task of joint entity and relation extraction. We showed that, with a global loss function, MRT could enhance the connection between the sub-models. Extensive experiments on benchmark datasets witness the effectiveness of the joint MRT.

Model	Relation		
	P	R	F
(Zheng et al., 2017)	61.5	41.4	49.5
NN	61.8	**43.3**	50.9
MRT	**67.4**	42.0	**51.7**
(Ren et al., 2017)	42.3	**51.1**	46.3
NN (exact match)	59.4	41.7	49.0
MRT (exact match)	**65.2**	40.6	**50.0**

Table 3: Results on the NYT dataset. To compare with (Ren et al., 2017), we give results under the "exact match" criterion as ACE05. To compare with (Zheng et al., 2017), we give results which ignore the entity type in the justification of relations. We use $\alpha = 1, \mu = 1, K = 2$ and $\Delta_{E+R} + \Gamma$.

Abstract

Experimental performance on the task of relation classification has generally improved using deep neural network architectures. One major drawback of reported studies is that individual models have been evaluated on a very narrow range of datasets, raising questions about the adaptability of the architectures, while making comparisons between approaches difficult. In this work, we present a systematic large-scale analysis of neural relation classification architectures on six benchmark datasets with widely varying characteristics. We propose a novel multi-channel LSTM model combined with a CNN that takes advantage of all currently popular linguistic and architectural features. Our 'Man for All Seasons' approach achieves state-of-the-art performance on two datasets. More importantly, in our view, the model allowed us to obtain direct insights into the continued challenges faced by neural language models on this task. Example data and source code are available at: `https://github.com/aidantee/MASS`.

1 Introduction

Determining the semantic relation between pairs of named entity mentions, *i.e.* relation classification, is useful in many fact extraction applications, ranging from identifying adverse drug reactions (Gurulingappa et al., 2012; Dandala et al., 2017), extracting drug abuse events (Jenhani et al., 2016), improving the access to scientific literature (Gábor et al., 2018), question answering (Lukovnikov et al., 2017; Das et al., 2017) to major life events extraction (Li et al., 2014; Cavalin et al., 2016). With a multitude of possible relation types, it is critical to understand how systems will behave in a variety of settings (see Table 1 for an example).

(i)	*<e1>**Three-dimensional digital subtraction angiographic**</e1> (<e2>**3D-DSA**</e2>) images from diagnostic cerebral angiography were obtained ...*
(ii)	*The metal <e1>**ball**</e1> makes a ding ding ding <e2>**noise**</e2> when it swings back and hits the metal body of the lamp.*

Table 1: Examples for different relation types: sentence (i) shows a *Synonym-of* relation, represented by an abbreviation pattern, which is very different from the predicate relation *Cause-effect* in (ii).

To the best of our knowledge, almost all relation classification models introduced so far have been experimentally validated on only a few datasets - often only one. This is despite the availability of established benchmarks. The lack of transparency as well as the possibility of having selection bias raise a question about the true capability of state-of-the-art methods for relation classification. In addition, despite such a wealth of studies, it still remains unclear which approach is superior and which factors set the limits on performance. For example, heuristic post-processing rules have been seen to significantly boost relation classification performance on several benchmarks; yet, they cannot be relied upon to generalize across domains. The novel approach we present in this paper draws inspiration from neural hybrid models such as that of Cai et al. (2016). In this work, we present a large-scale analysis of state-of-the-art neural network architectures on six benchmark datasets which represent a variety of language domains and semantic types. As a means of comparison against reported system performance, we propose a novel multi-channel long short term memory (Hochreiter and Schmidhuber, 1997, LSTM) model combined with a Convolutional Neural Network (Kim, 2014, CNN) that takes advantage of all major linguistic and architectural features cur-

rently employed. We designate this as a 'Man for All SeasonS' (MASS) model because it incorporates many popular elements reported by state of the art systems on individual datasets.

The main contributions of the paper are:

1. We presented a deep neural network model, in which each component is capable of taking advantage of a particular type of major linguistic or architectural feature. The model is robust and adaptable across different relation types in various domains without any architectural changes.

2. We investigated the impact of different components and features on the final performance, therefore, providing insights on which model components and features are useful for future research.

2 Related Works

We focus here on supervised approaches to relation classification. Alternatives include hand built patterns (Aone and Ramos-Santacruz, 2000), unsupervised approaches (Yan et al., 2009) and distantly supervised approaches (Mintz et al., 2009). Traditional supervised and kernel-based approaches have made use of a full range of linguistic features (Miwa et al., 2010) such as orthography, character n-grams, chunking as well as vertex and edge walks over the dependency graph. Hand crafting and modeling with such complex feature sets remains a challenge although performance tends to increase with the amount of syntactic information (Bunescu and Mooney, 2005).

Recent successes in deep learning have stimulated interest in applying neural architectures to the task. Convolutional Neural Networks (CNNs) (Nguyen and Grishman, 2015) were among early approaches to be applied. Following in this direction, (Lee et al., 2017) achieved state of the art performance on the ScienceIE task of SemEval 2017. Other recent variations of CNN architectures include a CNN with an attention mechanism in Shen and Huang (2016) and a CNN combined with maximum entropy in Gu et al. (2017). Various auxiliary information has been reported to improve the performance of CNNs, such as the document graph (Verga et al., 2018) and position embeddings (Shen and Huang, 2016; Lee et al., 2017; Verga et al., 2018). Recurrent Neural Networks (RNNs) are another approach to capturing relations and naturally good at modeling long distance relations within sequential language data. Approaches include Mehryary et al. (2016) with the original RNN and Li et al. (2017); Ammar et al. (2017); Zhou et al. (2018) with RNNs having LSTM units which are used to extend the range of context. Apart from sentences themselves, RNN-based models often take as input information extracted from dependency trees, such as shortest dependency paths (SDP) (Mehryary et al., 2016; Ammar et al., 2017), or even whole trees (Li et al., 2017). Since RNNs and CNNs each have their own distinct advantages, a few models have combined both in a single neural architecture (Cai et al., 2016; Zhang et al., 2018).

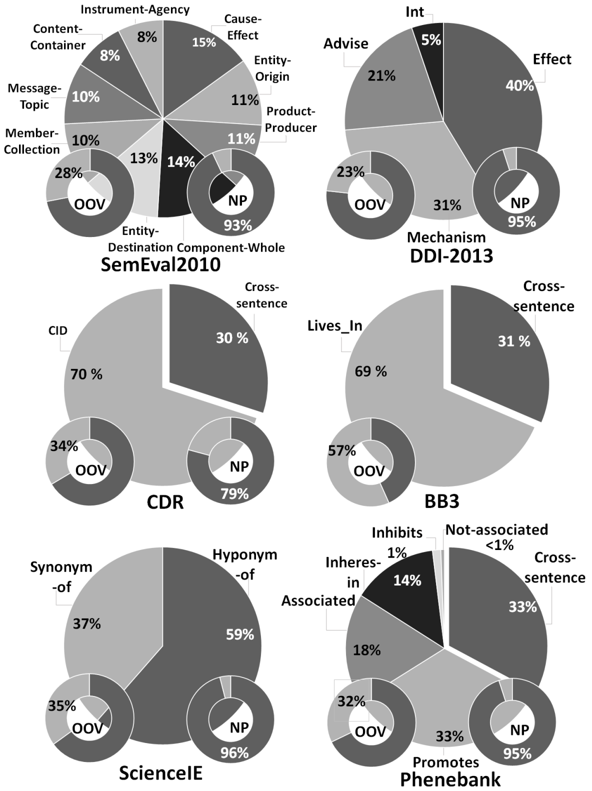

Figure 1: The statistics of corpora used in our experiments. Three aspects are considered: the distribution of relation types, the distribution of Out-Of-Vocabulary (OOV) in the test set and the distribution of new entity pairs (NP) that appeared in the test set but never appeared in the training data.

3 Materials and Methods

3.1 Gold Standard Corpora

As noted above, our experiments used six well-known benchmark corpora from different domains, which have been used to evaluate vari-

Domain: the domain of the corpus; IAA: the Inter-annotator Agreement score; Size: training set size (test set size in the brackets) in terms of the number of sentences (SemEval) or documents (all other corpora); Entity: the number of entity types; Relation: the number of relation types; % of negative: the distribution of positive and negative instances; Cross-sentence: if there are cross-sentence relations; Directed: if there are directed relations in the corpus; Undirected: if there are undirected relations in the corpus; SDP length: the averaged (max in brackets) length of the SDPs in the corpus.

ous state-of-the-art relation classification systems. ***SemEval*** is a generic domain benchmark dataset (Hendrickx et al., 2009). The next four chosen corpora are from various biomedical domains: the ***DDI-2013*** corpus (Herrero-Zazo et al., 2013; Segura-Bedmar et al., 2014), the ***CDR*** corpus (Li et al., 2016), the ***BB3*** corpus (Delėger et al., 2016), and the ***Phenebank*** corpus. Finally, ***ScienceIE*** corpus contains scientific journal articles from three sub-domains (Augenstein et al., 2017). Inter-annotator agreement (IAA) as measured with Cohens kappa on these corpora indicates high variability in the range of $[0.45, 0.74]$, *i.e. moderate* to *substantial* agreement (McHugh, 2012).

As shown in Table 2, each of these corpora is distinct in many respects. CDR and BB3 were only annotated with one relation type, whilst other corpora have several relation types. In all corpora except SemEval, negative instances must be automatically generated by pairing all the entities appearing in the same sentences that have not been annotated as positives. As there are a large number of such entities, the number of possible negatives accounts for a large percentage of set of instances, *i.e.* up to 80% of the total in DDI-2013, ScienceIE and Phenebank. Further, the small percentage of positive examples includes several types, causing a severe imbalance in the data (He and Garcia, 2009) (see Figure 1 for further details).

Another challenge for relation classification is in modeling the order of entities in a directed relation type (Lee et al., 2017). In the six corpora, several relations are directed and order-sensitive, such as the *Cause-Effect* relation in SemEval and *Hyponym-of* in ScienceIE. Such relations require the model to predict both relation types and the entity order correctly. In contrast, for undirected relations, such as *Synonym-of* in ScienceIE and *Associated* in Phenebank, both directions can be accepted.

An interesting factor is that the length of the SDP in SemEval is considerably shorter than in the other corpora. The mean and maximum length SDP values for CDR, BB3, ScienceIE and Phenebank are quite similar, *i.e.* ~ 7 and $22 - 26$ tokens. DDI-2013 contains very complex sentences, with an averaged SDP length of 9 and the longest SDP of 66 token.

Figure 1 shows the Out-Of-Vocabulary (OOV) ratios in six corpora, which are quite large, ranging from 23% to 57%. More interesting is the percentage of entities (or nominal) pairs in the test set that have never appeared in the training set (NP: 79% on CDR and more than 93% on SemEval, DDI-2013, ScienceIE and Phenebank). These two characteristics indicate the importance of understanding the mechanisms by which neural networks can generalize, *i.e.* make accurate predictions on novel instances.

3.2 Model Architecture

Our 'Man for All SeasonS' (MASS) model comprises an embeddings layer, multi-channel bidirectional Long Short-Term Memory (BLSTM)

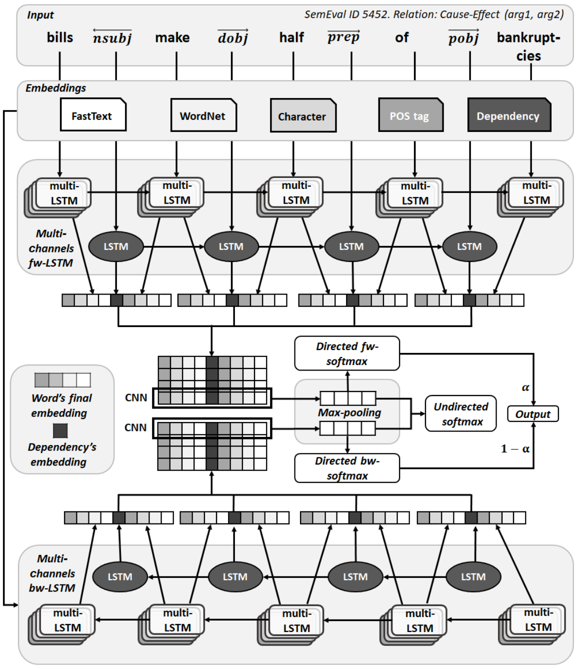

Figure 2: The architecture of MASS model for relation classification. An embeddings layer is followed by multi-channel bi-directional LSTM layers, two parallel CNNs and three *softmax* classifiers. The model's input makes use of words and dependencies along the SDP going from the first entity to the second one using both forwards and backwards sequences.

layers, two parallel Convolutional Neural Network (CNN) layers and three $softmax$ classifiers. The MASS model's architecture is depicted in Figure 2. MASS makes use of words and dependencies along the SDP going from the first entity to the second one using both forwards and backwards sequences. As is standard practice (Xu et al., 2015; Cai et al., 2016; Mehryary et al., 2016; Panyam et al., 2018) an entity pair is classified as having a relation if and only if the SDP between them is classified as having that relation.

3.2.1 Embeddings layer

Despite the presence of inter-sentential relations in the six corpora we make the simplifying assumption that relations occur only between entities (or nominals) in the same sentence. We model each such sentence using a dependency path. In order to classify novel dependency paths we represent a dependency relation d_i as a vector D_i that is the concatenation of two vectors as follow:

$$D_i = Dtyp_i \oplus Ddir_i$$

where $Dtyp$ is the undirected dependency vector, expressing the dependency type among 63 labels and, $Ddir$ is the orientation of the dependency vector *i.e.* from left-to-right or vice versa in the order of the SDP. Both are initialized randomly.

For **word representation**, we take advantage of four types of information, including:

- ***FastText pre-trained embeddings*** (Bojanowski et al., 2017) are the 300-dimensional vectors that represent words as the sum of the skip-gram vector and character n-gram vectors to incorporate sub-word information.

- ***WordNet embeddings*** are in the form of one-hot vectors that determine which sets in the 45 standard WordNet super-senses the tokens belong to.

- ***Character embeddings*** are denoted by $\mathbb{C}$, containing 76 entries for 26 letters in uppercase and lowercase forms, punctuation, and numbers. Each character $c_j \in \mathbb{C}$ is randomly initialized. They will be used to generate the token's character-based embeddings.

- ***POS tag embeddings*** capture (dis)similarities between grammatical properties of words and their lexical-syntactic roles within a sentence. We randomly initialized these vectors values for the 56 POS tags in OntoNotes v5.0.

Note that all initializations are generated by looking up the corresponding lookup table. The character and POS tag embeddings lookup tables were randomly constructed according to the $Glorot$ uniform initializer (Glorot and Bengio, 2010) and then treated as the model's parameters to be learned in the training phase.

3.2.2 Multi-channel Bi-LSTM

For a given linguistic feature type, LSTM networks (Hochreiter and Schmidhuber, 1997) are employed to capture long-distance dependencies along two directions, namely the forward and backward Bi-directional LSTM (BLSTM).

For the **dependencies**, BLSTMs take as input a sequence of dependency embeddings D_i, then gives output are the hidden states for dependencies between adjacent tokens w_i and w_{i+1} as $fwDEP_{ii+1}$ and $bwDEP_{ii+1}$.

Apart from the dependencies between tokens in SDPs, our model exploits four linguistic embeddings relating to words for **representing the**

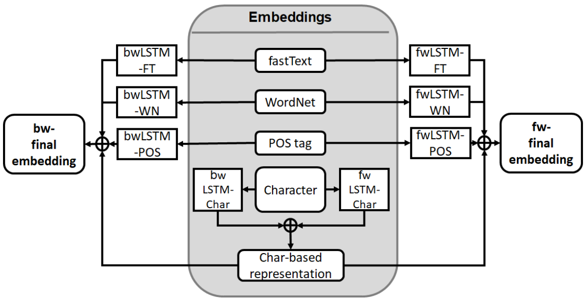

Figure 3: The multi-channel LSTM for word representation. Each token in the SDP is represented by using four word-related embeddings, including FastText word embedding, WordNet embedding, POS tag embedding and the character embedding. These four types of word-related information are fed into eight separate LSTMs, independently from each other during recurrent propagation.

words. These four types of word-related information are fed into eight separate LSTMs (four for each direction) independently from each other during recurrent propagation. These four BLSTM channels are illustrated in Figure 3. The morphological surface information is represented with character-based embedding using a BLSTM, in which the forward and backward LSTM hidden states are jointly concatenated (Ling et al., 2015; Dang et al., 2018). For other layers, the LSTM hidden states are concatenated separately as the forward and the backward vector to form two final embeddings for each token as follows:

$$fwW_i = fwFT_i \oplus fwWN_i \oplus Char_i \oplus fwPOS_i$$

$$bwW_i = bwFT_i \oplus bwWN_i \oplus Char_i \oplus bwPOS_i$$

3.2.3 CNN with dependency unit

Similar to Cai et al. (2016), the Convolutional Neural Networks (CNNs) in our model utilize **Dependency Units (DU)** to model the SDP. DU has the form of $[w_i - d_{ii+1} - w_{i+1}]$, in which w_i, w_{i+1} are two adjacent tokens and d_{ii+1} is the dependency between them. As a result, the low-dimensional forward and backward representation vectors of DU_j are created by concatenating the corresponding final embeddings of tokens w_j, w_{j+1} and the LSTM hidden state of the dependency d_{ii+1}. Formally, we have:

$$fwDU_j = fwW_j \oplus fwDEP_{jj+1} \oplus fwW_{j+1}$$

$$bwDU_j = bwW_j \oplus bwDEP_{jj+1} \oplus bwW_{j+1}$$

The forward and backward SDP representation matrices fwS and bwS are created by stacking the $fwDU$ and $bwDU$ vectors. We then apply two parallel CNNs to fwS and bwS to capture the context features (CF_j) around each dependency unit DU_j in the SDP as follows. These CNNs are designed similarly to the original CNN for sentence classification (Kim, 2014).

$$fwCF_j = f(We_{CNN} \cdot fwDU_j + b_{CNN})$$

$$bwCF_j = f^{'}(We^{'}_{CNN} \cdot bwDU_j + b^{'}_{CNN})$$

where We_{CNN} and $We^{'}_{CNN}$ are the weight matrices for the CNNs, b_{CNN} and $b^{'}_{CNN}$ are the bias terms for the hidden state vectors and f and $f^{'}$ are the non-linear activation functions.

The $n-$max pooling (Boureau et al., 2010) layer gathers the most useful global information G over the whole SDP (Collobert et al., 2011) from the context features of dependency units, which is defined as follows (in this work, we use $1-$max pooling).

$$fwG = \max_{d=1}^{k} fwCF_j$$

$$bwG = \max_{d=1}^{k} bwCF_j$$

where max is an element-wise function, and k is the number of dependency units in the SDP.

3.2.4 Softmax classifiers

Following (Cai et al., 2016), relation classification based on fwS and bwS simultaneously can strengthen the model's ability to judge the direction of relations. We, therefore, use two directed $softmax$ classifiers, one for each direction of the relation, with linear transformation to estimate the probability that each of fwS and bwS belongs to a directed relation (the direction taken into account). Formally we have:

$$p(fw) = softmax(W_f \cdot fwG + b_f)$$

$$p(bw) = softmax(W^{'}_f \cdot bwG + b^{'}_f)$$

where W_f and $W^{'}_f$ are the transformation matrices and b_f and $b^{'}_f$ are the bias vectors.

These two distributions are then combined to get the final distribution with a priority weight α:

$$p = \alpha \cdot p(fw) + (1 - \alpha) \cdot p(bw)$$

We also use the undirected $softmax$ to predict undirected distribution $p(ud)$. This $softmax$ is only used in the training objective function, which is the penalized cross-entropy of three $softmax$

classifiers. Our undirected softmax is quite similar to the idea of coarse-grain softmax used in Cai et al. (2016); Zhou et al. (2018).

$$p(ud) = softmax(W''_f \cdot [fwG \oplus bwG] + b''_f)$$

where W''_f is the transformation matrix and b'_f is the bias vector.

3.3 Additional Techniques

Mehryary et al. (2016) demonstrated that random initialization can, to some extent, have an impact on the model's performance on unseen data, i.e, individual trained models may perform substantially better (or worse) than the averaged results.

Further, an ensemble mechanism, was found to reduce variability whilst yielding better performance than the averaging mechanism. Two simple but effective ensemble methods include strict majority vote (Mehryary et al., 2016) and weighted sum over results (Ammar et al., 2017; Lim et al., 2018; Verga et al., 2018). Since the former brings better results in our experiments, our ensemble system runs the model for 20 times and uses the strict majority vote to obtain the final results.

For dealing with the imbalanced data problem, we apply an under-sampling technique (Yen and Lee, 2006) during pre-processing for the DDI-2013 and Phenebank corpora. For a fair comparison we also apply some simple rules that was used by comparison models as the pre/post-processing step for DDI-2013 (following Zhou et al. (2018)), BCR (following Gu et al. (2017)) and ScienceIE (following Lee et al. (2017)) (for further details, see Appendix A).

Finally, we use several techniques to overcome over-fitting, including: *max-norm regularization* for Gradient descent (Qin et al., 2016); adding *Gaussian noise* (Quan et al., 2016) with mean 0.001 to the input embeddings; applying *dropout* (Srivastava et al., 2014) at 0.5 after all embedding layers, LSTM layers and CNN layers; and using *early stopping* technique (Caruana et al., 2000).

4 Results and Discussion

For each benchmark dataset we adopt the official task evaluations for system with $F1$ score, precision P and recall R. All official evaluations only considered the actual relations (excluding the *Other* relation and negatives) and worked on the abstract level (excepted SemEval). For a clearer comparison, we also report both averaged and ensemble results, in which, the averaged results are calculated over 20 different runs. Both results of the MASS model with and without applying pre/post-processing rules are also reported.

Model	Source of information	F1
SVM (Rink and Harabagiu, 2010)	Rich features	82.2
CNN + Attention Shen and Huang (2016)	Position, WordNet, words around nominals	85.9
BLSTM + CNN (Cai et al., 2016)	NER, WordNet w/o inversed SDP* w/ inversed SDP	 83.8 86.3
BLSTM + CNN + attention (Zhang et al., 2018)	Position embedding	83.7
Baseline model	WordNet, Character embeds	85.0
MASS model	WordNet, Character embeds (+ Inversed SDP) + Ensemble	85.9 85.4 **86.3**

Table 3: Comparison of our system with top performing systems on the SemEval 2010 corpus. The official evaluation is based on the macro-averaged F1. Since most of the comparative models did not report their P and R, we only report our F1 for comparison. All deep learning models use word embedding and POS tag information. *We report results for our implementation of Cai et al.'s system, without using the inversed SDP.

We compare the performance of the MASS model against three types of competitors: (i) A baseline model is used to verify the effectiveness of the multi-channel LSTM, in which we concatenate all embedding vectors used in MASS directly. (ii) The first ranked in the original challenges. (iii) Recent models with state-of-the-art results. The comparative results are shown in Tables 3 - 8.

In all corpora, the MASS model's results are always better than the baseline model. This is because directly concatenating many vectors with various value ranges seems to be causing information interference, and we cannot take advantages of each sequence of information separately anymore.

In **SemEval2010 corpus** (see Table 3), the macro-averaged $F1$ of the original model is 85.9% with the standard deviation of 20 runs is 0.33. This result outperforms all comparative models but Cai et al. (2016) which fed the inversed SDP to enrich the training data (we also tried feeding inversed SDP to the model, but the result became worse since this technique may be unsuitable for our model). Applying ensemble procedure boosts $F1$ for 0.45%, outperforming all comparative models.

Model	Source of information	P	R	F1
2-phase classification Hybrid kernel SVM[1]	Heterogeneous set of feature, rule-based negative filtering	64.6	65.6	65.1
2-phase classification SVM[2]	Rich features	73.6	70.1	71.8
BLSTM + Attention (Zhou et al., 2018)	Position-aware attention + Pre-processing	75.8	70.3	73.0
Baseline model	WordNet, Character embeds	51.6	52.9	52.2
MASS model	WordNet, Character embeds	54.0	56.3	55.1
	+ Ensemble	56.5	57.3	56.0
	+ Pre-processing	57.0	56.5	56.7

Table 4: Results on the DDI-2013 corpus. The official evaluation is the micro-averaged P, R and F1 at abstract-level. Note that all deep learning models use word embedding and POS tag information. [1]Chowdhury and Lavelli (2013). [2]Raihani and Laachfoubi (2017).

For dealing with **DDI-2013** (see Table 4)- an imbalanced data, comparative models often consider it as two sub-tasks, *i.e.* detection and classification. Chowdhury and Lavelli (2013); Raihani and Laachfoubi (2017) applied a two-phrase classification, in which one classifier detects positive instance and the other then classifies them. Zhou et al. (2018) used a binary softmax together with a multi-class softmax. Obviously, our model encounters a serious problem with imbalanced data. Since we treat the RE problem as a multi-class classification, in which, negative is also considered as a class, our results are much lower than comparative models. We applied negative undersampling technique and the pre-processing rules from Zhou et al. (2018) to remove some negatives, however the rules improved performance only slightly (0.3%).

Since our system just extracts the relations within a sentence, for **CDR** (see Table 5)- a corpus where 30% instances are cross-sentence relations, it is reasonable to explain why our recall is much lower than the comparative systems that can extract cross-sentences relations (Gu et al., 2017; Verga et al., 2018). Our results are still extremely encouraging since the $F1$ is better than other models which do not extract cross-sentences relations (Gu et al., 2017; Panyam et al., 2018). For a clearer comparison, we also try applying post-processing rules used by Gu et al. (2017), and they help to increase the $F1$ by 3.3%. Our $F1$ is just a little lower than the combined model of CNN and ME which extracts cross-sentence relations (Gu et al., 2017). The results for BRAN (Verga et al., 2018) however are much better than our MASS model. It is a a strong competitor on this benchmark that is designed to focus on cross-sentence relation classification by creating the document-level graph and is also trained using auxiliary data.

Model	Source of information	P	R	F1
CNN + ME[1] (Gu et al., 2017)	Contextual of whole sentence	59.7	57.5	57.2
	+ Cross-sentence	60.9	59.5	60.2
	+ Post processing	55.7	68.1	**61.3**
ASM[2] (Panyam et al., 2018)	Dependency graph	49.0	67.4	56.8
BRAN[3] (Verga et al., 2018)	Position, multi-head att	55.6	70.8	62.1
	+ Data	64.0	69.2	**66.2**
	+ Ensemble	63.3	67.1	**65.1**
Baseline model	WordNet, character embeds	56.6	54.1	55.3
MASS model	WordNet, character embeds	58.9	54.9	56.9
	+ Ensemble	56.8	57.9	57.3
	+ Post-processing	52.8	71.1	60.6

Table 5: Results on the CDR corpus. The official evaluation is reported at abstract-leve. All deep learning models use word embedding and POS tag information. [1]CNN + Maximum Entropy. [2]Approximate Subgraph Matching. [3]CNN + attention at abstract-level graph.

Model	Source of information	P	R	F1	IntraF
VERSE (SVM)[1]	Rich features	51.0	61.5	55.8	63.4
TurkuNLP (RNN)[2]		62.3	44.8	52.1	62.0
DET-BLSTM (Li et al., 2017)	Dynamic ext dep tree, distance embeddings	56.3	58.0	**57.1**	–
Baseline model	WordNet, Char embds	60.8	47.2	53.1	62.5
MASS model	WordNet, Char embds	59.8	51.3	55.2	64.6
	+ Ensemble	59.2	52.2	55.5	**64.8**

Table 6: Results on the BB3 corpus. The official evaluation is reported at both abstract- and intra sentence levels. All deep learning models use word embedding and POS tag information. [1]Lever and Jones (2016). [2]Mehryary et al. (2016)

In the **BB3** corpus (see Table 6), the original system outperforms all previously reported results at intra-sentence F. Using ensemble procedure, our results increase, but not much and still lower than the DT-BLSTM model, which is based on Dynamic Extended Tree (Li et al., 2017).

In the **ScienceIE** corpus (see Table 7), our results are only outperformed by one competitor. The reason may come from the characteristic of Hyponym-of and Synonym-of relations. Neither of these relations is expressed frequently by the linguistic information of tokens appearing in the SDP. In many cases, they are represented by different patterns with the same SDP. Therefore, our conclusion is that maybe the use of SDP does not match the ScienceIE corpus. The system from

Model	Source of information	F1
NTNU-2 (SVM) (Barik and Marsi, 2017)	Rich features	50.0
MIT (CNN) (Lee et al., 2017)	Relative position, NER + Post-processing	**64.5**
S2_rel (BLSTM) (Ammar et al., 2017)	Semisupervised, language model + Ensemble	54.1 55.2
Baseline model	WordNet, character embeds	48.7
MASS model	WordNet, character embeds + Ensemble + Post- processing (Lee et al., 2017) + Post- processing (rules ++)	54.6 56.4 60.3 **73.0**

Table 7: Results on the ScienceIE corpus. The official evaluation is based on the micro-averaged F1 at abstract-level. Since most of comparative models did not report their P and R, we only report our F1 for comparison. All deep learning models use word embedding and POS tag information.

MIT (Lee et al., 2017) fed the whole sentence with the relative position as input, therefore it may catch many useful patterns which did not appear in the SDP. To test this hypothesis, we apply the post-processing rules used in Lee et al. (2017) and boosted $F1$ by 3.8%. In addition, when we applied some more simple linguistic rules to identify synonyms and hyponyms, the results improved beyond expectations by 16.6%, totally outperformed all other models.

For **Phenebank** (see Table 8), since this new corpus did not have an official evaluation, we report all possible MASS results. The micro-averaged results are much better than the macro-averaged. It is reasonable since Phenebank is an extremely imbalanced corpus, in which we can expect poor accuracy for rare classes, which together account for about 1% of positive data (and positive data only account for 23% of the whole corpus). The micro-averaged and macro-averaged results of the proposed model are always better than the baseline model, in both abstract and sentence-level. Interestingly, the ensemble model boosts the micro-averaged results (1.33% of $F1$ at sentence-level and 0.88% of $F1$ at abstract-level), but brings lower macro-averaged $F1$ (decreased 0.51% and 0.77% of $F1$ at sentence- and abstract-level respectively).

4.1 Components and Information resources

We study the contribution of each model's component and information sources to the system performance by ablating each of them in turn from the model and afterwards evaluating the model on all corpora. We compare these experimental results

			Baseline	Averaged	Ensemble
Sentence level	Macro-averaged	P	45.8	43.6	44.2
		R	39.2	42.6	41.1
		F	42.2	**43.1**	42.6
	Micro-averaged	P	56.5	53.2	55.4
		R	56.2	62.3	62.3
		F	56.4	57.3	**58.7**
Abstract level	Macro-averaged	P	45.8	43.6	44.2
		R	27.3	29.7	28.4
		F	34.3	**35.3**	34.6
	Micro-averaged	P	56.5	53.2	55.5
		R	37.5	41.6	41.6
		F	45.1	46.7	**47.5**

Table 8: Experimental results on the Phenebank corpus for the MASS model.

with the full system's results and then illustrate the changes of F1 in Figure 4. The changes of $F1$ show that all model's components and information sources help the system to boost its performance (in terms of the increments in $F1$) in all corpora. The contribution, however, varies among components, information types and among corpora.

Among information sources, FastText embedding (FT) often has the most important contribution, while using WordNet (WN) brings quite small improvements. Some examples clearly demonstrate that the impact of information sources varies greatly between benchmarks. The dependency embedding (DEP) and type embedding ($Dtyp$) have a very strong influence over the results in DDI-2013 and ScienceIE corpora but not much in other corpora. Furthermore, POS tag information (POS) plays a very important role in the BB3 corpus, surpassing FT, while its contribution in other corpora is not significant.

Also, the impact of model components shows relatively inconsistent across corpora. The baseline models always have lower $F1$ than MASS. This demonstrates the advantage of using a multi-channel LSTM to represent various linguistic information. Furthermore, the contributions of multi-channel LSTM and CNN are quite balanced. Interestingly, the undirected softmax always benefits the result although it was only used to calculate the penalty in the training step.

These experiments prove the effectiveness of using various information as well as architectural components. More importantly, these results show that our proposed MASS model can automatically adjust to each corpus, highlighting the flexibility of the MASS model which is able to adapt to various datasets with many different characteristics.

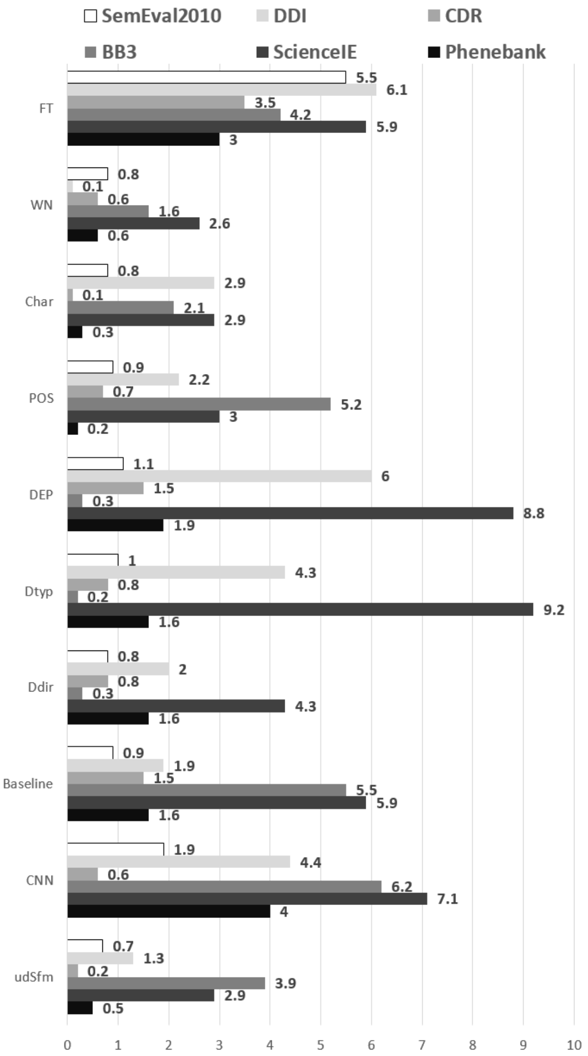

Figure 4: Ablation test results for various components and information sources: FastText (FT), WordNet (WN), Character-based (Char), POS tag, Dependency (DEP), dependency type (Dtyp) and dependency direction embedding (Ddir). Results are calculated based on the averaged F1 over 20 different runs. Baseline: Concatenating all embedding vectors to represent the words instead of using multi-channel LSTM. CNN: Using the final LSTM hidden states instead of CNN. udSfm: Removing the undirected softmax

4.2 Error Analysis

We studied model outputs to analyze system errors that defined the limitations of the model as well as to prioritize future directions. Many errors seem attributable to the parser. In some cases, we cannot generate the SDP, and in some cases where we have the SDP, information on the SDP is still insufficient or redundant to make the correct prediction. The directionality of relations is also challenging; in some cases the relation is predicted correctly but in the wrong direction. Other errors can be attributed to the limitations of our model, including (a) the inability to extract cross-sentence relations (accounting for 30% in CDR, BB3 and Phenebank), (b) the over-fitting problem (leading to wrong prediction - FP) and (c) limited generalisation power in predicting new relations (FN). Finally, we found some errors caused by the imperfect annotation. This problem may come from the different annotations assigned independently by two annotators (see IAA column in Table 2). We illustrate the above issues using realistic examples in Appendix C.

5 Conclusions

In this paper, we have presented a novel well-balanced relation classification model that consists of several deep learning components applied to the Dependency Unit of Shortest Dependency Path. We evaluated our model on six benchmark datasets, comparing the results with 15 recent state-of-the-art models. Experiments were also carried out to verify the rationality and impact of various model components and information sources. Experimental results demonstrated the robustness and adaptability of our system to classify different relation types in various domains without any architectural changes.

One existing issue with our model lies in its sensitiveness to class imbalance. This limitation resulted in significantly low performance on the DDI-2013 corpus (compared to state-of-the-art results). Our experiments also highlighted the existing challenges for neural relation classification models, including cross-sentence relations and imbalanced data. We aim to address these problems in future work.

Possessors Change Over Time: A Case Study with Artworks

Dhivya Chinnappa and **Eduardo Blanco**
Human Intelligence and Language Technologies Lab
University of North Texas

Abstract

This paper presents a corpus and experimental results to extract possession relations over time. We work with Wikipedia articles about artworks, and extract possession relations along with temporal information indicating when these relations are true. The annotation scheme yields many possessors over time for a given artwork, and experimental results show that an LSTM ensemble can automate the task.

1 Introduction

All languages have a way to express possessive relationships (Aikhenvald and Dixon, 2012). Possession is an asymmetric semantic relation between two entities, where one entity (the possessee) *belongs* to the other entity (the possessor) (Stassen, 2009). When it comes to defining possession, *belongs* includes a wide range of relationships, including kinship (e.g., *[my]*$_{\text{possessor}}$ *oldest [son]*$_{\text{possessee}}$), part-whole (e.g., *the [car]*$_{\text{possessor}}$*'s [dashboard]*$_{\text{possessee}}$), possession of something intangible (e.g., *[John]*$_{\text{possessor}}$ *got the [flu]*$_{\text{possessee}}$ *last year*), proximity (e.g., *The [shelf]*$_{\text{possessor}}$ *has a [glass sculpture]*$_{\text{possessee}}$), physical and temporary possession (e.g., *[I]*$_{\text{possessor}}$ *have John's [book]*$_{\text{possessee}}$), and ownership (e.g., *[John]*$_{\text{possessor}}$ *bought a [house]*$_{\text{possessee}}$ *last year*).

Possession relations can be divided into alienable (also referred to as acquired, transferable, non-intimate, etc.) and inalienable (also referred to as inherent, inseparable, intimate, etc.). Possessees that can be separated from their possessors are alienable, and possessees that cannot normally be separated from their possessors are inalienable (Heine, 1997). For example, *[John]*$_x$*'s [condo]*$_y$ is alienable, and *[John]*$_x$*'s [arm]*$_y$ is inalienable (some previous works would call the latter a part-whole relation instead). Tham (2004) defines control possession as a relation in which the possessor has temporary control of the possessee, but does not necessarily alienably possess it (e.g., *[John]*$_x$ *borrowed the [car]*$_y$ *for the weekend*). Following the aforecited works, possession goes beyond ownership of property.

In 1530 the painting was inherited by Margaret's niece Mary of Hungary, who [...]. It is clearly described in an inventory taken after her death in 1558, when it was inherited by Philip II of Spain.

Mary of Hungary: 1530–1558
Philip II of Spain: after 1558

Figure 1: Excerpt from the Wikipedia article about *Arnolfini Portrait* and its possessors over time.

Virtually all possessees change possessors over time, especially if possession relationships are understood in a broad sense as outlined above. Consider the excerpt of the Wikipedia article about the Arnolfini Portrait in Figure 1. From this excerpt, we know that the painting had at least two possessors (*Mary of Hungary* and *Philip II of Spain*), and that they were the possessors from 1530 to 1558 and after 1558 respectively.

In this paper, we track possessors of selected possessees over time. Unlike most previous works (Section 3), we (a) start with a document relevant to the possessee of interest, (b) select plausible possessors and years without syntactic restrictions and including inter-sentential pairs, and then (c) determine whether the plausible possessors are actual possessors with respect to the years. The main contributions of this paper are: (a) 88 Wikipedia articles about artworks annotated with their possessors over time;[1] (b) a detailed corpus analysis (e.g., unique possessors, years and possessor-year pairs); and (c) experimental results showing that an LSTM ensemble outperforms SVM.

2 Previous Work

We briefly summarize work on possession relationships from a theoretical perspective, and then move to work in computational linguistics.

2.1 Possession relations

The very definition of possession is not set in stone. Aikhenvald (2013) distinguishes three core meanings for possessive noun phrases that occur across languages: ownership (of property), whole-part (often referred to as part-whole), and kinship. Following a cross-linguistic perspective, she discusses possessions and time (present and former possession relationships, e.g., *my tooth* vs. *my former axe*), temporary and permanent possession (e.g., *borrow* vs. *acquire*) and others. Heine (1997) classifies possession relationships depending on the possessor and possessee. First, he makes a distinction between human (e.g., *[I]*$_x$ *have a [house]*$_y$) and non-human possessors (e.g. *[This house]*$_x$ *has [two bedrooms]*$_y$). Second, he differentiates three kinds of possession depending on the possessee: concrete possession (e.g., *[I]*$_x$ *have [two cats]*$_y$), social possession (e.g., *[I]*$_x$ *have [two sisters]*$_y$), and abstract possession (e.g., *[I]*$_x$ *have [an idea]*$_y$). Miller and Johnson-Laird (1976) differentiate between three kinds of possession: inherent, accidental, and physical; and provide the following example: *He owns an umbrella (inherent), but she's borrowed it (accidental), though she doesn't have it with her (physical).*

Possession relations have also been defined in terms of parameters. For example, Stassen (2009) considers two parameters (permanent contact and control) and Heine (1997) defines five parameters (human possessor, concrete possessee, spatial proximity, temporal permanence, and control).

While we do not closely follow any of these previous works, we borrow from them the broad definition of possession relations, and the motivation to work with possessions over time.

2.2 Computational Linguistics

Within computational linguistics, possession relations have been mostly studied as one of the many relations encoded in a given syntactic construction. For example, Tratz and Hovy (2013) extract semantic relations within English possessives. They propose a set of 18 relations, e.g. *temporal* (e.g., *[today]*$_x$*'s [rates]*$_y$), *extent* (e.g., *[6 hours]*$_y$*' [drive]*$_x$). Their *controller / owner / user* relation (one relation with three aliases) is the closest relation to the possession relations we target in this paper. Extracting semantic relations between noun compounds (Nakov and Hearst, 2013; Tratz and Hovy, 2010) usually includes extracting possession relations, e.g., *[family]*$_x$ *[estate]*$_y$. These previous works extract all semantic relations—including possessions—between arguments that follow a syntactic construction.

In our previous work (Chinnappa and Blanco, 2018), we identify possession relations between a deterministically chosen person (possessor) and a concrete object (possessee) within a sentence. If a possession relation exists, we also identify the possession type (alienable or control). Finally, we temporally anchor the possession relation with respect to the verb of which the possessor is the subject. In this paper, we take a complementary approach. We start with text relevant to the possessee of interest—specifically, its Wikipedia article—and then extract its possessors without any restrictions beyond considering as possessors only named entities. Furthermore, we specify in which years the possessions were true.

To the best of our knowledge, the work by Banea et al. (2016) is the only one on extracting possession relations without imposing syntactic constraints. Banea and Mihalcea (2018) build a corpus working with personal blogs, and present results on automatic extraction of possession using a naive bayes approach. They consider as possessors the author of a blog, and as possessees concrete nouns in blog posts. Regarding time, they annotate possessions at the time of the utterance (when the blog posts were published). Unlike them, we work with one possessee per Wikipedia article (i.e., the artwork the article is about), and then find possessors in the article. Additionally, we extract when a possessor-possessee relation is true with respect to the years in the article, and present results using SVM and end-to-end neural networks.

3 Annotating Possessions Over Time

In this section, we detail the methodology to create a corpus of possession relations over time. We first discuss the selection of source documents and possessees of interest. Then, we detail what is considered as a potential possessor, and how these possessors are paired with years. Finally, we describe

		#	%
x, potential possessor	PERSON	1,152	48.0
	ORG	986	30.5
	GPE, LOC	692	21.5
	All	3,230	100.0
y, year	All	940	100.0
(x, y) pairs	x is PERSON	6,304	48.8
	x is ORG	3,840	29.7
	x is GPE, LOC	2,769	21.4
	All	12,913	100.0

Table 1: Counts of potential possessors (x) and years (y), and (x, y) pairs selected for annotation.

the annotation process (is the potential possessor an actual possessor with respect to the years?) and analyze the resulting corpus.

3.1 Selecting Source Documents

Our goal is to target possessors of a given possessee over time. A natural choice is to work with documents about specific objects, as they are likely to describe the history and key events involving the objects. We decided to work with Wikipedia articles about important artworks. The methodology presented here, however, is not limited to artworks, and we believe it is applicable to any article about an object of interest.

We selected 100 artworks using online content, including Google queries for *famous artwork* and *famous paintings*, and online lists.[2] Then, we downloaded the full content of the corresponding Wikipedia articles. Some of the selected artworks are The Third of May 1808, Philosopher in Meditation, and Saturn Devouring His Son. The final corpus has 88 articles because we discarded articles if we could not select at least three (potential possessor, year) pairs (see below).

3.2 Selecting Potential Possessors and Years

Once possessees and their Wikipedia articles were selected, we identified potential possessors and years following the five steps below for each section in each Wikipedia article:

1. Run the named entity recognizers in spaCy[3] and Stanford CoreNLP (Manning et al., 2014).

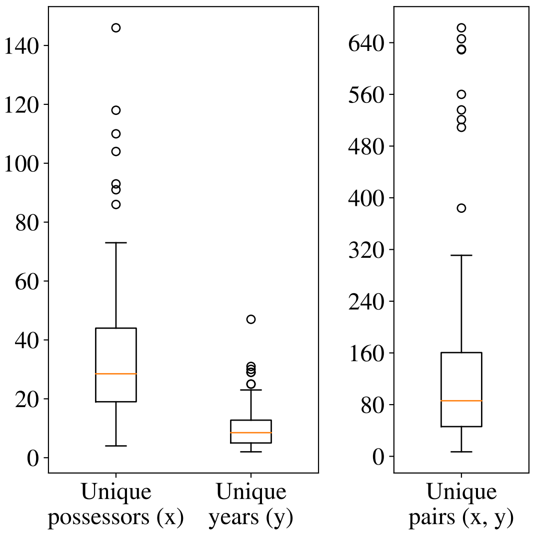

Figure 2: Distribution of unique potential possessors, unique years and unique pairs per article. Each boxplot displays the minimum, first quartile, median, third quartile and maximum.

2. Select as potential possessors all instances of the following named entities: PERSON, ORGANIZATION, LOCATION, and GPE.
3. Select as years all sequences of four digits inside a DATE named entity.
4. Remove all duplicate potential possessors and years from steps 2 and 3.
5. Generate all pairs of potential possessors and years.

Table 1 presents basic counts and percentages of the potential possessors and years after removing duplicates (Step 4), and the pairs generated (Step 5) for all documents. There are 3,230 potential possessors and 940 years, and 12,913 (potential possessor, year) pairs. The most common named entity of potential possessors is PERSON (48%), followed by ORG (30.5%) and GPE / LOC (21.5%). The percentage of (potential possessor, year) pairs depending on the named entity of the potential possessor almost follows an identical distribution (48.8%, 29.7% and 21.4%).

Figure 2 shows the distributions of unique potential possessors, years and (potential possessor, year) pairs generated per article (or equivalently, per possessee). While the distributions are far from uniform, the boxplots show that most articles have a substantial number of potential possessors, years and pairs. The minimum number of potential possessors is 4, of years 2, and of pairs 7. But

	Cohen's κ
Before	0.69
During	0.59
After	0.77
All	0.70

Table 2: Inter-annotator agreement (Cohen's kappa). Values over 0.6 are considered *substantial*, over 0.8 are considered *perfect* (Artstein and Poesio, 2008).

over 75% of articles have at least 19 unique potential possessors, 5 years and 46 pairs; and over 50% of articles have at least 28 unique potential possessors, 8 years and 86 pairs. In other words, our corpus takes into account many potential possessors and years for the vast majority of articles.

3.3 Validating Possessors and Years

After (potential possessor, year) pairs were generated, they were validated manually. To do so, we asked the following questions to annotators:

- Did a possession relation exist between the potential possessor and the possessee at any point of time *before year*?
- Did a possession relation exist between the potential possessor and the possessee at any point of time *during year*?
- Did a possession relation exist between the potential possessor and the possessee at any point of time *after year*?

In all questions, *possessee* refers to the artwork the Wikipedia article is about. Annotators had to choose from two answers: `yes` or `no`, where `no` indicates all cases in which there is not enough information to determine that a possession relation exists at any point of time before / during / after year. In other words, `no` does not mean that the potential possessor did not possess the possessee, and it may mean that there is no information about whether a possession relations exists.

The annotation interface showed the title of the article and the section to which the potential possessor and year belong to (section title + text). Annotators were instructed to first read the section and then answer all questions. Thus, annotators reveal possession information involving possessors and years that are potentially far away (different clauses, sentences, etc.). Recall that all potential possessors and years within a section are paired, thus we allow to cross sentence boundaries.

Annotation Quality. Annotations were done in-house by two graduate students. Both of them annotated 25% of the articles individually. Table 2 shows inter-annotator agreements (Cohen's kappa) for each question. Overall, inter-annotator agreement is 0.70 (values between 0.60 and 0.80 are considered substantial (Artstein and Poesio, 2008)). Agreements are higher for *Before* and *After* than *During* (0.69 and 0.77 vs. 0.59). The remaining articles were annotated once.

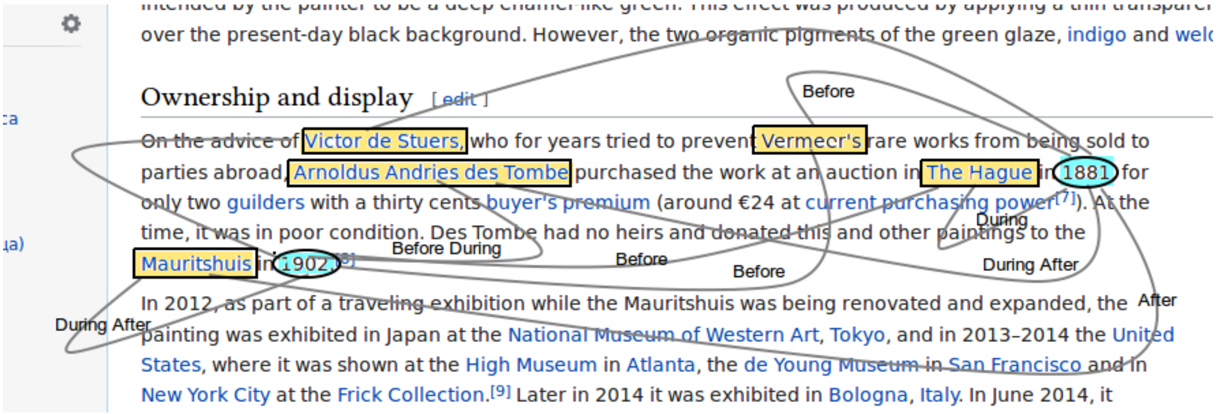
Annotation Examples. Figure 3 shows the annotations for one paragraph of the Wikipedia article about *Girl with a Pearl Earring* (more specifically, from the section titled *Ownership and display*). The figure shows the annotations on top of a screenshot of the article for clarity purposes, but the annotation interface only showed one section at a time along with all the generated pairs (Section 3.3, equivalent to pre-drawing edges).

Five potential possessors and two years were selected, thus ten (potential possessor, year) pairs were generated. The annotations reveal the intuitive possession information contained within the paragraph. First, *Victor de Stuers* was an advisor to *Arnoldus Andries des Tombe*, so there is no evidence that he was a possessor at any point of time (missing label edges). Second, *Vermeer* is the artist who made *Girl with a Pearl Earring*, so there are possession relations before *1881* and *1902*. Third, *Arnoldus* purchased the piece in *The Hague* in 1881, and in 1902 it was donated to *Mauritshuis*. So *Arnoldus* was a possessor in 1881 and after 1881 (until 1902), *The Hague* in 1881 (recall that non-humans can be possessors, spatial proximity is also considered possession, Section 2.1), and *Mauritshuis* during and after 1902. We discuss the limitation of the annotation approach in Section 3.5.

3.4 Annotation Analysis.

Counts of `yes` labels for the three questions (before, during and after) are rather low (17%, 9% and 19%, Figure 4). This is not surprising, as any PERSON, ORG, LOC and GPE named entity is considered as potential possessors. We note, however, that we annotated a possession relation (`yes` label) in 35% of (potential possessor, year) pairs generated (either before, during or after *year*).

Figure 5 depicts the distribution of labels per article for (potential possessor, year) pairs generated from the same and different sentences. It is worth noting a couple of interesting patterns. First, the annotations contain many more possessions because we pair potential possessors and years that



over the present-day black background. However, the two organic pigments of the green glaze, indigo and wel

Ownership and display [edit]

On the advice of Victor de Stuers, who for years tried to prevent Vermeer's rare works from being sold to parties abroad, Arnoldus Andries des Tombe purchased the work at an auction in The Hague in 1881 for only two guilders with a thirty cents buyer's premium (around €24 at current purchasing power[7]). At the time, it was in poor condition. Des Tombe had no heirs and donated this and other paintings to the Mauritshuis in 1902.[8]

In 2012, as part of a traveling exhibition while the Mauritshuis was being renovated and expanded, the painting was exhibited in Japan at the National Museum of Western Art, Tokyo, and in 2013–2014 the United States, where it was shown at the High Museum in Atlanta, the de Young Museum in San Francisco and in New York City at the Frick Collection.[9] Later in 2014 it was exhibited in Bologna, Italy. In June 2014, it

Figure 3: Excerpt of the Wikipedia article of *Girl with a Pearl Earring* and annotations. Edges indicate (potential possessor, year) pairs generated. Edge labels indicate *yes* label for *before*, *during* and *after*; missing edge labels indicates all annotations are *no* (i.e., the potential possessor was invalid).

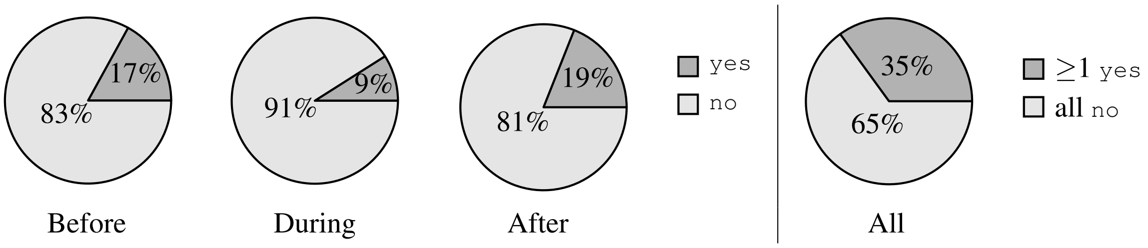


Figure 4: Label percentages for each question (left). While most labels are `no`, one of the three questions (before, during or after) was answered with `yes` in 35% of (potential possessor, year) pairs (right).

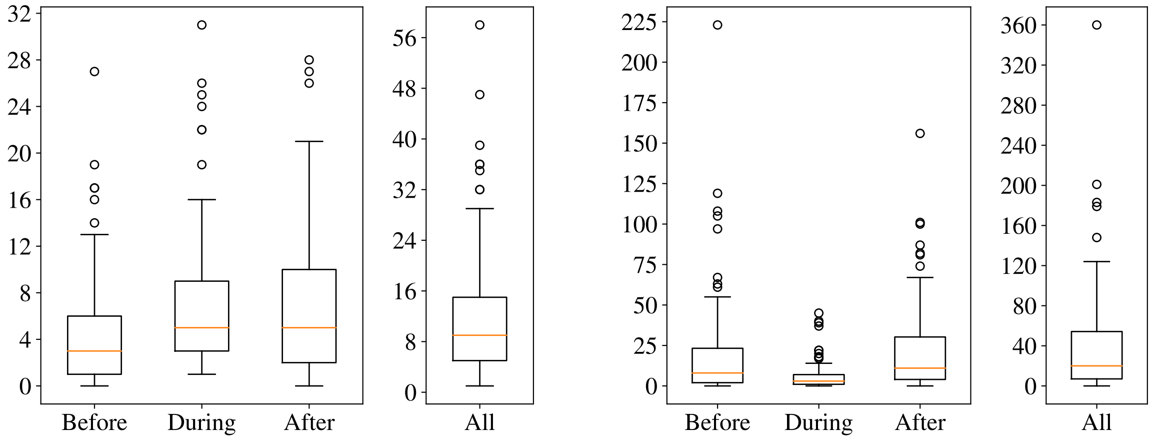

Possessor and year from the same sentence

Possessor and year from different sentences

Figure 5: Distribution of *yes* label per article. We provide distributions for each temporal anchor (at some point of time before, during or after *year*) and for all anchors, and distinguish between possessors and years belonging to the same sentence (left) or different sentences (right). Each boxplot shows the minimum, first quartile, median, third quartile, and maximum.

belong to different sentences (note the different scales in the y-axis). Second, for pairs generated from different sentences, `yes` label for *during* questions is much less likely than for the labels *before* and *after*.

Finally, Figure 6 shows the distribution of `yes` label for all generated pairs. At a minimum, each possessee has at least two possession relations. There are a few outliers articles in which annotators identified over 150 possessors in time. The

From the possessor and year: the concatenation of tokens; binary flags for each token; the syntactic head (token, lemma and part-of-speech tag); and the named entity type.
From the sentences to which the possessor and year belong to: for (a) a window of 4 tokens to the left and right, (b) all the verbs to the left and right, (c) all the verbs that are ancestors or children in the depedency tree, and (d) all the left and right siblings in the dependency tree, the tokens, lemmas and part-of-speech tags.
Other and Wikipedia article: whether the possessor and year belong to the same sentence, whether the possessor appears before or after the year, the Wikipedia article tile (concatenation of tokens and binary flags for each token), and the section title (concatenation of tokens and binary flags for each token).

Table 3: Feature set used with Support Vector Machines.

first quartile is 14, the median 30, and the third quartile 65 (All, right most boxplot). Thus the procedure presented here reveals a substantial amount of possession relations along with temporal information anchored in the form of years.

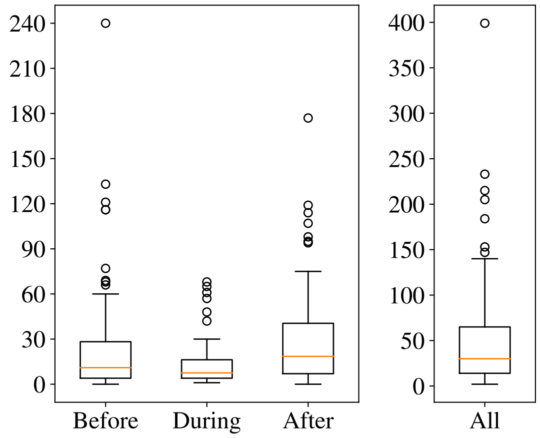

Figure 6: Distribution of *yes* label per article for all possessors and years.

3.5 Limitations

While the proposed procedure successfully identifies possession relations over time, we acknowledge limitations in both the possessors and temporal information considered.

First, we only consider named entities as potential possessors, so it is possible we miss some possessors (e.g., pronouns, *the artist*, *his son*). Because of the source documents we work with (Wikipedia articles about artwork) and the fact that we pair all potential possessors and years within a section, this is not a big issue: most Wikipedia sections do not have mentions that cannot be resolved to a named entity within the same section. We note, however, that coreference resolution (Pradhan et al., 2011) would alleviate this problem.

Second, we only consider four digits within a DATE named entity as temporal information. This means that temporal information encoded in relative dates (e.g., four years later) or historical events (e.g. after World War II) is disregarded. Additionally, we cannot distinguish between several possessors within a year, finer-grained times would be required to do so. To address these issues, temporal parsers (Lee et al., 2014; Strötgen and Gertz, 2015) and anchoring events in time (Reimers et al., 2016) are required.

4 Experiments and Results

We experiment with traditional Support Vector Machines and neural networks. We divided the articles (and the corresponding (potential possessor, year) pairs) into train (80%) and test (20%), and report results obtained with the test split. Note that splitting pairs randomly would be unsound, as possession relations for the same possessee would be in the train and test splits. We build three classifiers with both SVMs and neural networks (one per question: before, during and after), and all of them predict two labels: `yes` or `no`.

4.1 Support Vector Machines

We trained the three classifiers using the SVM implementation in scikit-learn (Pedregosa et al., 2011), and tuned hyper-parameters C and γ using 10-fold cross-validation with the train split. We used features extracted from the possessor, the year, and the sentences they belong to. Additionally, we also included the Wikipedia article title and the section title from which the possessor and year were selected. The full feature set is described in Table 3 and we do not elaborate further. Our motivation to try SVMs is to establish a strong supervised baseline, and to compare with neural networks that take as input only plain text.

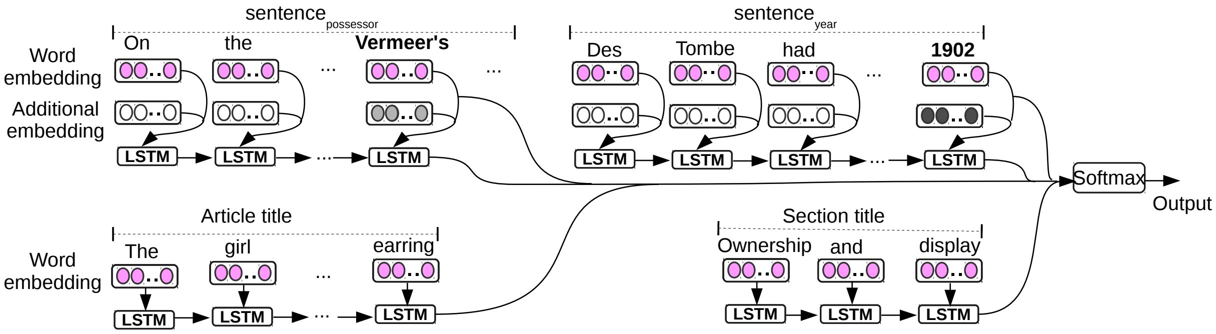

Figure 7: Neural network architecture to predict whether a *potential possessor* is a possessor before, during or after *year*. We exemplify the input to the network with the (*Vermeer*, *1902*) pair from Figure 3.

4.2 Neural Networks

We use the implementations provided by the Keras neural network API (Chollet et al., 2015) with TensorFlow backend (Abadi et al., 2015). Additionally, we use GloVe embeddings with 300 dimensions (Pennington et al., 2014)[4] to transform words into their distributed representations, the Adam optimizer (Kingma and Ba, 2014) and categorical cross entropy as a loss function. We train the network with batch size 16 for up to 200 epochs, but stop earlier if no improvement is observed in the validation set for 5 epochs. We reserve 20% of the train split for validation.

The neural network is composed of four Long Short-Term Memory networks (Hochreiter and Schmidhuber, 1997) with 200 units. The outputs of the LSTMs are concatenated along with the embeddings of the possessor and year, and the final output is calculated with a Softmax layer. Each LSTM has as its input a different chunk of text:

- The first LSTM takes as input the sequence of tokens in the sentence containing the *possessor* (top left in Figure 7). Each token is represented by the corresponding word embedding, and an additional embedding (also with 300 dimensions) for the possessor and all other tokens (there are only two unique additional embeddings, white and light gray in Figure 7). Unlike the word embedding from GloVe, the additional embeddings are initialized randomly and are updated during the training process. Our rationale to add the additional embeddings is to provide the LSTM with information to learn which tokens surrounding the *possessor* are more important.
- The second LSTM takes as input the sentence containing the *year* (top right in Figure 7). The input representation is very similar to the one used in the first LSTM, the only difference is that the additional embeddings (white and dark grey) indicate the *year* and any other token. Again, our rationale for the additional embeddings is to provide the LSTM with information to learn which tokens surrounding the *year* are more important.
- The third LSTM (bottom left in Figure 7) takes as input the Wikipedia article (i.e., the name of the possessee). The input words are represented with their GloVe embeddings.
- The fourth LSTM (bottom right) takes as input the section title from which the *possessor* and *year* were selected. The input words are also represented with their GloVe embeddings and no additional information. Our rationale is that some sections are less likely to contain valid possessors (e.g., *Cultural Impact* (low likelihood) vs. *Ownership and display* (high likelihood).

4.3 Results

Results obtained with the test set are provided in Table 4. F-measures are always higher for `no` than `yes`, but recall that only `yes` label allows us to extract valid possession relations.

Baselines. The majority baseline always predicts `no` label for all temporal tags (before, during and after, see percentages in Figure 4), thus it fails to extract any possession information.

SVMs. SVMs obtain higher-than-chance results, but F-scores with `yes` label are relatively low (before: 0.33, during: 0.31 and after: 0.44).

Neural Networks. The full neural network always outperforms SVMs, but the difference in F-score

	`no`	0.88	0.87	0.88	0.94	0.82	0.88	0.93	0.69	0.79
NN Full - LSTM$_{\text{article\_title}}$	`yes`	0.33	0.42	0.37	0.21	0.65	0.31	0.33	0.77	0.46
	`no`	0.87	0.82	0.85	0.95	0.74	0.83	0.93	0.66	0.77
NN Full - LSTM$_{\text{section\_title}}$	`yes`	0.41	0.50	0.45	0.25	0.46	0.33	0.38	0.80	0.48
	`no`	0.89	0.85	0.87	0.94	0.86	0.90	0.94	0.67	0.78

Table 4: Results obtained in the test set using SVMs (all features), and the neural network (the full architecture and after disabling some components). Recall that `yes` is the only label that enables us to extract possession relations, results with `no` are mostly irrelevant.

with `yes` label is minimal for *during* (before: 0.40 vs 0.33, +21.2%; during: 0.32 vs. 0.31, +3.2%; after: 0.53 vs. 0.44, +20.5%).

We also experimented with modifications of the full neural network to provide insights into which components are more useful. Specifically, we report results not using the additional embeddings for the possessor and year, and disabling the LSTMs for the article title and section title. Note that while `yes` F-scores for *during* barely vary regardless of the modifications to the network, we found interesting patterns for *before* and *after*. All F-scores discussed below are for `yes` label, the only label that is useful to extract possession relations.

- First, the additional embeddings for the possessor and year are beneficial for *after* (0.47 vs 0.53, +12.8%) and *during* (0.29 vs 0.32, +10.3%), and neutral for *before*. This leads to the conclusion that the LSTM learns the contexts surrounding the possessor and year successfully only for *after* and *during*. Note that the additional embeddings provides information regarding the position of the possessor and year within their sentences.
- Second, the LSTM that takes as its input the article title is beneficial for *before* (0.37 vs. 0.40, +8.1%) and *after* (0.46 vs 0.53, +15.2%), and barely for *during* (0.31 vs. 0.32, +3.1%). Thus we can conclude that the article title contains useful information to determine the existence of possession relations, and that pretrained word embeddings capture this information.
- Third, the LSTM that takes as its input the section title is beneficial for *after* (0.48 vs 0.53, +10.4%), detrimental for *before* (0.45 vs. 0.40, -11.1%) and barely detrimental for *during* (0.32 vs. 0.33, -3.0%). These results lead to the conclusion that the section title only contains useful information to determine possession relations in future years with respect to the years mentioned in the section.

5 Conclusions

Possession is an asymmetric semantic relation between two entities, where one entity (the possessee) *belongs* to the other entity (the possessor). Following theoretical works, we understand *belongs* in a broad sense, including physical, temporal, and control possessions.

In this paper, we track possession relations over time. Specifically, we work with Wikipedia articles about artworks, and extract their possessors as well as temporal information with respect to the years explicitly mentioned (before, during or after). We have presented an approach to extract potential possessors and pair them with years, and an annotation scheme to validate them. Overall inter-annotator agreement (Cohen's kappa) is 0.70, and the resulting corpus has substantial information regarding possessors over time: in 75% of articles we validate at least 14 (possessor, year) pairs, and in 50%, at least 30 pairs.

Experimental results show that the task can be automated, although we obtain moderate results. We present an LSTM ensemble that outperforms a traditional SVM. Disabling certain components of the full network show that the article title and section title benefit different temporal tags, and that the additional embeddings for the possessor and year are beneficial for *during*.

Using Lexical Alignment and Referring Ability to Address Data Sparsity in Situated Dialog Reference Resolution

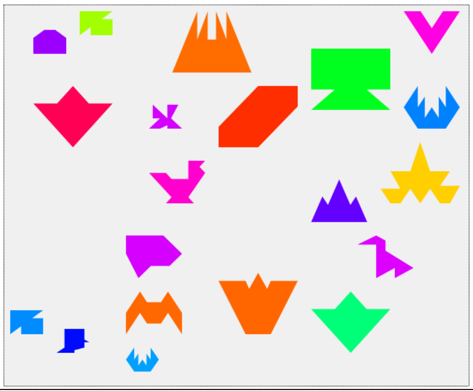
Abstract

Referring to entities in situated dialog is a collaborative process, whereby interlocutors often expand, repair and/or replace referring expressions in an iterative process, converging on conceptual pacts of referring language use in doing so. Nevertheless, much work on exophoric reference resolution (i.e. resolution of references to entities outside of a given text) follows a literary model, whereby individual referring expressions are interpreted as unique identifiers of their referents given the state of the dialog the referring expression is initiated. In this paper, we address this collaborative nature to improve dialogic reference resolution in two ways: First, we trained a words-as-classifiers logistic regression model of word semantics and incrementally adapt the model to idiosyncratic language between dyad partners during evaluation of the dialog. We then used these semantic models to learn the general referring ability of each word, which is independent of referent features. These methods facilitate accurate automatic reference resolution in situated dialog without annotation of referring expressions, even with little background data.

1 Introduction

A crucial part of dialog situated in a physical environment is **exophoric references**, i.e. language used by the participants to make entities in the shared environment salient to each other for the purposes of communication (Poesio and Vieira, 1998). Several studies in exophoric reference resolution have investigated how **referential semantics** can be learned automatically via the relationship of a referent's features to the language referring to it (cf. Kennington et al., 2015; Shore and Skantze, 2017) or the state of the interaction a dialog is situated in (cf. Prasov and Chai, 2008; Iida et al., 2010), inferring a relationship between e.g. the word *red* and the individual features it refers to, e.g. a particular range of hue values.



Speaker	Utterance
A	*it's the one to the left*
B	*the purple pinkish uh weird?*
A	*the pinkish one yeah it looks like an asteroid or something big*
B	*the very big?*
A	*yeah*

Figure 1: Collaborative reference in dialog situated in a reference communication task (cf. Krauss and Weinheimer, 1964).

Most works in exophoric reference resolution have assumed the identification of certain subsets of language known as **referring expressions** (REs) that have been either manually or automatically annotated (cf. Schutte et al., 2011; Meena et al., 2012; Zarrieß et al., 2016; Shore and Skantze, 2017). However, discerning REs from non-referring language in dialog is not trivial. For example, Figure 1 illustrates an interaction between two participants in a reference communication task like that of Krauss and Weinheimer (1964), whereby speaker **A** describes a particular

[†] Deceased 2 July 2018.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2288–2297
Brussels, Belgium, October 31 - November 4, 2018.

referent which must be resolved by speaker **B**. [1].

While REs are idealized as contiguous, single noun phrases (NPs) such as *the pinkish one*, reference in unrestricted, natural dialog is in fact a collaborative process to which both partners in a dyad contribute (Clark and Wilkes-Gibbs, 1986), and not all referring language (RL) is nominal, e.g. *big* in Figure 1. Both participants contribute RL in a cumulative fashion, but often no complete nominal RE is produced, e.g. *the big pinkish asteroid to the left*. Due to this, it is difficult to infer from syntax alone the **referring ability** (RA) of language, i.e. the overall ability of a subset of language to unambiguously refer to entities in discourse (Ariel, 1988; Reboul, 1997). In context (e.g. given the set of possible abstract shapes to choose from), it is easy to infer which words have the greatest RA, but without context this is more difficult. This makes recognizing "non-ideal" cases of RL difficult, as the boundary between RL and non-RL is often fuzzy.

Moreover, participants in dialog tend to develop so-called **conceptual pacts**, which means that they converge on commonly-used RL for unique referents in dialog (Brennan and Clark, 1996). As an example, they may repeatedly refer to a given entity as e.g. *the asteroid* even though *asteroid* may only rarely be used to refer to similar entities in the general population. Thus, RL varies less within a given dialog than across dialogs, and variation of RL has an inverse relationship with the length of the time two participants interact due to alignment of dialog participants' use of language (Clark and Wilkes-Gibbs, 1986; Garrod and Anderson, 1987; Brennan, 1996).

In this paper, we present two contributions to the automatic learning of referential semantics for reference resolution in situated dialog that address these problems: Firstly, we show the benefits of adapting models of RL semantics to a specific dialog as it progresses to accommodate the dyad's idiosyncratic use of RL. Secondly, we present a method for deriving a gradient (non-binary) measure of RA in situated dialog. Thus, instead of first identifying REs and then resolving which entity they refer to, we treat all language in the dialog as being more or less referential, and use this gradual measure together with the referential semantics to derive which entity is being talked about. Our assumption is that while the exact referential semantics of words vary greatly across dyads, the general ability of a given word to successfully refer to entities varies little across dyads. Thus, it should be possible to statistically measure the ability of a set of language to refer to entities in general, irrespective of the language's semantic content (e.g. the exact hue understood as *pink* by a dyad). This knowledge, combined with dialogic adaptation, facilitates accurate automatic reference resolution in situated dialog without annotation of REs, even with little background data.

2 Background

Both behavioral studies on reference resolution and RL and computational models thereof have illustrated the context-sensitive nature of reference resolution and RL and the gradient nature of RA.

2.1 Collaboration in Reference Resolution

Traditionally, reference resolution in dialog was analyzed using a literary model of reference, whereby individual REs are seen as unique identifiers of a referent as in written discourse, i.e. each RE is assumed to be "atomic" in its reference to a particular entity (Clark and Wilkes-Gibbs, 1986, 3). However, shortcomings in this approach have long since been identified (cf. Olson, 1970): REs often do not unambiguously identify their referent when initiated but rather comprise a larger process of collaborative reference resolution, whereby multiple dialog participants iteratively extend, repair and even replace REs initiated by themselves or others (Clark and Wilkes-Gibbs, 1986; Heeman and Hirst, 1995).

In Figure 1, speaker **A** initiates the RE *the one to the left* and immediately expands it in an episodic manner (Clark and Wilkes-Gibbs, 1986, 4, 17). Given a literary model of reference, they should have supplied exactly enough information to identify the referent and no more (*the big pinkish asteroid to the left*), adhering to Grice's (1975) maxim of quantity. However, RL can undergo not only expansion but also replacement: For color, speaker **B** proposes both *purple* and *pinkish*, but only *pinkish* is then accepted by **A**.

In contrast to a literary model of reference, a collaborative model represents reference resolution as a process of iteratively presenting RL to the other participant(s) in a dialog, which is then either accepted as being sufficient to identify a referent or rejected as insufficient (Clark and Wilkes-

---

[1] Examples are from the dataset of Shore et al. (2018)

Gibbs, 1986, 9). This more accurately models reference observed in spoken dialog.

2.2 Referring Language Syntax

Literary reference models fail to account not only for the collaborative nature of reference resolution but also for the syntactic structure of RL itself: Ideally, a reference is expressed linguistically as an NP, but this ideal does not hold in unrestricted dialog (Clark and Wilkes-Gibbs, 1986).

Since an RE cannot be defined as an atomic referring unit, a model of RL should ideally be able to measure the RA of any given set of language rather than simply classifying language as (part of) an RE in a binary decision, such as by using hand-crafted rules (cf. Shore and Skantze, 2017) or expert annotation (cf. Spanger et al., 2009; Kennington et al., 2015).

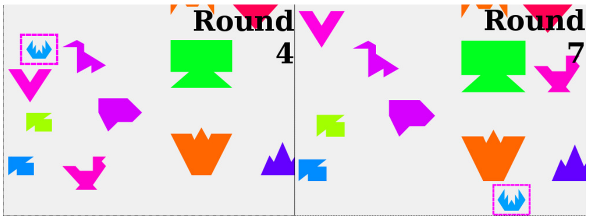
2.3 Modeling Referring Language

There have already been some efforts in automatic annotation of REs: For example, Schutte et al. (2011) algorithmically extracted RL as utterance(s) preceding a discrete event in a shared environment within a certain timeframe. However, one drawback to this method is that "the references must be contained in instructions that cause events involving the referents" and "it must be possible to automatically detect these events" (Schutte et al., 2011, 189). Thus, REs not referring to a detectable event cannot be detected in this manner. Moreover, not all language extracted is that of REs: For example, in the instruction *go through that door*, only half of the tokens constitute RL (*that door*). This means that this method must either be supplemented with additional methods to extract RL or tolerate a high noise-to-signal ratio.

Other approaches use language structure to infer RL, namely in parsing said language using a combination of statistical or rule-based methods. However, both entail that a solution be specialized for language specific to a given domain, such as for route-following instructions (Meena et al., 2012) or for a specific instructor-manipulator pair task (Shore and Skantze, 2017): Meena et al. (2012) used the highly-structured nature of route-following instructions to great effect, while Shore and Skantze (2017) used a phrase-structure parser pre-trained on out-of-domain data and supplemented it with hand-crafted rules to extract NPs according to the literary ideal of RL.

Finally, many works simply ignore the distinction between RL and non-RL and focus solely on learning reference resolution as a function of language and extra-linguistic knowledge such as entity features (cf. Kennington et al., 2015; Shore and Skantze, 2017), discourse and action history (cf. Iida et al., 2010), perception (cf. Matuszek et al., 2012) or gesture (cf. Matuszek et al., 2014). Although these methods improve the resolution of what RL *refers to*, they do not resolve what language *is RL*. Moreover, none of these works address the strong dyadic and dialogic entrainment effects on RL which include the formation of CPs, reinforcing the use of RL specific to a given dialog even if it diverges from population RL use.

3 Data Description



Speaker	Round	Utterance
B	4	*eh it looks like a blue crab sticking up his claws*
		…
A	7	*it's the same the the little crab again*

Figure 2: Example of repeated reference across rounds; the referent the participants have to collaboratively resolve is indicated here with a magenta square.

The data used is that of Shore et al. (2018), a set of $|D| = 42$ task-oriented dialogs (mean duration μ = 15:25 minutes, standard deviation SD = 1:13, total 647:35) in which one participant is an instructor referring to specific pieces on a shared game board which the other participant, the manipulator, must then attempt to resolve by selecting without the aid of extra-linguistic cues (see Figures 1–2): They sit at different locations and communicate solely through an audio channel. Upon successful selection, the piece moves to a random free place on the board and the participants alternate roles. This dataset is somewhat larger than that for similar tasks (cf. Iida et al., 2010; Matuszek et al., 2012; Malinowski and Fritz, 2014; Kennington et al., 2015). However, unlike in many other works, participants were allowed to refer to pieces in any way they wish and both were allowed to speak freely.

Each dialog $d \in D$ has $|R| = 20$ randomly-generated game pieces and is divided into individual game **rounds** $d \triangleq \langle d'_1 \dots d'_n \rangle$, in each of which $d' \triangleq (R, \hat{r}, T)$ a single entity is pre-selected by the game as the entity $\hat{r} \in R$ which must be successfully resolved for that round. Each dialog presents the same 20 referents aside from their changing position, so participants must also refer to pieces which have already been referenced before: After 40 rounds, all pieces are guaranteed to have been referred to and so every reference thereafter is a coreference (see Figure 2).

Each entity $r \in R$ has features representing shape, size, color and position during the given round. A sequence of tokens T was transcribed from the speech of both participants using Penn Treebank tokenization rules (Marcus et al., 1993). See the Supplementary Material for further information on the dataset.

4 Baseline

The reference resolution method used as a baseline was a **words-as-classifiers** (WaC) regression model (cf. Kennington et al., 2015). In this framework, an individual logistic regression model $p_t(r) \triangleq \sigma(w_t^T r + b_t)$ is trained for each token type t, predicting the probability of a given entity r being the token's TRUE referent $\hat{r}$, given the feature vector r representing shape, size, color and position (see the Supplementary Material for details). For example, if trained successfully, the model for the token "red" should be sensitive to the entity's hue, but not to its size. Common non-descriptive words such as "the" should not be sensitive to any of the entity's properties, yielding an output of 0.5 for all entities. The score of a given entity r being the referent $r = \hat{r}$ of a set of RL tokens T is defined as the normalized linear combination of the tokens' corresponding classifiers $p_t(r)$:

$$p'(r = \hat{r}, T) \triangleq \frac{1}{n} \sum_{t \in T}^{n} p_t(r) \tag{1}$$

For training, language in each round $(R, \hat{r}, T)$ is defined as a bag of words T referring to the referent $\hat{r}$. For each token $t \in T$, a training example is defined for the referent $\hat{r}$ (with a target score of 1) as well as for each non-referent entity $r \in R \setminus \hat{r}$ (with a target score of 0). To address model bias, the training example for $\hat{r}$ is weighted by its complement set size, $|R \setminus \hat{r}| = 19$.

Initial experiments showed that lemmatization did not affect the performance on our dataset. Thus, each inflected lexical form is considered a unique **word** (i.e., vocabulary item). Unlike Kennington et al. (2015), no smoothing was used, instead ignoring words of fewer than $\alpha \triangleq 3$ occurrences. The motivation for this is that a general out-of-vocabulary model is not expected to increase the performance, since it basically learns to ignore entity properties, similar to the models for common words such as "the". This was also confirmed in our initial experiments.

Note that all language from both the instructor and the manipulator in each round is used. This is unlike Kennington et al. (2015), who only used language from (manually annotated) REs. As argued above, REs cannot easily be identified in the type of dialog data we are addressing. This of course makes the task much more challenging, and the baseline performance can be expected to be lower than that reported in Kennington et al. (2015).

We did 42-fold cross-validation, in each fold using 40 dialogs for training as **background data**, one for testing and one for use as random data to compare the effects of dialog-specific data to (see Section 5 below). Each round in the test dialog is evaluated by the **reciprocal rank** (RR) of the referent $\hat{r}$ in the set of entities R ordered by their combined score for all word classifiers in the round $\sum_{t \in T} p_t(r)$, and its mean (MRR) is then calculated.

Statistic	Mean	SD	SEM
Rank	2.8060	3.2427	0.0566
RR	0.6892	0.3648	0.0064

Table 1: Baseline results for 42-fold cross-validation.

The cross-validation results for the baseline WaC model are shown in Table 1. As expected, this is indeed worse than e.g. Kennington et al. (2015)'s reported mean rank of 2.16 when only using speech features. The WaC model is nevertheless a simple and effective representation of referential semantics in domains where features for each individual referent can be easily represented (cf. Kennington and Schlangen, 2015). Still, it has two shortcomings: Firstly, it infers a static model of referential semantics which is good across dialogs but is suboptimal for language within dialogs due to effects of language alignment (Garrod and Anderson, 1987; Brennan, 1996; Brennan and Clark, 1996). Secondly, it encodes RA only indirectly: Given a large enough dataset, logistic regression for non-RL such as *okay now I'm ready* should have an even distribution between TRUE and FALSE classes, i.e. these classifiers should decide nothing. Conversely, strong RL such as *red* should entail strong relationships between certain features and decisions. However, due to the effects of idiosyncrasy and alignment on dialogic language, understanding low-frequency words is crucial despite that they cannot be conditioned for as well as can be done for high-frequency ones.

5 Dialogic Model Adaptation

We evaluated the benefits of adapting reference resolution parameters to the language of individual dialogs by initially conditioning WaC models on the training set as background data and then adapting the model during evaluation by retraining using data from previous states in the dialog being evaluated: The RR for the i^{th} round $(R, \hat{r}, T)_i$ is calculated using a model trained on both background data and **interaction data** defined as the rounds observed thus far in the given dialog $(R, \hat{r}, T)_{i'<i}$. The parameters for the logistic regression models representing individual words are optimized using quasi-Newton hybrid conjugate gradient descent from *Weka* v3.8.0 (Dai and Yuan, 2001; Frank et al., 2016). A ridge $\lambda = 100$ was used to avoid over-fitting of models for low-frequency words, tuned using cross-validation over the dataset (le Cessie and van Houwelingen, 1992). The same cross-validation method determined an optimal interaction data weight of 3 relative to background data, i.e. an observation in a given dialog is three times as relevant as one from the background data[2].

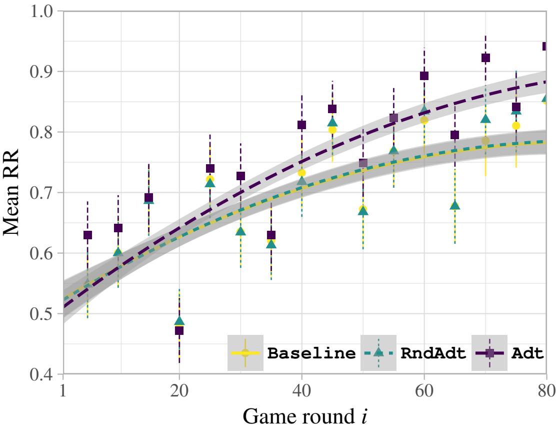


Figure 3: RR as a quadratic function of ROUND $i \cdot i^2$ for model adaptation using interaction data (CI 0.95; error bars are SEM; showing every 5th round).

Figure 3 compares the improvement of RR from adapting model parameters using dialog interaction data (`Adt`) to the `Baseline` as well as effects of adding data from a randomly-chosen round from another unseen dialog (`RndAdt`): The condition `RndAdt` is used to rule out the possibility that model fit improves simply due to more training data in general. We fit a linear mixed model with conditions `Adt`, `RndAdt`, `Wgt` and scaled `Tokens` as linear fixed effects and game round ordinality (ROUND) as a quadratic fixed effect: `Wgt` denotes weighting word classifiers by RA, which will be discussed in Section 6. `Tokens` denotes the number of word tokens produced by both speakers in the given round[3]. DYAD (the pair of participants in a given dialog) was included as a random intercept with a random slope for `Adt` and `Wgt`. We selected the best-fitting model using backwards selection with log-likelihood ratio tests: Starting from the maximally complex model (Barr et al., 2013), we first simplified the random structure and then removed fixed effects not contributing to fit. This showed that including `RndAdt` does not significantly improve fit ($\chi^2 = 0.00003, p = 0.99599$), meaning model fit improves from data specific to the given dialog and not merely from more training data.

We refit the final model using maximum-likelihood estimation with Satterthwaite approximation to degrees of freedom (see the Supplementary Material for details). Despite that RR correlates with ROUND i even for the baseline method due to dialogic lexical alignment (cf. Shore and Skantze, 2017; Shore et al., 2018), there is a significant improvement in RR from `Adt` ($B = 0.04882, t(40) = 7.65, p < 0.001$).

Since adding a small amount of data from a dialog significantly improves reference resolution for that dialog, dialogic reference resolution can be seen as a model adaptation problem, where in-domain data (that from the dialog being evaluated)

---

[2] Interaction data weight values tested were $1, 3, 5, 7, 10$.

[3] Adding the count of coreferences to a given referent as a fixed effect prevented model convergence when included with `Tokens`. Regardless, adding it in lieu of `Tokens` did not significantly improve fit ($\chi^2 = 3.7329,, p = 0.05335$).

is relatively sparse compared to out-of-domain data (that from other dialogs). This suggests that the effect of dyadic alignment on reference resolution is amplified: As ROUND i increases, not only is more data specific to the given dialog available, but the data observed becomes more homogeneous. Thus, the benefit of this method increases with time, as the ratio of interaction to background data increases.

6 Weighting by Referring Ability

While the method above facilitates the adaption of referential semantics models to dyad-specific language, not all language which is rare and/or observed in only one dyad has great RA: For example, in the dataset used, there were 19 observations of the word *awesome* but 15 of those were in a single dialog. Even when evaluating on that dialog, a classifier would be inferred from the $19 - 15 > \alpha$ remaining observations, and even adapting the word models with interaction data as done in Section 5 will only add noise since it only occurs as non-RL (e.g. *awesome good work*). Conversely, a word such as *piece* is semantically heavy in general English but is by itself a poor signifier of referents given the task at hand. So, we evaluated the benefit of weighting word classifiers by their RA in order to mitigate the effects of such spurious observations. To do this, we define the RA of a word t as the mean difference between the probability of the actual referent $\hat{r}$ being TRUE $p_t(\hat{r})$ and the mean probability for all other entities $R \setminus \hat{r}$ for every occurrence of the word in the training data:

$$\begin{aligned} w_t &\triangleq \frac{1}{n} \sum_{\substack{d \in D \\ (R,\hat{r},T) \in d}}^{n} p''_t(R,\hat{r},T) \\ p''_t(R,\hat{r},T) &\triangleq p'_t(\hat{r},T) - \frac{1}{m} \sum_{r \in R \setminus \hat{r}}^{m} p'_t(r,T) \quad (2) \\ p'_t(r,T) &\triangleq p_t(r) \sum_{i=1}^{|T|} [T_i = t] \end{aligned}$$

One alternative to this metric that we considered was the area under the receiver operating characteristic (ROC) curve (AUC). However, the metric above is more conservative in cases of word models with few observations by penalizing their score due to the logistic ridge used, thus putting more "trust" in word models with more observations; The AUC does not account for this directly.

Although this metric is derived from referential semantics learned for a specific domain, the WaC logistic regression model(s) encoding referential semantics are simple and thus can easily be re-trained for other domains. It can also be derived from other models of referential semantics.

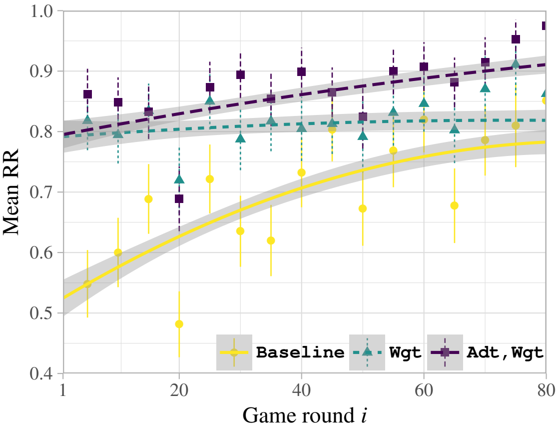

Figure 4: RR as a quadratic function of ROUND $i \cdot i^2$ for weighting model scores by RA $p_t(r) \cdot w_t$ (CI 0.95; error bars are SEM; showing every 5th round).

Figure 4 compares the improvement of RR from weighting each classifier $p_t(r)$ by its RA w_t (`Wgt`) to the `Baseline` and finally to that from combining adaptation from Section 5 with weighting (`Adt,Wgt`); Using the same linear mixed model described in Section 5, a significant improvement in RR was found for `Wgt` over the baseline ($B = 0.1314, t(39) = 11.79, p < 0.001$) although the effect weakens over time. However, this is likely not a weakness of the method but rather an effect of repeated reference on participants' RL use: With repeated reference, the length of RL reduces (Clark and Wilkes-Gibbs, 1986), meaning that the mean RA of each word increases due to fewer tokens of weak RA being uttered. Indeed, a significant interaction between `Round` and `Tokens` was found in their effects on RA (see Supplementary Material). Figure 5 shows a significant correlation of ROUND i and mean RA of all tokens for that round $\frac{1}{n} \sum_{t \in T_i}^{n} w_t$. Additionally, Figure 6 shows a significant inverse relationship with token count $|T_i|$. Since the referent $\hat{r}$ is chosen at random by the game, the amount of references to an entity increases with round ordinality, and so this corresponds with Clark and Wilkes-Gibbs (1986).

A qualitative assessment shows that vocabulary items with the great RA are typically nouns

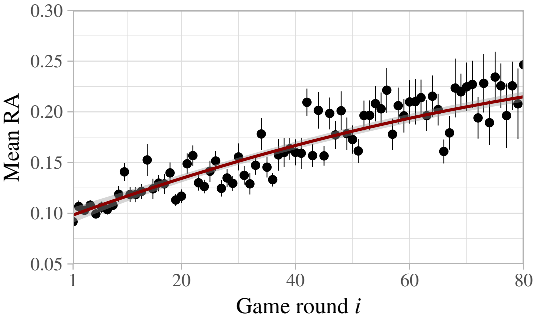

Figure 5: RA w_t for $t \in T_i$ as a quadratic function of ROUND $i \cdot i^2$ (CI 0.95; error bars are SEM).

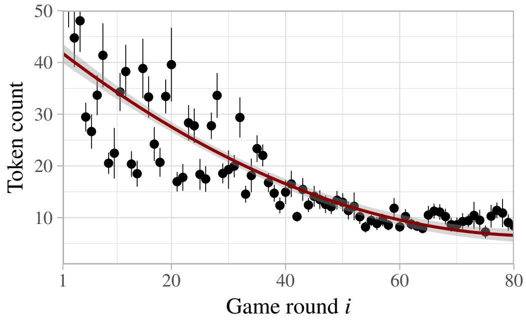

Figure 6: Token count $|T_i|$ as a quadratic function of ROUND $i \cdot i^2$ (CI 0.95; error bars are SEM).

strongly associated with the task at hand: The 31 words with greatest RA are all nouns referring to shapes. Despite this, however, great RA is not exclusive to nouns: In Table 2, *inside*, a preposition, is considered semantically lighter in general English than nouns are (Froud, 2001), but has RA greater than the mean ($\mu = 0.2424$, $SD = 0.1266$). On the other hand, the noun *color* has relatively little RA given the task at hand.

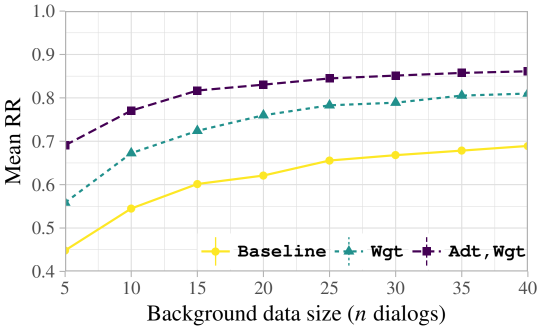

Figure 7: MRR per background training set size.

Word t	RA w_t	Count
K	0.7567	108
bat	0.6382	69
house	0.6374	153
chicken	0.6340	85
computer	0.6181	96
	…	
inside	0.3985	13
	…	
color	0.0291	195
	…	
's	0.0066	1593
it	0.0051	1731
okay	0.0048	1115
the	0.0040	2478

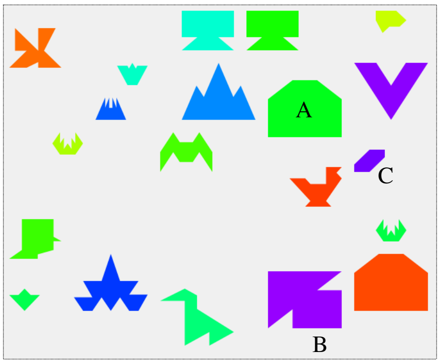
Table 2: Sample vocabulary items ordered by RA.

Moreover, including `Adt` and `Wgt` using dialog interaction data (`Adt,Wgt`) shows significant improvements over either alone: During model selection, including `Wgt` significantly improved fit ($\chi^2 = 61.425, p < 0.001$). This means that both methods can be used together and complement each other: Weighting is particularly beneficial for shorter interactions, where little in-domain interaction data is present, while adaptation provides greater benefit for longer interactions (cf. Figure 3). In fact, Figure 7 shows that `Wgt` has better MRR using only 12 randomly-chosen dialogs as background data than the `Baseline` does with 40, and adaptation and weighting together (`Adt,Wgt`) has better MRR with only 7. Figure 8 illustrates the effects of the two conditions on reference resolution in the task used for evaluation: The baseline classifier has a rank of 10 for the referent $\hat{r}$ out of $|R| = 20$ possible referents. In the baseline ***(A)***, the classifier for e.g. *color* has as much weight as e.g. *rectangle* although the former is not a useful signifier for the given task. When weighting by RA ***(B)***, however, the less-useful words contribute less to the total $\sum_{t \in T} (p_t(\hat{r}) \cdot w_t)$, improving rank to 5. Finally, when adapting the model with interaction data ***(C)***, models for semantically-heavy words like *violet* better fit the dyad's RL use, bringing rank to 1.

When both incrementally adapting semantic models with in-domain dialog data and weighting by RA, MRR for reference resolution was improved by 32.5% over the baseline (see Table 3).

7 Conclusion and Discussion

We have shown that it is possible to improve reference resolution for situated dialog by incrementally adapting word semantic model parameters to



(A) Baseline (Target rank 10)

	the	slanted	rectangle	with	two	triangles	violet	in	color
	the	slanted	rectangle	with	two	triangles	violet	in	color
Score	0.51	0.50	0.74	0.31	0.42	0.23	0.41	0.53	0.31

(B) Weighting by RA (Target rank 5)

	the	slanted	rectangle	with	two	triangles	violet	in	color
			rectangle	with	two	triangles	violet	in	color
Score	0.51	0.50	0.74	0.31	0.42	0.23	0.41	0.53	0.31
RA	0.00	0.00	0.32	0.15	0.19	0.31	0.34	0.02	0.05

(C) Adapting and Weighting by RA (Target rank 1)

	the	slanted	rectangle	with	two	triangles	violet	in	color
		slanted	rectangle	with	two	triangles	violet	in	color
Score	0.51	0.64	0.80	0.31	0.60	0.63	0.70	0.53	0.46
RA	0.00	0.56	0.34	0.15	0.19	0.30	0.34	0.02	0.04

Figure 8: Reference resolution with different conditions: The TRUE referent $\hat{r}$ is labeled *C*. Word hue denotes semantic score $p_t(\hat{r})$ (green = 1.0, yellow = 0.5, red = 0.0). Saturation denotes RA w_t.

a given dialog in order to accommodate idiosyncratic language use by dyad partners, and the effect of the partners' own alignment makes this method even more beneficial over time. Additionally, we have defined a metric of word referring ability which is derived from a word's referential semantics in situated dialog but holds across individual dialogs despite dyadic variation in RL use. We showed that this metric can be used to automatically determine the usefulness of a given word for reference resolution, meaning that RE annotation is not necessary. Both of these aspects are beneficial to natural language understanding (NLU) for situated dialog due to the difficulty of acquiring data domain-appropriate data.

Model adaption using dialogic knowledge can be effective for improving NLU (cf. Riccardi and Gorin, 2000) despite that little work has been done in this regard specifically for reference resolution. Our experiments with model adaptation in Section 5 suggest that it may be beneficial to treat reference resolution in situated dialog as a model adaptation task, where a given dialog being evaluated is considered "in-domain" data and all other dialogs considered "out-of-domain" data. Moreover, due to the fact that dialog participants' use of RL converges over time (Garrod and Anderson, 1987; Brennan, 1996; Brennan and Clark, 1996), the task should adapt a pre-trained reference resolution model not only for a given dialog but also to the given state of that dialog; On the other hand, Iida et al. (2010) incorporate intra-dialogic knowledge but do not adapt to inter-dialogic effects.

Condition	*Rank*	SD$_{Rank}$	SEM$_{Rank}$
`Baseline`	2.8060	3.2427	0.0566
`Adt`	2.4224	2.8614	0.0499
`Wgt`	1.9373	2.3288	0.0406
`Adt,Wgt`	1.5693	1.6685	0.0291
Condition	***RR***	**SD$_{RR}$**	**SEM$_{RR}$**
`Baseline`	0.6892	0.3648	0.0064
`Adt`	0.7372	0.3470	0.0061
`Wgt`	0.8099	0.3116	0.0054
`Adt,Wgt`	0.8613	0.2686	0.0047

Table 3: Overall results for conditions evaluated.

Lastly, weighting by RA w_t as derived from logistic word classifier scores $p_t(r)$ in Section 6 was shown to be effective and can be easily inferred from data. However, this inaccurately assumes inter-word independence, since it does not encode a word's context: For example, the RA of *not* was 0.0638, which is relatively low. While it is a poor signifier in itself, it reverses the polarity of the predicate it modifies. For example, in *it's the baby blue K the light one not the dark one*, the NP *the dark one* should in fact have negative RA: Entities with a low semantic score $\sum_{t \in \langle \mathit{the,dark,one} \rangle} p_t(r)$ should in fact be preferred over those those with a high score. This could be addressed via structural prediction (e.g. conditional random fields or neural networks) or even higher-order n-grams, but these methods cannot be easily utilized given the typically small size of situated dialog datasets.

Abstract

Developing agents to engage in complex goal-oriented dialogues is challenging partly because the main learning signals are very sparse in long conversations. In this paper, we propose a divide-and-conquer approach that discovers and exploits the hidden structure of the task to enable efficient policy learning. First, given successful example dialogues, we propose the *Subgoal Discovery Network* (SDN) to divide a complex goal-oriented task into a set of simpler subgoals in an *unsupervised* fashion. We then use these subgoals to learn a multi-level policy by hierarchical reinforcement learning. We demonstrate our method by building a dialogue agent for the composite task of travel planning. Experiments with simulated and real users show that our approach performs competitively against a state-of-the-art method that requires human-defined subgoals. Moreover, we show that the learned subgoals are often human comprehensible.

1 Introduction

Consider we want to plan a trip to a distant city using a dialogue agent. The agent must make choices at each leg, e.g., whether to fly or to drive, whether to book a hotel. Each of these steps in turn involves making a sequence of decisions all the way down to *lower*-level actions. For example, to book a hotel involves identifying the location, specifying the check-in date and time, and negotiating the price etc.

The above process of the agent has a natural hierarchy: a top-level process selects which subgoal to complete, and a low-level process chooses primitive actions to accomplish the selected subgoal. Within the reinforcement learning (RL) paradigm, such a hierarchical decision making process can be formulated in the *options* framework (Sutton et al., 1999), where subgoals with their own reward functions are used to learn policies for achieving these subgoals. These learned policies are then used as temporally extended actions, or options, for solving the entire task.

Based on the options framework, researchers have developed dialogue agents for complex tasks, such as travel planning, using hierarchical reinforcement learning (HRL) (Cuayáhuitl et al., 2010). Recently, Peng et al. (2017b) showed that the use of subgoals mitigates the reward sparsity and leads to more effective exploration for dialogue policy learning. However, these subgoals need to be human-defined which limits the applicability of the approach in practice because the domain knowledge required to properly define subgoals is often not available in many cases.

In this paper, we propose a simple yet effective *Subgoal Discovery Network* (SDN) that discovers useful subgoals automatically for an RL-based dialogue agent. The SDN takes as input a collection of successful conversations, and identifies "hub" states as subgoals. Intuitively, a hub state is a region in the agent's state space that the agent tends to visit frequently on successful paths to a goal but not on unsuccessful paths. Given the discovered subgoals, HRL can be applied to learn a hierarchical dialogue policy which consists of (1) a top-level policy that selects among subgoals, and (2) a low-level policy that chooses primitive actions to achieve selected subgoals.

We present the first study of learning dialogue agents with automatically discovered subgoals. We demonstrate the effectiveness of our approach by building a composite task-completion dialogue agent for travel planning. Experiments with both simulated and real users show that an agent learned with discovered subgoals performs competitively against an agent learned using expert-defined subgoals, and significantly outperforms an agent learned without subgoals. We also find that

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2298–2309
Brussels, Belgium, October 31 - November 4, 2018.

the subgoals discovered by SDN are often human comprehensible.

2 Background

A goal-oriented dialogue can be formulated as a Markov decision process, or MDP (Levin et al., 2000), in which the agent interacts with its environment over a sequence of discrete steps. At each step $t \in \{0, 1, \ldots\}$, the agent observes the current state s_t of the conversation (Henderson, 2015; Mrkšić et al., 2017; Li et al., 2017), and chooses action a_t according to a policy π. Here, the action may be a natural-language sentence or a speech act, among others. Then, the agent receives a numerical reward r_t and switches to next state s_{t+1}. The process repeats until the dialogue terminates. The agent is to learn to choose *optimal* actions $\{a_t\}_{t=1,2,\ldots}$ so as to maximize the total *discounted* reward $r_0 + \gamma r_1 + \gamma^2 r_2 + \cdots$, where $\gamma \in [0, 1]$ is a discount factor. This learning paradigm is known as reinforcement learning, or RL (Sutton and Barto, 1998).

When facing a complex task, it is often more efficient to divide it into multiple simpler subtasks, solve them, and combine the partial solutions into a full solution for the original task. Such an approach may be formalized as hierarchical RL (HRL) in the options framework (Sutton et al., 1999). An option can be understood as a subgoal, which consists of an initiation condition (when the subgoal can be triggered), an option policy to solve the subgoal, and a termination condition (when the subgoal is considered finished).

When subgoals are given, there exist effective RL algorithms to learn a hierarchical policy. A major open challenge is the automatic discovery of subgoals from data, the main innovation of this work is covered in the next section.

3 Subgoal Discovery for HRL

Figure 1 shows the overall workflow of our proposed method of using automatic subgoal discovery for HRL. First a dialogue session is divided into several segments. Then at the end of those segments (subgoals), we equip an intrinsic or extrinsic reward for the HRL algorithm to learn a hierarchical dialogue policy. Note that only the last segment has an extrinsic reward. The details of the segmentation algorithm and how to use subgoals for HRL are presented in Section 3.1 and Section 3.3.

Figure 1: The workflow for HRL with subgoal discovery. In addition to the extrinsic reward at the end of the dialogue session, HRL also uses intrinsic rewards induced by the subgoals (or the ends of dialogue segments). Section 3.2 details the reward design for HRL.

3.1 Subgoal Discovery Network

Assume that we have collected a set of successful state trajectories of a task, as shown in Figure 2. We want to find subgoal states, such as the three red states s_4, s_9 and s_{13}, which form the "hubs" of these trajectories. These hub states indicate the subgoals, and thus divide a state trajectory into several segments, each for an option[1].

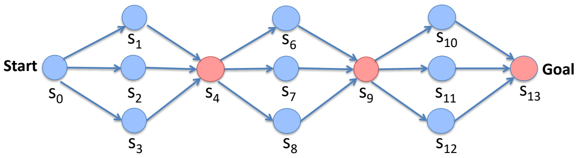

Figure 2: Illustration of "subgoals". Assuming that there are three state trajectories $(s_0, s_1, s_4, s_6, s_9, s_{10}, s_{13})$, $(s_0, s_2, s_4, s_7, s_9, s_{11}, s_{13})$ and $(s_0, s_3, s_4, s_8, s_9, s_{12}, s_{13})$. Then red states s_4, s_9, s_{13} could be good candidates for "subgoals".

Thus, discovering subgoals by identifying hubs in state trajectories is equivalent to segmenting state trajectories into options. In this work, we formulate subgoal discovery as a state trajectory segmentation problem, and address it using the Subgoal Discovery Network (SDN), inspired by the sequence segmentation model (Wang et al., 2017).

The SDN architecture. SDN repeats a two-stage process of generating a state trajectory segment, until a trajectory termination symbol is generated: first it uses an initial segment hidden state

---

[1] There are many ways of creating a new option $\langle I, \pi, \beta \rangle$ for a discovered subgoal state. For example, when a subgoal state is identified at time step t, we add to I the set of states visited by the agent from time $t - n$ to t, where n is a pre-set parameter. I is therefore the union of all such states over all the state trajectories. The termination condition β is set to 1 when the subgoal is reached or when the agent is no longer in I, and to 0 otherwise. In the deep RL setting where states are represented by continuous vectors, β is a probability whose value is proportional to the vector distance e.g., between current state and subgoal state.

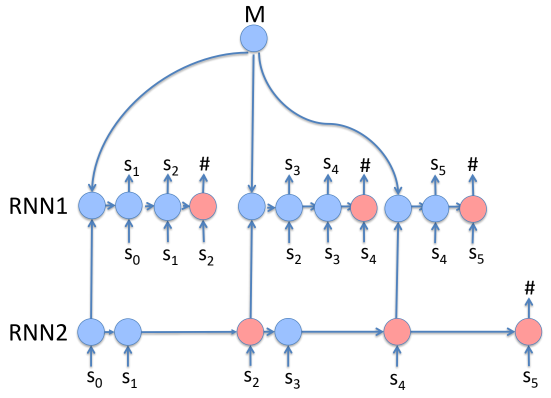

Figure 3: Illustration of SDN for state trajectory $(s_0, \ldots, s_5)$ with s_2, s_4 and s_5 as subgoals. Symbol # is the termination. The top-level RNN (RNN1) models segments and the low-level RNN (RNN2) provides information about previous states from RNN1. The embedding matrix M maps the outputs of RNN2 to low dimensional representations so as to be consistent with the input dimensionality of RNN1. Note that state s_5 is associated with two termination symbols #; one is for the termination of the last segment and the other is for the termination of the entire trajectory.

to start a new segment, or a trajectory termination symbol to terminate the trajectory, given all previous states; if the trajectory is not terminated, then keep generating the next state in this trajectory segment given previous states until a segment termination symbol is generated. We illustrated this process in Figure 3.

We model the likelihood of each segment using an RNN, denoted as RNN1. During the training, at each time step, RNN1 predicts the next state with the current state as input, until it reaches the option termination symbol #. Since different options are under different conditions, it is not plausible to apply a fixed initial input to each segment. Therefore, we use another RNN (RNN2) to encode all previous states to provide relevant information and we transform these information to low dimensional representations as the initial inputs for the RNN1 instances. This is based on the *causality* assumption of the options framework (Sutton et al., 1999) — the agent should be able to determine the next option given all previous information, and this should not depend on information related to any later state. The low dimensional representations are obtained via a global subgoal embedding matrix $M \in \mathbb{R}^{d \times D}$, where d and D are the dimensionality of RNN1's input layer and RNN2's output layer, respectively. Mathematically, if the output of RNN2 at time step t is o_t, then from time t the RNN1 instance has $M \cdot \mathrm{softmax}(o_t)$ as its initial input[2]. D is the number of subgoals we aim to learn. Ideally, the vector $\mathrm{softmax}(o_t)$ in a well-trained SDN is close to an one-hot vector. Therefore, $M \cdot \mathrm{softmax}(o_t)$ should be close to one column in M and we can view that M provides at most D different "embedding vectors" for RNN1 as inputs, indicating at most D different subgoals. Even in the case where $\mathrm{softmax}(o_t)$ is not close to any one-hot vector, choosing a small D helps avoid overfitting.

Segmentation likelihood. Given the state trajectory $(s_0, \ldots, s_5)$, assuming that s_2, s_4 and s_5 are the discovered subgoal states, we model the conditional likelihood of a proposed segmentation $\sigma = ((s_0, s_1, s_2), (s_2, s_3, s_4), (s_4, s_5))$ as $p(\sigma|s_0) = p((s_0, s_1, s_2)|s_0) \cdot p((s_2, s_3, s_4)|s_{0:2}) \cdot p((s_4, s_5)|s_{0:4})$, where each probability term $p(\cdot|s_{0:i})$ is based on an RNN1 instance. And for the whole trajectory $(s_0, \ldots, s_5)$, its likelihood is the sum over all possible segmentations.

Generally, for state trajectory $\boldsymbol{s} = (s_0, \ldots, s_T)$, we model its likelihood as follows[3]:

$$L_S(\boldsymbol{s}) = \sum_{\sigma \subseteq \mathcal{S}(\boldsymbol{s}), \mathrm{length}(\sigma) \leq S} \prod_{i=1}^{\mathrm{length}(\sigma)} p(\sigma_i | \tau(\sigma_{1:i})), \tag{1}$$

where $\mathcal{S}(\boldsymbol{s})$ is the set of all possible segmentations for the trajectory $\boldsymbol{s}$, σ_i denotes the i^{th} segment in the segmentation σ, and τ is the concatenation operator. S is an upper limit on the maximal number of segments. This parameter is important for learning subgoals in our setting since we usually prefer a small number of subgoals. This is different from Wang et al. (2017), where a maximum segment length is enforced.

We use maximum likelihood estimation with Eq. (1) for training. However, the number of possible segmentations is exponential in $\mathcal{S}(\boldsymbol{s})$ and the naive enumeration is intractable. Here, dynamic programming is employed to compute the likelihood in Eq. (1) efficiently: for a trajectory $\boldsymbol{s} = (s_0, \ldots, s_T)$, if we denote the sub-trajectory $(s_i, \ldots, s_t)$ of $\boldsymbol{s}$ as $\boldsymbol{s}_{i:t}$, then its likelihood follows

---

[2] $\mathrm{softmax}(o_t)_i = \exp(o_{t,i}) / \sum_{i'=1}^{D} \exp(o_{t,i'}) \in \mathbb{R}^D$ for $o_t = (o_{t,1}, \ldots, o_{t,D})$.

[3] For notation convenience, we include s_0 into the observational sequence, though s_0 is always conditioned upon.

the below recursion:

$$L_m(\boldsymbol{s}_{0:t}) = \begin{cases} \sum\limits_{i=0}^{t-1} L_{m-1}(\boldsymbol{s}_{0:i}) p(\boldsymbol{s}_{i:t}|\boldsymbol{s}_{0:i}), & m > 0, \\ I[t=0], & m = 0. \end{cases}$$

Here, $L_m(\boldsymbol{s}_{0:t})$ denotes the likelihood of sub-trajectory $\boldsymbol{s}_{0:t}$ with no more than m segments and $I[\cdot]$ is an indicator function. $p(\boldsymbol{s}_{i:t}|\boldsymbol{s}_{0:i})$ is the likelihood segment $\boldsymbol{s}_{i:t}$ given the previous history, where RNN1 models the segment and RNN2 models the history as shown in Figure 3. With this recursion, we can compute the likelihood $L_S(\boldsymbol{s})$ for the trajectory $\boldsymbol{s} = (s_0, \ldots, s_T)$ in $O(ST^2)$ time.

Learning algorithm. We denote θ^s as the model parameter including the parameters of the embedding matrix M, RNN1 and RNN2. We then parameterize the segment likelihood function as $p(\boldsymbol{s}_{i:t}|\boldsymbol{s}_{0:i}) = p(\boldsymbol{s}_{i:t}|\boldsymbol{s}_{0:i}; \theta^s)$, and the trajectory likelihood function as $L_m(\boldsymbol{s}_{0:t}) = L_m(\boldsymbol{s}_{0:t}; \theta^s)$.

Given a set of N state trajectories $(\boldsymbol{s}^{(1)}, \ldots, \boldsymbol{s}^{(N)})$, we optimize θ^s by minimizing the negative mean log-likelihood with L_2 regularization term $\frac{1}{2}\lambda||\theta^s||^2$ where $\lambda > 0$, using stochastic gradient descent:

$$\mathcal{L}_S(\theta^s, \lambda) = -\frac{1}{N}\sum_{i=1}^{N} \log L_S(\boldsymbol{s}^{(i)}, \theta^s) + \frac{1}{2}\lambda||\theta^s||^2. \quad (2)$$

Algorithm 1 outlines the training procedure for SDN using stochastic gradient descent.

Algorithm 1 Learning SDN

```
Input: A set of state trajectories $(\boldsymbol{s}_1, \ldots \boldsymbol{s}_N)$, the number of segments limit $S$, initial learning rate $\eta > 0$.
Initialize the SDN parameter $\theta^s$.
while not converged do
    Compute the gradient $\nabla_{\theta^s}\mathcal{L}_S(\theta^s, \lambda)$ of the loss $\mathcal{L}_S(\theta^s, \lambda)$ as in Eq. (2).
    Update $\theta^s \leftarrow \theta^s - \eta\nabla_{\theta^s}\mathcal{L}_S(\theta^s, \lambda)$.
    Update the learning rate $\eta$.
end while
```

3.2 Hierarchical Dialogue Policy Learning

Before describing how we use a trained SDN model for HRL, we first present a short review of HRL for a task-oriented dialogue system. Following the *options* framework (Sutton et al., 1999), assume that we have a state set $\mathcal{S}$, an option set $\mathcal{G}$ and a finite primitive action set $\mathcal{A}$.

The HRL approach we take learns two Q-functions (Peng et al., 2017b), parameterized by θ_e and θ_i, respectively:

- The top-level $Q^*(s, g; \theta_e)$ measures the maximum total discounted *extrinsic* reward received by choosing subgoal g in state s and then following an optimal policy. These extrinsic rewards are the objective to be maximized by the entire dialogue policy.
- The low-level $Q^*(s, a, g; \theta_i)$ measures the maximum total discounted intrinsic reward received to achieve a *given* subgoal g, by choosing action a in state s and then following an optimal option policy. These intrinsic rewards are used to learn an option policy to achieve a given subgoal.

Suppose we have a dialogue session of T turns: $\tau = (s_0, a_0, r_0, \ldots, s_T)$, which is segmented into a sequence of subgoals $g_0, g_1, \ldots \in \mathcal{G}$. Consider one of these subgoals g which starts and ends in steps t_0 and t_1, respectively.

The top-level Q-function is learned using Q-learning, by treating subgoals as temporally extended actions:

$$\theta_e \leftarrow \theta_e + \alpha \cdot (q - Q(s_t, g; \theta_e)) \cdot \nabla_{\theta_e} Q(s_t, g; \theta_e)\,,$$

where

$$q = \sum_{t=t_0}^{t_1-1} \gamma^{t-t_0} r_t^e + \gamma^{t_1-t_0} \max_{g' \in \mathcal{G}} Q(s_{t_1}, g'; \theta_e)\,,$$

and α is the step-size parameter, $\gamma \in [0, 1]$ is a discount factor. In the above expression of q, the first term refers to the total discounted reward during fulfillment of subgoal g, and the second to the maximum total discounted after g is fulfilled.

The low-level Q-function is learned in a similar way, and follows the standard Q-learning update, except that intrinsic rewards for subgoal g are used. Specifically, for $t = t_0, t_0 + 1, \ldots, t_1 - 1$:

$$\theta_i \leftarrow \theta_i + \alpha \cdot (q_t - Q(s_t, a_t, g; \theta_e)) \cdot \nabla_{\theta_i} Q(s_t, a_t, g; \theta_i)\,,$$

where

$$q_t = r_t^i + \gamma \max_{a' \in \mathcal{A}} Q(s_{t+1}, a', g; \theta_i)\,.$$

Here, the intrinsic reward r_t^i is provided by the internal critic of dialogue manager. More details are in Appendix A.

In hierarchical policy learning, the combination of the extrinsic and intrinsic rewards is expected to help the agent to successfully accomplish a composite task as fast as possible while trying to avoid unnecessary subtask switches. Hence, we define the extrinsic and intrinsic rewards as follows:

Extrinsic Reward. Let L be the maximum number of turns of a dialogue, and K the number of subgoals. At the end of a dialogue, the agent receives a positive extrinsic reward of $2L$ for a success dialogue, or $-L$ for a failure dialogue; for each turn, the agent receives an extrinsic reward of -1 to encourage shorter dialogues.

Intrinsic Reward. When a subgoal terminates, the agent receives a positive intrinsic reward of $2L/K$ if a subgoal is completed successfully, or a negative intrinsic reward of -1 otherwise; for each turn, the agent receives an intrinsic reward -1 to encourage shorter dialogues.

3.3 Hierarchical Policy Learning with SDN

We use a trained SDN in HRL as follows. The agent starts from the initial state s_0, keeps sampling the output from the distribution related to the top-level RNN (RNN1) until a termination symbol # is generated, which indicates the agent reaches a subgoal. In this process, intrinsic rewards are generated as specified in the previous subsection. After # is generated, the agent selects a new option, and repeats this process.

This type of naive sampling may allow the option to terminate at some places with a low probability. To stabilize the HRL training, we introduce a threshold $p \in (0, 1)$, which directs the agent to terminate an option if and only if the probability of outputting # is at least p. We found this modification leads to better behavior of the HRL agent than the naive sampling method, since it normally has a smaller variance.

In the HRL training, the agent only uses the probability of outputting # to decide subgoal termination. Algorithm 2 outlines the full procedure of one episode for hierarchical dialogue policies with a trained SDN in the composite task-completion dialogue system.

4 Experiments and Results

We evaluate the proposed model on a travel planning scenario for composite task-oriented dialogues (Peng et al., 2017b). Over the exchange of a conversation, the agent gathers information about the user's intent before booking a trip. The environment then assesses a binary outcome (success or failure) at the end of the conversation, based on (1) whether a trip is booked, and (2) whether the trip satisfies the user's constraints.

Algorithm 2 HRL episode with a trained SDN

```
Input: A trained SDN $\mathcal{M}$, initial state $s_0$ of an episode, threshold $p$, the HRL agent $\mathcal{A}$.
Initialize an RNN2 instance $R_2$ with parameters from $\mathcal{M}$ and $s_0$ as the initial input.
Initialize an RNN1 instance $R_1$ with parameters from $\mathcal{M}$ and $M \cdot \text{softmax}(o_0^{\text{RNN2}})$ as the initial input, where $M$ is the embedding matrix (from $\mathcal{M}$) and $o_0^{\text{RNN2}}$ is the initial output of $R_2$.
Current state $s \leftarrow s_0$.
Select an option $o$ using the agent $\mathcal{A}$.
while Not reached the final goal do
    Select an action $a$ according to $s$ and $o$ using the agent $\mathcal{A}$. Get the reward $r$ and the next state $s'$ from the environment.
    Place $s'$ to $R_2$, denote $o_t^{\text{RNN2}}$ as $R_2$'s latest output and take $M \cdot \text{softmax}(o_t^{\text{RNN2}})$ as the $R_1$'s new input. Let $p_{s'}$ be the probability of outputting the termination symbol #.
    if $p_{s'} \geq p$ then
        Select a new option $o$ using the agent $\mathcal{A}$.
        Re-initialize $R_1$ using the latest output from $R_2$ and the embedding matrix $M$.
    end if
end while
```

Dataset. The raw dataset in our experiments is from a publicly available multi-domain dialogue corpus (El Asri et al., 2017). Following Peng et al. (2017b), a few changes were made to introduce dependencies among subtasks. For example, the hotel check-in date should be the same with the departure flight arrival date. The data was mainly used to create simulated users, and to build the knowledge bases for the subtasks of booking flights and reserving hotels.

User Simulator. In order to learn good policies, RL algorithms typically need an environment to interact with. In the dialogue research community, it is common to use simulated users for this purpose (Schatzmann et al., 2007; Li et al., 2017; Liu and Lane, 2017). In this work, we adapted a publicly available user simulator (Li et al., 2016) to the composite task-completion dialogue setting with the dataset described above. During training, the simulator provides the agent with an (extrinsic) reward signal at the end of the dialogue. A dialogue is considered to be successful only when a travel plan is booked successfully, and the information provided by the agent satisfies user's constraints.

Baseline Agents. We benchmarked the proposed agent (referred to as the *m-HRL Agent*) against three baseline agents:

- A *Rule Agent* uses a sophisticated, hand-crafted dialogue policy, which requests and informs a hand-picked subset of necessary slots, and then confirms with the user about the reserved trip before booking the flight and hotel.

- A *flat RL Agent* is trained with a standard deep reinforcement learning method, DQN (Mnih et al., 2015), which learns a flat dialogue policy using extrinsic rewards only.
- A *h-HRL Agent* is trained with hierarchical deep reinforcement learning (HDQN), which learns a hierarchical dialogue policy based on human-defined subgoals (Peng et al., 2017b).

Collecting State Trajectories. Recall that our subgoal discovery approach takes as input a set of state trajectories which lead to successful outcomes. In practice, one can collect a large set of successful state trajectories, either by asking human experts to demonstrate (e.g., in a call center), or by rolling out a reasonably good policy (e.g., a policy designed by human experts). In this paper, we obtain dialogue state trajectories from a rule-based agent which is handcrafted by a domain expert, the performance of this rule-based agent can achieve success rate of 32.2% as shown in Figure 4 and Table 1. We only collect the successful dialogue sessions from the roll-outs of the rule-based agent, and try to learn the subgoals from these dialogue state trajectories.

Experiment Settings. To train SDN, we use RMSProp (Tieleman and Hinton, 2012) to optimize the model parameters. For both RNN1 and RNN2, we use LSTM (Hochreiter and Schmidhuber, 1997) as hidden units and set the hidden size to 50. We set embedding matrix M with $D = 4$ columns. As we discussed in Section 3.1, D captures the maximum number of subgoals that the model is expected to learn. Again, to avoid SDN from learning many unnecessary subgoals, we only allow segmentation with at most $S = 4$ segments during subgoal training. The values for D and S are usually set to be a little bit larger than the expected number of subgoals (e.g., 2 or 3 for this task) since we expect a great proportion of the subgoals that SDN learns are useful, but not necessary for all of them. As long as SDN discovers useful subgoals that guide the agent to learn policies faster, it is beneficial for HRL training, even if some non-perfect subgoals are found. During the HRL training, we use the learned SDN to propose subgoal-completion queries. In our experiment, we set the maximum turn $L = 60$.

We collected $N = 1634$ successful, but imperfect, dialogue episodes from the rule-based agent in Table 1 and randomly choose 80% of these dialogue state trajectories for training SDN. The remaining 20% were used as a validation set.

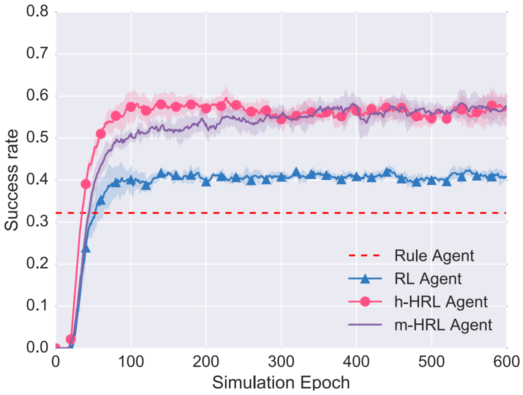

Figure 4: Learning curves of agents under simulation.

Agent	Success Rate	Turns	Reward
Rule	.3220	46.23	-24.02
RL	.4440	45.50	-1.834
h-HRL	.6485	44.23	35.32
m-HRL	.6455	44.85	34.77

Table 1: Performance of agents with simulated user.

As illustrated in Section 3.3, SDN starts a new RNN1 instance and issues a subgoal-completion query when the probability of outputting the termination symbol # is above a certain threshold p (as in Algorithm 2). In our experiment, p is set to be 0.2, which was manually picked according to the termination probability during SDN training.

In dialogue policy learning, for the baseline RL agent, we set the size of the hidden layer to 80. For the HRL agents, both top-level and low-level dialogue policies have a hidden layer size of 80. RMSprop was applied to optimize the parameters. We set the batch size to be 16. During training, we used ϵ-greedy strategy for exploration with annealing and set $\gamma = 0.95$. For each simulation epoch, we simulated 100 dialogues and stored these state transition tuples in the experience replay buffers. At the end of each simulation epoch, the model was updated with all the transition tuples in the buffers in a batch manner.

4.1 Simulated User Evaluation

In the composite task-completion dialogue scenario, we compared the proposed *m-HRL* agent

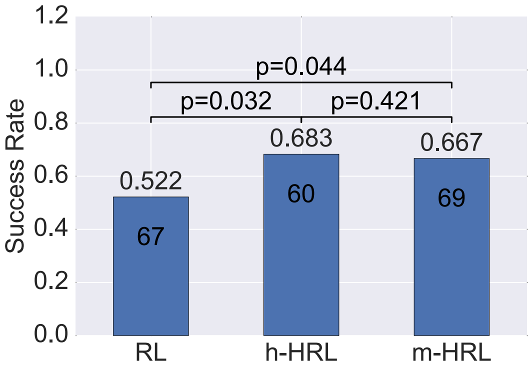

Figure 5: Performance of three agents tested with real users: success rate, number of dialogues and p-value are indicated on each bar (difference in mean is significant with $p < 0.05$).

with three baseline agents in terms of three metrics: success rate[4], average rewards and average turns per dialogue session.

Figure 4 shows the learning curves of all four agents trained against the simulated user. Each learning curve was averaged over 5 runs. Table 1 shows the test performance where each number was averaged over 5 runs and each run generated 2000 simulated dialogues. We find that the HRL agents generated higher success rates and needed fewer conversation turns to achieve the users' goals than the rule-based agent and the flat RL agent. The performance of the m-HRL agent is tied with that of the h-HRL agent, even though the latter requires high-quality subgoals designed by human experts.

4.2 Human Evaluation

We further evaluated the agents that were trained on simulated users against real users, who were recruited from the authors' organization. We conducted a study using the one RL agent and two HRL agents {RL, h-HRL, m-HRL}, and compared two pairs: {RL, m-HRL} and {h-HRL, m-HRL}. In each dialogue session, one agent was randomly selected from the pool to interact with a user. The user was *not* aware of which agent was selected to avoid systematic bias. The user was presented with a goal sampled from a user-goal corpus, then was instructed to converse with the agent to complete the given task. At the end of each dialogue session, the user was asked to give a rating on a scale from 1 to 5 based on the naturalness and coherence of the dialogue; here, 1 is the worst rating and 5 the best. In total, we collected 196 dialogue sessions from 10 human users.

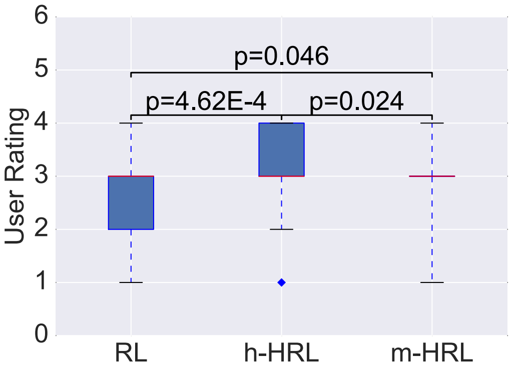

Figure 6: Distribution of user ratings for three agents in human evaluation

Figure 5 summarizes the performances of these agents against real users in terms of success rate. Figure 6 shows the distribution of user ratings for each agent. For these two metrics, both HRL agents were significantly better than the flat RL agent. Another interesting observation is that the m-HRL agent performs similarly to the h-HRL agent in terms of success rate in the real user study as shown on Figure 5. Meanwhile in Figure 6, the h-HRL agent is significantly better than m-HRL agent in terms of real user ratings. This may be caused by the probabilistic termination of subgoals: we used a threshold strategy to decide whether to terminate a subgoal. This could introduce variance so the agent might not behave reasonably compared with human-defined subgoals which terminate deterministically.

4.3 Subgoal Visualization

Table 2 shows the subgoals discovered by SDN in a sample dialogue by a rule-based agent interacting with the simulated user. The rule-based agent is equipped with a human-defined subtask structure, which always solves subtask *flight* (turns 1–15) before *hotel* (turns 16–23), as shown in the first column. At turn 10, the user starts to talk about *hotel* while the rule-based agent is still working on the pre-defined, unfinished *flight* subtask until subtask *flight* is finished at turn 15. At turn 16, the user switches to *hotel*, and so does the rule-based agent until the end of the dialogue. For this rule-based agent, the human-defined subgoal (*flight*) terminates at turn 15. Meanwhile, our SDN model detected two subgoals (except for the final goal):

---

[4] Success rate is the fraction of dialogues which accomplished the task successfully within the maximum turns.

h-Task	ID	Text
Flight	1	*agt*: Hi, may I know your departure city?
	2	*usr*: I depart from Fort Lauderdale.
	3	*agt*: And what is your destination city?
	4	*usr*: I need economy seat to Pittsburgh.
	5	*agt*: What is your departure date?
	6	*usr*: 2016-09-12, what time is available for the flight?
	7	*agt*: There is one flight at 21:00:00.
	8	*usr*: What is the price for that flight?
	9	*agt*: $423.
		Subgoal 1: A detected subgoal terminates!
	10	*usr*: I need to reserve a hotel for five people.
	11	*agt*: What is your return date for the trip?
	12	*usr*: 2016-09-18, I need to book 5 tickets for the flight.
	13	*agt*: What time do you prefer for return flight?
	14	*usr*: What time is available that day?
	15	*agt*: There is one flight departing at 11:00:00AM.
Hotel		Subgoal 2: A detected subgoal terminates!
	16	*usr*: What hotel is available?
	17	*agt*: There is one hotel called Winter Hill Inn available.
	18	*usr*: What is the price for hotel?
	19	*agt*: $410.
	20	*usr*: Great, could you book the trip for me?
	21	*agt*: Okay. Trip tickets are issued.
	22	*usr*: Thanks very much!
	23	*agt*: You are welcome!

Table 2: Discovered subgoals (except for the final goal) in a sample dialogue by a rule-based agent interacting with user simulator. The left column (h-Task) shows the human-defined subtasks for the rule-based agent. SDN detects two subgoals that terminate at turn 9 and 15 respectively. (h-Task: human-defined subtask, ID: turn ID, *agt*: Agent, *usr*: User)

one terminating at turn 9 (Subgoal 1), and another terminating at turn 15 (Subgoal 2). Subgoal 2 is consistent with the human-defined subgoal. Subgoal 1 is also reasonable since the user tries to switch to *hotel* at turn 10. In Appendix B, Table 3 shows a sample dialogue session by m-HRL agent interacting with a real user.

5 Related Work

Task-completion dialogue systems have attracted numerous research efforts, and there is growing interest in leveraging reinforcement learning for policy learning. One line of research is on single-domain task-completion dialogues with flat deep reinforcement learning algorithms such as DQN (Zhao and Eskenazi, 2016; Li et al., 2017; Peng et al., 2018), actor-critic (Peng et al., 2017a; Liu and Lane, 2017) and policy gradients (Williams et al., 2017; Liu et al., 2017). Another line of research addresses multi-domain dialogues where each domain is handled by a separate agent (Gašić et al., 2015; Gašić et al., 2015; Cuayáhuitl et al., 2016). Recently, Peng et al. (2017b) presented a composite task-completion dialogue system. Unlike multi-domain dialogue systems, composite tasks introduce inter-subtask constraints. As a result, the completion of a set of individual subtasks does *not* guarantee the solution of the entire task.

Cuayáhuitl et al. (2010) applied HRL to dialogue policy learning, although they focus on problems with a small state space. Later, Budzianowski et al. (2017) used HRL in multi-domain dialogue systems. Peng et al. (2017b) first presented an HRL agent with a global state tracker to learn the dialogue policy in the composite task-completion dialogue systems. All these works are built based on subgoals that were pre-defined with human domain knowledge for the specific tasks. The only job of the policy learner is to learn a hierarchical dialogue policy, which leaves the subgoal discovery problem unsolved. In addition to the applications in dialogue systems, subgoal is also widely studied in the linguistics research community (Allwood, 2000; Linell, 2009).

In the literature, researchers have proposed algorithms to automatically discovery subgoals for hierarchical RL. One large body of work is based on analyzing the spatial structure of the state transition graphs, by identifying bottleneck states or clusters, among others (Stolle and Precup, 2002; McGovern and Barto, 2001; Mannor et al., 2004; Şimşek et al., 2005; Entezari et al., 2011; Bacon, 2013). Another family of algorithms identifies commonalities of policies and extracts these partial policies as useful skills (Thrun and Schwartz, 1994; Pickett and Barto, 2002; Brunskill and Li, 2014). While similar in spirit to ours, these methods do not easily scale to continuous problems as in dialogue systems. More recently, researchers have proposed deep learning models to discover subgoals in continuous-state MDPs (Bacon et al., 2017; Machado et al., 2017; Vezhnevets et al., 2017). It would be interesting to see how effective they are for dialogue management.

Segmental structures are common in human languages. In the NLP community, some related research on segmentation includes word segmentation (Gao et al., 2005; Zhang et al., 2016) to divide the words into meaningful units. Alternatively, topic detection and tracking (Allan et al., 1998; Sun et al., 2007) segment a stream of data and identify stories or events in news or social text. In this work, we formulate subgoal discovery as a trajectory segmentation problem. Section 3.1 presents our approach to subgoal discovery which is inspired by a probabilistic sequence segmentation model (Wang et al., 2017).

6 Discussion and Conclusion

We have proposed the Subgoal Discovery Network to learn subgoals automatically in an unsupervised fashion without human domain knowledge. Based on the discovered subgoals, we learn the dialogue policy for complex task-completion dialogue agents using HRL. Our experiments with both simulated and real users on a composite task of travel planning, show that an agent trained with automatically discovered subgoals performs competitively against an agent with human-defined subgoals, and significantly outperforms an agent without subgoals. Through visualization, we find that SDN discovers reasonable, comprehensible subgoals given only a small amount of suboptimal but successful dialogue state trajectories.

These promising results suggest several directions for future research. First, we want to integrate subgoal discovery into dialogue policy learning rather than treat them as two separate processes. Second, we would like to extend SDN to identify multi-level hierarchical structures among subgoals so that we can handle more complex tasks than those studied in this paper. Third, we would like to generalize SDN to a wide range of complex goal-oriented tasks beyond dialogue, such as the particularly challenging Atari game of Montezuma's Revenge (Kulkarni et al., 2016).

A Hierarchical Dialogue Policy Learning

This section provides more algorithmic details for Section 3.2. Again, assume a conversation of length T:

$$\tau = (s_0, a_0, r_0, \dots, s_{T-1}, a_{T-1}, r_{T-1}, s_T)\,.$$

Suppose an HRL agent segments the trajectory into a sequence of subgoals as $g_0, g_1, \ldots \in \mathcal{G}$, and the corresponding subgoal termination time steps as $t_{g_0}, t_{g_1}, \ldots \in \mathbb{N}^*$. Furthermore, denote the intrinsic reward at time step t by r_t^i. The top-level and low-level Q-functions satisfy the following Bellman equations:

$$\begin{aligned} Q^*(s,g) = \mathbb{E}\Big[& \sum_{i=t_{g_j}}^{t_{g_{j+1}}-1} \gamma^{i-t_{g_j}} r_{t+1}^{e} \\ & + \gamma^{t_{g_{j+1}}-t_{g_j}} \cdot \max_{g'\in\mathcal{G}} Q^*(s_{t_{g_{j+1}}}, g') \\ & | s_{t_{g_j}} = s, g_j = g\Big] \end{aligned}$$

and

$$\begin{aligned} Q^*(s,a,g) = \mathbb{E}\Big[& r_t^i + \gamma \cdot \max_{a'\in\mathcal{A}} Q_i^*(s_{t+1}, g_j, a') \\ & | s_t = s, g_j = g, a_t = a, \\ & t \in [t_{g_j}, t_{g_{j+1}})\Big]\,. \end{aligned}$$

Here $\gamma \in [0,1]$ is a discount factor, and the expectations are taken over the randomness of the reward and the state transition,

We use deep neural networks to approximate the two Q-value functions as $Q^*(s,a,g) \approx Q(s,a,g;\theta_i)$ and $Q^*(s,g) \approx Q(s,g;\theta_e)$. The parameters θ_i and θ_e are optimized to minimize the following quadratic loss functions:

$$\begin{aligned} L_i(\theta_i) =& \frac{1}{2|D^i|} \sum_{(s,a,g,s',r^i)\in\mathcal{D}^i} [(y^i - Q(s,a,g;\theta_i))^2] \\ y^i =& r^i + \gamma \cdot \max_{a'\in\mathcal{A}} Q_i(s', a', g; \theta_i) \end{aligned} \tag{3}$$

and

$$\begin{aligned} L_e(\theta_e) =& \frac{1}{2|D^e|} \sum_{(s,g,s',r^e)\in\mathcal{D}^e} [(y^e - Q(s,g;\theta_e))^2] \\ y^e =& r^e + \gamma \cdot \max_{g'\in\mathcal{G}} Q(s', g'; \theta_e)\,. \end{aligned} \tag{4}$$

Here, $\mathcal{D}^e$, $\mathcal{D}^i$ are the replay buffers storing dialogue experience for training top-level and low-level policies.

Optimization of parameters θ_i and θ_e can be done by stochastic gradient descent on the two loss functions in Equations (3) and (4). The gradients of the two loss functions w.r.t their parameters are

$$\begin{aligned} \nabla_{\theta_i} L_i = \frac{1}{|D^i|} \sum_{(s,a,g,s',r^i)\in\mathcal{D}^i} \Big[& \nabla_{\theta_i} Q(s,a,g;\theta_i) \cdot \\ & (y^i - Q_i(s,a,g;\theta_i))\Big] \end{aligned}$$

and

$$\begin{aligned} \nabla_{\theta_e} L_e = \frac{1}{|D^e|} \sum_{(s,g,s',r^e)\in\mathcal{D}^e} \Big[& \nabla_{\theta_e} Q(s,g;\theta_e) \cdot \\ & (y^e - Q_e(s,g;\theta_e))\Big]\,. \end{aligned}$$

To avoid overfitting, we also add L_2-regularization to the objective functions above.

Abstract

Modern automated dialog systems require complex dialog managers able to deal with user intent triggered by high-level semantic questions. In this paper, we propose a model for automatically clustering questions into user intents to help the design tasks. Since questions are short texts, uncovering their semantics to group them together can be very challenging. We approach the problem by using powerful semantic classifiers from question duplicate/matching research along with a novel idea of supervised clustering methods based on structured output. We test our approach on two intent clustering corpora, showing an impressive improvement over previous methods for two languages/domains.

1 Introduction

The recent years have seen a resurgent interest for dialog systems, ranging from help desks and more complex task-based dialog to general purpose conversational agents, e.g., Alexa, Cortana or Siri. All these different application scenarios show that users expect to formulate complex information needs in natural language, with no limitation to their expressiveness. In other words, standard shallow semantic parsing based on concept segmentation and labeling is no longer sufficient for dialog modeling in today's applications. In particular, when designing dialog managers, we need to consider *user intents* expressed by articulated natural language text.

Current solutions to the intent detection problem consist in manually analyzing user questions and creating a taxonomy of intents to be attached to the appropriate actions. For example, if several semantically similar/identical questions regard `BookFlight`, the designer will build a category. This is a rather costly, difficult and time consuming task, which can often prevent the fast prototyping of dialog systems even for small domains. Moreover, the effort is extremely task- and system-specific, with very limited possibilities of porting the intent model, at least partially, across platforms, domains and languages. For example, in the recent 2016/2017 Natural Language Understanding Benchmarks (Coucke et al., 2017), the organizers have evaluated built-in intents generated by the major dialog managers (Apple's SiriKit, Amazon's Alexa, Microsoft's Luis, Google's Dialogflow, and Snips.ai) against a rather small set of relatively generic intents (e.g., `GetWeather`). This involved a considerable effort on aligning different system outputs.

To our knowledge, no previous work has been dedicated to automatizing this task, mainly because the underlying problem, semantic question paraphrasing, is very challenging. However, recent initiatives for automatic question duplicate detection[1], question relatedness (Nakov et al., 2016, 2017) and semantic textual similarity (Agirre et al., 2012; Cer et al., 2017) have shown that current technology achieves good accuracy in matching short text expressing similar semantics.

In this paper, we propose a model for automatically clustering questions into user intent categories, which can help the design of dialog systems. Our approach aims at overcoming the difficulty of providing a unique definition of intent from either a theoretical or practical perspective. Collaborating with stakeholders, we observe that it is very challenging to capture the intent property that can optimize dialogue/chatbot engineering work in terms of design and effort. The important aspect of our approach is that given a notion of intent, explicitly provided by annotated data, our

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2310–2321
Brussels, Belgium, October 31 - November 4, 2018.

model can create clusterings driven by such intrinsic definition. This is one of our major contributions: providing an effective supervised clustering approach, which can learn definitions from examples.

Regarding the technical solution our approach is bridging (i) the state-of-the-art methods for question similarity/paraphrasing with (ii) powerful supervised clustering algorithms. The former are obtained by exploiting previous research, e.g., on Quora, whereas the latter, are obtained by capitalizing on the structured output machine learning methods used for coreference resolution (CR), e.g., (Yu and Joachims, 2009; Fernandes et al., 2014). The main difference with CR consists in substituting mentions and their vector representation with the one of entire questions. It should be noted that structured output methods require a representation of edges connecting questions, which we obtain from question similarity research.

To train our model, we define a clustering corpus by automatically deriving question clusters from the Quora data, complementing the available question pair annotation with the transitive closure of the semantic matching property. Additionally, since Quora data is noisy, we manually annotate a question sample, defining an intent hierarchical taxonomy. To test the applicability of our methodology across languages and domains, we run evaluation experiments on another intent-based corpus, a collection of FAQs for an Italian online service.

We evaluate our approach comparing it to the classical k-means using (i) tf-idf model, (ii) our learned question similarity, and (iii) the similarity with spectral clustering. The last two methods can be considered another relatively novel contribution. Our results show that our new structured output method for question clustering: (i) highly outperforms all its competitors with respect to the standard clustering accuracy/purity as well as the measures defined in the CR domain, (ii) provides clustering accuracy of 80% with respect to the original Quora annotation and a still valuable accuracy of 65% with respect to the intent classes designed by an expert in Dialog modeling. This is a promising result as our designer can only provide one of the many interpretations of the intent taxonomy, which can be effectively applied.

Finally, a particular strength of our approach lies in identifying new intents (singleton clusters). These unseen intents are clearly problematic for dialogue management and cannot be covered by traditional approaches (e.g., our unsupervised clustering baselines show much lower performance on singleton clusters).

2 Related Work

Intent is a key concept for building dialog systems and is therefore a central research topic in the area. In particular, recent general-purpose dialog systems have to rely on extensive intent modeling to be able to correctly analyze a wide variety of user queries. This has led to a considerable amount of research on data-driven intent modeling.

In particular, Xu et al. (2013) represent query's intent as trees and employ a procedure for mapping an NL query into a tree-structured intent. The problem of this approach is that a new set of intent trees is required for new domains. Kim et al. (2016); Celikyilmaz et al. (2011) use semi-supervised approaches with large amounts of unlabeled data to improve the accuracy in mapping user queries into intents. However, they still require a small amount of labeled data in order to learn a given intent. Chen et al. (2016a) train a Convolutional Deep Neural Network to jointly learn the representations of human intents and associated utterances. Chen et al. (2016b) propose feature-enriched matrix factorization to model open domain intents. This leverages knowledge from Wikipedia and Freebase to acquire information from unexplored domains according to new users' requests. Unfortunately, it also requires external knowledge bases to induce concepts appearing within the intents.

Approaching the same problem from the opposite direction, several studies investigate algorithms for automatic question clustering. Wen et al. (2001) propose to cluster together queries that lead to the same group of web pages that are frequently selected by users. Jeon et al. (2005) use machine translation to estimate word translation probabilities and retrieve similar questions from question archives. Li et al. (2008) try to infer the intent of unlabeled queries according to the proximity with respect to the labeled queries in a click graph. Beitzel et al. (2007) propose to automatically classify web queries from logs into a set of topics by using a combination of different techniques, either supervised or unsupervised. The extracted topics are further used for efficient web search. Deepak (2016) presents MiXKmeans, a variation of k-means algorithm, suited for clustering threads present on forums and Community Question Answering websites. However, most techniques use unsupervised clustering to group similar questions/queries, without modeling intents. In contrast, our study relies on supervised clustering to learn intent-based similarity.

Finally, our work is related to a large body of research on dialog acts (Stolcke et al., 2000; Kim et al., 2010; Chen et al., 2018): our low-level intent labels (Table 1) can be seen as very fine-grained dialog acts (Core and Allen, 1997; Bunt et al., 2010; Oraby et al., 2017).

However, our paper's objective is different as our goal is not to rigidly define intents and then exploit them to derive a semantic interpretation. We focus on two contributions: first, we aim at providing a tool to help implementing dialog managers such that the designer can more easily create categories from precomputed clusters. Note that having in mind hundreds of questions to create intent category from scratch is clearly an exigent task.

Second, our approach can dynamically cluster questions with the same semantics, without any concept annotation. Indeed, the important concepts will be learned from the training data, which constitutes a much simpler annotation task than the creation of ad hoc dialogue acts. In particular, this can help with domain-specific intents: the domain-level semantics will be learned from data with no need for advanced manual engineering.

3 Question Clustering Algorithms

In this paper, we explore techniques for clustering questions into user intent. To this end, an input set of questions Q undergoes splitting into subsets (clusters), $c_i = \{q^i_j\}_{j=1}^{N_i}$, where q^i_j is the j-th question in the cluster i of size N_i and $\bigsqcup_i c_i = Q$. Each c_i is assumed to contain questions with the same intent, i.e., to represent a distinct intent. Performing a clustering of a new question set Q in an unsupervised manner may generally be troublesome due to the lack of any information about the structure of Q and the target number of distinct intents in it. To overcome this issue, we learn a clustering function from data annotated with gold question clusters.

In this work, we pose the task as a supervised clustering problem following the formulation by Finley and Joachims (2005). Having the training examples of the form $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{n}$, where each input $\mathbf{x}_i$ is a set of elements of some nature and $\mathbf{y}_i$ – the corresponding gold standard clustering of such a set, the goal is to learn a predictor $h : X \rightarrow Y$, from the space of sets X to the space of clusterings Y. Supervised clustering has been shown particularly effective for the NLP task of coreference resolution (Yu and Joachims, 2009; Fernandes et al., 2014). These models learn to infer an optimal clustering $\mathbf{y}$ of an input set $\mathbf{x}$ in a structured way, i.e., as one output object optimizing a global scoring function $f : X \times Y \rightarrow \mathbb{R}$. This is different from local models, which aggregate multiple clustering decisions taken with respect to pairs of elements.

At the test time, the global models draw predictions by finding

$$\hat{\mathbf{y}} = \underset{\mathbf{y} \in Y}{argmax}\ f(\mathbf{x}, \mathbf{y}). \qquad (1)$$

In the following, we give the necessary details of the original approach of Yu and Joachims (2009) and its adaptation for clustering questions.

3.1 Structured Output Clustering

To facilitate the inference of the optimal clustering in Equation 1, Yu and Joachims represent clustering variables $\mathbf{y}$ using graph structures. For an input $\mathbf{x}$, they construct a fully-connected undirected graph G, whose nodes are elements x_i of the input $\mathbf{x}$ and edges are all the pairwise links between them (x_i, x_j).[2] Any spanning forest $\mathbf{h}$ on G straightforwardly translates into a clustering $\mathbf{y}$. The nodes, aka elements represented by them, in each connected component (spanning tree) of $\mathbf{h}$ are considered to belong to the same cluster. The authors incorporate the spanning forest structures $\mathbf{h}$ as latent variables and decompose the feature representation of the input-output pair $(\mathbf{x}, \mathbf{y})$, which is extended with $\mathbf{h}$, over the edges of $\mathbf{h}$:

$$\Phi(\mathbf{x}, \mathbf{y}, \mathbf{h}) = \sum_{(x_i, x_j) \in \mathbf{h}} \phi(x_i, x_j). \qquad (2)$$

They employ Kruskal's spanning algorithm (Kruskal, 1956) to infer the optimal $\mathbf{h}$, and, respectively, $\mathbf{y}$.

A linear model $\mathbf{w}$ is trained using the Latent formulation of the Structural SVM learner (LSSVM),

---

[2] Note that we distinguish between boldface letters which we use to denote structural input/output variables, and normal font letters - for their rather elementary constituents, and simple variables.

to score the output clusterings according to the function $f(\mathbf{x},\mathbf{y},\mathbf{h}) = \mathbf{w} \cdot \Phi(\mathbf{x},\mathbf{y},\mathbf{h})$. In fact, $\mathbf{w}$ learns to score the edges since the structural feature vector decomposes over the edges. However, imposing a structure onto the output is supposed to produce a better $\mathbf{w}$, which we test in our experiments described in Section 5.

Alternatively, we employ the same structural model with another learning algorithm – latent structured perceptron (LSP) by Sun et al. (2009); Fernandes et al. (2014).

3.2 Pairwise question similarity classifier

Our intent clustering algorithm relies on the pairwise similarity between questions (edge score). To provide an accurate estimation of question-question similarity, we build upon an extensive state-of-the-art research in semantic similarity for short text, more specifically, on our previous work (Filice et al., 2016, 2017; Barrón-Cedeño et al., 2016; Da San Martino et al., 2016) solutions/features shown effective in the shared tasks by Nakov et al. (2016, 2017); Agirre et al. (2012, 2013).

In such work, the classifier is trained with SVMs, which learn a classification function $f : Q \times Q \rightarrow \{0,1\}$ on duplicate vs. non-duplicate pairs of questions belonging to the question set Q. The classifier score is used to decide if two questions in the dataset q_i and q_j are duplicate or not. We represent question pairs as vectors of similarity features derived between two questions.

Feature Vectors are built for questions pairs, (q_i, q_j), using a set of *text similarity* features that capture the relations between two questions. More specifically, we compute 20 similarity features $sim(q_i, q_j)$ using word n-grams ($n = [1, \ldots, 4]$), after stopword removal, greedy string tiling (Wise, 1996), longest common subsequences (Allison and Dix, 1986), Jaccard coefficient (Jaccard, 1901), word containment (Lyon et al., 2001), and cosine similarity.

4 Building Intent clusters

In this study, we rely on two datasets, providing some important insights on question semantics. None of them, however, fully annotates intents explicitly. Below we describe our approach for converting these resources into intent corpora, relying on an automatic procedure followed by a manual post-annotation step. Our intent corpora as well as the larger raw question clusters collections are available to the research community.[3]

4.1 Quora corpus

The original Quora task requires detecting whether two questions are semantically duplicate or not. The associated dataset contains over 404, 348 pairs of questions, posted by users on Quora website, labeled as a duplicate pair or not. For example, *How do you start a bakery?* and *How can one start a bakery business?* are duplicate, while *What are natural numbers?* and *What is a least natural number?* are not. Note that the coders label pairs in isolation, only having access to one pair to be labeled at a time on Quora website (answer base). The pairs to be labeled are not selected randomly. To make the task more challenging, as well as more useful for practical applications, the organizers only offer pairs of questions that are somewhat semantically related:

(3) q_1: How does an automobile works?
q_2: How does automobile R&D work?
(4) q_1: Will I lose weight if I fast ?
q_2: Why am I losing weight so fast ?
q_3: How can I lose my weight fast ?

In (3), the lexical material is very similar, yet the questions are rather distinct, as reflected in the Quora annotation. They also express very different user intents: while q_1 is a generic curiosity question about automobiles, q_2 is a practical request for information on R&D in the automotive industry. Example (4) shows why Quora duplicate detection task is very challenging and requires a very good level of NL Understanding: while these three questions are very similar on the surface level, they all convey distinct semantics.

4.1.1 Question clusters from Quora

Differently from the original task, in this work, we are interested in automatically acquiring intents from large question repositories. Given this, we need a corpus that contains clusters of questions annotated by their underlying intent. As a first step in this direction, we approximate intent clusters with the clusters of similar questions from Quora. These can be obtained by exploiting the pairwise annotation and relying on the transitivity property: for each pair q_1, q_2 annotated as a duplicate, we assign q_1 and q_2 to the same cluster;

---

[3] `https://ikernels-portal.disi.unitn.it/repository/intent-qa`

negative pairs (non-duplicate question) do not impact the clustering in any way.

This procedure has obvious limitations by design: (i) it will not give us any intent labels, only the clusters and (ii) it will not provide any hierarchy of intents, or any general/large intent categories. Still, it provides data for a large number of user-generated intents that fully manual annotation initiatives (e.g., Natural Language Understanding Benchmarks) cannot guarantee.

4.1.2 Manually annotating intent clusters

The use of Quora dataset to derive intent raises several potential issues: (i) no consistency is enforced across labels, (ii) duplicate or very similar Quora *answers* potentially pollute the annotation for their corresponding questions, (iii) specific decisions may depend on availability and granularity of the underlying answers, and (iv) the annotation of popular questions might be very spurious since the users have no access to all the other related questions. The first issue has also been noted by the Quora competition[4] participants, who found the same pairs of questions appearing several times in the training set with different labels. Moreover, we found numerous cases where the annotation does not respect the transitivity property:

(5) q_1: What are, if any, the medical benefits of fasting?
q_2: What are the benefits of water fasting?
q_3: What are the health benefits of fasting?

Here, the three independent coders have produced inconsistent labeling: although q_2 and q_3 are explicitly labeled as non-duplicate, they are both considered duplicates of q_1.

The second issue arises when the answer base contains (near-)duplicate entries. For example, the following two very similar questions are considered non-duplicates since they lead to two distinct answers:

(6) q_1: Which is better - DC or Marvel?
q_2: DC VS Marvel: which do you like more? [non-duplicate]

Note that this typically happens for rather popular questions that are therefore important to be analyzed correctly, either manually or automatically.

The third issue is extremely important for areas only partially covered by the answer DB. For example, for the set of questions, *Why is Saltwater Taffy candy imported in LOCATION?*, most LOCATIONs are covered by a generic answer, and all the corresponding questions are judged duplicates. However, some specific LOCATIONs, e.g., Fiji, have a dedicated answer and thus the corresponding questions form singleton clusters.

Finally, the annotation coherence problem arises for very popular areas covering a lot of closely related questions. Thus, more than 100 questions cover different aspects of *Weight Loss*. Since the coders do not have any access to all the questions on the same topic, the individual decisions are not coordinated, which leads to rather arbitrary partitioning of the area into clusters:

(7) **Gold Quora Cluster 1:**
How can I lose weight ?
What is the easiest way to lose weight faster ?
How can you lose weight quickly ?
How do I lose 7kgs in 2 weeks ?
What a great diet to lose weight fast and not make you hungry or keep on measuring portions ?
.. many more
Gold Quora Cluster 2:
How can I lose 3 kg in one week?
Gold Quora Cluster 3:
What are the good diets for weight loss ?
What is the best diet plan for weight loss?

To overcome these issues, we manually re-annotated a portion of the original Quora dataset with intent-based clusters. Starting from automatically induced clusters described above, we first re-assess the partitioning, correcting eventual mistakes and then assign intent-based labels to our clusters. Our labels are hierarchical, thus allowing for a better flexibility when designing dialog managers: the dialog flow/actions can be defined in terms of more generic (e.g., `Advice`) or more specific (e.g., `Advice-WeightLoss-diet`) intents, depending on different implementation considerations (query frequency for specific intents, overall importance for the application, difficulty of processing inter alia). To stay inline with the recent intent-based dialogue research, we also annotate *slots*, where applicable: entities external to the intent, yet playing an essential role for the correct semantic interpretation of the question. Table 1 shows an example of the intent-based cluster annotation.

4.2 FAQ: Hype Intent corpus

Our second corpus, Hype, allows for a more direct evaluation of the intent clustering algorithm. The data come from a set of questions asked by

---

[4] `https://www.kaggle.com/c/quora-question-pairs/discussion/30435`

Intent	Slots	Questions
Recommend-TourismCuisine	streetfood, Delhi	What are the best street food in Delhi ?
Recommend-TourismCuisine	streetfood, Delhi	What is the best street food in Delhi ?
Recommend-TourismCuisine	streetfood, Delhi	What are the best street foods in delhi ?
Recommend-TourismRestaurant	streetfood, Delhi	What are the best street food places of delhi ?

Table 1: Manually annotated intent clusters for Quora

users to a conversational agent, collected and manually processed for constructing a FAQ section for Hype—an online service that offers a credit card, a bank account number and an ibanking app to its customers. Unlike Quora, the questions are explicitly assigned to clusters by human annotators, and these clusters correspond to intents by construction. However, they do not have any informative labels and there is therefore no associated hierarchy. While this corpus provides very valuable data for our study, its main disadvantage is a very limited number of questions. Some questions are reported below:

(8) q_0: Cos'é HYPE? (What is HYPE?)
q_1: Volevo dei chiarimente di cos'é la app hype (I'd like to have more information about the hype app)
q_2: mi puó spiegare cose'é la app hype (could you please explain me what the hype app is?)
q_3: informazione applicazione hype (information about hype app)

At the current stage of our research, we use the FAQ/Hype corpus directly, with no automatic or manual adjustments as we did for Quora. We plan to annotate the FAQ categories with explicit intent labels in future work.

5 Experiments

We describe our comparative experiments on our clustering models on two corpora in two different languages.

5.1 Setup

We used two different corpora, described in Section 4:

The Quora Intent corpus contains 270, 146 and 212 clusters in the training, development and test sets. The clusters contain different numbers of questions, ranging from singletons to groups of 100+ questions. The singletons are the dominant group in the Quora dataset. This is probably due to the inclusion of non-duplicate questions that appear in the original Quora dataset. Overall, there are 1,334 questions distributed in 628 clusters (an average of 2.12 questions/cluster).

The FAQ/Hype corpus contains no small-size (< 3) clusters by construction since smaller clusters are typically not selected as FAQ entries. The largest groups of clusters are those of size 8 and 9. Overall, the FAQ Intent corpus contains 147 questions spread in 28 intent-based clusters, which correspond to an average of 5.25 questions/cluster.

Models To perform supervised clustering, we use: (i) the original implementation of the Latent SVM^{struct} [5] – LSSVM, and (ii) our implementation of the LSP algorithm based on the same clustering inference on undirected graphs using Kruskal's spanning algorithm.

We compare these approaches to two unsupervised clustering baselines: (i) spectral clustering (Ng et al., 2001), for which we employ the implementation from the *smile*[6] library, and (ii) relational k-means (Szalkai, 2013). The former implementation takes a matrix of pairwise similarities between data points as input, whereas the latter approach is a generalization of k-means to an arbitrary matrix of pairwise distances. Thus, they can be run on the scores relative to the question pairs (q_i, q_j).

We provide two variants of such scores: first, we run both the methods on the scores obtained from a binary pairwise similarity classifier, described in Section 3.2. Second, we run the clustering baselines on the tf-idf scores computed for the question pairs. Note that our use of the scores from a trained pairwise classifier introduces some supervision in standard unsupervised clustering approaches, originating new hybrid methods.

Parametrization LSSVM and LSP require the tuning of a regularization parameter, C, and of a specific loss parameter, r (penalty for adding an incorrect edge), which we select on the dev. set. We pick up C from $\{1.0, 10.0, 100.0, 1000.0\}$, and the r values from $\{0.1, 0.5, 1.0\}$. K-means and spectral clustering algorithms require the indication of the number of clusters k. In all of our

SVM					26.25	72.23	**38.50**	75.50

Table 2: Supervised vs. unsupervised clustering models and pairwise classification baselines on the test set, where the gold labels are from the original Quora annotation. Note that pairwise classification does not provide a good estimation of clustering accuracy.

experiments, we use the gold standard k of each example (clustering) as parameter to run the baseline approaches. This corresponds to comparing with an upperbound of the baselines.

Measures We compare the output clustering $\hat{\mathbf{y}} = \bigsqcup_j \hat{c}_j$ to the ground truth $\mathbf{y}^* = \bigsqcup_i c_i$, where c_i, in our case, are either the clusters obtained with transitive closure from Quora annotation or the manually annotated categories (see Section 4.1).

For evaluation purposes, we assign each cluster $\hat{c}_j$ to the most frequent gold class (cluster), i.e., $argmax_i|c_i \cap \hat{c}_j|$, and compute the average precision over the clustering as:

$$Precision = \frac{1}{N}\sum_{j=1}^{\hat{k}} max_i|c_i \cap \hat{c}_j|, \qquad (9)$$

where N is the number of questions to be clustered, and $\hat{k}$ is the number of output clusters. This number is exactly the standard clustering purity by Zhao and Karypis (2002). Since the purity is known to favor the clustering outputs with the large number of clusters, we interchange the roles of output and gold clusters, which gives us the clustering

$$Recall = \frac{1}{N}\sum_{j=1}^{k} max_i|\hat{c}_i \cap c_j|, \qquad (10)$$

where k is the number of gold standard clusters. We then compute F1 from the above measures.

The defined majority-class based clustering measure allows assigning more than one cluster to the same gold cluster. The coreference resolution metric CEAF (Luo, 2005; Cai and Strube, 2010) solves this issue by finding one-to-one alignment between the clusters in the output and in the ground truth, based on which the final score is computed. We use CEAF$_e$, the variant with the entity-based similarity, as an alternative evaluation measure.[7] Note that, although we split the data into samples, all the clustering measures we use, the majority-based, defined by equations 9 and 10, and CEAF, are computed over the whole test sets (not by averaging scores separately for each sample).

We evaluate the results as well in terms of the classification scores relative to the correctness of the models in detecting the pairs of questions with the same/different intent. This enables the comparison against the pairwise classification approaches and an evaluation of their impact. We compute the Precision, Recall, and Accuracy of question pairs with the same intent.

5.2 Experiments on Quora

Original question label-based evaluation: first, we test the models on the clustering data from the Quora corpus, derived as described in Section 4.1. We train LSSVM, LSP, and the SVM classifier on the training part. The results of all the models on the test set are depicted in Table 2. In terms of clustering accuracy (the left half of the table), the LSSVM approach outperforms all the clustering baselines, improving about 10 points the highest baseline model, i.e., SVM + k-means both in terms of F1 and CEAF. LSP, in this setting, shows a slightly worse F1 than LSSVM, producing a model with high recall.

To study the impact of the pairwise classifier, we consider all the pairs of questions predicted by the clustering approaches as belonging to the same cluster as positive and the rest – as negative. All the clustering models show high accuracy, superior to that shown by the SVM classifier, but this is mainly due to the fact that there are much more negative question pairs. Interestingly, only LSSVM, though, among all the clus-

Table 3: Supervised vs. unsupervised clustering models and pairwise classification baselines on the test set, where the gold labels are provided by the intent-based manual annotation on a portion of the test set.

tering model, approaches the classifier in terms of classification F1. However, the cluster accuracy depends on many factors in addition to the pairwise classification accuracy.

Intent-based evaluation In Table 3, we present the results obtained on the portion of the test set which we manually annotated with the intent clusters. Here, we apply the same LSSVM, LSP, and the SVM classifier models trained in the experiments of the previous paragraph. However, we recompute all the four unsupervised clustering baselines supplying them with the new k – the number of gold intent-based annotated clusters.

In spite of being trained on data with different style of annotation (clusters automatically derived form Quora annotation), which is potentially rather noisy, LSSVM is able to recover the new intent categories better than the baseline approaches in terms of all the clustering metrics. The difference from the closest unsupervised clustering approach, which is the same as in the previous experiment, is now reduced in terms of CEAF. However, the information about the number of clusters in the ground truth critically impacts on the accuracy. The LSP model scored the best with respect to the new annotation. The lower classification accuracy of LSSVM with respect to the pairwise classifier is expected as the cluster number changed notably with the new annotation.

5.3 Evaluation on the FAQ dataset

Due to the limited size of the FAQ HYPE dataset, we split it into two parts, each of which forms one sample. We use the one containing 19 out of 28 clusters for training and the other with the remaining 9 clusters – for testing. The training sample comprises 97 questions, while the test sample – 50. The plots in Figure 1 illustrate the performance of LSSVM and LSP in terms of the clustering F1 in confront to the clustering baselines. We run the k-means and the spectral clustering algorithms with k in the range $(1, 50)$, which covers all the possible values for the given test set size.

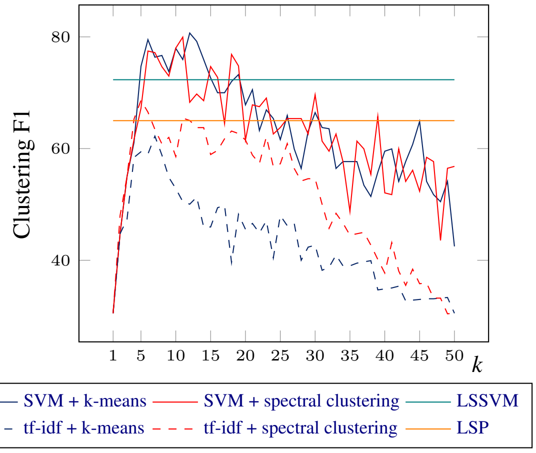

Figure 1: LSSVM and baseline clustering models; the latter vary with the cluster number k, on the FAQ HYPE test set.

LSSVM is better than the spectral clustering models with any k. k-means curves surpass LSSVM only in a narrow interval, showing high unstability. This suggests that guessing the k value in a realistic scenario in the absence of supervision does not seem an easy task. It should be also taken into consideration that we deal with very scarce training data. This also explains slightly insufficient accuracy of LSP compared to the k-means baseline.

5.4 Error Analysis and Discussion

As seen in tables 2 and 3, the structural output model consistently outperforms approaches based on spectral and k-means clustering on the Quora dataset. The most prominent improvement comes from singleton clusters: questions that are not duplicate with any other entries. Recall that the original dataset is constructed in such a way that singleton clusters are somewhat similar or related to existing material, but are still considered distinct by Quora annotators. LSSVM correctly recovers

71% of singleton clusters, whereas other methods perform much worse (5-30%). In the question-answering setting, singleton clusters correspond to novel questions that require setting up of a new entry in the answer base. Accurate recognition of singletons would allow for a timely allocation of resources to keep the answer base up-to-date and in line with incoming user requests.

Larger clusters are problematic for all the compared methods. Still, as evidenced by the CEAF score[8], the structural clustering is doing a better job at recovering non-singleton clusters. This mirrors our observations that even human annotators have difficulties correctly and consistently detecting duplicates in complex over-populated semantic areas (see Example 7) in the absence of the global context (e.g., list of all the related questions).

Finally, the clusters created by the LSSVM approach are more semantically related. Thus, 97% of all the suggested clusters contain questions with the same intent but, possibly, incorrect `slots`. For example, in the following question cluster:

(11) **gold cluster**
`Advice-Weightloss: fast,deadline`
q_1: How do I loose 50 lbs by Dec 2016?
q_2: How do I loose weight fast for operation ?
q_3: How can I lose 20 lbs super fast to audition for a small role in a movie ?
q_4: I want to lose weight for an event coming up in 2 weeks and I really don't care if I gain it back afterwords. What should I do ?

the user wants advice on losing their weight very fast by a specific deadline. LSSVM groups these questions with some others, more generic queries on fast weight loss (*How do I loose weight fast?*). This means that LSSVM captures the intent hierarchy well, providing meaningful clusters, although occasionally missing some important details. Other methods, on the contrary, form more poorly-related clusters (25-42% of clusters suggested by unsupervised approaches contain unrelated intents). Thus, the questions from Example (11) get grouped by other methods with such unrelated queries as *How is it to be in true love?* (spectral clustering over tf-idf).

Note that neither LSSVM nor unsupervised approaches have any access to the cluster labels and their hierarchy: in the training data, we only specify the clustering itself. Yet, by taking into account the global cluster structure, the LSSVM method can uncover the underlying hierarchy.

In the FAQ setting, most clusters are mid-size (5-9 questions). All the methods are doing a moderate job at recuperating the intent structure in this experiment. However, LSSVM shows better performance (cf. Section 5.3). Moreover, structural output is the only method that perfectly recuperates at least some clusters, e.g.:

(12) q_1: Non ricordo piú la password per accedere all'App (I don't remember the password for the App)
q_2: mi sono dimenticato la password (I forgot the password)
q_3: reimpostare la password (reset the password)
q_4: cambio password (change the password)

Here, LSSVM predicts the correct cluster exactly. K-means based approaches put $q_1 - q_4$ into the same cluster, however, they also merge them with *bloccare gli acquisti online (block the online purchases)*. Finally, spectral clustering does a poor job on this particular example, tearing either q_1 (tf-idf based spectral clustering) or q_2 (SVM pairwise classifier-based spectral clustering) apart and introducing a lot of spurious material.

6 Conclusion

We have proposed structured output methods fed with semantic question paraphrasing models to automatically extract user intents from question repositories. Our approach provides clustering accuracy of 80% with respect to the original Quora annotation and still valuable accuracy of 65% with respect one to of the many interpretations of question intent of our dataset, carried out by our expert in dialog modeling. This line of research looks promising as it can potentially simplify and speed up the work of Dialog Manager engineers. Although a deeper study is required to assess the benefits of our approach, the feedback of our designer clearly suggests that automatic clusters, even if were not perfect, simplify the annotation work. Several future research directions are enabled by our study, ranging from the use of neural clustering models to the application of our models to fast and semi-automatic prototyping of Dialog Systems. For this purpose, we make our data and software available to the research community.

Abstract

Existing dialog datasets contain a sequence of utterances and responses without any explicit background knowledge associated with them. This has resulted in the development of models which treat conversation as a sequence-to-sequence generation task (*i.e.*, given a sequence of utterances generate the response sequence). This is not only an overly simplistic view of conversation but it is also emphatically different from the way humans converse by heavily relying on their background knowledge about the topic (as opposed to simply relying on the previous sequence of utterances). For example, it is common for humans to (involuntarily) produce utterances which are copied or suitably modified from background articles they have read about the topic. To facilitate the development of such natural conversation models which mimic the human process of conversing, we create a new dataset containing movie chats wherein each response is explicitly generated by copying and/or modifying sentences from unstructured background knowledge such as plots, comments and reviews about the movie. We establish baseline results on this dataset (90K utterances from 9K conversations) using three different models: (i) pure generation based models which ignore the background knowledge (ii) generation based models which learn to copy information from the background knowledge when required and (iii) span prediction based models which predict the appropriate response span in the background knowledge.

1 Introduction

Background knowledge plays a very important role in human conversations. For example, to have a meaningful conversation about a movie, one uses their knowledge about the plot, reviews, comments and facts about the movie. A typical conversation involves recalling important points from this background knowledge and producing them appropriately in the context of the conversation. However, most existing large scale datasets (Lowe et al., 2015b; Ritter et al., 2010; Serban et al., 2016) simply contain a sequence of utterances and responses without any *explicit* background knowledge associated with them. This has led to the development of models which treat conversation as a simple sequence-to-sequence generation task and often produce output which is both syntactically incorrect and incoherent (off topic). To make conversations more coherent, there is an increasing interest in integrating structured and unstructured knowledge sources with neural conversation models. While there are already some works in this direction (Rojas-Barahona et al., 2017; Williams et al., 2016; Lowe et al., 2015a; Ghazvininejad et al., 2017) which try to integrate external knowledge sources with existing datasets, we believe that building new datasets where the utterances are *explicitly* linked to external background knowledge will further facilitate the development of such background aware conversation models.

With this motivation, we built a new background aware conversation dataset using crowdsourcing. Specifically, we asked workers to chat about a movie using structured and unstructured resources about the movie such as plots, reviews, comments, fact tables (see Figure 1). For every even numbered utterance, we asked the workers to consult the available background knowledge and try to construct a sentence which contains information from this background knowledge and is relevant in the current context of the conversation (akin to how humans recall things from their background knowledge and insert them appropriately in the conversation). For example, in Turn 2, Speaker 2 picked a sentence from the plot which is relevant to the current context of the conversation. Similarly, in Turn 3, Speaker 2 picked a

Plot

... The lab works on spiders and has even managed to create new species of spiders through genetic manipulation. While Peter is taking photographs of Mary Jane for the school newspaper, one of these new spiders lands on his hand and bites him Peter comes home feeling ill and immediately goes to bed. ...

Review

... I thoroughly enjoyed "Spider-Man" which I saw in a screening. I thought the movie was very engrossing. Director Sam Raimi kept the action quotient high, but also emphasized the human element of the story. Tobey was brilliant as a gawky teenager...

Movie: Spider-Man

Speaker 1(N): Which is your favourite character?

Speaker 2(C): My favorite character was Tobey Maguire.

Speaker 1(N): I thought he did an excellent job as peter parker, I didn't see what it was that turned him into Spider-Man though.

Speaker 2(P): Well this happens while Peter is taking photographs of Mary Jane for the school newspaper, one of these new spiders lands on his hand and bites him.

Speaker 1 (N): I see. I was very excited to see this film and it did not disappoint!

Speaker 2(R): I agree, I thoroughly enjoyed "Spider-Man"

Speaker 1(N): I loved that they stayed true to the comic.

Speaker 2(C): Yeah, it was a really great comic book adaptation

Speaker 1(N): The movie is a great life lesson on balancing power.

Speaker 2(F): That is my most favorite line in the movie, "With great power comes great responsibility."

Comments

... Crazy attention to detail. My favorite character was Tobey Maguire. I can't get over the "I'm gonna kill you dead" line. It was too heavily reliant on constant light-hearted humor. However the constant joking around kinda bogged it down for me. A really great comic book adaptation. ....

Figure 1: A sample chat from our dataset which uses background resources. The chosen spans used in the conversation are shown in blue. The letters in the brackets denote the type of resource that was chosen - P, C ,R, F and N indicate **P**lot, **C**omments, **R**eview, **F**act Table and **N**one respectively.

sentence from the movie review. We also asked the workers to suitably modify the content picked from the background knowledge, if needed, so that the conversation remains coherent. We collected around 9K such conversations containing a total of 90K utterances pertaining to about 921 movies. These conversations along with the background resources will be made publicly available[1]. For every utterance, we also provide information about the exact span in the resource from which this utterance was created. Lastly note that unlike existing datasets, our *test set* contains multiple reference responses for each test context thereby facilitating better evaluation of conversation models. We believe that this dataset will allow the community to take a fresh look at conversation modeling and will lead to the development of models which can learn to exploit background knowledge to pick appropriate responses instead of generating responses from scratch. Such a conversation strategy which produces responses from background knowledge would be useful in various domains. For example, a troubleshooting bot could exploit the information available in manuals, reviews and previous bug reports about the software. Similarly, an e-commerce bot could exploit the rich information available in product descriptions, reviews, fact tables, *etc.* about the product. While the proposed dataset is domain specific, it serves as a good benchmark for developing creative background-knowledge-aware models which can then be ported to different domains by building similar datasets for other domains.

We establish some initial baselines using three different paradigms to demonstrate the various models that can be developed and evaluated using this dataset. For the sake of completeness, the first paradigm is a hierarchical variant of the sequence to sequence architecture which does not exploit any background knowledge. The second paradigm is the copy-and-generate paradigm wherein the model tries to copy text from the given resources whenever appropriate and generate it otherwise. The third paradigm borrows from the span prediction based models which are predominantly being used for Question Answering (QA). These baseline results along with the dataset would hopefully shape future research in the area of background aware conversation models.

2 Related Work

There has been an active interest in building datasets (Serban et al., 2015) for training dialog systems. Some of these datasets contain transcripts of human-bot conversations (Williams et al., 2013; Henderson et al., 2014a,b) while others are created using a fixed set of natural language patterns (Bordes and Weston, 2017; Dodge et al., 2016). The advent of deep learning created

---

[1] https://github.com/nikitacs16/Holl-E

interest in the construction of large-scale dialog datasets (Lowe et al., 2015b; Ritter et al., 2010; Sordoni et al., 2015) leading to the development of several end-to-end conversation systems (Shang et al., 2015; Vinyals and Le, 2015; Li et al., 2016; Serban et al., 2016) which treat dialog as a sequence generation task.

To make the output of these models more coherent, there is an increasing effort in integrating external background knowledge with these models. This is because human beings rely on background knowledge for conversations as well as other tasks (Schallert, 2002). There has been considerable work on incorporating background knowledge in the context of goal-oriented dialog datasets even before the advent of large-scale datasets for deep learning (Raux et al., 2005; Seneff et al., 1991) as well as in recent times (Rojas-Barahona et al., 2017; Williams et al., 2016; Eric et al., 2017) where datasets include small sized knowledge graphs as background knowledge. However, the conversations in these datasets are very templated and nowhere close to open conversations in specific domains such as the ones contained in our dataset.

Even in the case of open domain conversations, there are some works which have integrated external knowledge sources. Most of the entries in 2017 Amazon Alexa Prize (Ram et al., 2017) relied on background knowledge for meaningful response generation. Milabot (Serban et al., 2017a) and even the winning entry SoundingBoard (Liu et al., 2018) used Reddit pages, Amazon's Evi Service, and large databases like OMDB, Google Knowledge Graph and Wikidata as external knowledge. The submission named Eigen (Guss et al., 2017) used several dialog datasets and corpora belonging to related Natural Language Processing tasks to make their responses more informative. We refer the reader to (Ram et al., 2017) for detailed analysis of these systems. In the space of academic datasets, Lowe et al. (2015a) report results on the Ubuntu dataset using manpages as external knowledge whereas Ghazvininejad et al. (2017) use Foursquare tips as external knowledge for social media conversations. However, unlike our work both these works do not create a new dataset where the responses are explicitly linked to a knowledge source. The infusion of external knowledge in both these works is post facto (as opposed to our work where we take a bottom-up approach and explicitly create a dataset which allows exploitation of background knowledge). Additionally, existing large-scale datasets are noisy as they are extracted from online forums which are inherently noisy. In contrast, since we use crowdsourcing, the extent of noise is reduced since there are humans in the loop who were explicitly instructed to use only clean sentences from the external knowledge sources.

We would also like to mention some existing works such as (He et al., 2017; Lewis et al., 2017; Krause et al., 2017) which have used crowdsourcing for creating conversation datasets. In fact, our data collection method is inspired by the work of Krause et al. (2017) where the authors use self-dialogs to collect conversation data about movies, music and sports. They are referred to as self-dialogs because the same worker plays the role of both parties in the conversation. However, our work differs from Krause et al. (2017) as we provide explicit background knowledge sources to the workers from where they can copy text with the addition of suitable prefixes and suffixes to generate appropriate coherent responses.

3 Dataset

In the following sub-sections we describe the various stages involved in collecting our dataset.

3.1 Curating a list of popular movies

We created a list of 921 movies containing (i) top 10 popular movies within the past five years, (ii) top 250 movies as per IMDb rankings, (iii) top 10 movies in popular genres, and (iv) other popular movie lists made available elsewhere on the Internet. These movies belonged to 22 different genres such as sci-fi, action, horror, fantasy, adventure, romance, *etc.* thereby ensuring that our dataset is not limited to a specific genre. We considered those movies for which enough background information such as plots, reviews, comments, facts, *etc.* were available on the Internet irrespective of whether they were box-office successes or not. Please find the respective urls in the Appendix.

3.2 Collecting background knowledge

For each movie, we collected the following background knowledge:

1. Review (R): For each movie, we asked some in-house workers to fetch the top 2 most popular reviews for this movie from IMDb using the *sort* *by Total Votes* option. We also instructed them to avoid choosing reviews which were less than 50 words but this was typically never the case with popular reviews. **2. Plot (P):** For each movie, we extracted information about the "Plot" of the movie from the Wikipedia page of the movie. Wikipedia pages of movies have an explicit section on "Plot" making it easy to extract this information using scripts. **3. Comments (C):** Websites like *Reddit* have a segment called "official discussion page about X" (where X is a movie name) containing small comments about various aspects of movie. We identified such pages and extracted the first comment on every thread on this page. We bundled all these comments into a single text file and refer to it as the resource containing "Comments". For a few movies, the official discussion page was not present in which case we used the review titles of all the IMDb reviews of the movie as comments. The difference between Reviews and Comments is that a Review is an opinion piece given by one person thus typically exhibiting one sentiment throughout while Comments include opinions of several people about the same movie ensuring that positive, negative and factual aspects of the movie are captured as well as some banter.

4. Meta data or Fact Table (F): For each movie, we also collected factual details about the movie, *viz.*, box office collection, similar movies (for recommendations), awards and tag-lines from the corresponding IMDb pages and Wikipedia Infoboxes. Such information would be useful for inserting facts in the conversation, for example, *"Did you know that the movie won an Oscar?"*. We included only 4 fields in our fact table instead of showing the entire Wikipedia Infobox to reduce the cognitive load on turkers who already had to read the plot, reviews and comments of the movie.

3.3 Collecting conversation starters

During our initial pilots, we observed that if we asked the workers to converse for at least 8 turns, they used a lot of the initial turns in greetings and general chit-chat before actually chatting about a movie. To avoid this, we collected opening statements using Amazon Mechanical Turk (AMT) where the task for the workers was to answer the following questions "*What is your favorite scene from the movie X ?*", "*What is your favorite character from the movie X ?*" and "*What is your opinion about the movie X?*" (X is the movie name). We paid the workers 0.04$ per movie and showed the same movie to 3 different workers, thereby collecting 9 different opening statements for every movie. By using these statements as conversation starters in our data collection, the workers could now directly start conversing about the movie.

3.4 Collecting background knowledge aware conversations via crowdsourcing

Our aim is to create a conversation dataset wherein every response is explicitly linked to some structured or unstructured background knowledge. Creating such a dataset using dedicated in-house workers would obviously be expensive and time consuming and so we decided to use crowdsourcing. However, unlike other NLP and Vision tasks, where crowdsourcing has been very successful, collecting conversations via crowdsourcing is a bit challenging. The main difficulty arises from the fact that conversation is inherently a task involving two persons but it is hard to get two workers to synchronize and chat on AMT. We did try a few pilot experiments where we setup a server to connect two AMT workers but we found that the probability of two workers simultaneously logging in was very low. Thus, most workers logged in and left in a few seconds because no other worker joined simultaneously. Finally, we took inspiration from the idea of self chats Krause et al. (2017) in which, the same worker plays the role of both Speaker 1 and Speaker 2 to create the chat. In the above self chat setup, we showed every worker 3 to 4 resources related to the movie, *viz.*, plot (P), review (R), comments (C) and fact table (F). We also showed them a randomly selected opening statement from the 9 opening statements that we had collected for each movie and requested them to continue the conversation from that point. The workers were asked to add at least 8 utterances to this initial chat. While playing the role of Speaker 1, the worker was not restricted to copy/modify sentences from the background resources but was given the freedom to create (write) original sentences. However, when playing the role of Speaker 2, the worker was strictly instructed to copy/modify sentences from the shown resources such that they were relevant in the current context of the conversation. The reason for not imposing any restrictions on Speaker 1 was to ensure that the chats look more natural and coherent. Further, Speaker 2 was allowed to add words at the beginning or end of the span selected from the resources to make the chats more coherent and natural (for example, see the prefix in utterance 2 of Speaker 2 in Figure 1). We paid the workers 40 cents for every chat. Please refer to the Appendix for the instruction screen shots.

3.5 Verification of the collected chats

Every chat that was collected by the above process was verified by an in-house evaluator to check if the workers adhered to the instructions and produced coherent chats. Since humans typically tend to paraphrase the background knowledge acquired by reading articles, one could argue that such conversations may not look very natural because of this restriction to copy/modify content from the provided resources. To verify this, we conducted a separate human evaluation wherein we asked 15 in-house evaluators to read conversations (without the background resources) from our dataset and rate them on five different parameters. Specifically, they were asked to check if the conversations were 1) **intelligible:** *i.e.*, an average reader could understand the conversation 2) **coherent:** *i.e.*, there were no abrupt context switches 3) **grammatically correct** 4) **on-topic:** *i.e.*, the chat revolved around the concerned movie with digression limited to related movies/characters/actors and 5) **natural two-person chats:** *i.e.*, the role-play setup does not make the chat look unnatural. These evaluators were post-graduate students who were fluent in English and had watched at least 100 Hollywood movies. We did not give them any information about the data creation process. We used a total of 500 chats for the evaluation and every chat was shown to 3 different evaluators. The evaluators rated the conversations on a scale of 1 (very poor) to 5 (very good). We computed inter-annotator agreement using the mean linearly weighted Cohen's κ (Cohen, 1968) and mean Krippendorff's α (Hayes and Krippendorff, 2007). The average rating for each of the 5 parameters along with the inter annotator agreement are reported in Table 1 and are very encouraging.

Metric	**Rating**	α	κ
Intelligible	4.47 ± 0.52	0.70	0.69
Coherent	4.33 ± 0.93	0.57	0.71
Grammar	4.41 ± 0.56	0.60	0.69
Two-person-chat	4.47 ± 0.46	0.64	0.70
On Topic	4.57 ± 0.43	0.72	0.70

Table 1: Average human evaluation scores with standard deviations for conversations (scale 1-5). We also report mean Krippendorff's α and mean Cohen's κ

#chats	9071
#movies	921
#utterances	90810
Average # of utterances per chat	10.01
Average # of words per utterance	15.29
Average # of words per chat	153.07
Average # of words in Plot	186.10
Average # of words in Review	384.44
Average # of words in Comments	123.81
Average # of words in Fact Table	33.47
# unique Plots	5157
# unique Reviews	1817
# unique Comments	12740

Table 2: Statistics of the dataset

3.6 Statistics

In Table 2, we show different statistics about the dataset collected using the above process. These include average number of utterances per chat, average number of words per utterance, and so on followed by the statistics of the different resources which were used as background knowledge. Please note that the # unique Plots and # unique Reviews correspond to unique paragraphs while the # unique Comments is the count of unique sentences. We observed that 41.2%, 34.6%, 16.1% and 8.1% of Speaker 2 responses came from Reviews, Comments, Plots and Fact Table respectively.

4 Models

We evaluate three different types of models as described below. Since these are popular existing models, we describe them very briefly below and refer the reader to the original papers for more details. Note that in this work we merge the comments, reviews, plots and facts into one single document and refer to it as background knowledge. In the rest of the paper, when we refer to a *resource* we mean this single document which is a merger of all the resources unless specified otherwise.

4.1 Generation based models

We use the standard Hierarchical Recurrent Encoder Decoder model (HRED) (Serban et al., 2016) instead of its variant (Serban et al., 2017b) as the standard model performs only slightly poorly than the variant and is much easier to implement. It decomposes the context of the conversation as two level hierarchy using Recurrent Neural Networks (RNN). The lower RNN encodes individual utterances (sequence of words) which is then fed into the higher level RNN as a sequence of utterances. The decoder RNN then generates the output based on this hierarchical context representation.

4.2 Generate-or-Copy models

Get To The Point (GTTP) (See et al., 2017) proposed a hybrid pointer generator network for abstractive summarization that learns to copy words from the source document when required and otherwise generates a word like any sequence-to-sequence model. In the summarization task, the input is a *document* and the output is a *summary* whereas in our case the input is a {*document, context*} pair and the output is a *response*. Here, the context includes the previous two utterances and the current utterance. We modified the architecture to suit our task. We use an RNN to compute the representation of the document (like the original model) and introduce another RNN to compute a representation of the context by treating it as a single sequence of words. The decoder which is also an RNN then uses the document representation, context representation and its own internal state representation to compute a (i) probability score which indicates whether the next word should be copied or generated (ii) probability distribution over the vocabulary if the next word needs to be generated and (iii) probability distribution over the input words if the next word needs to be copied. These three probability distributions are then combined to produce the next word in the response.

4.3 Span prediction models

Bi-directional Attention Flow Model (BiDAF) (Seo et al., 2017) model is a QA model which was proposed in the context of the SQuAD dataset (Rajpurkar et al., 2016). Given a *document* and a *question*, the model uses a six-layered architecture to predict the span in the document which contains the answer. We can use their model as it is for our task without any modifications by simply treating the *context* as the *question* and the *resource* as the *document*.

We chose to evaluate on the modified generate-or-copy model instead of other variants such as (Ghazvininejad et al., 2017; Lowe et al., 2015a) as the modified model already contains the extra encoder for background model which is present in these models. Moreover, the modified model uses a hybrid copy-or-generate decoder which is well-suited to our task.

5 Experimental Setup

In this section we describe the train-validation-test splits, the process used for creating training instances, the manner in which the models were trained using our data and the evaluation metrics.

5.1 Creating train/valid/test splits

On average we have 9.14 chats per movie. We divide the collected chats into train, validation, and test splits such that all the chats corresponding to a given movie are in exactly one of the splits. This ensures that a movie seen in the test or validation set is never seen at training time. We create the splits such that the percentage of chats in the train-validation-test set is roughly 80%-10%-10%.

5.2 Creating training instances

For each chat in the training data, we construct training instances of the form {*resource, context, response*} where the *context* is taken as previous two utterances and current utterance. We consider only the even numbered utterances as training examples as they are generated from the background resources thus emulating a human-bot setup. If a chat has 10 turns, we will have 5 instances. The task then is to train a model which can predict these even numbered responses. At test time the model is shown {*resource, context*} and predicts the response. Note that, HRED will ignore the *resource* and only use {*context, response*} as input-output pairs. BiDAF and GTTP will use {*resource, context, response*} as training data with relevant *span* instead of *response* for BiDAF.

5.3 Merging resources into a single document

As stated earlier, we simply merge all the background information to create a single document which we collectively refer to as *resource*. For the BiDAF model, we had to restrict the length of the resource to 256 words because we found that even on a K80 GPU with 12GB RAM, this model gives an out of memory error for longer documents. We found this to be a severe limitation of this and other span based models (for example, R-Net (Wang et al., 2017)) . We experimented with three methods of creating this resource. The first method *oracle* uses the actual resource (plot or comments or reviews) from which the next response was generated as a resource. If that resource itself has more than 256 words then we truncate it from the beginning and the end such that the span containing the actual response is contained within the retained 256 words. The number of words that are discarded from the start or the end is chosen at random so that the correct spans do not end up in similar positions throughout the dataset. The next two methods *mixed-short* and *mixed-long* are created by merging the individual resources. We retain each resource in the merged document proportional to its length. (*i.e,*if there are 400 words in the plot, 200 words in the review and 100 in the comments, the merged resource will contain contiguous sentences from these three resources in the ratio of 4:2:1.) Further, we ensure that the merged resource contains the actual response span. In this way, we create *mixed-short* with 256 words and *mixed-long* with 1200 words (the maximum length of the merged resources). We will henceforth denote *oracle*, *mixed-long* and *mixed-short* using '(o) ', '(ms) 'and '(ml) 'respectively. We report results for BiDAF(o), BiDAF (ms), GTTP (o) and GTTP (ml).

5.4 Evaluation metrics

As HRED and GTTP models are generation based models we use BLEU-4, ROUGE-1, ROUGE-2 and ROUGE-L as the evaluation metrics. For BiDAF we use the above metrics by comparing the predicted span with the reference span. For BiDAF, we also report F1 as stated in Rajpurkar et al. (2016).

In addition to the automatic evaluation, we also collected human judgments using 100 test responses generated for every model for every setup (oracle, mixed-short, mixed-long). These evaluators had the same qualifications as the evaluators who earlier helped us evaluate our dataset. They were asked to rate the response on scale of 1 to 5 (with 1 being the least) on the following four metrics: (1) Fluency(Flu), (2) appropriateness/relevance (apt) of the response in the current context language (3) humanness (Hum) of the response, *i.e.,* whether the responses look as if they were generated by a human (4) and specificity (spec) of the response, *i.e.*, whether the model produced movie-specific responses or generic responses such as "This movie is amazing". We report these results in Table 4.

5.5 Collecting multiple reference responses

One common issue with evaluating dialog systems is that existing datasets typically contain only one reference response whereas in practice several responses can be correct in a given context. To solve this to a certain extent, we collected three reference responses for every Speaker 2 utterance in our dataset (note that Speaker 2 is treated as the bot while training/testing our models). We show the previous utterances ending with Speaker 1's response and ask workers to provide three appropriate responses from the given resources. We found that in some cases there was only one appropriate response like factual response and the workers could not provide multiple references . In this way we were able to create a multiple reference test set where 78.04% of the test instances have multiple responses. In Table 3, we report two sets of scores based on single-reference test dataset and multi-reference test dataset. While calculating the scores for multi-reference dataset, we take the maximum score over multiple reference responses.

Please refer to the Appendix section for the details of the model, hyperparameters, example of multiple references in our dataset and sample outputs produced by different models.

6 Results and Discussion

In this section, we discuss the results of our experiments as summarized in Tables 3 and 4.

Generation based models v/s Span prediction models: We compare the generation based models and span prediction models only based on results in the *oracle* setting. Here, the span based model (BiDAF) outperforms the generation based models (HRED and GTTP). This confirms our belief that the natural language generation (NLG) capabilities of current generation based models are far from being acceptable even in case of generate-or-copy modes. This also emphasizes the importance of this data which allows building models which can exploit well-formed sentences in the background knowledge and reproduce them with minor modifications instead of generating them from scratch. While the results for BiDAF are

Model	**F1**		**BLEU**		**Rouge-1**		**Rouge-2**		**Rouge-L**	
HRED	-	-	5.23	5.38	24.55	25.38	7.61	8.35	18.87	19.67
GTTP (o)	-	-	13.92	16.46	30.32	31.6	17.78	21.21	25.67	27.83
GTTP (ms)	-	-	11.05	15.68	29.66	31.71	17.70	19.72	25.13	27.35
GTTP (ml)	-	-	7.51	8.73	23.20	21.55	9.91	10.42	17.35	18.12
BiDAF (o)	39.69	47.18	28.85	34.98	39.68	46.49	33.72	40.58	35.91	42.64
BiDAF (ms)	45.73	51.35	32.95	39.39	45.69	50.73	40.18	45.01	43.46	46.95

Table 3: Performance of the proposed models on our dataset. The figures on the left in each column indicate scores on single-reference test dataset while the figures on the right denote scores on multi-reference dataset.

Model	**Hum**	**Apt**	**Flu**	**Spec**
HRED	3.08	2.49	2.64	2.06
GTTP (o)	4.10	3.73	4.03	3.33
GTTP (ml)	2.93	2.97	3.42	2.60
BiDAF (o)	3.78	3.71	4.05	3.76
BiDAF(ms)	3.41	3.38	3.47	3.30

Table 4: Human evaluation results on the model performances.

encouraging, we reiterate that it does not scale to longer documents (we were not able to run it in the *mixed-long* setting). We still need much better models as BiDAF on SQuAD dataset gives an F1 of 81.52 % which is much higher than the results on our dataset. Further, note that using the predicted span as a response is not natural. This is evident from human likeliness (Hum) score of GTTP (o) being higher than both the BiDAF models. We need models which can suitably alter the span to retain the coherence of the context.

Effect of including background knowledge: We observe that there isn't much difference between the performance of HRED which does not use any background knowledge when compared to GTTP (ml) which actually uses a lot of background knowledge. However, there is a substantial difference between the performance of HRED and GTTP (o) which uses only the relevant background knowledge. Further, without background knowledge, HRED learns to produce very generic responses (Spec score = 2.06). This shows that the background knowledge is important, but the models should learn to focus on the right background knowledge relevant to the current context. Alternately, we can have a two-stage network which first predicts the right resource (plot, review, comments) from which the span should be selected and then selects the span from this chosen resource.

***Oracle* v/s *mixed-short* resource:** We observe that the performance of BiDAF (ms) is actually better than BiDAF (o) even when the resource length for both is 256 words. We would expect a poor performance for BiDAF (ms) as the resource has more noise because of the sentences from irrelevant resources. However, we speculate the model learns to regard irrelevant sentences as noise and learns to focus on sentences corresponding to the correct resource resulting in improved performance (however, this is only a hypothesis and it needs to be verified). We realize that this is clearly a poor baseline and we need better span prediction based models which can work with longer documents. At the same time, GTTP (o) and GTTP (ms) have comparable (yet poor) performance. There is no co-attention mechanism in this model which can effectively filter out noisy sentences.

Observations from the copy-and-gen model: We observed that this model produced sentences where on average of 82.18% (*oracle*) and 71.95% (*mixed-long*) of the tokens were copied. One interesting observation was that it easily learns to copy longer contiguous sequences one word at a time. However, as is evident from the automatic evaluation metrics, in many cases, the 'copied' spans are not relevant to the current context.

Evaluating with multiple references: When considering multiple references, the performance numbers as reported in Table 3 indeed improve. This shows the importance of having multiple references and the need to develop metrics which account for multiple dissimilar references.

7 Conclusion

We introduce a new dataset for building dialog systems which would hopefully allow the community to take a fresh look at this task. Unlike existing datasets which only contain a sequence of utterances, in our dataset each response is explicitly linked to some background knowledge. This mimics how humans converse by recalling information from their background knowledge and use it appropriately in the context of the conversation. Using this dataset, we evaluated models belonging to three different paradigms, *viz.*, generation based models, generate-or-copy models and span prediction models. Our results suggest that the NLG capabilities of existing seq-to-seq models are still far from desirable while span based models which completely bypass the process of NLG show some promise but with clear scope for improvement.

Going forward, we would like to build models which are a hybrid of span prediction models and generation models. Specifically, we would like to build models which can learn to copy a large sequence from the input instead of one word at a time. Another important aspect is to build less complex models which can handle longer documents. For example, the BiDAF model has an expensive outer product between two large matrices which makes it infeasible for long documents (because the size of these matrices grows with the length of the document). Alternately, we would like to build two-stage models which first select the correct resource from which the next response is to be generated and then generate or copy the response from the resource.

Acknowledgements

We would like to thank Department of Computer Science and Engineering, and Robert Bosch Center for Data Sciences and Artificial Intelligence, IIT Madras (RBC-DSAI) for providing us with adequate resources. We also thank Gurneet Singh and Sarath Chandar for helping us in the data collection phase two and three respectively. Lastly, we thank all the AMT workers around the world and our in-house evaluators.

Decoupling Strategy and Generation in Negotiation Dialogues

Abstract

We consider negotiation settings in which two agents use natural language to bargain on goods. Agents need to decide on both high-level strategy (e.g., proposing $50) and the execution of that strategy (e.g., generating *"The bike is brand new. Selling for just $50!"*). Recent work on negotiation trains neural models, but their end-to-end nature makes it hard to control their strategy, and reinforcement learning tends to lead to degenerate solutions. In this paper, we propose a modular approach based on coarse dialogue acts (e.g., propose(price=50)) that decouples strategy and generation. We show that we can flexibly set the strategy using supervised learning, reinforcement learning, or domain-specific knowledge without degeneracy, while our retrieval-based generation can maintain context-awareness and produce diverse utterances. We test our approach on the recently proposed DEALORNODEAL game, and we also collect a richer dataset based on real items on Craigslist. Human evaluation shows that our systems achieve higher task success rate and more human-like negotiation behavior than previous approaches.

1 Introduction

A good negotiator needs to decide on the *strategy* for achieving a certain goal (e.g., proposing $6000) and the realization of that strategy via *generation* of natural language (e.g., *"I really need a car so I can go to work, but all I have is 6000, any more and I won't be able to feed my children."*).

Most past work in NLP on negotiation focuses on strategy (dialogue management) with either no natural language (Cuayáhuitl et al., 2015; Cao et al., 2018) or canned responses (Keizer et al., 2017; Traum et al., 2008). Recently, end-to-end neural models (Lewis et al., 2017; He et al., 2017) are used to simultaneously learn dialogue strategy and language realization from human-human dialogues, following the trend of using neural network models on both goal-oriented dialogue (Wen et al., 2017a; Dhingra et al., 2017) and open-domain dialogue (Sordoni et al., 2015; Li et al., 2017; Lowe et al., 2017). However, these models have two problems: (i) it is hard to control and interpret the strategies, and (ii) directly optimizing the agent's goal through reinforcement learning often leads to degenerate solutions where the utterances become ungrammatical (Lewis et al., 2017) or repetitive (Li et al., 2016).

To alleviate these problems, our key idea is to decouple strategy and generation, which gives us control over the strategy such that we can achieve different negotiation goals (e.g., maximizing utility, achieving a fair deal) with the same language generator. Our framework consists of three components shown in Figure 1: First, the parser identifies keywords and entities to map each utterance to a *coarse dialogue act* capturing the high-level strategic move. Then, the dialogue manager chooses a responding dialogue act based on a sequence-to-sequence model over coarse dialogue acts learned from parsed training dialogues. Finally, the generator produces an utterance given the dialogue act and the utterance history.

Our framework follows that of traditional goal-oriented dialogue systems (Young et al., 2013), with one important difference: coarse dialogue acts are not intended to and cannot capture the full meaning of an utterance. As negotiation dialogues are fairly open-ended, the generator needs to depend on the full utterance history. For example, consider the first turn in Figure 1. We cannot generate a response given only the dialogue act inform; we must also look at the previous question. However, we still optimize the dialogue manager in the coarse dialogue act space using supervised learning, reinforcement learning, or domain-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2333–2343
Brussels, Belgium, October 31 - November 4, 2018.

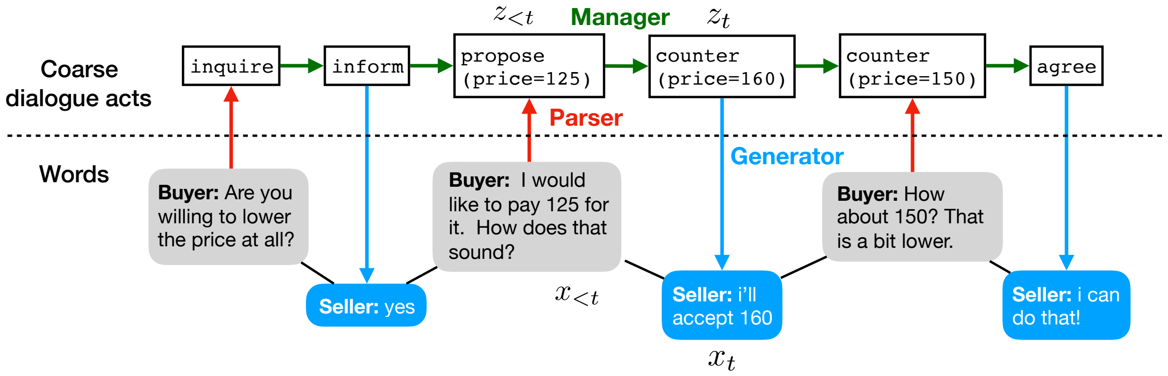

Figure 1: Our modular framework consists of three components similar to traditional goal-oriented dialogue systems. (1) The parser maps received utterances to coarse dialogue acts (an intent and its arguments) that capture the high-level dialogue flow. (2) The manager generates the next coarse dialogue act z_t conditioned on past dialogue acts $z_{<t}$. (3) The generator then produces a response conditioned on both the predicted coarse dialogue act z_t and the dialogue history $x_{<t}$. Importantly, unlike in traditional systems, coarse dialogue acts only capture the rough shape of a dialogue, not the full meaning of its utterances, e.g., `inform` does not specify the answer to the question.

specific knowledge.

Existing human-human negotiation datasets are grounded in closed-domain games with a fixed set of objects such as Settlers of Catan (lumber, coal, brick, wheat, and sheep) (Afantenos et al., 2012; Asher et al., 2016) or item division (book, hat, and ball) (DeVault et al., 2015; Lewis et al., 2017). These objects lack the richness of the real world. To study human negotiation in more open-ended settings that involve real goods, we scraped postings of items for sale from `craigslist.org` as our negotiation scenario. By hiring workers on Amazon Mechanical Turk (AMT) to play the role of buyers and sellers, we collected a new dataset (CRAIGSLISTBARGAIN) of negotiation dialogues.[1] Compared to existing datasets, our more realistic scenario invites richer negotiation behavior involving open-ended aspects such as cheap talk or side offers.

We evaluate two families of systems modeling coarse dialogue acts and words respectively, which are optimized by supervised learning, reinforcement learning, or domain knowledge. Each system is evaluated on our new CRAIGSLISTBARGAIN dataset and the DEALORNODEAL dataset of Lewis et al. (2017) by asking AMT workers to chat with the system in an A/B testing setting. We focus on two metrics: task-specific scores (e.g., utility) and human-likeness. We show that reinforcement learning on coarse dialogue acts avoids degenerate solutions, which was a problem in Li et al. (2016); Lewis et al. (2017). Our modular model maintains reasonable human-like behavior while still optimizes the objective. Furthermore, we find that models trained over coarse dialogue acts are stronger negotiators (even with only supervised learning) and produce more diverse utterances than models trained over words. Finally, the interpretability of coarse dialogue acts allows system developers to combine the learned dialogue policy with hand-coded rules, thus imposing stronger control over the desired strategy.

2 Craigslist Negotiation Dataset

Previous negotiation datasets were collected in the context of games. For example, Asher et al. (2016) collected chat logs from online Settlers of Catan. Lewis et al. (2017) asked two people to divide a set of hats, books, and balls. While such games are convenient for grounding and evaluation, it restricts the dialogue domain and the richness of the language. Most utterances are direct offers such as *"has anyone got wood for me?"* and *"I want the ball."*, whereas real-world negotiation would involve more information gathering and persuasion.

To encourage more open-ended, realistic negotiation, we propose the CRAIGSLISTBARGAIN task. Two agents are assigned the role of a buyer and a seller; they are asked to negotiate the price of an item for sale on Craigslist given a description and photos. As with the real platform, the listing price is shown to both agents. We addition-

JVC HD-ILA 1080P 70 Inch TV

Tv is approximately 10 years old. Just installed new lamp. There are 2 HDMI inputs. Works and looks like new.
Listing price: $275
Buyer's target price: $192

Agent	Utterance	Dialogue Act
Buyer	Hello do you still have the TV?	greet
Seller	Hello, yes the TV is still available	greet
Buyer	What condition is it in? Any scratches or problems? I see it recently got repaired	inquire
Seller	It is in great condition and works like a champ! I just installed a new lamp in it. There aren't any scratches or problems.	inform
Buyer	All right. Well I think 275 is a little high for a 10 year old TV. Can you lower the price some? How about 150?	propose(150)
Seller	I am willing to lower the price, but $150 is a little too low. How about $245 and if you are not too far from me, I will deliver it to you for free?	counter(245)
Buyer	It's still 10 years old and the technology is much older. Will you do 225 and you deliver it. How's that sound?	counter(225)
Seller	Okay, that sounds like a deal!	agree
Buyer	Great thanks!	agree
Seller	OFFER $225.0	offer(225)
Buyer	ACCEPT	accept

Table 1: Example dialogue between two people negotiating the price of a used TV.

ally suggest a private price to the buyer as a target. Agents chat freely in alternating turns. Either agent can enter an offer price at any time, which can be accepted or rejected by the partner. Agents also have the option to quit, in which case the task is completed with no agreement.

To generate the negotiation scenarios, we scraped postings on `sfbay.craigslist.org` from the 6 most popular categories (housing, furniture, cars, bikes, phones, and electronics). Each posting produces three scenarios with the buyer's target prices at 0.5x, 0.7x and 0.9x of the listing price. Statistics of the scenarios are shown in Table 2.

We collected 6682 human-human dialogues on AMT using the interface shown in Appendix A Figure 2. The dataset statistics in Table 3 show that CraigslistBargain has longer dialogues and more diverse utterances compared to prior datasets. Furthermore, workers were encouraged to embellish the item and negotiate side offers such as free delivery or pick-up. This highly relatable scenario leads to richer dialogues such as the one shown in Table 1. We also observed various persuasion techniques listed in Table 4 such as embellishment, side offers, and appeals to sympathy.

# of unique postings	1402
% with images	80.8
Avg # of tokens per description	42.6
Avg # of tokens per title	33.8
Vocab size	12872

3 Approach

3.1 Motivation

While end-to-end neural models have made promising progress in dialogue systems (Wen et al., 2017a; Dhingra et al., 2017), we find they struggle to simultaneously learn the strategy and the rich utterances necessary to succeed in the CraigslistBargain domain, e.g., Table 8(a) shows a typical dialogue between a human and a sequence-to-sequence-based bot, where the bot easily agrees. We wish to now separate negotiation strategy and language generation. Suppose the buyer says: *"All right. Well I think 275 is a little high for a 10 year old TV. Can you lower the price some? How about 150?"* We can capture the highest-order bit with a coarse dialogue act propose(price=150). Then, to generate the seller's response, the agent can first focus on this coarse

Phenomenon	Example
Embellishment	It is in great condition and **works like a champ! I just installed a new lamp in it.** There aren't any scratches or problems.
Cheap talk	How about i give you $20 and you keep the helmet. **its for my daughter for her job, she delivers lemonade**.
Side offers	**Throw in a couple of movies** with that DVD player, and you have yourself a deal.
Appeal to sympathy	I would love to have this for my mother, **she is very sick** and this would help her and with me taking care of her and having to take a leave from work I can't pay very much of it
World knowledge	For a **Beemer 5 series** in this condition, I really can't go that low.

Table 4: Rich negotiation language in our CRAIGSLISTBARGAIN dataset.

dialogue act rather than having to ingest the free-form text all at once. Once a counter price is decided, the rest is open-ended justification for the proposed price, e.g., emphasizing the quality of the TV despite its age.

Motivated by these observations, we now describe a modular framework that extracts coarse dialogue acts from utterances, learns to optimize strategy in the dialogue act space, and uses retrieval to fill in the open-ended parts conditioned on the full dialogue history.

3.2 Overview

Our goal is to build a dialogue agent that takes the dialogue history, i.e. a sequence of utterances $x_1, \dots, x_{t-1}$ along with the dialogue scenario c (e.g., item description), and produces a distribution over the responding utterance x_t.

For each utterance x_t (e.g., *"I am willing to pay $15"*), we define a coarse dialogue act z_t (e.g., propose(price=15)); the coarse dialogue act serves as a logical skeleton which does not attempt to capture the full semantics of the utterance. Following the strategy of traditional goal-oriented dialogue systems (Young et al., 2013), we broadly define our model in terms of the following three modules:

1. A **parser** that (deterministically) maps an input utterance x_{t-1} into a coarse dialogue act z_{t-1} given the dialogue history $x_{<t}$ and $z_{<t}$, as well as the scenario c.
2. A **manager** that predicts the responding dialogue act z_t given past coarse dialogue acts $z_{<t}$ and the scenario c.
3. A **generator** that turns the coarse dialogue act z_t to a natural language response x_t given the full dialogue history $x_{<t}$.

Because coarse dialogue acts do not capture the full semantics, the parser and the generator maintains full access to the dialogue history. The main restriction is the manager examining the dialogue acts, which we show will reduce the risk of degeneracy during reinforcement learning Section 4.4. We now describe each module in detail (Figure 1).

3.3 Parser

Our framework is centered around the coarse dialogue act z, which consists of an intent and a set of arguments. For example, *"I am willing to pay $15"* is mapped to propose(price=15). The fact that our coarse dialogue acts do not intend to capture the full semantics of a sentence allows us to use a simple rule-based parser. It detects the intent and its arguments by regular expression matching and a few if-then rules. Our parser starts by detecting entities (e.g., prices, objects) and matching keyword patterns (e.g., *"go lower"*). These signals are checked against an ordered list of rules, where we choose the first matched intent in the case of multiple matches. An unknown act is output if no rule is triggered. The list of intent parsing rules used are shown in Table 5. Please refer to Appendix B for argument parsing based on entity detection.

3.4 Manager

The dialogue manager decides what action z_t the dialogue agent should take at each time step t given the sequence of past coarse dialogue acts $z_{<t}$ and the scenario c. Below, we describe three ways to learn the dialogue manager with increasing controllability: modeling human behavior in the training corpus (supervised learning), explicitly optimizing a reward function (reinforcement learning), and injecting hand-coded rules (hybrid policy).

Supervised learning. Given a parsed training corpus, each training example is a sequence of coarse dialogue acts over one dialogue, $z_1, \dots, z_T$. We learn the transition probabilities

Generic Rules	
Intent	Matching Patterns
greet	*hi, hello, hey, hiya, howdy*
disagree	*no, not, n't, nothing, dont*
agree	not disagree and *ok, okay, great, perfect, deal, that works, i can do that*
insist	the same offer as the previous one is detected
inquire	starts with an interrogative word (e.g., *what, when, where*) or particle (e.g., *do, are*)
CRAIGSLISTBARGAIN Rules	
Intent	Matching Patterns
intro	greet or *how are you, interested*
propose	first price mention
vague-price	no price mention and *come down, highest, lowest, go higher/lower, too high/low*
counter	new price detected
inform	previous coarse dialogue act was inquire
DEALORNODEAL Rules	
Intent	Matching Patterns
propose	items and respective counts are detected

Table 5: Rules for intent detection in the parser.

$p_\theta(z_t \mid z_{<t}, c)$ by maximizing the likelihood of the training data.

We use a standard sequence-to-sequence model with attention. Each coarse dialogue act is represented as a sequence of tokens, i.e. an intent followed by each of its arguments, e.g., "offer 150". During the agent's listening turn, an LSTM encodes the received coarse dialogue act; during its speaking turn, another LSTM decodes the tokens in the coarse dialogue act. The hidden states are carried over the entire dialogue to provide full history.

The vocabulary of coarse dialogue acts is much smaller than the word vocabulary. For example, our implementation includes fewer than 10 intents and argument values are normalized and binned (see Section 4.2).

Reinforcement learning. Supervised learning aims to mimic the average human behavior, but sometimes we want to directly optimize for a particular dialogue goal. In reinforcement learning, we define a reward $R(z_{1:T})$ on the entire sequence of coarse dialogue acts. Specifically, we experiment with three reward functions:

- **Utility** is the objective of a self-interested agent. For CRAIGSLISTBARGAIN, we set the utility function to be a linear function of the final price, such that the buyer has a utility of 1 at their target price, the seller has a utility of 1 at the listing price, and both agents have a utility of zero at the midpoint of the listing price and the buyer's target price, making it a zero-sum game. For DEALORNODEAL, utility is the total value of objects given to the agent.
- **Fairness** aims to achieve equal outcome for both agents, i.e. the difference between two agents' utilities.
- **Length** is the number of utterances in a dialogue, thus encourages agents to chat as long as possible.

The reward is -1 if no agreement is reached.

We use policy gradient (Williams, 1992) for optimization. Given a sampled trajectory $z_{1:T}$ and the final reward r, let a_i be the i-th generated token (i.e. "action" taken by the policy) along the trajectory. We update the parameters θ by

$$\theta \leftarrow \theta - \eta \sum_i \nabla_\theta \log p_\theta(a_i \mid a_{<i}, c)(r - b) \quad (1)$$

where η is the learning rate and b is a baseline estimated by the average return so far for variance reduction.

Hybrid policy. Given the interpretable coarse dialogue acts, a simple option is to write a rule-based manager with domain knowledge, e.g., if z_{t-1} = greet, then z_t = greet. We combine these rules with a learned manager to fine-tune the dialogue policy. Specifically, the dialogue manager predicts the intent from a learned sequence model but fills in the arguments (e.g., price) using rules. For example, given a predicted intent propose, we can set the price to be the average of the buyer's and seller's current proposals (a split-the-difference strategy).

3.5 Generator

We use retrieval-based generation to condition on both the coarse dialogue act and the dialogue history. Each candidate in our database for retrieval is a tuple of an utterance x_t and its dialogue context x_{t-1}, represented by both templates and coarse dialogue acts. i.e. $(d(x_{t-1}), z_{t-1}, d(x_t), z_t)$, where d is the template extractor. Specifically, given a parsed training set, each utterance is converted to a template by delexicalizing arguments in its coarse dialogue act. For example, *"How about $150?"*

becomes “How about [price]?”, where [price] is a placeholder to be filled in at generation time.

At test time, given z_t from the dialogue manager, the generator first retrieves candidates with the same intent as z_t and z_{t-1}. Next, candidates are ranked by similarity between their context templates and the current dialogue context. Specifically, we represent the context $d(x_{t-1})$ as a TF-IDF weighted bag-of-words vector and similarity is computed by a dot product of two context vectors. To encourage diversity, the generator samples an utterance from the top K candidates according to the distribution given by a trigram language model estimated on the training data.

4 Experiments

4.1 Tasks

We test our approach on two negotiation tasks. **CRAIGSLISTBARGAIN** (Section 2) asks a buyer and a seller to negotiate the price of an item for sale given its Craigslist post. **DEALORNODEAL** (Lewis et al., 2017) asks two agents to divide a set of items given their private utility functions.

4.2 Models

We compare two families of models: end-to-end neural models that directly map the input dialogue context to a sequence of output words, and our modular models that use coarse dialogue acts as the intermediate representation.

We start by training the word-based model and the act-based model with supervised learning (SL).

- **SL(word)**: a sequence-to-sequence model with attention over previous utterances and the scenario, both embedded as a continuous Bag-of-Words;
- **SL(act)**: our model described in Section 3 with a rule-based parser, a learned neural dialogue manager, and a retrieval-based generator.

To handle the large range of argument values (prices) in CRAIGSLISTBARGAIN for act-based models, we normalize the prices such that an agent’s target price is 1 and the bottomline price is 0. For the buyer, the target is given and the bottomline is the listing price. For the seller, the target is the listing price and the bottomline is set to 0.7x of the listing price. The prices are then binned according to their approximate values with two digits after the decimal point.

Model	z	Parser	Manager	Generator
SL/RL(word)	vector	learned	learned	generative
SL/RL(act)	logical	rules	learned	retrieval
SL(act)+rule	logical	rules	hybrid	retrieval

Table 6: Comparison of different implementation of the core modules in our framework.

Next, given the pretrained SL models, we fine-tune them with the three reward functions (Section 3.4), producing $\mathbf{RL_{utility}}$, $\mathbf{RL_{fairness}}$, and $\mathbf{RL_{length}}$.

In addition, we compare with the hybrid model, **SL(act)+rule**. It predicts the next intent using a trigram language model learned over intent sequences in the training data, and fills in the arguments with hand-coded rules. For CRAIGSLISTBARGAIN, the only argument is the price. The agent always splits the difference when making counter proposals, rejects an offer if it is worse than its bottomline and accepts otherwise. For DEALORNODEAL, the agent maintains an estimate of the partner’s private utility function. In case of disagreement, it gives up the item with the lowest value of (own utility − partner utility) and takes an item of estimated zero utility to the partner. The agent agrees whenever a proposal is better than the last one or its predefined target. A high-level comparison of all models is shown in Table 6.

4.3 Training Details

CRAIGSLISTBARGAIN For SL(word), we use a sequence-to-sequence model with attention over 3 previous utterances and the negotiation scenario (embedded as a continuous Bag-of-Words). For both SL(word) and SL(act), we use 300-dimensional word vectors initialized by pretrained GloVe word vectors (Pennington et al., 2014), and a two-layer LSTM with 300 hidden units for both the encoder and the decoder. Parameters are initialized by sampling from a uniform distribution between -0.1 and 0.1. For optimization, we use AdaGrad (Duchi et al., 2010) with a learning rate of 0.01 and a mini-batch size of 128. We train the model for 20 epochs and choose the model with the lowest validation loss.

For RL, we first fit a partner model using supervised learning (e.g., SL(word)), then run RL

	CraigslistBargain					DealOrNoDeal

RL$_{\text{length}}$(act)	**3.0**	0.89	-1.78	0.40	11.8	**2.5**	2.5 vs. 3.1	-0.6	0.54	11.0

Table 7: Human evaluation results on human-likeness (Hu), agreement rate (Ag), and RL objectives, including agent utility (Ut), deal fairness (Fa), and dialogue length (Len). Results are grouped by the optimization objective. For each group of RL models, the column of the optimization objective is highlighted. For human-likeness, scores that are better than others in the same group with statistical significance ($p < 0.05$ given by paired t-tests) are in **bold**. Overall, with SL, all models are human-like, however, act-based models better matches human statistics across all metrics; with RL, word-based models becomes degenerate, whereas act-based models optimize the reward while maintaining human-likeness.

against it. One agent is updated by policy gradient and the partner model is fixed during training. We use a learning rate of 0.001 and train for 5000 episodes (dialogues). The model with the highest reward on the validation set is chosen.

DealOrNoDeal For act-based models, we use the same parameterization as CraigslistBargain. For word-based models, we use the implementation from Lewis et al. (2017).[2] Note that for fair comparison, we did not apply SL interleaving during RL training and rollouts during inference.

4.4 Human Evaluation

We evaluated each system on two metrics: task-specific scores (e.g., utility) and human-likeness. The scores tell us how well the system is playing the game, and human-likeness tells us whether the bot deviates from human behavior, presumably due to over-optimization.

We put up all 9 systems online and hired workers from AMT to chat with the bots. Each worker was randomly paired with one of the bots or another worker, so as to compare the bots with human performance under the same conditions. At the end of a chat, workers were asked the question *"Do you think your partner demonstrated reasonable human behavior?"*. They provided answers on a Likert scale from 1 (not at all) to 5 (definitely). Table 7 shows the human evaluation results on CraigslistBargain and DealOrNoDeal respectively. We also show example human-bot dialogues in Table 8 and Appendix C.

SL(act) learns more human-like behavior. We first compare performance of SL models over words and coarse dialogue acts. Both SL(word) and SL(act) achieved similar scores on human-likeness (no statistically significant difference). However, SL(word) better matched human statistics such as dialogue length and utility. For instance, SL(word) tended to produce short, generic utterances as shown in Table 8(a); they also agreed on a deal more quickly because utterances such as *"deal"* and *"I can do that"* are frequent in negotiation dialogues. This behavior is reflected by the shorter dialogue length and lower utility of SL(word) models.

RL(word) leads to degeneracy. On CraigslistBargain, all RL(word) models clearly have low scores on human-likeness in Table 7. They merely learned to repeat a few sentences: The three most frequent

Title: Fitbit Flex + 2 Bands Activity Tracker	**Listing Price:** $60
Description: Hi, I'm selling a Fitbit Activity Tracker. Track your day including steps, distance, calories burned, active minutes. Track your night including hours slept, times to woken up, sleep quality, Wake with a silent vibrating alarm. You can set a ...	
(a) A: SL(word) (Buyer) B: Human (Seller)	(b) A: SL(act) (Buyer) B: Human (Seller)
A: **hi, i 'm interested in your fitbit.** B: Great. It really is a good deal. A: **great.** B: Do you have any questions about it? A: **i 'm interested in your fitbit. i 'm not sure i 'm not sure i 'm interested.** B: It has so many functions that are great. I particularly like the sleep tracking. Plus it is waterproof. How about I will deliver it to you and you give me 60 dollars? A: **i can do $52 if you come pick it up.** B: Well I am selling it. So I will deliver it for 60. Deal? A: **yes, i can do that.** B: OFFER($60) A: **ACCEPT**	A: **how we doing today** B: Hi! A: **yes, i really need one, what color is it?** B: It has a black band and a white band. A: **i see, so you bought an extra one by mistake?** B: No, it comes with 2 bands A: **i would like to make you a offer of 36** B: Ooooh....yeah, I can't. Sorry. It's wireless, has Bluetooth, extra bands, and is water resistant. I could do $50. A: **49?** B: You know..I'd do $49. A: **thank you so much!** B: OFFER($49) A: **ACCEPT**
(c) A: RL$_{\text{length}}$(word) (Buyer) B: Human (Seller)	(d) A: RL$_{\text{length}}$(act) (Buyer) B: Human (Seller)
A: **hello** B: Hi how are you? A: **i am.** B: you are interested in the fitbit flex and the 2 trackers? A: **it's in good condition condition.** B: yes A: **ok, that sounds good.** B: I am selling it at $60? A: **it's in good condition condition.** B: yes A: **ok, that sounds good.** B: $60 A: **i can go that low.**	A: **hi, i saw your ad about the item.** B: Okay great, i'm selling a Fitbit Flex plus 2 bands A: **how old is the item?** B: I've only had it for about a few months. A: **but it does work correct?** B: yes it does work, it's in great condition. A: **excellent. would you consider taking 36 for it?** B: I'm selling for $60 but $36 would be way too low. A: **how about 36?** B: no I cannot accept $36, I'm sorry A: **i'm sorry. would you accept 36?** B: I am not going lower than $50 A: **OFFER($36)** A: REJECT

Table 8: Example human-bot chats on CRAIGSLISTBARGAIN, where bot utterances are in bold. SL(word) produced generic responses, while SL(act) is more human-like. RL$_{\text{length}}$(word) devolved into degenerate behavior repeating itself while RL$_{\text{length}}$(act) maintained coherency. Only the first half of the item description and the RL$_{\text{length}}$(word) chat are shown due to space limit.

sentences of RL$_{\text{utility}}$(word), RL$_{\text{fairness}}$(word), and RL$_{\text{length}}$(word) account for 81.6%, 100% and 100% of all utterances. For example, RL$_{\text{utility}}$(word) almost always opened with *"i can pick it up"*, then offer its target price. RL$_{\text{length}}$(word) repeated generic sentences until the partner submitted a price. While they scored high on the reward being optimized, the conversations are unnatural.

On DEALORNODEAL, we have observed similar patterns. A general strategy learned by RL(word) was to pick an offer depending on its objective, then repeat the same utterance over and over again (e.g., *"i need the ball."*), resulting in low human-likeness scores. One exception is RL$_{\text{fairness}}$(word), since most of its offers were reasonable and agreed on immediately (it has the shorted dialogue length), the conversations are natural.

RL(act) optimizes different negotiation goals while being human-like. On both tasks, RL(act) models optimized their rewards while maintaining reasonable human-likeness scores. We now show that different models demonstrated different negotiation behavior. Two main strategies learned by RL$_{\text{length}}$(act) were to ask questions and to postpone offer submission. On CRAIGSLISTBARGAIN, when acting as a buyer, 42.4% of its utterances were questions, compared to 30.2% for other models. On both tasks, it tended to wait for the partner to submit an offer (even after a deal was agreed on), compared to RL$_{\text{margin}}$(act) which almost always submitted offers first. For RL$_{\text{fairness}}$(act), it aimed to agree on a price in the middle of the listing price and the buyer's target price for CRAIGSLISTBARGAIN. Since the buyer's target was hidden, when the agent was the seller, it tended to wait for the buyer to propose prices first. Similary, on DEALORNoDeal it waited to hear the parter's offer and sometimes changed its offer afterwards, whereas the other models often insisted on one offer.

On both tasks, $\text{RL}_{\text{utility}}$(act) learned to insist on its offer and refuse to budge. This ended up frustrating many people, which is why it has a low agreement rate. The problem is that our human model is simply a SL model trained on human-human dialogues, which may not accurately reflects real human behavior during human-bot chat. For example, the SL model often agrees after a few turns of insistence on a proposal, whereas humans get annoyed if the partner is not willing to make compromises at all. However, by injecting domain knowledge to SL(act)+rule, e.g., making a small compromise is better than stubbornly being fixed on a single price, we were able to achieve high utility and human-likeness on both CraigslistBargain and DealOrNoDeal.

5 Related Work and Discussion

Recent work has explored the space between goal-oriented dialogue and open-domain chit-chat through collaborative or competitive language games, such as collecting cards in a maze (Potts, 2012), finding a mutual friend (He et al., 2017), or splitting a set of items (DeVault et al., 2015; Lewis et al., 2017). Our CraigslistBargain dialogue falls in this category, but exhibits richer and more diverse language than prior datasets. Our dataset calls for systems that can handle both strategic decision-making and open-ended text generation.

Traditional goal-oriented dialogue systems build a pipeline of modules (Young et al., 2013; Williams et al., 2016). Due to the laborious dialogue state design and annotation, recent work has been exploring ways to replace these modules with neural networks and end-to-end training while still having a logical backbone (Wen et al., 2017a; Bordes and Weston, 2017; He et al., 2017). Our work is closely related to the Hybrid Code Network (Williams et al., 2017), but the key difference is that Williams et al. (2017) uses a neural dialogue state, whereas we keep a structured, interpretable dialogue state which allows for stronger top-down control. Another line of work tackles this problem by introducing latent stochastic variables to model the dialogue state (Wen et al., 2017b; Zhao et al., 2017; Cao and Clark, 2017). While the latent discrete variable allows for post-hoc discovery of dialogue acts and increased utterance diversity, it does not provide controllability over the dialogue strategy.

Our work is also related to a large body of literature on dialogue policies in negotiation (English and Heeman, 2005; Efstathiou and Lemon, 2014; Hiraoka et al., 2015; Cao et al., 2018). These work mostly focus on learning good negotiation policies in a domain-specific action space, whereas our model operates in an open-ended space of natural language. An interesting future direction is to connect with game theory (Brams, 2003) for complex multi-issue bargaining. Another direction is learning to generate persuasive utterances, e.g., through framing (Takuya et al., 2014) or accounting for the social and cultural context (Elnaz et al., 2012).

To conclude, we have introduced CraigslistBargain, a rich dataset of human-human negotiation dialogues. We have also presented a modular approach based on coarse dialogue acts that models a rough strategic backbone as well allowing for open-ended generation. We hope this work will spur more research in hybrid approaches that can work in open-ended, goal-oriented settings.

Large-scale Cloze Test Dataset Created by Teachers

Abstract

Cloze tests are widely adopted in language exams to evaluate students' language proficiency. In this paper, we propose the first large-scale human-created cloze test dataset CLOTH [1] [2], containing questions used in middle-school and high-school language exams. With missing blanks carefully created by teachers and candidate choices purposely designed to be nuanced, CLOTH requires a deeper language understanding and a wider attention span than previously automatically-generated cloze datasets. We test the performance of dedicatedly designed baseline models including a language model trained on the One Billion Word Corpus and show humans outperform them by a significant margin. We investigate the source of the performance gap, trace model deficiencies to some distinct properties of CLOTH, and identify the limited ability of comprehending the long-term context to be the key bottleneck.

1 Introduction

Being a classic language exercise, the cloze test (Taylor, 1953) is an accurate assessment of language proficiency (Fotos, 1991; Jonz, 1991; Tremblay, 2011) and has been widely employed in language examinations. Under a typical setting, a cloze test requires examinees to fill in missing words (or sentences) to best fit the surrounding context. To facilitate natural language understanding, automatically-generated cloze datasets are introduced to measure the ability of machines in reading comprehension (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016). In these datasets, each cloze question typically consists of a context paragraph and a question sentence. By randomly replacing a particular word in the question sentence with a blank symbol, a single test case is created. For instance, CNN/Daily Mail datasets (Hermann et al., 2015) use news articles as contexts and summary bullet points as the question sentence. Only named entities are removed when creating the blanks. Similarly, in Children's Books test (CBT) (Hill et al., 2016), cloze questions are obtained by removing a word in the last sentence of every consecutive 21 sentences, with the first 20 sentences being the context. Different from CNN/Daily Mail datasets, CBT also provides each question with a candidate answer set, consisting of randomly sampled words with the same part-of-speech tag from the context as that of the correct answer.

Thanks to the automatic generation process, these datasets can be very large in size, leading to significant research progresses. However, compared to how humans would create cloze questions and evaluate reading comprehension ability, the automatic generation process bears some inevitable issues. Firstly, blanks are chosen uniformly without considering which aspect of the language phenomenon that questions will test. Hence, quite a portion of automatically-generated questions can be purposeless or even trivial to answer. Another issue involves the ambiguity of answers. Given a context and a sentence with a blank, there can be multiple words that fit almost equally well into the blank. A possible solution is to include a candidate option set, as done by CBT, to get rid of the ambiguity. However, automatically generating the candidate option set can be problematic since it cannot guarantee the ambiguity is removed. More importantly, automatically-generated candidates can be totally irrelevant or simply grammatically unsuitable for the blank, resulting in again purposeless or trivial questions.

---

Probably due to these unsatisfactory issues, neural models have achieved comparable results to the human-level performance within a very short time (Chen et al., 2016; Dhingra et al., 2016; Seo et al., 2016). While there have been works trying to incorporate human design into cloze question generation (Zweig and Burges, 2011; Paperno et al., 2016), due to the expensive labeling process, the MSR Sentence Completion Challenge created by this effort has $1,040$ questions and the LAMBADA (Paperno et al., 2016) dataset has $10,022$ questions, limiting the possibility of developing powerful neural models on it. As a result of the small size, human-created questions are only used to compose development sets and test sets. Motivated by the aforementioned drawbacks, we propose CLOTH, a large-scale cloze test dataset collected from English exams. Questions in the dataset are designed by middle-school and high-school teachers to prepare Chinese students for entrance exams. To design a cloze test, teachers firstly determine the words that can test students' knowledge of vocabulary, reasoning or grammar; then replace those words with blanks and provide other three candidate options for each blank. If a question does not specifically test grammar usage, all of the candidate options would complete the sentence with correct grammar, leading to highly nuanced questions. As a result, human-created questions are usually harder and are a better assessment of language proficiency. A general cloze test evaluates several aspects of language proficiency including vocabulary, reasoning and grammar, which are key components of comprehending natural language.

To verify if human-created cloze questions are difficult for current models, we train and evaluate the state-of-the-art language model (LM) and machine comprehension models on this dataset, including a language model trained on the One Billion Word Corpus. We find that the state-of-the-art model lags behind human performance even if the model is trained on a large external corpus. We analyze where the model fails compared to humans who perform well. After conducting error analysis, we assume the performance gap results from the model's inability to use a long-term context. To examine this assumption, we evaluate human-level performance when the human subjects are only allowed to see one sentence as the context. Our assumption is confirmed by the matched performances of the models and human when given only one sentence. In addition, we demonstrate that human-created data is more difficult than automatically-generated data. Specifically, it is much easier for the same model to perform well on automatically-generated data.

We hope that CLOTH provides a valuable testbed for both the language modeling community and the machine comprehension community. Specifically, the language modeling community can use CLOTH to evaluate their models' abilities in modeling long contexts, while the machine comprehension community can use CLOTH to test machine's understanding of language phenomena.

2 Related Work

Large-scale automatically-generated cloze tests (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016) lead to significant research advancements. However, generated questions do not consider language phenomenon to be tested and are relatively easy to solve. Recently proposed reading comprehension datasets are all labeled by humans to ensure a high quality (Rajpurkar et al., 2016; Joshi et al., 2017; Trischler et al., 2016; Nguyen et al., 2016).

Perhaps the closet work to CLOTH is the LAMBADA dataset (Paperno et al., 2016). LAMBADA also targets at finding challenging words to test LM's ability in comprehending a longer context. However, LAMBADA does not provide a candidate set for each question, which can cause ambiguities when multiple words can fit in. Furthermore, only test set and development set are labeled manually. The provided training set is the unlabeled Book Corpus (Zhu et al., 2015). Such unlabeled data do not emphasize long-dependency questions and have a mismatched distribution with the test set, as showed in Section 5. Further, the Book Corpus is too large to allow rapid algorithm development for researchers who do not have access to a huge amount of computational power.

Aiming to evaluate machines under the same conditions that the humans are evaluated, there is a growing interest in obtaining data from examinations. NTCIR QA Lab (Shibuki et al., 2014) contains a set of real-world college entrance exam questions. The Entrance Exams task at CLEF QA Track (Peñas et al., 2014; Rodrigo et al., 2015) evaluates machine's reading comprehension ability. The AI2 Reasoning Challenge (Clark et al., 2018; Schoenick et al., 2017) contains approximately eight thousand scientific questions used in middle school. Lai et al. (2017) proposes the first large-scale machine comprehension dataset obtained from exams. They show that questions designed by teachers have a significantly larger proportion of reasoning questions. Our dataset focuses on evaluating both language proficiency and reasoning abilities.

3 CLOTH Dataset

In this section, we introduce the CLOTH dataset that is collected from English examinations, and study its abilities of assessment.

3.1 Data Collection and Statistics

We collect the raw data from three free and public websites in China that gather exams created by English teachers to prepare students for college/high school entrance exams[3]. Before cleaning, there are $20,605$ passages and $332,755$ questions. We perform the following processes to ensure the validity of data: Firstly, we remove questions with an inconsistent format such as questions with more than four options. Then we filter all questions whose validity relies on external information such as pictures or tables. Further, we find that half of the total passages are duplicates and we delete those passages. Lastly, on one of the websites, the answers are stored as images. We use two OCR software programs[4] to extract the answers from images. We discard the questions when results from the two software are different. After the cleaning process, we obtain a clean dataset of $7,131$ passages and $99,433$ questions.

Since high school questions are more difficult than middle school questions, we divide the datasets into CLOTH-M and CLOTH-H, which stand for the middle school part and the high school part. We split 11% of the data for both the test set and the development set. The detailed statistics of the whole dataset and two subsets are presented in Table 1. Note that the questions were created to test non-native speakers, hence the vocabulary size is not very large.

3.2 Question Type Analysis

In order to evaluate students' mastery of a language, teachers usually design tests in a way that questions cover different aspects of a language. Specifically, they first identify words in the passage that can examine students' knowledge in vocabulary, logic, or grammar. Then, they replace the words with blanks and prepare three incorrect but nuanced candidate options to make the test non-trivial. A sample passage is presented in Table 2.

To understand the abilities of assessment on this dataset, we divide questions into several types and label the proportion of each type. According to English teachers who regularly create cloze test questions for English exams in China, there are largely three types: grammar, vocabulary and reasoning. Grammar questions are easily differentiated from other two categories. However, the teachers themselves cannot specify a clear distinction between reasoning questions and vocabulary questions since all questions require comprehending the words within the context and conducting some level of reasoning by recognizing incomplete information or conceptual overlap.

Hence, we divided the questions except grammar questions based on the difficulty level for a machine to answer the question, following works on analyzing machine comprehension datasets (Chen et al., 2016; Trischler et al., 2016). In particular, we divide them in terms of their dependency ranges, since questions that only involve a single sentence are easier to answer than questions involving evidence distributed in multiple sentences. Further, we divided questions involving long-term dependency into matching/paraphrasing questions and reasoning questions since matching questions are easier. The four types include:

- Grammar: The question is about grammar usage, involving tense, preposition usage, active/passive voices, subjunctive mood and so on.
- Short-term-reasoning: The question is about content words and can be answered based on the information within the same sentence. Note that the content words can evaluate knowledge of both vocabulary and reasoning.
- Matching/paraphrasing: The question is answered by copying/paraphrasing a word in the context.

---

Dataset	CLOTH-M			CLOTH-H			CLOTH (Total)		
	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
# passages	2,341	355	335	3,172	450	478	5,513	805	813
# questions	22,056	3,273	3,198	54,794	7,794	8,318	76,850	11,067	11,516
Vocab. size	15,096			32,212			37,235		
Avg. # sentence	16.26			18.92			17.79		
Avg. # words	242.88			365.1			313.16		

Table 1: The statistics of the training, development and test sets of CLOTH-M (middle school questions), CLOTH-H (high school questions) and CLOTH

- Long-term-reasoning: The answer must be inferred from synthesizing information distributed across multiple sentences.

We sample 100 passages in the high school category and the middle school category respectively with totally $3,000$ questions. The types of these questions are labeled on Amazon Turk. We pay $1 and $0.5 for high school passages and middle school passages respectively. We refer readers to Appendix A.1 for details of the labeling processes and the labeled sample passage.

The proportion of different questions is shown in Table 3. The majority of questions are short-term-reasoning questions while approximately 22.4% of the data needs long-term information, in which the long-term-reasoning questions constitute a large proportion.

4 Exploring Models' Limits

In this section, we investigate if human-created cloze test is a challenging problem for state-of-the-art models. We find that LM trained on the One Billion Word Corpus can achieve a remarkable score but cannot solve the cloze test. After conducting an error analysis, we hypothesize that the model is not able to deal with long-term dependencies. We verify the hypothesis by comparing the model's performance with the human performance when the information humans obtain is limited to one sentence.

4.1 Human and Model Performance

LSTM To test the performance of RNN-based supervised models, we train a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to predict the missing word given the context with only labeled data. The implementation details are in Appendix A.3.

Attentive Readers To enable the model to gather information from a longer context, we augment the supervised LSTM model with the attention mechanism (Bahdanau et al., 2014), so that the representation at the blank is used as a query to find the relevant context in the document and a blank-specific representation of the document is used to score each candidate answer. Specifically, we adapt the Stanford Attentive Reader (Chen et al., 2016) and the position-aware attention model (Zhang et al., 2017) to the cloze test problem. With the position-aware attention model, the attention scores are based on both the context match and the distance from a context to the blank. Both attention models are trained only with human-created blanks just as the LSTM model.

LM In cloze test, the context on both sides may be enough to determine the correct answer. Suppose x_i is the missing word and $x_1, \cdots, x_{i-1}$, $x_{i+1}, \cdots, x_n$ are the context, we choose x_i that maximizes the joint probability $p(x_1, \cdots, x_n)$, which essentially maximizes the conditional likelihood $p(x_i \mid x_1, \cdots, x_{i-1}, x_{i+1}, \cdots, x_n)$. Therefore, LM can be naturally adapted to cloze test.

In essence, LM treats each word as a possible blank and learns to predict it. As a result, it receives more supervision than the LSTM trained on human-labeled questions. Besides training a neural LM on our dataset, interested in whether the state-of-the-art LM can solve cloze test, we also test the LM trained on the One Billion Word Benchmark (Chelba et al., 2013) (referred as 1B-LM) that achieves a perplexity of 30.0 (Jozefowicz et al., 2016)[5]. To make the evaluation time tractable, we limit the context length to one sentence or three sentences. Note that the One Billion Word Corpus does not overlap with the CLOTH

---

[5] The pre-trained model is obtained from https://github.com/tensorflow/models/tree/master/research/lm_1b

Passage: Nancy had just got a job as a secretary in a company. Monday was the first day she went to work, so she was very _1_ and arrived early. She _2_ the door open and found nobody there. ”I am the _3_ to arrive.” She thought and came to her desk. She was surprised to find a bunch of _4_ on it. They were fresh. She _5_ them and they were sweet. She looked around for a _6_ to put them in. ”Somebody has sent me flowers the very first day!” she thought _7_ . ” But who could it be?” she began to _8_ . The day passed quickly and Nancy did everything with _9_ interest. For the following days of the _10_ , the first thing Nancy did was to change water for the followers and then set about her work.
Then came another Monday. _11_ she came near her desk she was overjoyed to see a(n) _12_ bunch of flowers there. She quickly put them in the vase, _13_ the old ones. The same thing happened again the next Monday. Nancy began to think of ways to find out the _14_ . On Tuesday afternoon, she was sent to hand in a plan to the _15_ . She waited for his directives at his secretary's _16_ . She happened to see on the desk a half-opened notebook, which _17_ : ”In order to keep the secretaries in high spirits, the company has decided that every Monday morning a bunch of fresh flowers should be put on each secretarys desk.” Later, she was told that their general manager was a business management psychologist.

Questions:

1.	A. depressed	B. encouraged	**C. excited**	D. surprised
2.	A. turned	**B. pushed**	C. knocked	D. forced
3.	A. last	B. second	C. third	**D. first**
4.	A. keys	B. grapes	**C. flowers**	D. bananas
5.	**A. smelled**	B. ate	C. took	D. held
6.	**A. vase**	B. room	C. glass	D. bottle
7.	A. angrily	B. quietly	C. strangely	**D. happily**
8.	A. seek	**B. wonder**	C. work	D. ask
9.	A. low	B. little	**C. great**	D. general
10.	A. month	B. period	C. year	**D. week**
11.	A. Unless	**B. When**	C. Since	D. Before
12.	A. old	B. red	C. blue	**D. new**
13.	A. covering	B. demanding	**C. replacing**	D. forbidding
14.	**A. sender**	B. receiver	C. secretary	D. waiter
15.	A. assistant	B. colleague	C. employee	**D. manager**
16.	A. notebook	**B. desk**	C. office	D. house
17.	**A. said**	B. written	C. printed	D. signed

Table 2: A Sample passage from our dataset. Bold faces highlight the correct answers. There is only one best answer among four candidates, although several candidates may seem correct.

	Short-term		Long-term		
Dataset	GM	STR	MP	LTR	O
CLOTH	0.265	0.503	0.044	0.180	0.007
CLOTH-M	0.330	0.413	0.068	0.174	0.014
CLOTH-H	0.240	0.539	0.035	0.183	0.004

Table 3: The question type statistics of 3000 sampled questions where GM, STR, MP, LTR and O denotes grammar, short-term-reasoning, matching/paraphrasing, long-term-reasoning and others respectively.

Model	CLOTH	CLOTH-M	CLOTH-H
LSTM	0.484	0.518	0.471
Stanford AR	0.487	0.529	0.471
Position-aware AR	0.485	0.523	0.471
LM	0.548	0.646	0.506
1B-LM (one sent.)	0.695	0.723	0.685
1B-LM (three sent.)	0.707	0.745	0.693
Human performance	0.859	0.897	0.845

Table 4: Models' performance and human-level performance on CLOTH. LSTM, Stanford Attentive Reader and Attentive Reader with position-aware attention shown in the top part only use supervised data labelled by human. LM outperforms LSTM since it receives more supervisions in learning to predict each word. Training on large external corpus further significantly enhances LM's accuracy.

corpus.

Human performance We measure the performance of Amazon Mechanical Turkers on $3,000$ sampled questions when the whole passage is given.

Results The comparison is shown in Table 4. Both attentive readers achieve similar accuracy to the LSTM. We hypothesize that the reason of the attention model's unsatisfactory performance is that the evidence of a question cannot be simply found by matching the context. Similarly, on reading comprehension, though attention-based models (Wang et al., 2017; Seo et al., 2016; Dhingra et al., 2016) have reached human performance on the SQuAD dataset (Rajpurkar et al., 2016), their performance is still not comparable to human performance on datasets that focus more on reasoning where the evidence cannot be simply found by a matching behavior (Lai et al., 2017; Xu et al., 2017). Since the focus of this paper is to analyze the proposed dataset, we leave the design of reasoning oriented attention models for future work.

The LM achieves much better performance than LSTM. The gap is larger when the LM is trained on the 1 Billion Word Corpus, indicating that more training data results in a better generalization. Specifically, the accuracy of 1B-LM is 0.695 when one sentence is used as the context. It indicates that LM can learn sophisticated language regularities when given sufficient data. The same conclusion can also be drawn from the success of a concurrent work ELMo which uses LM representations as word vectors and achieves state-of-the-art results on six language tasks (Peters et al., 2018). However, if we increase the context length to three sentences, the accuracy of 1B-LM only has a marginal improvement. In contrast, humans outperform 1B-LM by a significant margin, which demonstrates that deliberately designed questions in CLOTH are not completely solved even for state-of-the-art models.

4.2 Analyzing 1B-LM's Strengths and Weaknesses

In this section, we would like to understand why 1B-LM lags behind human performance. We find that most of the errors involve long-term reasoning. Additionally, in a lot of cases, the dependency is within the context of three sentences. We show several errors made by the 1B-LM in Table 5. In the first example, the model does not know that Nancy found nobody in the company means that Nancy was the first one to arrive at the company. In the second and third example, the model fails probably because of not recognizing "they" referred to "flowers". The dependency in the last case is longer. It depends on the fact that Nancy was alone in the company.

Based on the case study, we hypothesize that the LM is not able to take long-term information into account, although it achieves a surprisingly good overall performance. Additionally, the 1B-LM is trained on the sentence level, which might also result in the inability to track paragraph level information. However, to investigate the differences between training on sentence level and on paragraph level, a prohibitive amount of computational resource is required to train a large model on the 1 Billion Word Corpus.

On the other hand, a practical comparison is to test the model's performance on different types of questions. We find that the model's accuracy is 0.591 on long-term-reasoning questions of CLOTH-H while it achieves 0.693 on short-term-reasoning (a comprehensive type-specific performance is available in Appendix A.3), which partially confirms that long-term-reasoning is harder. However, we could not completely rely on the performance on specific questions types, partly due to a large variance caused by the small sample size. Another reason is that the reliability of question type labels depends on whether turkers are careful enough. For example, in the error analysis shown in Table 5, a careless turker would label the second example as short-term-reasoning without noticing that the meaning of "they" relies on a long context.

To objectively verify if the LM's strengths lie in dealing with short-term information, we obtain the ceiling performance of only utilizing short-term information. Showing only one sentence as the context, we ask the Turkers to select an option based on their best guesses given the insufficient information. By limiting the context span manually, the ceiling performance with the access to only a short context is estimated accurately.

As shown in Table 6, The performance of 1B-LM using one sentence as the context can almost match the human ceiling performance of only using short-term information. Hence we conclude that the LM can almost perfectly solve all short-term cloze questions. However, the performance of LM is not improved significantly when a long-term context is given, indicating that the performance gap is due to the inability of long-term reasoning.

5 Comparing Human-created Data and Automatically-generated Data

In this section, we demonstrate that human-created data is a better testbed than automatically-generated cloze test since it results in a larger gap between model's performance and human performance.

A casual observation is that a cloze test can be created by randomly deleting words and randomly sampling candidate options. In fact, to generate large-scale data, similar generation processes have been introduced and widely used in machine comprehension (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016). However, research on cloze test design (Sachs et al., 1997) shows that tests created by deliberately deleting words are more reliable than tests created by randomly or periodically deleting words. To design accurate language proficiency assessment, teachers usually deliberately select words in order to examine students' proficiency in grammar, vocabulary and reasoning. Moreover, in order to make the question non-trivial, three incorrect options provided by teachers are usually grammatically correct and relevant to the context. For instance, in the fourth problem of the sample passage shown in Table 2, "grapes", "flowers" and "bananas" all fit the description of being fresh.

Hence we naturally hypothesize that human-generated data has distinct characteristics when

Context	Options			
She pushed the door open and found nobody there. "I am the __ to arrive." She thought and came to her desk.	*A. last*	B. second	C. third	**D. first**
They were fresh. She __ them and they were sweet. She looked around for a vase to put them in.	**A. smelled**	*B. ate*	C. took	D. held
She smelled them and they were sweet. She looked around for a __ to put them in. "Somebody has sent me flowers the very first day!"	**A. vase**	*B. room*	C. glass	D. bottle
"But who could it be?" she began to __ . The day passed quickly and Nancy did everything with great interest.	A. seek	**B. wonder**	C. work	*D. ask*

Table 5: Error analysis of 1-billion-language-model with three sentences as the context. The questions are sampled from the sample passage shown in Table 2. The correct answer is in bold text. The incorrectly selected options are in italics.

	Model	CLOTH	CLOTH-M	CLOTH-H
Short context	1B-LM	0.695	0.723	0.685
	Human	0.713	0.771	0.691
Long context	1B-LM	0.707	0.745	0.693
	Human	0.859	0.897	0.845

Table 6: Humans' performance compared with 1-billion-language-model. In the short context part, both 1B-LM and humans only use information of one sentence. In the long context part, humans have the whole passage as the context, while 1B-LM uses contexts of three sentences.

compared with automatically-generated data. To verify this assumption, we compare the LSTM model's performance when given different proportions of the two types of data. Specifically, to train a model with α percent of automatically-generated data, we randomly replace a percent blanks with blanks at random positions, while keeping the remaining $1-\alpha$ percent questions the same. The candidate options for the generated blanks are random words sampled from the unigram distribution. We test models obtained with varying α on human-created data and automatically-generated data respectively.

$\alpha\%$ Test	0%	25%	50%	75%	100%
human-created	0.484	0.475	0.469	0.423	0.381
Generated	0.422	0.699	0.757	0.785	0.815

Table 7: The model's performance when trained on α percent of automatically-generated data and $100-\alpha$ percent of human-created data

From the comparison in Table 7, we have the following observations: (1) human-created data leads to a larger gap between model's performance and the ceiling/human performance. The model's performance and human's performance on the human-created data are 0.484 and 0.859 respectively, as shown in Tab. 4, leading to a gap of 0.376. In comparison, the performance gap on the automatically-generated data is at most 0.185 since the model's performance reaches an accuracy of 0.815 when fully trained on generated data. (2) Although human-created data may provide more information in distinguishing similar words, the distributional mismatch between two types of data makes it non-trivial to transfer the knowledge gained from human-created data to tackle automatically-generated data. Specifically, the model's performance on automatically-generated data monotonically decreases when given a higher ratio of human-created data.

6 Combining Human-created Data with Automatically-generated Data

In Section 4.1, we show that LM is able to take advantage of more supervision since it predicts each word based on the context. At the same time, we also show that human-created data and the automatically-generated data are quite different in Section 5. In this section, we propose a model that takes advantage of both sources.

6.1 Representative-based Model

Specifically, for each question, regardless of being human-created or automatically-generated, we can compute the negative log likelihood of the correct answer as the loss function. Suppose J_{H} is the average negative log likelihood loss for human-created questions and J_{R} is the loss function on generated questions, we combine losses on human-created questions and generated questions by simply adding them together, i.e., $J_{\mathrm{R}} + J_{\mathrm{H}}$ is used as the final loss function. We will introduce the definition of J_{R} in the following paragraphs.

Although automatically-generated data has a large quantity and is valuable to the model training, as shown in the previous Section, automatically-generated questions are quite different from human-created questions. Ideally, a large amount of human-created questions is more desirable than a large amount of automatically-generated questions. A possible avenue towards having large-scale human-created data is to automatically pick out a large number of generated questions which are *representative* of or similar to human-created questions. In other words, we train a network to predict whether a question is a generated question or a human-created question. A generated question is representative of human-created questions if it has a high probability of being a human-created question. Then we can give higher weights to questions that resemble human-created question.

We first introduce our method to obtain the representativeness information. Let x denote the passage and z denote whether a word is selected as a question by human, i.e., z is 1 if this word is selected to be filled in the original passage or 0 otherwise. Suppose h_i is the representation of i-th word given by a bidirectional LSTM. The network computes the probability p_i of x_i being a human-created question as follows:

$$l_i = h_i^T w_{x_i}; \quad p_i = \text{Sigmoid}(l_i)$$

where l_i is the logit which will be used as in the final model and w_{x_i} is the the word embedding. We train the network to minimize the binary cross entropy between p and ground-truth labels at each token.

After obtaining the representativeness information, we define the representativeness weighted loss function as

$$J_{\text{R}} = \sum_{i \notin H} \text{Softmax}_i(\frac{l_1}{\alpha}, \cdots, \frac{l_n}{\alpha}) J_i$$

where J_i denotes the negative log likelihood loss for the $i-$th question and let l_i be the output representativeness of the i-th question and H is the set of all human-generated questions and α is the temperature of the Softmax function. The model degenerates into assigning a uniform weight to all questions when the temperature is $+\infty$. We set α to 2 based on the performance on the dev set. [6].

Model	Ex.	CLOTH	CLOTH-M	CLOTH-H
Our model	No	**0.583**	**0.673**	**0.549**
LM		0.548	0.646	0.506
LSTM		0.484	0.518	0.471
Stanford AR		0.487	0.529	0.471
1B-LM	Yes	0.707	0.745	0.693
Human		0.859	0.897	0.845

Table 8: Overall results on CLOTH. Ex. denotes external data.

Model	CLOTH	CLOTH-M	CLOTH-H
Our model	**0.583**	**0.673**	**0.549**
w.o. rep.	0.566	0.662	0.528
w.o. hum.	0.565	0.665	0.526
w.o. rep. or hum.	0.543	0.643	0.505

Table 9: Ablation study on using the representativeness information (denoted as rep.) and the human-created data (denoted as hum.)

6.2 Results

We summarize performances of all models in Table 8. Our representativeness model outperforms all other models that do not use external data on CLOTH, CLOTH-H and CLOTH-M.

6.3 Analysis

In this section, we verify the effectiveness of the representativeness-based averaging by ablation studies. When we remove the representativeness information by setting α to infinity, the accuracy drops from 0.583 to 0.566. When we further remove the human-created data so that only generated data is employed, the accuracy drops to 0.543, similar to the performance of LM. The results further confirm that it is beneficial to incorporate human-created questions into training.

A sample of the predicted representativeness is shown in Figure 1[7]. Clearly, words that are too obvious have low scores, such as punctuation marks, simple words "a" and "the". In contrast, content words whose semantics are directly related to the context have a higher score, e.g., "same", "similar", "difference" have a high score when the difference between two objects is discussed and "secrets" has a high score since it is related to the subsequent sentence "does not want to share with others". Our prediction model achieves an F1 score of 36.5 on the test set, which is understandable since

years ago , if a teenager had some problems in his life , he might go home and write in his diary now , a teenager
with the same problems might go onto the internet and write about them in a blog . in many ways , a diary and a blog
are very ***similar*** . but what makes UNK different from writing in a (n) ***traditional*** diary ? the biggest difference
is that a blog is much more ***public*** than a diary . usually , a teenager treats his diary like a book full of ***secrets***
that he does not want to ***share*** with others . it's interesting that someone who writes in a blog instead of a diary
will probably write nearly the same information . i have a little sister , and sometimes i go online to read her ***blog***
. she writes about things like waking up early for swimming practice and not studying enough for her chemistry test . ***when***
i was her age , i wrote about the same things , but ***only*** in my dairy . then , after i had finished writing , i
would hide my diary in a secret place because i was ***worried*** that my sister might read it . the biggest ***problem*** with
blogging is that anyone can read what you write . if i was angry with a friend during high school and wrote something
mean about him in my diary , he would never know . ***however*** , if my sister ever wrote something bad about a friend
, that friend might ***read*** her blog and get angry . there are also ***advantages*** to blogging , of course . if i was feeling
sad one day and wrote in my diary , `` nobody cares about me '' , because no one would ***know*** about it . however ,
if my sister wrote the same sentence in her blog , her best friends would quickly ***respond*** and tell her how much they
like her . blogs help people ***stay*** in contact with their friends and know what the people around them are doing .

Figure 1: Representativeness prediction for each word. Lighter color means less representative. The words deleted by human as blanks are in bold text.

there are many plausible questions within a passage.

It has been shown that features such as morphology information and readability are beneficial in cloze test prediction (Skory and Eskenazi, 2010; Correia et al., 2012, 2010; Kurtasov, 2013). We leave investigating the advanced approaches of automatically designing cloze test to future work.

7 Conclusion and Discussion

In this paper, we propose a large-scale cloze test dataset CLOTH that is designed by teachers. With missing blanks and candidate options carefully created by teachers to test different aspects of language phenomena, CLOTH requires a deep language understanding and better captures the complexity of human language. We find that human outperforms 1B-LM by a significant margin. After detailed analysis, we find that the performance gap is due to the model's inability to understanding a long context. We also show that, compared to automatically-generated questions, human-created questions are more difficult and lead to a larger margin between human performance and the model's performance.

Despite the excellent performance of 1B-LM when compared with models trained only on CLOTH, it is still important to investigate and create more effective models and algorithms which provide complementary advantages to having a large amount of data. For rapid algorithm developments, we suggest training models only on the training set of CLOTH and comparing with models that do not utilize external data.

We hope our dataset provides a valuable testbed to the language modeling community and the machine comprehension community. In particular, the language modeling community can use CLOTH to evaluate their models' abilities in modeling a long context. In addition, the machine comprehension community may also find CLOTH useful in evaluating machine's understanding of language phenomena including vocabulary, reasoning and grammar, which are key components of comprehending natural language.

In our future work, we would like to design algorithms to better model a long context, to utilize external knowledge, and to explore more effective semi-supervised learning approaches. Firstly, we would like to investigate efficient ways of utilizing external knowledge such as paraphrasing and semantic concepts like prior works (Dong et al., 2017; Dasigi et al., 2017). In comparison, training on a large external dataset is actually a time-consuming way of utilizing external knowledge. Secondly, to use the generated questions more effectively, the representative-based semi-supervised approach might be improved by techniques studied in active learning and hard example mining (Settles, 2009; Shrivastava et al., 2016; Chang et al., 2017).

Figure 2: Model and human's performance on questions with different types. Our model will be introduced in Sec. 6.

A Appendix

A.1 Question Type Labeling

To label the questions, we provided the definition and an example for each question category to the Amazon Mechanical Turkers. To ensure quality, we limited the workers to master Turkers who are experienced and maintain a high acceptance rate. However, we did not restrict the backgrounds of the Turkers since master Turkers should have a reasonable amount of knowledge about English to conduct previous tasks. In addition, the vocabulary used in CLOTH are usually not difficult since they are constructed to test non-native speakers in middle school or high school. To get a concrete idea of the nature of question types, please refer to examples shown in Tab. 10.

A.2 Type-specific Performance Analysis

We can also further verify the strengths and weaknesses of the 1B-LM by studying the performance of models and human on different question categories. Note that the performance presented here may be subject to a high variance due to the limited number of samples in each category. From the comparison shown in Figure 2, we see that 1B-LM is indeed good at short-term questions. Specifically, when the human only has access to the context of one sentence, 1B-LM is close to human's performance on almost all categories. Further, comparing LM and 1B-LM, we find that training on the large corpus leads to improvements on all categories, showing that training on a large amount of data leads to a substantial improvement in learning complex language regularities.

A.3 Implementation Details

We implement our models using PyTorch (Paszke et al., 2017). We train our model on all questions in CLOTH and test it on CLOTH-M and CLOTH-H separately. For our final model, we use Adam (Kingma and Ba, 2014) with the learning rate of 0.001. The hidden dimension is set to 650 and we initialize the word embedding by 300-dimensional Glove word vector (Pennington et al., 2014). The temperature α is set to 2. We tried to increase the dimensionality of the model but do not observe performance improvement.

When we train the small LM on CLOTH, we largely follow the recommended hyperparameters in the Pytorch LM example[8]. Specifically, we employ a 2-layer LSTM with hidden dimension as 1024. The input embedding and output weight matrix are tied. We set the dropout rate to 0.5. The initial learning rate is set to 10 and divided by 4 whenever the PPL stops improving on the dev set.

We predict the answer for each blank independently for all of the models mentioned in this paper, since we do not observe significant performance improvements in our preliminary experiments when an auto-regressive approach is employed, i.e., when we fill all previous blanks with predicted answers. We hypothesize that, regardless of whether there exist inter-blank dependencies, since blanks are usually

---

[8] https://github.com/pytorch/examples/tree/master/word_language_model

distributed far away from each other, LSTM is not able to capture such long dependencies. When testing language models, we use the longest text spans that do not contain blanks.

Passage: Nancy had just got a job as a secretary in a company. Monday was the first day she went to work, so she was very _1_ and arrived early. She _2_ the door open and found nobody there. ”I am the _3_ to arrive.” She thought and came to her desk. She was surprised to find a bunch of _4_ on it. They were fresh. She _5_ them and they were sweet. She looked around for a _6_ to put them in. ”Somebody has sent me flowers the very first day!” she thought _7_ . ” But who could it be?” she began to _8_ . The day passed quickly and Nancy did everything with _9_ interest. For the following days of the _10_ , the first thing Nancy did was to change water for the followers and then set about her work.

Then came another Monday. _11_ she came near her desk she was overjoyed to see a(n) _12_ bunch of flowers there. She quickly put them in the vase, _13_ the old ones. The same thing happened again the next Monday. Nancy began to think of ways to find out the _14_ . On Tuesday afternoon, she was sent to hand in a plan to the _15_ . She waited for his directives at his secretary's _16_ . She happened to see on the desk a half-opened notebook, which _17_ : ”In order to keep the secretaries in high spirits, the company has decided that every Monday morning a bunch of fresh flowers should be put on each secretarys desk.” Later, she was told that their general manager was a business management psychologist.

Abstract

We propose a novel methodology to generate domain-specific large-scale question answering (QA) datasets by re-purposing existing annotations for other NLP tasks. We demonstrate an instance of this methodology in generating a large-scale QA dataset for electronic medical records by leveraging existing expert annotations on clinical notes for various NLP tasks from the community shared i2b2 datasets[§]. The resulting corpus (emrQA) has 1 million questions-logical form and 400,000+ question-answer evidence pairs. We characterize the dataset and explore its learning potential by training baseline models for question to logical form and question to answer mapping.

1 Introduction

Automatic question answering (QA) has made big strides with several open-domain and machine comprehension systems built using large-scale annotated datasets (Voorhees et al., 1999; Ferrucci et al., 2010; Rajpurkar et al., 2016; Joshi et al., 2017). However, in the clinical domain this problem remains relatively unexplored. Physicians frequently seek answers to questions from unstructured electronic medical records (EMRs) to support clinical decision-making (Demner-Fushman et al., 2009). But in a significant majority of cases, they are unable to unearth the information they want from EMRs (Tang et al., 1994). Moreover to date, there is no general system for answering natural language questions asked by physicians on a patient's EMR (Figure 1) due to lack of large-scale datasets (Raghavan and Patwardhan, 2016).

EMRs are a longitudinal record of a patient's health information in the form of unstructured clinical notes (progress notes, discharge summaries etc.) and structured vocabularies. Physicians wish to answer questions about medical entities and relations from the EMR, requiring a deeper understanding of clinical notes. While this may be likened to machine comprehension, the longitudinal nature of clinical discourse, little to no redundancy in facts, abundant use of domain-specific terminology, temporal narratives with multiple related diseases, symptoms, medications that go back and forth in time, and misspellings, make it complex and difficult to apply existing NLP tools (Demner-Fushman et al., 2009; Raghavan and Patwardhan, 2016). Moreover, answers may be implicit or explicit and may require domain-knowledge and reasoning across clinical notes. Thus, building a credible QA system for patient-specific EMR QA requires large-scale question and answer annotations that sufficiently capture the challenging nature of clinical narratives in the EMR. However, serious privacy concerns about sharing personal health information (Devereaux, 2013; Krumholz et al., 2016), and the tedious nature of assimilating answer annotations from across longitudinal clinical notes, makes this task impractical and possibly erroneous to do manually (Lee et al., 2017).

Record Date: 08/09/98

08/31/96 ascending aortic root replacement with homograft with omentopexy. The patient continued to be hemodynamically stable making good progress. Physical examination: BMI: 33.4 Obese, high risk. Pulse: 60. resp. rate: 18

Question: Has the patient ever had an abnormal BMI?

Answer: BMI: 33.4 Obese, high risk

Question: When did the patient last receive a homograft replacement ?

Answer: 08/31/96 ascending aortic root replacement with homograft with omentopexy.

ation framework that allows for minimal expert involvement and re-purposes existing annotations available for other clinical NLP tasks (i2b2 challenge datasets (Guo et al., 2006)). The annotations serve as a proxy-expert in generating questions, answers, and logical forms. Logical forms provide a human-comprehensible symbolic representation, linking questions to answers, and help build interpretable models, critical to the medical domain (Davis et al., 1977; Vellido et al., 2012). We analyze the emrQA dataset in terms of question complexity, relations, and the reasoning required to answer questions, and provide neural and heuristic baselines for learning to predict question-logical forms and question-answers.

The main contributions of this work are as follows:

- A novel framework for systematic generation of domain-specific large-scale QA datasets that can be used in any domain where manual annotations are challenging to obtain but limited annotations may be available for other NLP tasks.

- The first accessible patient-specific EMR QA dataset, emrQA[*], consisting of 400,000 question-answer pairs and 1 million question-logical form pairs. The logical forms will allow users to train and benchmark interpretable models that justify answers with corresponding logical forms.

- Two new reasoning challenges, namely arithmetic and temporal reasoning, that are absent in open-domain datasets like SQuAD (Rajpurkar et al., 2016).

2 Related Work

Question Answering (QA) datasets are classified into two main categories: (1) machine comprehension (MC) using unstructured documents, and (2) QA using Knowledge Bases (KBs).

MC systems aim to answer any question that could be posed against a reference text. Recent advances in crowd-sourcing and search engines have resulted in an explosion of large-scale (100K) MC datasets for factoid QA, having ample redundant evidence in text (Rajpurkar et al., 2016; Trischler et al., 2016; Joshi et al., 2017; Dhingra et al., 2017). On the other hand, complex domain-specific MC datasets such as MCTest (Richardson et al., 2013), biological process modeling (Berant et al., 2014), BioASQ (Tsatsaronis et al., 2015), InsuranceQA (Feng et al., 2015), etc have been limited in scale (500-10K) because of the complexity of the task or the need for expert annotations that cannot be crowd-sourced or gathered from the web. In contrast to the open-domain, EMR data cannot be released publicly due to privacy concerns (Šuster et al., 2017). Also, annotating unstructured EMRs requires a medical expert who can understand and interpret clinical text. Thus, very few datasets like i2b2, MIMIC (Johnson et al., 2016) (developed over several years in collaboration with large medical groups and hospitals), share small-scale annotated clinical notes. In this work, we take advantage of the limited expertly annotated resources to generate emrQA.

KB-based QA datasets, used for semantic parsing, are traditionally limited by the requirement of annotated question and logical form (LF) pairs for supervision where the LF are used to retrieve answers from a schema (Cai and Yates, 2013; Lopez et al., 2013; Bordes et al., 2015). Roberts and Demner-Fushman (2016) generated a corpus by

manually annotating LFs on 468 EMR questions (not released publicly), thus limiting its ability to create large scale datasets. In contrast, we only collect LFs for question templates from a domain-expert - the rest of our corpus is automatically generated.

Recent advances in QA combine logic-based and neural MC approaches to build hybrid models (Usbeck et al., 2015; Feng et al., 2016; Palangi et al., 2018). These models are driven to combine the accuracy of neural approaches (Hermann et al., 2015) and the interpretability of the symbolic representations in logic-based methods (Gao et al.; Chabierski et al., 2017). Building interpretable yet accurate models is extremely important in the medical domain (Shickel et al., 2017). We generate large-scale ground truth annotations (questions, logical forms, and answers) that can provide supervision to learn such hybrid models. Our approach to generating emrQA is in the same spirit as Su et al. (2016), who generate graph queries (logical forms) from a structured KB and use them to collect answers. In contrast, our framework can be applied to generate QA dataset in any domain with minimal expert input using annotations from other NLP tasks.

3 QA Dataset Generation Framework

Our general framework for generating a large-scale QA corpus given certain resources consists of three steps: (1) collecting questions to capture domain-specific user needs, followed by normalizing the collected questions to templates by replacing entities (that may be related via binary or composite relations) in the question with placeholders. The entity types replaced in the question are grounded in an ontology like WordNet (Miller, 1995), UMLS (Bodenreider, 2004), or a user-generated schema that defines and relates different entity types. (2) We associate question templates with expert-annotated logical form templates; logical forms are symbolic representations using relations from the ontology/schema to express the relations in the question, and associate the question entity type with an answer entity type. (3) We then proceed to the important step of re-purposing existing NLP annotations to populate question-logical form templates and generate answers. QA is a complex task that requires addressing several fundamental NLP problems before accurately answering a question. Hence, obtaining expert manual annotations in complex domains is infeasible as it is tedious to expert-annotate answers that may be found across long document collections (e.g., longitudinal EMR) (Lee et al., 2017). Thus, we reverse engineer the process where we reuse expert annotations available in NLP tasks such as entity recognition, coreference, and relation learning, based on the information captured in the logical forms to populate entity placeholders in templates and generate answers. Reverse engineering serves as a proxy expert ensuring that the generated QA annotations are credible. The only manual effort is in annotating logical forms, thus significantly reducing expert labor. Moreover, in domain specific instances such as EMRs, manually annotated logical forms allow the experts to express information essential for natural language understanding such as domain knowledge, temporal relations, and negation (Gao et al.; Chabierski et al., 2017). This knowledge, once captured, can be used to generate QA pairs on new documents, making the framework scalable.

4 Generating the emrQA Dataset

We apply the proposed framework to generate the emrQA corpus consisting of questions posed by physicians against longitudinal EMRs of a patient, using annotations provided by i2b2 (Figure 2).

4.1 Question Collection and Normalization

We collect questions for EMR QA by, 1) polling physicians at the Veterans Administration for what they frequently want to know from the EMR (976 questions), 2) using an existing source of 5,696 questions generated by a team of medical experts from 71 patient records (Raghavan et al., 2017) and 3) using 15 prototypical questions from an ob-

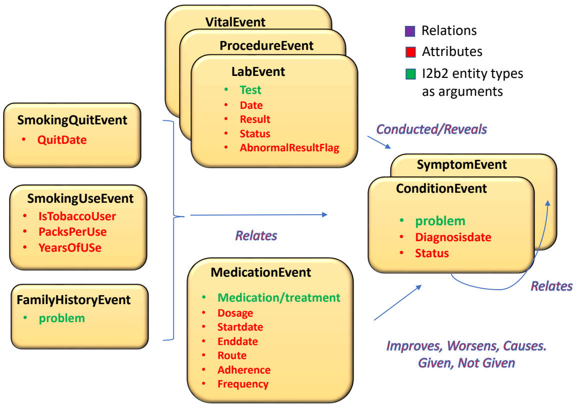

Figure 3: Events, attributes & relations in emrQA's logical forms. Events & attributes accept i2b2 entities as arguments.

servational study done by physicians (Tang et al., 1994). To obtain templates, the questions were automatically normalized by identifying medical entities (using MetaMap (Aronson, 2001)) in questions and replacing them with generic placeholders. The resulting ∼2K noisy templates were expert reviewed and corrected (to account for any entity recognition errors by MetaMap). We align our entity types to those defined in the i2b2 concept extraction tasks (Uzuner et al., 2010a, 2011) - *problem, test, treatment, mode and medication.* E.g., The question *What is the dosage of insulin?* from the collection gets converted to the template *What is the dosage of* $|medication|$*?* as shown in Fig.2. This process resulted in 680 question templates. We do not correct for the usage/spelling errors in these templates, such as usage of "pt" for "patient", or make the templates gender neutral in order to provide a true representation of physicians' questions. Further, analyzing these templates shows that physicians most frequently ask about test results (11%), medications for problem (9%), and problem existence (8%). The long tail following this includes questions about medication dosage, response to treatment, medication duration, prescription date, etiology, etc. Temporal constraints were frequently imposed on questions related to tests, problem diagnosis and medication start/stop.

4.2 Associating Templates w/ Logical Forms

The 680 question templates were annotated by a physician with their corresponding logical form (LF) templates, which resulted in 94 unique LF templates. More than one question template that map to the same LF are considered paraphrases of each other and correspond to a particular question type (Table 2). Logical forms are defined based on an ontology schema designed by medical experts (Figure 3). This schema captures entities in unstructured clinical notes through medical events and their attributes, interconnected through relations. We align the entity and relation types of i2b2 to this schema.

A formal representation of the LF grammar using this schema (Figure 3) is as follows. Medical events are denoted as ME_i (e.g LabEvent, ConditionEvent) and relations are denoted as RE_i (e.g conducted/reveals). Now, $ME[a_1, .., a_j, .., oper(a_n)]$ is a medical event where a_j represents the attribute of the event (such as result in LabEvent). An event may optionally include constraints on attributes captured by an operator ($oper() \in$ sort, range, check for null values, compare). These operators sometimes require values from external medical KB (indicated by *ref*, e.g. lab.*ref*low/lab.*ref*high to indicate range of reference standards considered healthy in lab results) indicating the need for medical knowledge to answer the question. Using these constructs, a LF can be defined using the following rules,

$LF \rightarrow ME_i \mid M_1$ relation M_2
$M_1 \rightarrow ME_i$, $M_2 \rightarrow ME_j$
$M_1 \rightarrow M_1$ relation M_2, $M_2 \rightarrow M_1$ relation M_2
$relation \rightarrow OR \mid AND \mid RE_i$

Advantages of our LF representation include the ability to represent composite relations, define attributes for medical events and constrain the attributes to precisely capture the information need in the question. While these can be achieved using different methods that combine lambda calculus and first order logic (Roberts and Demner-Fushman, 2016), our representation is more human comprehensible. This allows a physician to consider an ontology like Figure 3 and easily define a logical form. Some example question templates with their LF annotations are described in Table 3 using the above notation. The LF representation of the question in Figure 2 is *MedicationEvent(*$|medication|$*) [dosage=x]*. The entities seen in LF are the entities posed in the question and entity marked x indicates the answer entity type.

4.3 Template Filling and Answer Extraction

The next step in the process is to populate the question and logical form (QL) templates with existing annotations in the i2b2 clinical datasets and extract answer evidence for the questions.

Property	Example Annotation	Stats.
Fine grained answer type (attribute entity is answer)	Q: What is the **dosage** of $\vert medication\vert$? LF: MedicationEvent ($\vert medication\vert$) **[dosage=x]**	62.7%
Course grained answer type (event entity is answer)	Q: **What** does the patient take $\vert medication\vert$ for? LF: MedicationEvent($\vert medication\vert$)given{ConditionEvent(**x**) OR SymptomEvent(**x**)}	52.1%
Questions with operators on entities	Q: What are the last set of labs with **elevated** numbers out of range? LF: LabEvent (x) [date=x, (result=x)>lab.refhigh]	25.5%
Questions which require medical KB	Q: What are the last set of labs with **elevated numbers out of range**? LF: LabEvent (x) [date=x, (result=x)>**lab.refhigh**]	11.7%
At least one event relation	What lab results does he have that are pertinent to $\vert problem\vert$ **diagnosis** LF: LabEvent (x) [date=x, result=x] **conducted/reveals** ConditionEvent ($\vert problem\vert$)	46.8%

Table 3: Properties of question templates inferred from the corresponding logical form templates. The boldface words hint at the presence of the corresponding property in both question and the logical form template.

The i2b2 datasets are expert annotated with fine-grained annotations (Guo et al., 2006) that were developed for various shared NLP challenge tasks, including (1) smoking status classification (Uzuner et al., 2008), (2) diagnosis of obesity and its co-morbidities (Uzuner, 2009), extraction of (3) medication concepts (Uzuner et al., 2010a), (4) relations, concepts, assertions (Uzuner et al., 2010b, 2011) (5) co-reference resolution (Uzuner et al., 2012) and (6) heart disease risk factor identification (Stubbs and Uzuner, 2015). In Figure 2, this would correspond to leveraging annotations from medications challenge between medications and their dosages, such as *medication=Nitroglycerin, dosage=40mg*, to populate |medication| and generate several instances of the question "What is the dosage of $|medication|$?" and its corresponding logical form *MedicationEvent(*$|medication|$*)[dosage=x]*. The answer would be derived from the value of the dosage entity in the dataset.

Preprocessing: The i2b2 entities are preprocessed before using them with our templates to ensure syntactic correctness of the generated questions. The pre-processing steps are designed based on the i2b2 annotations syntax guidelines (Guo et al., 2006). To estimate grammatical correctness, we randomly sampled 500 generated questions and found that <5% had errors. These errors include, among others, incorrect usage of article with the entity and incorrect entity phrasing.

Answer Extraction: The final step in the process is generating answer evidence corresponding to each question. The answers in emrQA are defined differently; instead of a single word or phrase we provide the entire i2b2 annotation line from the clinical note as the answer. This is because the context in which the answer entity or phrase is mentioned is extremely important in clinical decision making (Demner-Fushman et al., 2009). Hence, we call them answer evidence instead of just answers. For example, consider the question *Is the patient's* $hypertension$ *controlled?*. The answer to this question is not a simple *yes/no* since the status of the patient's $hypertension$ can change through the course of treatment. The answer evidence to this question in emrQA are multiple lines across the longitudinal notes that reflect this potentially changing status of the patients condition, e.g. *Hypertension-borderline today*. Additionally, for questions seeking specific answers we also provide the corresponding answer entities.

The overall process for answer evidence generation was vetted by a physician. Here is a brief overview of how the different i2b2 datasets were used in generating answers. The *relations challenge* datasets have various event-relation annotations across single/multiple lines in a clinical note. We used a combination of one or more of these, to generate answers for a question; in doing so we used the annotations provided by the *i2b2 co-reference* datasets. Similarly, the *medications challenge* dataset has various event-attribute annotations but since this dataset is not provided with co-reference annotations, it is currently not possible to combine all valid answers. The *heart disease challenge dataset* has longitudinal notes (~5 per patient) with record dates. The events in this dataset are also provided with time annotations and are rich in quantitative entities. This dataset was primarily used to answer questions that require temporal and arithmetic reasoning on events. The patient records in the *smoking and obesity challenge* datasets are categorized into classes with no entity annotations. Thus, for questions generated on these datasets, the entire document acts as evidence and the annotated class information (7 classes) needs to be predicted as the answer.

The total questions, LFs and answers generated using this framework are summarized in Table 1. Consider the question *How much does the patient smoke?* for which we do not have i2b2-annotations to provide an answer. In cases where the answer entity is empty, we only generate the question and LF, resulting in more question types being used for QL than QA pairs: only 53% of question types have answers.

5 emrQA Dataset Analysis

We analyze the complexity of emrQA by considering the LFs for question characteristics, variations in paraphrases, and the type of reasoning required for answering questions (Table 2, 3, 4).

5.1 Question/Logical Form Characteristics

A quantitative and qualitative analysis of emrQA question templates is shown in Table 3, where logical forms help formalize their characteristics (Su et al., 2016). Questions may request specific fine-grained information (attribute values like dosage) or may express a more coarse-grained need (event entities like medications etc), or a combination of both. 25% of questions require complex operators (e.g compare(>)) and 12% of questions express the need for external medical knowledge (e.g. lab.refhigh). The questions in emrQA are highly compositional, where 47% of question templates have at least one event relation.

5.2 Paraphrase Complexity Analysis

Questions templates that map to the same LF are considered paraphrases (e.g, Table 2) and correspond to the same question type. In emrQA, an average of 7 paraphrase templates exist per question type. This is representative of FAQ types that are perhaps more important to the physician. Good paraphrases are lexically dissimilar to each other (Chen and Dolan, 2011). In order to understand the lexical variation within our paraphrases, we randomly select a question from the list of paraphrases as a reference and evaluate the others with respect to the reference, and report the average BLEU (0.74 $\pm$ 0.06) and Jaccard Score (0.72 $\pm$ 0.19). The low BLEU and Jaccard score with large standard deviation indicates the lexical diversity captured by emrQA's paraphrases (Papineni et al., 2002; Niwattanakul et al., 2013).

5.3 Answer Evidence Analysis

33% of the questions in emrQA have more than one answer evidence, with the number ranging from 2 to 61. E.g., the question *Medications Record?* has all medications in the patient's longitudinal record as answer evidence. In order to analyze the reasoning required to answer emrQA questions, we sampled 35 clinical notes from the corpus and analyzed 3 random questions per note by manually labeling them with the categories described in Table 4. Categories are not mutually exclusive: a single example can fall into multiple categories. We compare and contrast this analysis with SQuAD (Rajpurkar et al., 2016), a popular MC dataset generated through crowdsourcing, to show that the framework is capable of generating a corpus as representative and even more complex. Compared to SQuAD, emrQA offers two new reasoning categories, temporal and arithmetic which make up 31% of the dataset. Additionally, over two times as many questions in emrQA require reasoning over multiple sentences. Long and noisy documents make the question answering task more difficult (Joshi et al., 2017). EMRs are inherently noisy and hence 29% have incomplete context and the document length is 27 times more than SQuAD which offers new challenges to existing QA models. Owing to the domain specific nature of the task, 39% of the examples required some form of medical/world knowledge.

As discussed in Section 4.3, 12% of the questions in emrQA corpus require a class category from *i2b2 smoking and obesity datasets* to be predicted. We also found 6% of the questions had other possible answers that were not included by emrQA, this is because of the lack of co-reference annotations for the *medications challenge*.

6 Baseline Methods

We implement baseline models using neural and heuristic methods for question to logical form (Q-L) and question to answer (Q-A) mapping.

6.1 Q-L Mapping

Heuristic Models: We use a template-matching approach where we first split the data into train/test sets, and then normalize questions in the test set into templates by replacing entities with placeholders. The templates are then scored against the ground truth templates of the questions in the train set, to find the best match. The placeholders in the LF template corresponding to the best matched question template is then filled with the normalized entities to obtain the predicted LF. To normalize the test questions we use CLiNER

Reasoning	Description	Example Annotation	emrQA	SQuAD
Lexical Variation (Synonym)	Major correspondence between the question and answer sentence are synonyms.	Q: Has this patient ever been **treated** with insulin? E: Patient sugars were **managed** o/n with sliding scale insulin and diabetic	15.2%	33.3%
Lexical Variation (world/medical knowledge)	Major correspondence between the question and answer sentence requires world/medical knowledge to resolve	Q: Has the patient complained of any **CAD symptoms**? E: 70-year-old female who comes in with ***substernal chest pressure***	39.0%	9.1%
Syntactic Variation	After the question is paraphrased into declarative form, its syntactic dependency structure does not match that of the answer sentence	Q: Has this patient ever been **treated** with ffp? E: attempt to reverse anticoagulation , one unit of **FFP was begun**	60.0%	64.1%
Multiple Sentence	Co-reference and higher level fusion of multiple sentences	Q: What happened when the patient was given **ascending aortic root replacement**? E: The patient tolerated **the procedure** fairly well and was transferred to the ICU with his *chest open*	23.8%	13.6%
Arithmetic	Knowing comparison and subtraction operators.	Q: Show me any **LDL** $>$ **100 mg/dl** in the last 6 years? E: gluc 192, ***LDL 115***, TG 71, HDL 36	13.3%	N.A.
Temporal	Reasoning based on time frame	Q: What were the results of the abnormal A1C on **2115-12-14**? E: HBA1C **12/14/2115** *11.80*	18.1%	N.A.
Incomplete Context	Unstructured clinical text is noisy and may have missing context	Q: What is her current dose of iron? E: Iron *325 mg* p.o. t.i.d.	28.6%	N.A.
Class Prediction	Questions for which a specific predefined class needs to be predicted	Q: Is the patient currently Obese? E: Yes	12.4%	N.A.

Table 4: We manually labeled 105 examples into one or more of the above categories. Words relevant to the corresponding reasoning type are in bold and the answer entity (if any) in the evidence is in *italics*. We compare this analysis with SQuAD.

Dataset	Train/Test	HM-1	HM-2	Neural
GeoQuery	600/280	32.8%	52.1%	74.6%[†]
ATIS	4,473/448	20.8%	52.2%	69.9%[†]
emrQL-1	1M/253K	0.3%	26.3%	22.4%
emrQL-2	1.1M/296K	31.6%	32.0%	42.7%

Table 5: Heuristic (HM) and neural (seq2seq) models performance on question to logical form learning in emrQA.

(Boag et al., 2015) for emrQA and Jia and Liang (2016)'s work for ATIS and GeoQuery. Scoring and matching is done using two heuristics: (1) HM-1, which computes an identical match, and (2) HM-2, which generates a GloVe vector (Arora et al., 2016) representation of the templates using sentence2vec and then computes pairwise cosine similarity.

Neural Model: We train a sequence-to-sequence (seq2seq) (Sutskever et al., 2014) with attention paradigm (Bahdanau et al., 2014; Luong et al., 2017) as our neural baseline (2 layers, each with 64 hidden units). The same setting when used with Geoquery and ATIS gives poor results because the parameters are not appropriate for the nature of that dataset. Hence, for comparison with GeoQuery and ATIS, we use the results of seq2seq model with a single 200 hidden units layer (Jia and Liang, 2016). At test time we automatically balance missing right parentheses.

6.1.1 Experimental Setup

We randomly partition the QL pairs in the dataset in train(80%) and test(20%) sets in two ways. (1) In emrQL-1, we first split the paraphrase templates corresponding to a single LF template into train and test, and then generate the instances of QL pairs. (2) In emrQL-2, we first generate the instances of QL pairs from the templates and then distribute them into train and test sets. As a result, emrQL-1 has more lexical variation between train and test distribution compared to emrQL-2, resulting in increased paraphrase complexity. We use accuracy i.e, the total number of logical forms predicted correctly as a metric to evaluate our model.

6.1.2 Results

The performance of the proposed models is summarized in Table 5. emrQL results are not directly comparable with GeoQuery and ATIS because of the differences in the lexicon and tools available for the domains. However, it helps us establish that QL learning in emrQA is non-trivial and supports significant future work.

Error analysis of heuristic models on emrQL-1 and emrQL-2 showed that 70% of the errors occurred because of incorrect question normalization. In fact, 30% of these questions had not been normalized at all. This shows that the entities

---

[†] results from Jia and Liang (2016)

added to the templates are complex and diverse and make the inverse process of template generation non trivial. This makes a challenging QL corpus that cannot trivially be solved by template matching based approaches.

Errors made by the neural model on both emrQL-1 and emrQL-2 are due to long LFs (20%) and incorrectly identified entities (10%), which are harder for the attention-based model (Jia and Liang, 2016). The increased paraphrase complexity in emrQL-1 compared to emrQL-2 resulted in 20% more structural errors in emrQL-1, where the predicted event/grammar structure deviates significantly from the ground truth. This shows that the model is not adequately capturing the semantics in the questions to generalize to new paraphrases. Therefore, emrQL-1 can be used to benchmark QL models robust to paraphrasing.

6.2 Q-A Mapping

Question-answering on emrQA consists of two different tasks, (1) extraction of answer line from the clinical note (machine comprehension (MC)) and (2) prediction of answer class based on the entire clinical note. We provide baseline models to illustrate the complexity in doing both these tasks.

Machine Comprehension: To do extractive QA on EMRs, we use DrQA's (Chen et al., 2017) document reader which is a multi-layer RNN based MC model. We use their best performing settings trained for SQuAD data using Glove vectors (300 dim-840B).

Class Prediction: We build a multi-class logistic regression model for predicting a class as an answer based on the patient's clinical note. Features input to the classifier are TF-IDF vectors of the question and the clinical notes taken from *i2b2 smoking and obesity datasets*.

6.2.1 Experimental setup

We consider a 80-20 split of the data for train-test. In order to evaluate worst-case performance, we train on question-evidence pairs in a clinical note obtained by using only one random paraphrase for a question instead of all the paraphrases. We use a slightly modified[‡] version of the two popularly reported metrics in MC for evaluation since our evidence span is longer: Exact Match (EM) and F1. Wherever the answer entity in an evidence is explicitly known, EM checks if the answer entity is present within the evidence, otherwise it checks if the predicted evidence span lies within ±20 characters of the ground truth evidence. For F1 we construct a bag of tokens for each evidence string and measure the F1 score of the overlap between the two bags of tokens. Since there may be multiple evidence for a given question, we consider only the top 10 predictions and report an average of EM and F1 over ground truth number of answers. In the class prediction setting, we report the subset accuracy.

Model	Train/Test	Exact Match	F1
DrQA (MC)	47,605/9,966	59.2%	60.6
Class Prediction	1276/320	36.6%	n.a

Table 7: Performance of baseline models on the two QA sub tasks, machine comprehension (MC) and class prediction.

6.2.2 Results

The performance of the proposed models is summarized in Table 7. DrQA is one of the best performing models on SQuAD with an F1 of 78.8 and EM of 69.5. The relatively low performance of the models on emrQA (60.6 F1 and 59.2 EM) shows that QA on EMRs is a complex task and offers new challenges to existing QA models.

To understand model performance, we macro-average the EM across all the questions corresponding to a LF template. We observe that LFs representing temporal and arithmetic[§] needs had $<$ 16% EM. LFs expressing the need for medical KB[§] performed poorly since we used general Glove embeddings. An analysis of LFs which had approximately equal number of QA pair representation in the test set revealed an interesting relation between the model performance and LF complexity, as summarized in Table 6. The trend shows that performance is worse on multiple relation questions as compared to single relation and attribute questions, showing that the LFs sufficiently capture the complexity of the questions and give us an ability to do a qualitative model analysis.

Error analysis on a random sample of 50 questions containing at least one answer entity in an evidence showed that: (1) 38% of the examples required multiple sentence reasoning of which 16% were due to a missing evidence in a multiple evidence question, (2) 14% were due to syntactic variation, (3) 10% required medical reasoning and (4) in 14%, DrQA predicted an incomplete evidence span missing the answer entity in it.

[‡] using the original definitions, the evaluated values were far less than those obtained in Table 7

[§] maximum representation of these templates comes from the i2b2 heart disease risk dataset

Logical Form template	Property	Exact Match
MedicationEvent ($\|medication\|$) **[enddate=x]**	single attribute	55.3%
{LabEvent ($\|test\|$) OR ProcedureEvent ($\|test\|$)} **conducted** {ConditionEvent(x) OR SymptomEvent (x)}	single relation	32.2%
{MedicationEvent($\|treatment\|$)ORProcedureEvent($\|treatment\|$)} **improves/worsens/causes** {ConditionEvent (x) OR SymptomEvent (x)}	multiple relation	12.6%

Table 6: Neural models (DrQA) performance on question-evidence corpus of emrQA stratified according to the logical form templates. Instance showing increasing complexity in the logical forms with decreasing model performance.

7 Discussion

In this section, we describe how our generation framework may also be applied to generate open-domain QA datasets given the availability of other NLP resources. We also discuss possible extensions of the framework to increase the complexity of the generated datasets.

Open domain QA dataset generation: Consider the popularly used SQuAD (Rajpurkar et al., 2016) reading comprehension dataset generated by crowdworkers, where the answer to every question is a segment of text from the corresponding passage in the Wikipedia article. This dataset can easily be generated or extended using our proposed framework with existing NLP annotations on Wikipedia (Auer et al., 2007; Nothman et al., 2008; Ghaddar and Langlais, 2017).

For instance, consider DBPedia (Auer et al., 2007), an existing dataset of entities and their relations extracted from Wikipedia. It also has its own ontology which can serve as the semantic frames schema to define logical forms. Using these resources, our reverse engineering technique for QA dataset generation can be applied as follows. (1) Question templates can be defined for each entity type and relation in DBPedia. For example[¶], consider the relation *[place, country]* field in DBpedia. For this we can define a question template *In what country is* $|place|$ *located?*. (2) Every such question template can be annotated with a logical form template using existing DBPedia ontology. (3) By considering the entity values of DBPedia fields such as *[place=Normandy, dbo:country=France]*, we can automatically generate the question *In what country is Normandy located?* and its corresponding logical form from the templates. The text span of *country=France* from the Wikipedia passage is then used as the answer (Daiber et al., 2013). Currently, this QA pair instance is a part of the SQuAD dev set. Using our framework we can generate many more instances like this example from different Wikipedia passages - without crowdsourcing efforts.

Extensions to the framework: The complexity of the generated dataset can be further extended as follows. (1) We can use a coreferred or a lexical variant of the original entity in the question-logical form generation. This can allow for increased lexical variation between the question and answer line entities in the passage. (2) It is possible to combine two or more question templates to make compositional questions with the answers to these questions similarly combined. This can also result in more multiple sentence reasoning questions. (3) We can generate questions with entities not related to the context in the passage. This can increase empty answer questions in the dataset, resulting in increased negative training examples.

8 Conclusions and Future Work

We propose a novel framework that can generate a large-scale QA dataset using existing resources and minimal expert input. This has the potential to make a huge impact in domains like medicine, where obtaining manual QA annotations is tedious and infeasible. We apply this framework to generate a large scale EMR QA corpus (emrQA), consisting of 400,000 question-answers pairs and 1 million question-logical forms, and analyze the complexity of the dataset to show its non-trivial nature. We show that the logical forms provide a symbolic representation that is very useful for corpus generation and for model analysis. The logical forms also provide an opportunity to build interpretable systems by perhaps jointly (or latently) learning the logical form and answer for a question. In future, this framework may be applied to also re-purpose and integrate other NLP datasets such as MIMIC and generate a more diverse and representative EMR QA corpus (Johnson et al., 2016).

Abstract

Existing question answering (QA) datasets fail to train QA systems to perform complex reasoning and provide explanations for answers. We introduce HOTPOTQA, a new dataset with 113k Wikipedia-based question-answer pairs with four key features: (1) the questions require finding and reasoning over multiple supporting documents to answer; (2) the questions are diverse and not constrained to any pre-existing knowledge bases or knowledge schemas; (3) we provide sentence-level supporting facts required for reasoning, allowing QA systems to reason with strong supervision and explain the predictions; (4) we offer a new type of factoid comparison questions to test QA systems' ability to extract relevant facts and perform necessary comparison. We show that HOTPOTQA is challenging for the latest QA systems, and the supporting facts enable models to improve performance and make explainable predictions.

1 Introduction

The ability to perform reasoning and inference over natural language is an important aspect of intelligence. The task of question answering (QA) provides a quantifiable and objective way to test the reasoning ability of intelligent systems. To this end, a few large-scale QA datasets have been proposed, which sparked significant progress in this direction. However, existing datasets have limitations that hinder further advancements of machine reasoning over natural language, especially in testing QA systems' ability to perform *multi-hop reasoning*, where the system has to reason with information taken from more than one document to arrive at the answer.

Paragraph A, Return to Olympus:
[1] *Return to Olympus is the only album by the alternative rock band Malfunkshun.* [2] *It was released after the band had broken up and after lead singer Andrew Wood (later of Mother Love Bone) had died of a drug overdose in 1990.* [3] Stone Gossard, of Pearl Jam, had compiled the songs and released the album on his label, Loosegroove Records.

Paragraph B, Mother Love Bone:
[4] *Mother Love Bone was an American rock band that formed in Seattle, Washington in 1987.* [5] The band was active from 1987 to 1990. [6] *Frontman Andrew Wood's personality and compositions helped to catapult the group to the top of the burgeoning late 1980s/early 1990s Seattle music scene.* [7] *Wood died only days before the scheduled release of the band's debut album, "Apple", thus ending the group's hopes of success.* [8] The album was finally released a few months later.

Q: What was the former band of the member of Mother Love Bone who died just before the release of "Apple"?
A: Malfunkshun
Supporting facts: 1, 2, 4, 6, 7

Figure 1: An example of the multi-hop questions in HOTPOTQA. We also highlight the supporting facts in *blue italics*, which are also part of the dataset.

First, some datasets mainly focus on testing the ability of reasoning within a single paragraph or document, or *single-hop reasoning*. For example, in SQuAD (Rajpurkar et al., 2016) questions are designed to be answered given a single paragraph as the context, and most of the questions can in fact be answered by matching the question with a single sentence in that paragraph. As a result, it has fallen short at testing systems' ability to reason over a larger context. TriviaQA (Joshi et al., 2017) and SearchQA (Dunn et al., 2017) create a more challenging setting by using information retrieval to collect multiple documents to form the context given existing question-answer pairs. Nevertheless, most of the questions can be answered by matching the question with a few nearby sentences in one single paragraph, which is limited as it does not require more complex reasoning (e.g.,

[†] Work done when WWC was at CMU.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2369–2380
Brussels, Belgium, October 31 - November 4, 2018.

over multiple paragraphs).

Second, existing datasets that target multi-hop reasoning, such as QAngaroo (Welbl et al., 2018) and COMPLEXWEBQUESTIONS (Talmor and Berant, 2018), are constructed using existing knowledge bases (KBs). As a result, these datasets are constrained by the schema of the KBs they use, and therefore the diversity of questions and answers is inherently limited.

Third, all of the above datasets only provide distant supervision; i.e., the systems only know what the answer is, but do not know what supporting facts lead to it. This makes it difficult for models to learn about the underlying reasoning process, as well as to make explainable predictions.

To address the above challenges, we aim at creating a QA dataset that requires reasoning over multiple documents, and does so in natural language, without constraining itself to an existing knowledge base or knowledge schema. We also want it to provide the system with strong supervision about what text the answer is actually derived from, to help guide systems to perform meaningful and explainable reasoning.

We present HOTPOTQA[1], a large-scale dataset that satisfies these desiderata. HOTPOTQA is collected by crowdsourcing based on Wikipedia articles, where crowd workers are shown multiple supporting context documents and asked explicitly to come up with questions requiring reasoning about all of the documents. This ensures it covers multi-hop questions that are more natural, and are not designed with any pre-existing knowledge base schema in mind. Moreover, we also ask the crowd workers to provide the supporting facts they use to answer the question, which we also provide as part of the dataset (see Figure 1 for an example). We have carefully designed a data collection pipeline for HOTPOTQA, since the collection of high-quality multi-hop questions is non-trivial. We hope that this pipeline also sheds light on future work in this direction. Finally, we also collected a novel type of questions—comparison questions—as part of HOTPOTQA, in which we require systems to compare two entities on some shared properties to test their understanding of both language and common concepts such as numerical magnitude. We make HOTPOTQA publicly available at **https://HotpotQA.github.io**.

2 Data Collection

The main goal of our work is to collect a diverse and explainable question answering dataset that requires multi-hop reasoning. One way to do so is to define reasoning chains based on a knowledge base (Welbl et al., 2018; Talmor and Berant, 2018). However, the resulting datasets are limited by the incompleteness of entity relations and the lack of diversity in the question types. Instead, in this work, we focus on text-based question answering in order to diversify the questions and answers. The overall setting is that given some context paragraphs (e.g., a few paragraphs, or the entire Web) and a question, a QA system answers the question by extracting a span of text from the context, similar to Rajpurkar et al. (2016). We additionally ensure that it is necessary to perform multi-hop reasoning to correctly answer the question.

It is non-trivial to collect text-based multi-hop questions. In our pilot studies, we found that simply giving an arbitrary set of paragraphs to crowd workers is counterproductive, because for most paragraph sets, it is difficult to ask a meaningful multi-hop question. To address this challenge, we carefully design a pipeline to collect text-based multi-hop questions. Below, we will highlight the key design choices in our pipeline.

Building a Wikipedia Hyperlink Graph. We use the entire English Wikipedia dump as our corpus.[2] In this corpus, we make two observations: (1) hyper-links in the Wikipedia articles often naturally entail a relation between two (already disambiguated) entities in the context, which could potentially be used to facilitate multi-hop reasoning; (2) the first paragraph of each article often contains much information that could be queried in a meaningful way. Based on these observations, we extract all the hyperlinks from the first paragraphs of all Wikipedia articles. With these hyperlinks, we build a directed graph G, where each edge (a, b) indicates there is a hyperlink from the first paragraph of article a to article b.

Generating Candidate Paragraph Pairs. To generate meaningful pairs of paragraphs for multi-hop question answering with G, we start by considering an example question "when was the singer and songwriter of Radiohead born?" To

---

[1] The name comes from the first three authors' arriving at the main idea during a discussion at a hot pot restaurant.

[2] `https://dumps.wikimedia.org/`

answer this question, one would need to first reason that the "singer and songwriter of Radiohead" is "Thom Yorke", and then figure out his birthday in the text. We call "Thom Yorke" a *bridge entity* in this example. Given an edge (a, b) in the hyperlink graph G, the entity of b can usually be viewed as a bridge entity that connects a and b. As we observe articles b usually determine the theme of the shared context between a and b, but not all articles b are suitable for collecting multi-hop questions. For example, entities like countries are frequently referred to in Wikipedia, but don't necessarily have much in common with all incoming links. It is also difficult, for instance, for the crowd workers to ask meaningful multi-hop questions about highly technical entities like the IPv4 protocol. To alleviate this issue, we constrain the bridge entities to a set of manually curated pages in Wikipedia (see Appendix A). After curating a set of pages B, we create candidate paragraph pairs by sampling edges (a, b) from the hyperlink graph such that $b \in B$.

Comparison Questions. In addition to questions collected using bridge entities, we also collect another type of multi-hop questions—comparison questions. The main idea is that comparing two entities from the same category usually results in interesting multi-hop questions, e.g., "Who has played for more NBA teams, Michael Jordan or Kobe Bryant?" To facilitate collecting this type of question, we manually curate 42 lists of similar entities (denoted as L) from Wikipedia.[3] To generate candidate paragraph pairs, we randomly sample two paragraphs from the same list and present them to the crowd worker.

To increase the diversity of multi-hop questions, we also introduce a subset of yes/no questions in comparison questions. This complements the original scope of comparison questions by offering new ways to require systems to reason over both paragraphs. For example, consider the entities Iron Maiden (from the UK) and AC/DC (from Australia). Questions like "Is Iron Maiden or AC/DC from the UK?" are not ideal, because one would deduce the answer is "Iron Maiden" even if one only had access to that article. With yes/no questions, one may ask "Are Iron Maiden and AC/DC from the same country?", which requires reasoning over both paragraphs.

Algorithm 1 Overall data collection procedure

```
Input: question type ratio $r_1 = 0.75$, yes/no ratio $r_2 = 0.5$
while not finished do
    if $\mathrm{random}() < r_1$ then
        Uniformly sample an entity $b \in B$
        Uniformly sample an edge $(a, b)$
        Workers ask a question about paragraphs $a$ and $b$
    else
        Sample a list from $L$, with probabilities weighted by list sizes
        Uniformly sample two entities $(a, b)$ from the list
        if $\mathrm{random}() < r_2$ then
            Workers ask a yes/no question to compare $a$ and $b$
        else
            Workers ask a question with a span answer to compare $a$ and $b$
        end if
    end if
    Workers provide the supporting facts
end while
```

To the best of our knowledge, text-based comparison questions are a novel type of questions that have not been considered by previous datasets. More importantly, answering these questions usually requires arithmetic comparison, such as comparing ages given birth dates, which presents a new challenge for future model development.

Collecting Supporting Facts. To enhance the explainability of question answering systems, we want them to output a set of *supporting facts* necessary to arrive at the answer, when the answer is generated. To this end, we also collect the sentences that determine the answers from crowd workers. These supporting facts can serve as strong supervision for what sentences to pay attention to. Moreover, we can now test the explainability of a model by comparing the predicted supporting facts to the ground truth ones.

The overall procedure of data collection is illustrated in Algorithm 1.

3 Processing and Benchmark Settings

We collected 112,779 valid examples in total on Amazon Mechanical Turk[4] using the ParlAI interface (Miller et al., 2017) (see Appendix A).To isolate potential single-hop questions from the desired multi-hop ones, we first split out a subset of data called *train-easy*. Specifically, we randomly sampled questions (~3–10 per Turker) from top-contributing turkers, and categorized all

---

[3] This is achieved by manually curating lists from the Wikipedia "List of lists of lists" (`https://wiki.sh/y8qv`). One example is "Highest Mountains on Earth".

test-fullwiki	hard multi-hop	test	7,405
Total			112,779

Table 1: Data split. The splits *train-easy*, *train-medium*, and *train-hard* are combined for training. The distractor and full wiki settings use different test sets so that the gold paragraphs in the full wiki test set remain unknown to any models.

their questions into the *train-easy* set if an overwhelming percentage in the sample only required reasoning over one of the paragraphs. We sampled these turkers because they contributed more than 70% of our data. This *train-easy* set contains 18,089 mostly single-hop examples.

We implemented a question answering model based on the current state-of-the-art architectures, which we discuss in detail in Section 5.1. Based on this model, we performed a three-fold cross validation on the remaining multi-hop examples. Among these examples, the models were able to correctly answer 60% of the questions with high confidence (determined by thresholding the model loss). These correctly-answered questions (56,814 in total, 60% of the multi-hop examples) are split out and marked as the *train-medium* subset, which will also be used as part of our training set.

After splitting out *train-easy* and *train-medium*, we are left with hard examples. As our ultimate goal is to solve multi-hop question answering, we focus on questions that the latest modeling techniques are not able to answer. Thus we constrain our dev and test sets to be hard examples. Specifically, we randomly divide the hard examples into four subsets, *train-hard*, *dev*, *test-distractor*, and *test-fullwiki*. Statistics about the data split can be found in Table 1. In Section 5, we will show that combining *train-easy*, *train-medium*, and *train-hard* to train models yields the best performance, so we use the combined set as our default training set. The two test sets *test-distractor* and *test-fullwiki* are used in two different benchmark settings, which we introduce next.

We create two benchmark settings. In the first setting, to challenge the model to find the true supporting facts in the presence of noise, for each example we employ bigram tf-idf (Chen et al., 2017) to retrieve 8 paragraphs from Wikipedia as *distractors*, using the question as the query. We mix them with the 2 gold paragraphs (the ones used to collect the question and answer) to construct the **distractor** setting. The 2 gold paragraphs and the 8 distractors are shuffled before they are fed to the model. In the second setting, we fully test the model's ability to locate relevant facts as well as reasoning about them by requiring it to answer the question given the first paragraphs of all Wikipedia articles without the gold paragraphs specified. This **full wiki** setting truly tests the performance of the systems' ability at multi-hop reasoning in the wild.[5] The two settings present different levels of difficulty, and would require techniques ranging from reading comprehension to information retrieval. As shown in Table 1, we use separate test sets for the two settings to avoid leaking information, because the gold paragraphs are available to a model in the distractor setting, but should not be accessible in the full wiki setting.

We also try to understand the model's good performance on the *train-medium* split. Manual analysis shows that the ratio of multi-hop questions in *train-medium* is similar to that of the hard examples (93.3% in *train-medium* vs. 92.0% in *dev*), but one of the question types appears more frequently in *train-medium* compared to the hard splits (Type II: 32.0% in *train-medium* vs. 15.0% in *dev*, see Section 4 for the definition of Type II questions). These observations demonstrate that given enough training data, existing neural architectures can be trained to answer certain types and certain subsets of the multi-hop questions. However, *train-medium* remains challenging when not just the gold paragraphs are present—we show in Appendix C that the retrieval problem on these examples are as difficult as that on their hard cousins.

4 Dataset Analysis

In this section, we analyze the types of questions, types of answers, and types of multi-hop reasoning covered in the dataset.

Question Types. We heuristically identified question types for each collected question. To identify the question type, we first locate the *central question word* (CQW) in the question. Since HOTPOTQA contains comparison questions and

---

[5] As we required the crowd workers to use complete entity names in the question, the majority of the questions are unambiguous in the full wiki setting.

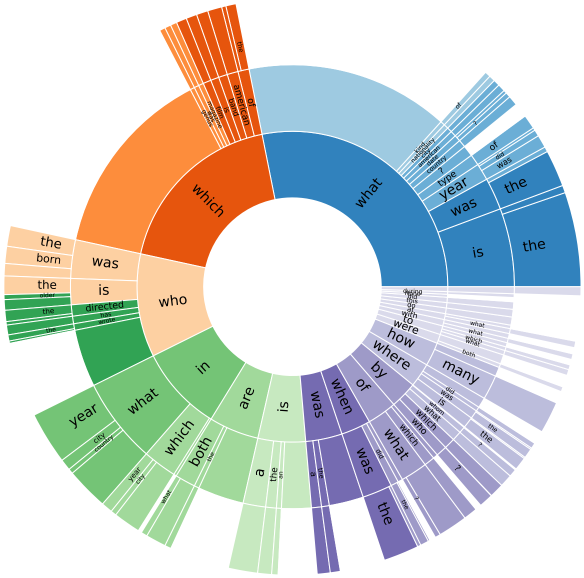

Figure 2: Types of questions covered in HOTPOTQA. Question types are extracted heuristically, starting at question words or prepositions preceding them. Empty colored blocks indicate suffixes that are too rare to show individually. See main text for more details.

yes/no questions, we consider as *question words* WH-words, copulas ("is", "are"), and auxiliary verbs ("does", "did"). Because questions often involve relative clauses beginning with WH-words, we define the CQW as the first question word in the question if it can be found in the first three tokens, or the last question word otherwise. Then, we determine question type by extracting words up to 2 tokens away to the right of the CQW, along with the token to the left if it is one of a few common prepositions (e.g., in the cases of "in which" and "by whom").

We visualize the distribution of question types in Figure 2, and label the ones shared among more than 250 questions. As is shown, our dataset covers a diverse variety of questions centered around entities, locations, events, dates, and numbers, as well as yes/no questions directed at comparing two entities ("Are both A and B ...?"), to name a few.

Answer Types. We further sample 100 examples from the dataset, and present the types of answers in Table 2. As can be seen, HOTPOTQA covers a broad range of answer types, which matches our initial analysis of question types. We find that a majority of the questions are about entities in the articles (68%), and a non-negligible amount of questions also ask about various properties like date (9%) and other descriptive properties such as numbers (8%) and adjectives (4%).

Answer Type	%	Example(s)
Person	30	King Edward II, Rihanna
Group / Org	13	Cartoonito, Apalachee
Location	10	Fort Richardson, California
Date	9	10th or even 13th century
Number	8	79.92 million, 17
Artwork	8	Die schweigsame Frau
Yes/No	6	-
Adjective	4	conservative
Event	1	Prix Benois de la Danse
Other proper noun	6	Cold War, Laban Movement Analysis
Common noun	5	comedy, both men and women

Table 2: Types of answers in HOTPOTQA.

Multi-hop Reasoning Types. We also sampled 100 examples from the dev and test sets and manually classified the types of reasoning required to answer each question. Besides comparing two entities, there are three main types of multi-hop reasoning required to answer these questions, which we show in Table 3 accompanied with examples.

Most of the questions require at least one supporting fact from each paragraph to answer. A majority of sampled questions (42%) require chain reasoning (Type I in the table), where the reader must first identify a bridge entity before the second hop can be answered by filling in the bridge. One strategy to answer these questions would be to decompose them into consecutive single-hop questions. The bridge entity could also be used implicitly to help infer properties of other entities related to it. In some questions (Type III), the entity in question shares certain properties with a bridge entity (e.g., they are collocated), and we can infer its properties through the bridge entity. Another type of question involves locating the answer entity by satisfying multiple properties simultaneously (Type II). Here, to answer the question, one could find the set of all entities that satisfy each of the properties mentioned, and take an intersection to arrive at the final answer. Questions comparing two entities (Comparison) also require the system to understand the properties in question about the two entities (e.g., nationality), and sometimes require arithmetic such as counting (as seen in the table) or comparing numerical values ("Who is older, A or B?"). Finally, we find that sometimes the questions require more than two supporting facts to answer (Other). In our analysis, we also find that for all of the examples shown in the table, the supporting facts provided by the Turkers match exactly with the limited context shown here,

Reasoning Type	%	Example(s)
Inferring the ***bridge entity*** to complete the 2nd-hop question (Type I)	42	**Paragraph A:** The 2015 Diamond Head Classic was a college basketball tournament ... ***Buddy Hield*** *was named the tournament's MVP*. **Paragraph B:** ***Chavano Rainier ”Buddy” Hield*** is a Bahamian professional basketball player for the **Sacramento Kings** of the NBA... **Q:** Which team does the player named 2015 Diamond Head Classic's MVP play for?
Comparing two entities (Comparison)	27	**Paragraph A:** LostAlone were a British rock band ... consisted of *Steven Battelle, Alan Williamson, and Mark Gibson*... **Paragraph B:** Guster is an American alternative rock band ... Founding members *Adam Gardner, Ryan Miller, and Brian Rosenworcel* began... **Q:** Did LostAlone and Guster have the same number of members? (**yes**)
Locating the **answer entity** by checking multiple properties (Type II)	15	**Paragraph A:** Several *current and former members of the Pittsburgh Pirates* – ... John Milner, **Dave Parker**, and Rod Scurry... **Paragraph B:** **David Gene Parker**, *nicknamed ”The Cobra”*, is an American former player in Major League Baseball... **Q:** Which former member of the Pittsburgh Pirates was nicknamed ”The Cobra”?
Inferring about the property of an entity in question through a ***bridge entity*** (Type III)	6	**Paragraph A:** *Marine Tactical Air Command Squadron 28* is a United States Marine Corps aviation command and control unit based at ***Marine Corps Air Station Cherry Point***... **Paragraph B:** ***Marine Corps Air Station Cherry Point*** ... is a United States Marine Corps airfield located in **Havelock, North Carolina**, USA ... **Q:** What city is the Marine Air Control Group 28 located in?
Other types of reasoning that require more than two supporting facts (Other)	2	**Paragraph A:** ... the towns of Yodobashi, **Okubo, Totsuka, and Ochiai town** *were merged into Yodobashi ward*. ... ***Yodobashi Camera*** *is a store with its name taken from the town and ward*. **Paragraph B**: ***Yodobashi Camera*** Co., Ltd. is *a major Japanese retail chain specializing in electronics, PCs, cameras and photographic equipment*. **Q:** Aside from Yodobashi, what other towns were merged into the ward which gave the major Japanese retail chain specializing in electronics, PCs, cameras, and photographic equipment it's name?

Table 3: Types of multi-hop reasoning required to answer questions in the HotpotQA dev and test sets. We show in ***orange bold italics*** bridge entities if applicable, *blue italics* supporting facts from the paragraphs that connect directly to the question, and **green bold** the answer in the paragraph or following the question. The remaining 8% are single-hop (6%) or unanswerable questions (2%) by our judgement.

showing that the supporting facts collected are of high quality.

Aside from the reasoning types mentioned above, we also estimate that about 6% of the sampled questions can be answered with one of the two paragraphs, and 2% of them unanswerable. We also randomly sampled 100 examples from *train-medium* and *train-hard* combined, and the proportions of reasoning types are: Type I 38%, Type II 29%, Comparison 20%, Other 7%, Type III 2%, single-hop 2%, and unanswerable 2%.

5 Experiments

5.1 Model Architecture and Training

To test the performance of leading QA systems on our data, we reimplemented the architecture described in Clark and Gardner (2017) as our baseline model. We note that our implementation without weight averaging achieves performance very close to what the authors reported on SQuAD (about 1 point worse in F_1). Our implemented model subsumes the latest technical advances on question answering, including character-level models, self-attention (Wang et al., 2017), and bi-attention (Seo et al., 2017). Combining these three key components is becoming standard practice, and various state-of-the-art or competitive architectures (Liu et al., 2018; Clark and Gardner, 2017; Wang et al., 2017; Seo et al., 2017; Pan et al., 2017; Salant and Berant, 2018; Xiong et al., 2018) on SQuAD can be viewed as similar to our implemented model. To accommodate yes/no questions, we also add a 3-way classifier after the last recurrent layer to produce the probabilities of "yes", "no", and span-based answers. During decoding, we first use the 3-way output to determine whether the answer is "yes", "no", or a text span. If it is a text span, we further search for the most probable span.

Supporting Facts as Strong Supervision. To evaluate the baseline model's performance in predicting explainable supporting facts, as well as how much they improve QA performance, we additionally design a component to incorporate

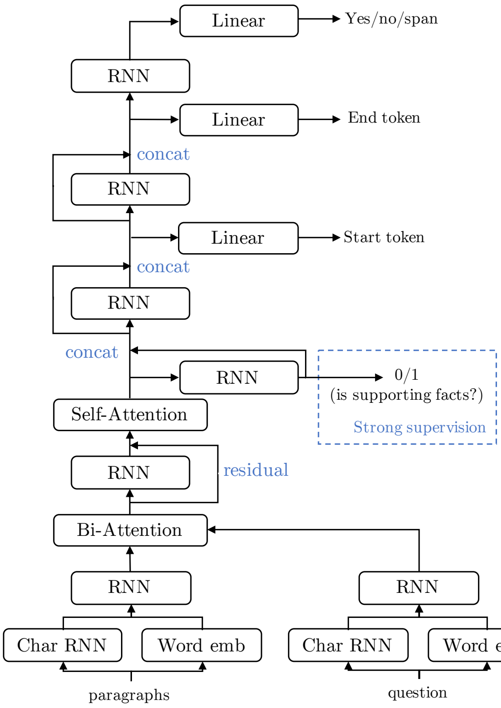

Figure 3: Our model architecture. Strong supervision over supporting facts is used in a multi-task setting.

such strong supervision into our model. For each sentence, we concatenate the output of the self-attention layer at the first and last positions, and use a binary linear classifier to predict the probability that the current sentence is a supporting fact. We minimize a binary cross entropy loss for this classifier. This objective is jointly optimized with the normal question answering objective in a multi-task learning setting, and they share the same low-level representations. With this classifier, the model can also be evaluated on the task of supporting fact prediction to gauge its explainability. Our overall architecture is illustrated in Figure 3. Though it is possible to build a pipeline system, in this work we focus on an end-to-end one, which is easier to tune and faster to train.

5.2 Results

We evaluate our model in the two benchmark settings. In the full wiki setting, to enable efficient tf-idf retrieval among 5,000,000+ wiki paragraphs, given a question we first return a candidate pool of at most 5,000 paragraphs using an inverted-index-based filtering strategy[6] and then select the top 10 paragraphs in the pool as the final candidates using bigram tf-idf.[7] Retrieval performance is shown in Table 5. After retrieving these 10 paragraphs, we then use the model trained in the distractor setting to evaluate its performance on these final candidate paragraphs.

Following previous work (Rajpurkar et al., 2016), we use exact match (EM) and F_1 as two evaluation metrics. To assess the explainability of the models, we further introduce two sets of metrics involving the supporting facts. The first set focuses on evaluating the supporting facts directly, namely EM and F_1 on the set of supporting fact sentences as compared to the gold set. The second set features joint metrics that combine the evaluation of answer spans and supporting facts as follows. For each example, given its precision and recall on the answer span $(P^{(\text{ans})}, R^{(\text{ans})})$ and the supporting facts $(P^{(\text{sup})}, R^{(\text{sup})})$, respectively, we calculate joint F_1 as

$$P^{(\text{joint})} = P^{(\text{ans})} P^{(\text{sup})}, \quad R^{(\text{joint})} = R^{(\text{ans})} R^{(\text{sup})},$$

$$\text{Joint } F_1 = \frac{2P^{(\text{joint})} R^{(\text{joint})}}{P^{(\text{joint})} + R^{(\text{joint})}}.$$

Joint EM is 1 only if both tasks achieve an exact match and otherwise 0. Intuitively, these metrics penalize systems that perform poorly on either task. All metrics are evaluated example-by-example, and then averaged over examples in the evaluation set.

The performance of our model on the benchmark settings is reported in Table 4, where all numbers are obtained with strong supervision over supporting facts. From the distractor setting to the full wiki setting, expanding the scope of the context increases the difficulty of question answering. The performance in the full wiki setting is substantially lower, which poses a challenge to existing techniques on retrieval-based question answering. Overall, model performance in all settings is significantly lower than human performance as shown in Section 5.3, which indicates that more technical advancements are needed in future work.

We also investigate the explainability of our model by measuring supporting fact prediction performance. Our model achieves 60+ supporting fact prediction F_1 and ~40 joint F_1, which indicates there is room for further improvement in terms of explainability.

In Table 6, we break down the performance on different question types. In the distractor setting, comparison questions have lower F_1 scores

---

[6] See Appendix C for details.

[7] We choose the number of final candidates as 10 to stay consistent with the distractor setting where candidates are 2 gold paragraphs plus 8 distractors.

Setting	Split	Answer		Sup Fact		Joint	
		EM	F_1	EM	F_1	EM	F_1
distractor	dev	44.44	58.28	21.95	66.66	11.56	40.86
distractor	test	45.46	58.99	22.24	66.62	12.04	41.37
full wiki	dev	24.68	34.36	5.28	40.98	2.54	17.73
full wiki	test	25.23	34.40	5.07	40.69	2.63	17.85

Table 4: Main results: the performance of question answering and supporting fact prediction in the two benchmark settings. We encourage researchers to report these metrics when evaluating their methods.

Set	MAP	Mean Rank	Hits@2	Hits@10
dev	43.93	314.71	39.43	56.06
test	43.21	314.05	38.67	55.88

Table 5: Retrieval performance in the full wiki setting. Mean Rank is averaged over the ranks of two gold paragraphs.

Setting	Br EM	Br F_1	Cp EM	Cp F_1
distractor	43.41	59.09	48.55	55.05
full wiki	19.76	30.42	43.87	50.70

Table 6: Performance breakdown over different question types on the dev set in the distractor setting. "Br" denotes questions collected using bridge entities, and "Cp" denotes comparison questions.

Setting	EM	F_1
our model	44.44	58.28
– sup fact	42.79	56.19
– sup fact, self attention	41.59	55.19
– sup fact, char model	41.66	55.25
– sup fact, train-easy	41.61	55.12
– sup fact, train-easy, train-medium	31.07	43.61
gold only	48.38	63.58
sup fact only	51.95	66.98

Table 7: Ablation study of question answering performance on the dev set in the distractor setting. "– sup fact" means removing strong supervision over supporting facts from our model. "– train-easy" and "– train-medium" means discarding the according data splits from training. "gold only" and "sup fact only" refer to using the gold paragraphs or the supporting facts as the only context input to the model.

than questions involving bridge entities (as defined in Section 2), which indicates that better modeling this novel question type might need better neural architectures. In the full wiki setting, the performance of bridge entity questions drops significantly while that of comparison questions decreases only marginally. This is because both entities usually appear in the comparison questions, and thus reduces the difficulty of retrieval. Combined with the retrieval performance in Table 5, we believe that the deterioration in the full wiki setting in Table 4 is largely due to the difficulty of retrieving both entities.

We perform an ablation study in the distractor setting, and report the results in Table 7. Both self-attention and character-level models contribute notably to the final performance, which is consistent with prior work. This means that techniques targeted at single-hop QA are still somewhat effective in our setting. Moreover, removing strong supervision over supporting facts decreases performance, which demonstrates the effectiveness of our approach and the usefulness of the supporting facts. We establish an estimate of the upper bound of strong supervision by only considering the supporting facts as the oracle context input to our model, which achieves a 10+ F_1 improvement over not using the supporting facts. Compared with the gain of strong supervision in our model ($\sim$2 points in F_1), our proposed method of incorporating supporting facts supervision is most likely suboptimal, and we leave the challenge of better modeling to future work. At last, we show that combining all data splits (*train-easy*, *train-medium*, and *train-hard*) yields the best performance, which is adopted as the default setting.

5.3 Establishing Human Performance

To establish human performance on our dataset, we randomly sampled 1,000 examples from the dev and test sets, and had at least three additional Turkers provide answers and supporting facts for these examples. As a baseline, we treat the original Turker during data collection as the prediction, and the newly collected answers and supporting facts as references, to evaluate human performance. For each example, we choose the answer and supporting fact reference that maximize the F_1 score to report the final metrics to reduce the effect of ambiguity (Rajpurkar et al., 2016).

Setting	Answer		Sp Fact		Joint
